AGING

1 DAILY HIGH-FREQUENCY STIMULATION DIFFERENTIALLY PROLONGS SYNAPTIC ENHANCEMENT IN MIDDLE-AGED AND SENESCENT RAT HIPPOCAMPUS.
C. A. Barnes and B. L. McNaughton. Dept. Psych., Dalhousie Univ., Halifax, Nova Scotia, CANADA, B3H 4J1.

The perforant path-granule cell synapse in the hippocampus has been shown to undergo an enduring enhancement of its efficacy after brief high-frequency bursts of stimulation (Bliss & Lømo, JP, 1973, 232, 331-356). Barnes (JCPP, 1979, 93, 74-104) found that the magnitude and decay time constant of enhancement following a single stimulus session were equivalent in middle-aged and old rats. The decay time constant, however, was extended from 4 to 29 days in the young animals by repetition of the enhancing stimulus at 24 hour intervals for three days. The time constant for the old rats failed to show an increase. In the present study we sought to determine whether the decay time constant of enhancement in old rats could ultimately be extended given a sufficient number of repetitions of the enhancing stimulus. A secondary goal was to determine whether the time constant in young animals tended towards some asymptote or whether it was extended indefinately with further repetition.

Thirty-six middle-aged (10 mo) and 36 senescent (29 mo) male Long Evans rats were bilaterally implanted with electrodes for chronic stimulation and extracellular recording of perforant path granule cell synaptic response as described in Barnes (1979). Animals with electrodes that failed to remain stable for the full period of observation were eliminated from the final data analysis. The stimulus current was set just above the threshold for granule cell discharge and was kept constant throughout the experiment. After baseline control responses were obtained, 12 high-frequency stimulation sessions (15, 20 msec bursts of 400 Hz stimuli) were given at 24 hour intervals. The response amplitude was measured prior to and following each high-frequency session, and at daily intervals for three weeks after the last (12th) session.

Synaptic enhancement reached an asymptotic value of approximately 60% in both age groups. The decay time constants reached maximal values of 37 and 17 days for the young and old groups respectively. The rate of growth of the time constant was a decreasing function of the number of stimulus repetitions.

We conclude from these data that the decay time constant of synaptic enhancement in the fascia dentata is considerably prolonged by daily repetition of the enhancing stimulus and that the process underlying the increase in the decay time constant, rather than enhancement per se, is deficient in senescent rats. Furthermore, it does not appear that enhancement can be made 'permanent' by any reasonable amount of stimulus repetition.

2 DIFFERENCES IN RETENTION OF INHIBITORY AVOIDANCE TASK AND BRAIN BIOCHEMISTRY IN MIDDLE-AGED MICE: EFFECTS OF CHRONIC CHOLINE-ENRICHED AND CHOLINE-DEFICIENT DIETS.
R. T. Bartus, J. Coupet*, R. L. Dean*, J. A. Goas, V. A. Szucs-Myers* and C. E. Rauh*, American Cyanamid Company, Med. Res. Div., Pearl River, NY 10965.

Considerable research indicates that cholinergic mechanisms play an important role in the expression of learning and memory. More recent evidence suggests that alterations in some of these same cholinergic mechanisms may be critically involved in the memory declines observed in aged human and non-human mammals. At the same time, it has been demonstrated that systemic administration, or dietary manipulation, of choline, the acetylcholine precursor, can significantly influence cholinergic function. For example, there have been reports of significant changes in levels or amount of brain choline, acetylcholine, choline acetyltransferase and nicotinic receptor binding following choline administration to young rodents and humans. These data collectively suggest that it might be possible to alter the development of age-related cognitive impairments by manipulating cholinergic function through proper precursor control.

The following study addressed this question directly by placing retired breeder C56Bl/6j mice (8.5 months old at the start of this study) on purified diets which were either deficient (0.5 - 1.0 mg/gm feed) or enriched (15.0 mg/gm) with free choline. The diets were given ad lib for a period of 4.5 months, after which time the mice were tested for effects on psychomotor coordination, closed field activity and retention of an inhibitory avoidance task (at 13 months old). All animals were then sacrificed and biochemical assays performed to assess possible differences in choline levels, as well as changes in receptor binding and enzymatic levels in the central cholinergic and dopaminergic systems.

Although little or no differences were observed on psychomotor coordination or general activity, a striking effect was observed on retention of the inhibitory avoidance task. In fact, mice fed the choline-enriched diet performed as well as young, 3 month old mice, whereas mice fed the choline-deficient diet performed as poorly as senescent mice (23 months and older). Preliminary biochemical analyses of the mouse brains demonstrated that significant differences in specific pre- and post-synaptic markers existed between the choline-enriched and choline-deficient groups. More detailed results will be presented. These data demonstrate that chronic manipulation of the cholinergic system, via precusor control, can produce significant changes in brain and behavior in middle-aged mice. Further, these changes are similar to those which occur naturally with old age, and suggest that certain debilitating effects of age may, therefore, be modulated through appropriate precusor control.

3 SHORT-TERM MEMORY AND AGING: LOCALIZATION OF CELLULAR CHANGES WITHIN MULTIMODAL SENSORY REGIONS OF THE CEREBRAL CORTEX AND LIMBIC SYSTEM IN THE RHESUS MONKEY.
K. R. Brizzee, R. T. Bartus, J. M. Ordy and T. Beavers. Delta Regional Primate Research Center Covington, La. 70433 and Lederle Cyanamid Corp., Pearl River, N.Y., 10965.

According to recent studies, some of the more prominent manifestations of aging include short-term memory impairment, cell loss, and lipofuscin pigment accumulation in the brain. Although nonhuman primates are of the same taxonomic order as man, they have not been used extensively for studies of age-related short-term memory impairments in relation to cellular changes in specific neuronal circuits that may be involved in the mediation of short-term memory within limbic and cerebral cortical centers. Using an automated delayed response test, and 0, 15, and 30 second retention of information intervals, significant impairments were observed in short-term visual memory at 15 and 30 second delays in aged (18-24 years) compared to young (3-5 years) rhesus monkeys ($p<.01$). Although declines in sensory function and age-dependent cellular changes, particularly loss of cells, dendritic spines, and lipofuscin age pigment accumulation, have been observed in modality-specific sensory pathways, considerable interest has been focused recently on age-related cellular changes in such convergent multimodal sensory regions as the entorhinal cortex, the hippocampus, thalamus, and frontal cortex in relation to the acquisition, storage, and retrieval of multimodal information designated as short-term memory. The aims of this study were to compare age differences in neuron numbers, in two of the major convergent multimodal sensory centers, the hippocampus of the limbic system and the gyrus principalis of the frontal cerebral cortex between young adult and aged short-term memory impaired rhesus monkeys. Morphometric studies in the lamina pyramidale of the hippocampus revealed that the mean number of neurons in the CA-1 zone, per transverse section, was significantly lower ($p<.01$) in aged animals than in young adults. The total dorsoventral depth of the hippocampal strata, in the CA-1 zone was also significantly less ($p<.05$) in aged than in young adult monkeys. In the gyrus principalis the mean cortical depth was significantly less in aged than in young adult animals ($p<.05$). The mean number of neurons in "core" samples of cerebral cortex, extending from the pia mater to the deepest part of lamina VI, was also significantly less ($p<.02$) in the old than in young adults. These studies indicate that significant age-dependent cellular changes occur in multimodal sensory pathways involved in the mediation of short-term memory. Supported by NIH Grant RR00164 and a grant from Lederle-American Cyanamid Corp.

4 AGE-RELATED CHANGES IN PAVLOVIAN CONDITIONING IN RABBITS: CNS CORRELATES.
Shirley L. Buchanan*, Linda Hernandez, and D. A. Powell, VA Medical Center, Columbia, S. C. and N.S. Shah, William S. Hall Psychiatric Institute, Columbia, S. C.

"Old" (mean age = 40 mos.) and "young" (mean age = 6 mos.) New Zealand albino rabbits were exposed to Pavlovian conditioning training in which corneoretinal potential (CRP), heart rate (HR), and electromyographic (EMG) CRs were assessed. Three experiments were performed in which 75 db tones served as CSs and a 300 msec., 3 ma paraorbital electric shock served as the US. Two experiments involved simple conditioning in which a .5 sec. 1216 Hz tone served as the CS. A third experiment involved differential conditioning in which 1 sec. 304 and 1216 Hz tones were CSs. At the end of conditioning, (a) free field activity, (b) paraorbital shock thresholds, and (c) HR URs were determined in selected animals. Regional CNS concentrations of norepinephrine (NE), serotonin (5HT) and dopamine (DA) were also determined in selected animals. DA receptor binding in the caudate nucleus was also studied in selected "old" and "young" Ss.

In all three experiments, CRP CR frequency was decreased and the rate of CRP acquisition impaired in the "old" Ss. However, CRP discrimination was unaffected by age. Data from two experiments suggest that these deficits were more pronounced in males than in females. HR CR magnitude was enhanced in old as compared to young Ss in all three experiments, although the HR orienting response to unreinforced tones was smaller in the old Ss. Sex differences again appeared, however; females revealed faster baseline HR and smaller bradycardiac CRs than males regardless of age. Free field activity, paraorbital shock thresholds, and HR URs in response to shock were unrelated to either age or sex. Regional differences in CNS monoamine distribution were, however, related to both age and sex in several instances. Moreover, hippocampal and cortical NE and 5HT concentrations were correlated with HR CR magnitude. NE concentration was directly related to HR CR magnitude; 5 HT concentration was inversely related to HR CR magnitude. Striatal DA concentration was also decreased in old as compared to young males, and decreased DA receptor density was also observed in the old animals. Previous experiments suggested that the striatum was related to Pavlovian CRP conditioning (D. A. Powell, et al., Physiology & Behavior, 1978, 20, 143-150). Thus age-related presynaptic and/or post-synaptic neostriatal changes may underlie the Pavlovian CRP conditioning deficits obtained in the old animals.

5 NEURAL INCREASE IN VARIOUS REGIONS OF THE FISH BRAIN. R.E. Coggeshall, R.B. Leonard, and S.C. Birse. Departments of Anatomy and of Physiology and Biophysics, The Marine Biomedical Institute, The University of Texas Medical Branch, Galveston, Texas 77550.

It is generally accepted that the number of neurons in most parts of the vertebrate nervous system is relatively constant in postembryonic life. It is clear in teleosts, however, that there is a constant addition of ganglion cells to the retina for as long as the animal lives. In elasmobranchs there seems to be a constant increase in dorsal root ganglion cells and axons and ventral root axons. This leads to the question as to whether neurons in all, or almost all, parts of the nervous system in lower vertebrates increase in number throughout the life of the animal. The present study is an attempt to obtain at least a partial answer to this question. Guppies (Lebistes) at various ages (Table I) were serially sectioned in paraffin and 1) the Purkinje cells of the cerebellum, 2) the neurons in the nucleus glomerulosus, 3) the dorsal root ganglion cells of the 2nd dorsal root ganglion and 4) the cells in the ventral horn of the 2nd segment were counted. The data are presented in Table I.

AGE IN DAYS	1	4	10	23	38	61	200
Pur. Cells	1706	1493	3036	----	3398	4558	5606
Nuc. Glom.	2199	2447	2886	4651	4620	7017	9153
D.R.G. Cells	330	372	667	670	433	910	1258
V.H. Cells	966	980	921	----	1090	1375	1640

These preliminary data suggest that there is a relatively steady increase in neuronal numbers in all of these areas. This would seem to imply that there is an increase in neural numbers in most parts of the brain in adult fish and in this respect, fish would seem to differ markedly from mammals. It is possible that this difference is related to the greater capacity of fish for neural regeneration as compared to mammals. This work is supported by NIH grants NS 07377 and NS 10161.

6 EFFECTS OF ENVIRONMENT AND SOCIAL INTERACTION BETWEEN YOUNG AND OLD RATS ON VISUAL CORTEX AND DENDRITIC BRANCHING. James R. Connor, Marian C. Diamond, and Ruth Johnson*. Department of Physiology-Anatomy, UC Berkeley, Berkeley, CA 94720.

The present study was designed to investigate whether the interaction between young and old rats in a specific environment influences the cortex and cortical structures. Seven 600 day old Long Evans male rats were separated into 2 conditions: 4 into an "enriched" environment (EC) and 3 remained together in a standard colony cage (SC). Eight 60 day old rats were placed in the enriched cage with the 4 old rats. Nine 60 day old rats were housed 3 to a standard colony cage. All animals were given access to food and water ad lib. The Mann-Whitney U and Students-t tests were used to analyze the data.

After 30 days, the brains were removed and placed in Golgi-Cox fixative. Dendritic branching was investigated on basal branches of pyramidal cells in layers II and III. Alternating sections were counterstained with thionine for determining cortical depth. The cortical thickness did not differ significantly between the 2 conditions when observed within the same age group. In compering between age groups (SC), the young animals had significantly thicker cortices in all areas but one (areas 18, 18a; $p < .01$, area 17; $p < .001$; area 39, NS). In the EC the significant difference between the age groups decreased in each case. All areas of the old rats' visual cortex showed some increase in the EC whereas in the young rats, 3 of the 4 areas increased (18, 18a, 17) while one (area 39) decreased.

Investigation of dendritic branching in 600 day old animals showed a near significant increase of 9% in the number of dendritic branches in the EC ($p = .057$, $\alpha = .05$). Although insignificant, the branching order of dendrites showed a tendency to be higher in the EC in all but one order (4°). The fifth order was most nearly significant ($p = .057$, $\alpha = .05$). The 60 day old animals did not differ significantly in either of the 2 conditions. The 60 day old animals in the SC had 9% more branching segments than the 600 day old animals (NS). When the enriched animals were compared, the 60 day old animals had 3.2% fewer branching segments than the 600 day old animals (NS).

The inability of the enriched environment plus old animals to increase the cortical thickness in young animals is puzzling. In previous investigations, using animals the same age, the visual cortex has increased in depth with enrichment. Possibly the tendency for old rats to show increased responsivity to the enriched environment is due to the loss of an inherent inhibitory regulatory system for dendritic growth. Thus, environmental stimuli may result in a random increase of dendritic projections. This may be related to the "lawless" growth reported by Scheibel & Tomiyasu (1978) in Alzheimer's disease.

7 SYNTHESIS OF MONOAMINE OXIDASE IN MICE AS RELATED TO AGING. Lucien J. Côté, Leon T. Kremzner,* and Angelika Huebner,* Departments of Rehabilitation Medicine and Neurology, College of Physicians and Surgeons, Columbia University, NY, NY 10032.

The rate of synthesis of both A and B forms of monoamine oxidase (MAO) was studied in mice as related to age, using pargyline as an irreversible inhibitor of the enzyme. The return of MAO activity after pargyline treatment depends solely on the de novo synthesis of the enzyme, providing a way to assess the rate of synthesis of MAO. Three groups of mice (Jackson C57BL/6J), 70, 416, and 730 days old were given a single dose of pargyline (50 mg/kg) i.p. and MAO-A and MAO-B activities were assayed at 1, 2, 5, 9, 15, and 26 days after treatment. Five to eight mice were used for each point. Non-treated mice of comparable age served as controls. MAO-A and MAO-B activities were 85% and 95% inhibited, respectively, at one day after treatment. There was a gradual return of activities; the pattern was similar for both forms of the enzyme. At nine days about 40% of the activity had returned. At 26 days after pargyline treatment, 75% of the basal activity had returned. There was no significant difference in the rate of recovery of activities, and thus synthesis, between young, middle age, and old mice. Our findings indicate that old mice can synthesize both forms of MAO at the same rate as young mice.

Studies of both acetylcholinesterase and nonspecific cholinesterase activities indicate that there is no apparent difference in the rate of return of enzyme activity in young versus old mice. However, studies with ornithine decarboxylase and S-adenosyl methionine decarboxylase, enzymes with extremely short half-lives (15-30 minutes), indicate that relative to young animals, old animals show a delay in the initiation of enzyme synthesis.

8 COMPARATIVE EFFECTS OF PROTEIN SYNTHESIS INHIBITION ON LEARNING AND MEMORY IN SENESCENT AND MATURE MICE. Dennis D. Crady* and Elton E. Quinton. Dept. Psych., Univ. of Louisville, Louisville, Kentucky 40208.

The processes of learning and memory are believed to be dependent upon protein synthesis. Senescence has been hypothesized to result from a chronological decrement in effeciency of protein synthesis and repair. If these theories are true one might expect to see a decrement in learning and memory abilities in senescent animals as well as an exaggerated impairment following protein synthesis inhibition. This study examined this possible interaction between protein synthesis inhibition, learning and memory processes, and aging.

Three age groups of C57Bl/6J mice (7-10 months, 28-31 months, and 35-36 months) were trained on a simultaneous five-choice visual discrimination active avoidance task. Animals were given 10 consecutive trials per session, with 10 daily sessions. Anisomycin (5 mg./kg.) or water was administered 5 minutes prior to the start of each daily session. Animals completed the session within 25 minutes of the drug administration.

All groups demonstrated a high degree of acquisition over the 10 sessions. The performance of the mature control group was superior to that of the senescent control group. Anisomycin significantly impaired the performance of the mature mice, but had no apparent effect on the performance of the senescent mice (compared with the control group).

These data support the hypothesized learning deficit in the senescent animals, but it was not clear that this deficit was a result of a decline in protein metabolism. An impairment in learning was demonstrated in the mature drugged group which was not similarly reflected in the senescent drugged group. Hence the hypothesized differential effect with a greater impairment in the senescent group was not obtained. These results suggest a differential effect of anisomycin on protein synthesis in mature and senescent mice.

9 CHANGES IN BEHAVIOR AND RECEPTOR BINDING IN AGED VS. YOUNG MICE. R. L. Dean*, J. A. Goas*, A. S. Lippa*, R. T. Bartus (SPON: R. Schoenfeld), American Cyanamid Co., Medical Research Division, Pearl River, NY 10965; and, R. Pelham* and J. K. Marquis*, Tufts-New England Medical Center, Dept. of Neurology and Biochemistry, Boston, MA 02111.

Interest in defining the behavioral impairments associated with age, and the biochemical sources of these impairments, has accelerated rapidly in recent years. It is clear from the data accumulated that although age-related deficits in performance do occur in human and non-human mammals, not all types of behaviors are impaired. Similarly, although many different biochemical changes have been reported, it remains unclear which changes are primarily responsible for the behavioral impairments. Because of the differences in the behaviors measured, biochemical assays performed and neurological regions evaluated, comparisons across studies have been difficult, while comparisons across species have been next to impossible. Yet, the ability to make comparsions such as these would seem to be an important pre-requisite for the development of effective animal models of aging.

One approach that might be useful would involve a comprehensive evaluation of the behavioral and biochemical changes occurring within the adult lifespan of a single species. For this reason, we tested four age groups of C57Bl/6J mice (3, 9, 23 and 31 months old) on a number of procedures. Highly reliable age-related behavioral differences were observed on retention of an inhibitory avoidance task. Smaller, but still significant, differences in degree of exploratory behavior (closed field activity) and behavioral rigidity (position reversal learning) were also observed. In contrast, no age-related differences were observed in tests intended to measure tonic reflexes, pain threshold and acquisition and retention of a simple position habit.

Following behavioral testing, all mice were sacrificed and their brains removed and frozen for receptor binding studies. Each brain was dissected into the medulla, pons, hippocampus, diencephalon, striatum and cortex. Binding of ^{3}H-quinuclidinyl benzilate (^{3}H-QNB) to muscarinic cholinergic receptors, of ^{125} I-alpha bungarotoxin (^{125} I-BTX) to nicotinic cholinergic receptors, of ^{3}H-strychnine to glycine receptors and ^{3}H-haloperidol to dopamine receptors was performed. Several age-specific, regional variations in receptor binding were observed. Most impressive among these were a decrease in strychnine binding in the medulla, an apparent increase in haloperidol binding in the striatum and a more general decrease in muscarinic receptor binding in multiple subcortical areas. These data will be discussed as they relate to possible neurochemical etiologies for the behavioral impairments observed with advancing age.

10 CONTINUING GROWTH IN THE AVIAN CILIARY GANGLION.A QUANTITATIVE LIGHT AND ELECTRON MICROSCOPIC STUDY. Mario G. Fiori* and Enrico Mugnaini. Lab. of Neuromorphology, Dept. Biobehavioral Sciences, Univ. of Connecticut, Storrs, CT 06268

Previous studies pointed out that synaptic contact between preganglionic oculomotor fiber and ciliary neuron in the chicken ciliary ganglion undergoes several changes during first 18 months of life. In particular, at the late embryonic stages and in the young chick, the fiber presents a large calyciform nerve ending embracing one pole of the egg-shaped neuron; during growth of the animal, the size of the ciliary neurons increases somewhat and the calyx is changed into a cup of closely apposed boutons. The present study was undertaken to ascertain whether this peculiar synapse shows additional changes during aging. In adult chickens 6-8 months old, an increasing number of ciliary neurons sprout a few short dendrites which intrude among the boutons; at the same time the perikaryon tends to flatten at the synaptic pole, so that the postsynaptic surface enlarges. On its turn, the preganglionic fiber forms an increasing number of synaptic, terminal and preterminal branches, some of which invaginate more or less deeply into the ciliary neuron. The number of neurons displaying invaginations increase with age, reaching the maximum at about 2 years (25 to 28% of ciliary neurons are invaginated at this time) and then decreasing slowly but progressively: in 7-year-old chickens only 9-10% of the ciliary neurons have invaginations.

Moreover, neurochemical studies (Giacobini et al., abstract, this meeting) indicate that ACh content in the ciliary ganglion increases during adulthood reaching a maximum at about 2 years of age and then decreasing progressively up to 7 years. Since in the chicken the body weight continues to increase beyond the first six months of age and, on the other hand, morphological data indicate regressive changes in the eyes of old birds, it is presumed that the changes at the ciliary ganglion cell accompany changes in the target tissue (sphincter iridis and ciliary body).

Supported by NIH Grant 09904.

11 EFFECT OF DIETARY RESTRICTION ON LIPOFUSCIN ACCUMULATION IN RAT CEREBELLAR PURKINJE CELLS. Wm. B. Forbes. Worcester Fndn. for Exptl. Biol., Shrewsbury, MA 01545.

Severe dietary restriction throughout adult life has been reported to significantly enhance the longevity of rodents in the laboratory. In order to evaluate the effect of longevity-promoting dietary regimens on aging-related changes in rat brain, lipofuscin accumulation in cerebellar purkinje cells was measured in three dietary treatment groups: rats reared in small litters (8 pups) and fed rat chow ad lib following weaning at 21 days of age (group HH); rats reared in large litters (16 pups) and fed ad lib following weaning (group LH); and rats reared in small litters and fed restricted amounts of chow throughout post-weaning life (group HL). Group LH exhibited a permanent body weight deficit in comparison with group HH of about 10%. Mean body weight of group HL was held at 200 gm. To date, group survivorship curves are consistent with the expectation that the HL animals will exhibit a mean life-span of about 150% that of group HH, while group LH will exhibit only a small increase in life-span.

At 220 days of age, 10 animals of each group were sacrificed for lipofuscin determination. In each animal, 20 individual purkinje cells in the cerebellar vermis were studied at 1560X magnification using unstained paraffin sections 6 μ thick. Lipofuscin volume within the perikaryon was estimated by counting the number of intersections of a grid reticle which overlay autofluorescent lipofuscin granules in a single plane of focus. Perikaryal volume was estimated in a similar manner using phase contrast elements. In comparison with group HH, groups HL and LH exhibited significantly less lipofuscin/cell ($t < .05$, one-tailed). However, group HL exhibited slightly and group LH significantly lower perikaryal volumes than group HH. Consequently, there were no significant group differences in lipofuscin volume/unit perikaryal volume. If these preliminary results are confirmed by additional data, it would imply that restricted rats are undergoing aging-related changes in brain at a normal rate. By virtue of its much greater life-span, the restricted rat may be a superior model for the study of senescence.

(Supported by NIA grant AG00779.)

12 LOSS OF AXON TERMINALS IN THE DENTATE GYRUS OF SENESCENT RATS. Y.Geinisman, K.D.Bennett* and M.E.Yates*. Dept. Anat., Sch. Med., Northwestern Univ., Chicago, IL 60611.

A loss of axo-dendritic and axo-somatic synapses was described by us earlier in the dentate gyrus of senescent rats (Neurosci. Abstr., 1977, 3: 106; 1978, 4: 113). This loss of synapses was determined in relation to the postsynaptic elements remaining in senescence, and it could, therefore, be due to a disappearance of synaptic densities or to a loss of presynaptic terminals. In the present study, an attempt has been made to elucidate the question whether a loss of presynaptic terminals underlies age-related synaptic loss.

Male rats of the Fischer-344 strain were used. A group of five senescent rats of 25 months of age was compared with a group of five young adult rats of 3 months of age. After perfusion of animals with Karnovsky's fixative, the rostral portion of the right dentate gyrus was embedded in Araldite. Coronal ultrathin sections were prepared to include the region of the dorsal blade of the dentate gyrus, which is opposite the free, lateral end of its ventral blade. These sections, stained with uranyl acetate and lead citrate, were used to obtain electron micrographs of granule cell bodies in the dorsal-most part of the granule cell layer and of the neuropil in the supragranular zone of the molecular layer. In the micrographs, axon terminals contacting neuronal soma membranes in the granule cell layer and axon terminals contacting membranes of longitudinally cut dendrites in the supragranular zone of the molecular layer were examined. The number of axon terminals was counted and expressed per unit length of neuronal plasma membrane. The membrane length was estimated with the help of a map-measurer.

Examination of axon terminals in contact with neuronal soma membrane showed that their number was significantly decreased in the group of senescent rats relative to the young adult group. The decrease in the number of axon terminals was found not to be associated with any significant change in the length of neuronal soma membrane in senescence. These results, taken together, indicate that an absolute loss of axon terminals contacting the neuronal soma membrane occurs in the dentate gyrus of senescent rats. The loss of axon terminals can account for the observed age-related loss of axo-somatic synapses, and further work is in progress to determine whether the same is true for the age-related loss of axo-dendritic synapses.

The loss of axon terminals in senescence may be considered as evidence of a primary impairment of presynaptic elements in the process of age-related synaptic loss.

Supported by NIH BRSG Grant RR 05370; animals were purchased by NIA Grant AG 00383.

13 AGING OF CHOLINERGIC SYNAPSES IN AUTONOMIC GANGLIA AND IRIS OF THE CHICK. Ezio Giacobini, Mario Marchi*, and Douglas Hoffman*. Lab. of Neuropsychopharmacology, Dept. of Biobehavioral Sciences, Univ. of Connecticut, Storrs, Ct. 06268.

Information of the aging process of cholinergic synapses in the peripheral nervous system is slight. We have followed the pattern of variation in the endogenous levels of acetylcholine (ACh) and choline (Ch) in sympathetic (lumbar) ganglia, a parasympathetic (ciliary) ganglion and its target organ, the iris, from 1 to 7 years of age in the chick. The radioenzymatic micromethod of McCaman and Stetzler (J. Neurochem. 26: 669, 1976) was used. The data are expressed as pmoles per ganglion or iris. In the iris, ACh levels remain constant between 1 and 1.7 yrs. (402 ± 42 to 488 ± 29). Following this period ACh levels decrease continuously from 289 ± 50 at 2 yrs. to 198 ± 40 at 5 yrs., and to 68 ± 11 at 7 yrs. At this latter age the amount of ACh is less than in the iris at 14 days of incubation (d.i.). The ACh content in the sympathetic ganglion is unvaried between 1 and 2 yrs. (182 ± 47 to 259 ± 42) and decreases slightly at 5 yrs. (130 ± 29) with no further decrease up to 7 yrs. (155 ± 48). The ACh levels of the ciliary ganglion show a different pattern. The ACh content increases > 2 fold (161 ± 40 to 384 ± 89) between 1 and 2 yrs., then declines at 3 yrs. (236 ± 60) with the value at 5 yrs. being the same as at 1 year of age. This slight fall continues up to 7 yrs. (96 ± 13). The Ch content parallels the ACh pattern in all three organs. The V_{max} for Ch uptake follows the same pattern as ACh levels. This is the same trend we observed during development (Marchi et al., 1979, abstract, this meeting). In conclusion: 1) Unexpectedly, the ACh content of the ciliary ganglion continues to increase during the first part of aging (1-2 years); whether or not these biochemical changes correlate with morphological changes in the maturing synapse remains to be seen. 2) On the contrary, ACh levels in the iris decrease during aging, reaching embryonic levels at 7 years. If these values are calculated per protein the ACh level of the iris is lower at 7 years of age than at 5 d.i., suggesting that these low levels of ACh may be sufficient for synaptic function at this age or that decline of function occurs. 3) Ch uptake seems to be a limiting factor in regulating ACh synthesis during aging as it is during development. Changes in V_{max} closely parallel changes in ACh levels.

14 SPONTANEOUS DIURNAL AND NOCTURNAL PROLACTIN SURGES IN AGED FEMALE RATS. D. P. Gilman, D. A. Damassa*, K. H. Lu*, H. L. Judd*, and C. H. Sawyer. Depts. of Anatomy and Obstetrics and Gynecology, UCLA Medical School, Los Angeles, CA 90024.

Aging female rats show a gradual cessation of regular ovulatory cycles. Initially this acyclicity is characterized by a state of constant estrus (CE) as revealed by persistent vaginal cornification and the presence of large ovarian follicles. Subsequently a state of persistent diestrus (PD) ensues interrupted by estrous cycles at irregular intervals. Since changes in prolactin secretion are seen in young females during periods of acyclicity (e.g., pseudopregnancy), the present study was undertaken to examine prolactin secretory patterns in aged PD and CE rats.

Female Long-Evans rats 20-28 months old were housed in standard animal facilities with an alternating light cycle of 14-hr of light (0500-1900 hr) and 10-hr of dark. Each animal was fitted with a chronic intraatrial cannula and allowed to recover for 2 days. Blood samples (0.15ml) were then obtained via the cannula every 3-hr for 24-hr. The 24-hr program of blood sampling was repeated for each animal 2 or 3 times over a 6 day period, and plasma prolactin was measured by radioimmunoassay using the NIAMDD kit and RP-1 standard.

PD females which were free of pituitary tumors and other gross pathology exhibited two distinct prolactin surges each day. The diurnal surges were relatively small with mean peak prolactin values of 90 ± 9(SE) ng/ml at 1400-1700 hr. The nocturnal surges were larger, showing peak titers of 385 ± 56 ng/ml at 0200-0500 hr. CE females without signs of pathology also showed both diurnal and nocturnal prolactin surges. In contrast to findings in PD rats, however, the diurnal surges were larger (434 ± 179 ng/ml) than the nocturnal surges (174 ± 29 ng/ml). In PD and CE animals which had evidence of pituitary tumors, plasma prolactin values were elevated and did not show any consistent patterns.

These findings reveal that aged female rats exhibit daily prolactin surges which are comparable in timing, and for PD rats also in magnitude, to those seen in young pseudopregnant rats. The prolactin surges in the aged rats, however, differ from those of pseudopregnancy in that they appear to be generated spontaneously and do not require cervical stimulation for activation. (Supported by grants from NIH and The Ford Foundation).

15 BRAIN UPTAKE INDEX FOR CHOLINE IN AGED RATS. P. Hicks*, C. Rolsten*, L. Hsu*, J. Schoolar, and T. Samorajski. Texas Research Institute of Mental Sciences, Houston, Texas 77030.

Recent studies indicate that there are cerebral vasculature changes with increasing age. There is loss of capillary endothelial cells, and increased capillary length and volume with age (Bar, Adv Neurol 20: 1, 1978). However, the functional integrity of the blood-brain barrier (BBB) in old animals has not been characterized. Rapoport, et al (J Gerontol 34: 162, 1979) did show minimal increased permeability of the BBB with age; however, no information is available in aged animals on the integrity of the BBB carrier systems characterized by Oldendorf (Crit Rev Toxicol 3: 159, 1975). This study tests the hypothesis that the function of the choline transport system at the BBB decreases with age.

Sprague-Dawley rats obtained from the NIA were used at 10 mo., 18 mo., and 26 mo. of age. The brain uptake index (BUI) was measured by the method of Oldendorf, using $^{3}H_2O$ as the diffusible substance and $^{99m}TcO_4$-Sn-EDTA as the indiffusible substance. In ten brain regions there were no age-related differences found in the choline chloride BUI, although in seven regions the mean BUI was lower in the older rats. The overall trend for decreased BUI of choline was significant ($p<.05$, Kendall Coefficient of Concordance).

Marked regional differences were found in the choline chloride BUI. The regions investigated in order of increasing choline BUI are striatum, septum-nucleus accumbens, midbrain, diencephalon, hippocampus, hypothalamus, cerebellum, cortex, pons, and medulla. The BUI in the medulla was about fourfold higher than in the striatum.

These findings indicate that there is some indication of decreased functional capacity of the BBB choline transport system in aged rats. The physiological significance of this observation needs further evaluation.

16 FINE STRUCTURAL EFFECTS OF AGE ON THE RAT PINEAL GLAND. John E. Johnson, Jr. National Institute on Aging, NIH, Gerontology Research Center, Baltimore City Hospitals, Baltimore, Md 21224.

The pineal is considered to be an endocrine gland having hormonal influences on the testes, ovaries, thyroid, pituitary and adrenals. It is thought that the pineal gland regulates, decreases or inhibits general somatic development and, specifically, the reproductive system. Recently data have accumulated suggesting that the pineal may play a role in the aging process by modulating feedback sensitivity of the hypothalamus. Since hypothalamic feedback sensitivity has been shown to be reduced with increasing age it was hypothesized that the aging pineal would show marked structural alterations.

Male Sprague-Dawley rats, 4 mos and 28 mos of age, and female Sprague-Dawley rats 9 mos and 23 mos of age, were sacrificed by aldehyde perfusion and the pineals processed for electron microscopy.

With advancing age it was found that the pineal capsule thickness increased and severe collagen infiltration was noted. Accompanying the collagen infiltration were patches of granular material and filaments. Definitive light, dark and intermediate density pinealocytes were present, and no consistent change in their relative frequency was found with increasing age. The number of pinealocytes with deep nuclear invaginations increased with advancing age in the male rats but no pattern was found in the females. Nuclear inclusions, possibly the "Kernkugeln" reported by Dimitrova in 1901, were identified in the pinealocytes. These inclusions consist of filaments 10nm in diameter and increased in frequency with advancing age. Cytoplasmic dense bodies increased in frequency as a function of age. The dense bodies have the structural characteristics of lipofuscin. The maximum diameter of lipid droplets tended to increase with age suggesting the possibility that the rate of secretion may decline in older animals. Occasional cells contained reticulated mitochondria and some cell processes had a similar appearance to neuroaxonal dystrophy seen in the dorsal columns of the brainstem in aging animals of several species.

17 AGING AND MINIATURE ENDPLATE POTENTIALS IN MICE. S.S. Kelly*, R.A. DeRosa*, and Norman Robbins. (SPON: A.C. Breuer) Dept. Anat. Case West. Res. Schl. Med., Cleveland OH 44106.

The frequency and amplitude of miniature endplate potentials (MEPPs) exhibit large changes between young and old (30-33 mo) rats (Gutmann et al., J.Physiol. 216:331,1971; Vyskocil & Gutmann, Experientia 28:280,1972). Those experiments, conducted at 20° C, showed that the changes (increased amplitude, decreased frequency) were greater in soleus than in diaphragm. In the present study, MEPPs were recorded in C57BL female mice age 7-8 or 31-33 months. Recordings were made from the extensor digitorum longus (EDL) and soleus muscles in vitro at 30°C. The amplitudes, corrected to a standard resting membrane potential of -80mV, and frequencies were calculated, and the results from 3 young and 4 old mice were compared using the Mann-Whitney nonparametric test.

In the EDL, mean amplitude of MEPPs increased significantly ($p<2\%$) from 0.46mV in the younger group to 0.62mV in the older group. Mean frequency decreased from 7.1Hz to 5.4Hz ($p<2\%$). In the soleus, MEPP amplitudes slightly increased from 0.56mV to 0.69mV ($p<7\%$), but there was no significant change in frequency from the value of 5.2Hz in younger mice.

These results differ from those found by Gutmann et al. in that the soleus shows little change, and even in the EDL, the changes were small compared to those reported in the rat. It appears that age-related changes in neuromuscular systems are a function of species and muscle type. The difference between EDL and soleus may relate either to fiber type (fast and slow, respectively) or to the different usage of the two muscles.

18 QUANTITATIVE ANALYSIS OF SYNAPTIC JUNCTIONS, AXON PRETERMINALS AND ASTROGLIAL PROCESSES IN THE HIPPOCAMPUS OF YOUNG AND OLD RHESUS MONKEYS. C.A. Knox*, S.K. Jirge*, K.R. Brizzee, J.M. Ordy and R.T. Barthus* (SPON: W. Sewell).Depts. Anat/Neurosurg. & Delta Regional Primate Research Center, Tulane University, New Orleans and Covington, LA and Lederle Laboratories, American Cyanamid, Pearl River, New York, 10965.

The hippocampus is one of the major convergent multimodal sensory centers in the forebrain concerned with the acquisition, storage and retrieval of multimodal information designated as short-term memory. One of the more prominent behavioral manifestations of aging is an impairment of short-term memory. In view of the above observations, it appears likely that age-related ultrastructural changes in the hippocampus, especially those having a bearing on neuronal connectivity, may have a direct relationship to the short-term memory impairments observed in the elderly. The purpose of the present study was to compare age differences in numerical density and volume density of the synaptic junctions, axon preterminals and astroglial processes in the stratum radiatum of the CA1 zone in young adult as compared with aged rhesus monkeys on the premise that the data may be extrapolated to the human situation with much greater confidence than in the case of similar studies in rodents.

Quantitative analysis of electron micrographs was performed in two young (approximately 6-8 years of age) and three old (approximately 20 years of age) rhesus monkeys. Fifty random electron micrographs at a final magnification of 25,000 times were prepared from each animal. Micrographs were quantitatively analyzed for numerical and volume density (random hit method) for synaptic junctions, axon preterminals and astroglial processes. The numerical density of synaptic junctions and axon preterminals was found to be decreased by 25% and 41%, respectively, in aged animals. In a similar manner, the decrease in volume density of these parameters was 33% and 30%, respectively. In contrast to the loss of synaptic junctions and axon preterminals, astroglial processes demonstrated a marked age-related increase in numerical density (225%) and in volume density (567%). These results confirm and support similar findings which have been reported in the dentate gyrus of the rat and in the human cerebral cortex during aging. This study also demonstrates that marked age-related ultrastructural alterations occur in the hippocampus, one of the primary convergent multimodal sensory centers in the brain concerned with the mediation of short-term memory.

19 MARKED ALTERATIONS IN RESPONSIVITY TO PSYCHOSTIMULANT AND CHOLINERGIC DRUGS ASSOCIATED WITH SENESCENCE IN THE FEMALE MOUSE. Harbans Lal*, Robert Gianforcaro* and Kalidas Nandy* (SPON: Robert Hill): Department Pharmacology & Toxicology, University of Rhode Island, College of Pharmacy, Kingston, RI, 02881, and GRECC, V. A. Hospital, Bedford, MA, 27710.

Elderly patients are known to respond differentially to a variety of psychotropic and other drugs but the mechanism underlying these differences are not known. Although significant pharmacokinetic changes have been reported in the elderly, overwhelming evidence suggests that pharmacodynamic factors play a more important role in determining their responsivity to the drugs. With a view to define in vivo changes in the pharmacodynamic factors, we studied selected cholinergic and dopaminergic drugs in the senescent (15-30 months old) female mice of C57BL6 strain. These mice did not show any deficit of spontaneous or exploratory motor activity related to senescence. However, there was a marked reduction in responsivity to amphetamine, a catecholaminergic stimulant drug, and to dexetimide, a specific anticholinergic drug, with respect to locomotor stimulation. In contrast, the responsivity to oxotremorine, a cholinergic agonist, was enhanced with respect to locomotor depression. Senescent mice also showed enhanced lethality due to oxotremorine. Because the changes in drug responsivity were not all in one direction, they are not likely to be due to pharmacokinetic factors. The observed changes in the amphetamine action suggest alterations of catecholaminergic systems in the senescence. Previously a reduction in the number of haloperidol and spiroperidol binding sites has been shown in the senescent animals. Enhanced activity of a cholinergic agonist and reduced sensitivity to a cholinergic antagonist is difficult to intepret but is probably due to hypersensitivity of the central cholinergic functions.

20 LONG-TERM ADRENALECTOMY REDUCES SOME MORPHOLOGICAL CORRELATES OF BRAIN AGING. P.W. Landfield[1], C. Wurtz[2]*, J.D. Lindsey[3]* and G. Lynch[4]. Dept. Physiol. & Pharmacol., Bowman Gray Sch. Med., Winston-Salem, NC 27103[1]; Dept. Psychobiol., Univ. Calif., Irvine, CA 92717[2-4]; Dept. Neurosci., UCSD Sch. Med., La Jolla, CA 92093[3].

In previous reports we noted that the hypertrophy of hippocampal astrocytes is a consistent correlate of brain aging in Fischer rats (Landfield et al., 77, J. Gerontol.). We also found evidence that this astroglial hypertrophy is related, in part, to adrenocortical hormones (Landfield et al., 78, Science; Soc. Neurosci. Abstracts, 78). To date, our findings are consistent with the hypothesis that endocrine systems, in particular the adrenocortical system, modulate the rate of development of some asepcts of brain aging (Landfield, In Parkinson's Disease II, Finch et al. (eds.), Plenum, 1978).

We report here the initial results from a study in which aging animals were adrenalectomized (Adrx.) at 14 mo. of age and maintained for 5½ mo. on 0.9% NaCl behind an air barrier system to prevent airborne infection. These Adrx. animals (low dose) received 10 µg/ml replacement glucocorticoid in the drinking saline. A control group was Adrx. at the same age and maintained in the same manner. However, these control animals received 250 µg/ml cortisol in the drinking saline (high dose). This dose was, however, adjusted on several occasions because of weight loss and some deaths in the high dose group. Final dose was 175 µg/ml. An intact control group was also included. Plasma glucocorticoids were analyzed after the animals were perfused.

Analysis of semithin brain sections appears to indicate that the low dose animals exhibit reduced numbers of hippocampal microglia and a reduced depth of the hippocampus. Both increased microglia and increased depth are correlates of aging in the hippocampus of rats (Landfield et al., Proc. Gerontol. Soc. 1978; Diamond et al., Behav. Biol. 1975; Lindsey et al., J. Gerontol. 1979). Lipofuscin appears unaffected by these treatments. Astrocyte analyses are still underway, as are more complete analyses of all variables. To this point, however, it appears as if adrenalectomy can reduce at least some correlates of brain aging in rats. Of course, whether these reductions are relevant to functional changes still remains to be determined.

21 REINSTATEMENT OF BRAIN STIMULATION REWARD IN AGED RATS BY AMPHETAMINE. M.J. Lewis, Dept. Psychology, Howard University, Washington, D.C. 20059.

A single low dose (0.2-0.35 mg/kg) of d-amphetamine sulfate reinstated lever-presses(l-p) for brain stimulation reward(BSR) in rats who prior to injection no longer l-p for BSR. These animals ranged in age from 400-550 days, but were implanted at 200-250 days with bipolar platinum electrodes in the medial forebrain bundle in regions of the lateral hypothalamus. All showed vigorous l-p after implantation and subsequently received drugs, but were drug-free at least 60 days prior to amphetamine injection. Food deprivation, increased stimulating current, frequent priming stimulation and reshaping failed to reinstate stable l-p. Amphetamine injected 5 minutes prior to session reinstated l-p in 7 of 11 rats with minimal priming and the remaining animals after one shaping session. BSR parameters threshold current and mean resistance to the stimulating current increased over initial values while rate of l-p remained unchanged. All animals exhibited l-p on two subsequent sessions without additional amphetamine injection. Three animals continued to l-p without further injection on five subsequent trials over a 1 month period. These data suggest that amphetamine may rejuvenate degenerating reward systems in aged animals.

22 ELECTROPHYSIOLOGICAL AND BIOCHEMICAL EVIDENCE FOR AGE-RELATED ALTERATIONS IN HIPPOCAMPAL CHOLINERGIC FUNCTIONING. A. S. Lippa*, D. J. Critchett*, R. T. Bartus (SPON: C. Latimer), Medical Research Division, American Cyanamid, Pearl River, NY 10965; and, W. Harrington* and R. W. Pelham*, Tufts-New England Medical Center, Dept. of Neurology, Boston, MA 02111.

While central cholinergic (ACh) mechanisms have recently been implicated in the cognitive disorders associated with old age, no direct evidence for age-related functional alterations in ACh mechanisms has been reported. Since hippocampus has also been implicated in memory functions, we have investigated muscarinic ACh receptors in dorsal hippocampus in male, albino rats aged either 6-9 months (YOUNG) or 26-29 months (OLD). All rats were anesthesized with chloral hydrate (400 mg/kg, intraperitoneally) and allowed to breath spontaneously. Microiontophoresis and recording were performed with stereotaxically placed 5-barrelled glass micropipettes of approximately 6 μM overall tip diameter. The center recording barrel was filled with 1.5 M NaCl and generally had a resistance of 3-12 Megohms. Three of the four side barrels were filled with either ACh (.5 M, pH 3.4) or L-glutamic acid (GLU; 1 M, pH 8.5) which were passed as cation and anion, respectively. The fourth barrel contained 4 M NaCl to balance drug ejection and holding currents. Dorsal hippocampal pyramidal cells were tentatively identified by their low firing rate and bursting firing pattern. At the end of each electrophysiological recording session, brains were removed and stored frozen for the subsequent measurement of ^{3}H-quinuclidinyl benzilate (^{3}H-QNB) binding and choline acetylase activity. Both ACh and GLU stimulated the firing of pyramidal cells in a dose-related manner (1, 2, 5 and 10 nA). However, the responses to ACh were significantly reduced ($p < .05$, analysis of covariance) in the OLD group with an approximately 50% reduction in the maximum amount of stimulation. No age-related differences in the responses to GLU were observed ($p > .05$, analysis of covariance). Scatchard analysis of ^{3}H-QNB binding in dorsal hippocampus revealed a significant reduction ($p < .004$, t test) in the number of binding sites (YOUNG B_{max} = 1580 + 50 fmol/mg protein; OLD B_{max} = 1330 + 40 fmol/mg protein) with no significant change ($p > .05$) in affinity (YOUNG Kd = .274 + .016 nM; OLD Kd = .294 + .035 nM). Choline acetylase activity, a marker of ACh neurons, was also unchanged. Since the responses to iontophoretically applied GLU were dose-related, but not age-related, the present results document a selective age-related functional impairment of hippocampal ACh mechanisms.

23 AGE DIFFERENCES IN CONDITIONED TASTE AVERSION: POSSIBLE ROLE OF VASOPRESSIN. M. Colleen McNamara and Ralph L. Cooper.* Center for the Study of Aging, Duke University Medical Center, Durham, North Carolina 27710.

If an animal becomes ill following the ingestion of a novel substance, the intake of that substance will be suppressed on subsequent presentations. This phenomenon is referred to as conditioned taste aversion (CTA). In an earlier study we found that young and old rats did not differ in their ability to acquire a CTA to saccharin (SAC) when averted with amphetamine. However, retention of the CTA was significantly impaired in the old animal. We also found that this deficit could not be attributed to changes in peripheral mechanisms (i.e., taste, illness, etc.), suggesting that age-dependent changes within the brain and/or pituitary may underlie the impaired performance of the aged rat on this task.

The effects of a variety of stressful experiences, such as CTA, have been shown to be mediated in part by changes in pituitary hormone secretion. In particular, vasopressin has been shown to restore the avoidance response in studies using young rats. Since there is ample evidence suggesting decreased synthesis and availability of vasopressin in the old rat, we investigated the possibility that treatment with exogenous vasopressin (LVP) may improve the performance of aged rats on the retention phase of the CTA.

Male rats 3, 6, 10 and 19 months of age were conditioned to avoid a 0.1% SAC solution by three pairings of the novel taste with a 0.5 mg/kg, ip injection of d-amphetamine. All animals were compared for acquisition and retention of a taste aversion with a two bottle choice process. Animals in all age groups tested acquired the aversion to SAC equally over a period of 2 months. The older animals treated with LVP(1ug/kg) every 5 days retained the CTA significantly longer than did the saline injected controls. The data suggest that the pituitary-adrenal axis may be involved in age-related behavioral deficits in fear -mediated responding.

24 MORPHOLOGICAL CORRELATES OF AGING IN THE MONKEY BRAIN - A LIGHT AND ELECTRON MICROSCOPIC STUDY. Ronald Mervis, Robert D. Terry* and Douglas Bowden. Dept. Pathol (Neuropathol), Ohio St. Univ. Col. Med., Columbus, OH 43210, Albert Einstein Col. Med., The Bronx, NY 10461, and Dept. Psychiat., Univ. Washington Sch. Med. Seattle, WA 98195

In a blind, coded study, the hippocampus and frontal cortex from 22 rhesus monkeys ranging in age from 4 to at least 20 years old were evaluated for age-related morphologic alterations at both the light and electron microscopic levels. Based on these findings, an attempt was made to categorize the subject's chronological age as either (I) Young, (II) Transitional, or (III) Aged. In general, both the light and electron microscopic findings were positively correlated with each other and with the various age groups. The light microscopic evaluation, which was based largely on the degree of senile (neuritic) plaque formation and amyloid deposition was, on the whole, a reliable indicator of age, particularly for those monkeys at either end of the chronological spectrum. EM appeared to provide a satisfactory evaluation for all age ranges, and was particularly effective in detecting those subtle morphological age-related changes in tissue from "Transitional" stage II subjects such as individual or small groupings of abnormal neurites which had not yet formed recognizable plaques. The major EM findings that were associated with advancing age were: an increase in lipofuscin deposit in both neurons and glia, accumulation of glial fibrillary content, enhanced myelin remodeling, and the presence of corpora amylacea and dystrophic and degenerating neurites. Hippocampal changes were usually, but not invariably, more pronounced than the neo-cortical findings.

(Supported by NIH Grant NS-02255)

25 BRAIN PROTEINS IN SCHIZOPHRENIA AND AGED CONTROLS AS ANALYZED BY COMPUTERIZED DENSITOMETRY. Gary D. Miner and Susan Maurer*. Dept. Biology, Northwest Nazarene College, Nampa, ID 83651.

Previous published (Prog. Neuro-Psychopharma. 2:107-115, 1978) and unpublished work of the senior author has demonstrated instability of a brain protein called '2.7' in a significant number of schizophrenic and related pathologies. These previous studies were primarily on chronic, aged individuals. The hypothesis tested in this current study states: "The instability of protein 2.7 is correlated with age rather than schizophrenia specifically." Groups of schizophrenic, old diseased (non-schizophrenic), old normals, young diseased, and young normals were compared. Although our sample sizes are small for many of the above categories yielding statistically non-significant data, the trends are consistent indicating the possible validity of our hypothesis.

26 AGING OF CIRCADIAN RHYTHMS IN FEMALE RATS. Sarah S. Mosko and Robert Y. Moore. Dept. Neurosciences, UCSD, La Jolla, CA 92093

During the normal course of aging in female rats, estrous cycling breaks down near the end of the first year and rats enter a constant vaginal estrous (CVE) state at 12-15 mo which is succeeded by a series of repetitive pseudopregnancies beginning at about 2 yrs. The primary deficit responsible for the breakdown in cycling is unknown. Rats with neonatal or adult lesions of the suprachiasmatic nucleus, which abolish circadian rhythmicity, exhibit a permanent CVE syndrome. The estrous cycle of rodents has a circadian organization which is timed by the light-dark cycle, and recent evidence indicates that there may exist a circadian signal for LH release which is responsible for the preovulatory LH surge. We compared circadian rhythms in 7 old constant estrous (OCE; 16-18 mo) and 4 old repetitive pseudopregnant (ORPP; 24-26 mo) rats to rhythms in 6 young cycling (YC; 3-4 mo) rats to determine if aging of circadian rhythm generating mechanisms could be a factor in the breakdown of estrous cycling in aging females. In addition, since neonatal androgenization induces a permanent CVE state which has been viewed as a model of early reproductive senescence, we also examined circadian rhythmicity in young, early androgenized (YEA; 3-4 mo) rats (100ug testosterone proprionate, s.c., on the day after birth).

Circadian rhythms in locomotor activity and drinking behavior were monitored in all rats (Long Evans, hooded) in both entrained (L:D, 14-10) and free-running (constant dim illumination, 1.0 lx) conditions. The results indicate that circadian rhythmicity in both behaviors declines with increasing age. In diurnal lighting, YC, OCE and ORPP rats restrict 72.7 $\pm$ 2.4%, 67.1 $\pm$ 1.7% and 58.9 $\pm$ 2.2%, respectively, of their drinking behavior to the 10 hrs of darkness. This percentage decrease in aged rats is primarily the result of fewer drinking events during the dark phase. Power spectral analyses of drinking events in both entrained and free-running conditions reveal a progressive flattening of the spectrum and a diminished circadian peak with advanced age. YEA rats, in contrast, exhibit normal rhythmicity in activity and drinking.

Our findings indicate that the amplitude of circadian functions declines significantly with advancing age in rats. Aging of central circadian rhythm generating mechanisms is implicated. Dampened circadian functions in old age could contribute to the normal pattern of reproductive senescence observed in female rats. The observation that YEA rats exhibit normal circadian rhythms may indicate that different mechanisms underlie the CVE states of the YEA rat and rat with suprachiasmatic nucleus ablation.

27 PROTEIN SYNTHESIS IN ORGAN CULTURES OF RAT BRAIN MICROVESSELS. Michael A. Moskowitz, Illana Gozes, Brenda L. Cronin*, Monica J. Williams*. Laboratory of Neuroendocrine Regulation, Department of Nutrition and Food Science, MIT, Cambridge, MA 02139.

Biochemical studies have shown that cerebral blood vessels exhibit age-related changes in their protein content which may be important in the development of vascular lesions. To examine the extent to which these changes reflect differences in protein synthesis, we have established an organ culture system capable of supporting protein synthesis in brain microvessels.

Intraparenchymal brain microvessels consisting of arterioles, capillaries, and venules were isolated from the forebrains of Sprague Dawley rats by isopycnic sucrose density gradient centrifugation and microsieving techniques. The microvessel preparations were free of contaminating neurons and glia, as shown by light and electron microscopy and by the absence of radioactivity within microvessels prepared after the addition of radiolabelled synaptosomes and cytoplasmic proteins to the whole brain homogenates. We also examined the protein patterns of these blood vessels by isoelectric focusing and by sodium dodecyl sulfate polyacrylamide gel electrophoresis, and found that they differ considerably from those of synaptosomes and brain homogenates. The isolated microvessels were incubated at 37°C in the presence of Eagle's minimal essential medium (devoid of methionine) and 35S-methionine under 95% O_2 / 5% CO_2 conditions. The incorporation of radiolabelled methionine into trichloroacetic acid-precipitable protein appeared proportional to the concentration of vascular protein at ranges of 1-2 mg/ml. The microvessels incorporated methionine at a linear rate up to at least 30 minutes. The newly synthesized proteins, resolved by sodium dodecyl sulfate polyacrylamide gel electrophoresis and by isoelectric focusing, exhibited some differences between animals of 4 and 21 months. Such studies appear useful as models for examining the biochemical activity of cerebral blood vessels during aging and other pathological states.

28 AGE-RELATED BEHAVIORAL, PHYSIOLOGICAL, AND ANATOMICAL CHANGES IN APLYSIA CALIFORNICA. B. Peretz,* R. Papka,* K. Rattan,* and J. Becker* (SPON: D. T. Frazier) Depts of Physiology and Anatomy, Univ. of Kentucky Med. Ctr., Lexington, Ky. 40536

The gill withdrawal reflex to gill stimulation and its neural correlates are age-dependent. The reflex and the physiology and anatomy of L_7 and R_2, central neurons in the parietovisceral ganglion were examined in old Aplysia, 500 gm and heavier, and in mature Aplysia, 100-250 gm. No less than 50 days of age separated the two groups. The reflex in old Aplysia was elicited by a stimulus of 1.5 gm or greater whereas in mature animals 0.2 gm was threshold. Habituation of the reflex, to 1.5 gm, was twice as fast in old Aplysia (n=7) as in mature animals (n=7). L_7 spiking did not reliably dishabituate the reflex in old animals as it did in mature ones. EPSP's, evoked by gill stimulation, in L_7 from old Aplysia, were correlated with reflex habituation but were 1/8 the size of those in L_7 from mature animals. Rin, of L_7 was 0.7 M in the old group as compared to 4.8 M in the mature one; decreased Rin can explain reduced PSP size. Time constant, T, in old animals was twice that in mature animals. Size of L_7 in living ganglia from the two groups were not significantly different. Rin, T, and size comparisons of R_2 were similar to those found for L_7. LM and EM studies of L_7 and R_2 revealed that with aging the number of glial cells increased, and there was increased membrane infolding probably accounting for decreased Rin and greater T. Age-pigment, lipofuscin, in close proximity to the infoldings and to trophospongiun, increased as a function of age and exhibited autofluorescence similar to that seen in vertebrate neurons (Brizee et al., 1969). In old Aplysia, EM showed that lipofuscin was a membrane bound amorphous body containing vacuoles and lamellated structures. The bodies attained sizes of about 5 μm in length. In mature Aplysia and those 60 days younger (20 gm or less), the bodies were round, had fewer or lacked lamellated structures, and were 0.5 - 1 μM. Behavioral and physiological signs of aging relate closely to the anatomical signs. The Aplysia nervous system is appropriate to study the life history of individual neurons, esp. those mediating behavior (NIMH; Sanders-Brown Ctr., U.K.)

29 DENDRITIC DYING BACK, NEUROFIBRILLARY TANGLES, AND LEARNING AND RETENTION IMPAIRMENT FOLLOWING ALUMINUM ADMINISTRATION: IMPLICATION FOR BRAIN AGING. Ted L. Petit and Gerald B. Biederman*, Div. Life Sci. & Dept. Psychol., Univ. Toronto, West Hill, Ont., Canada.

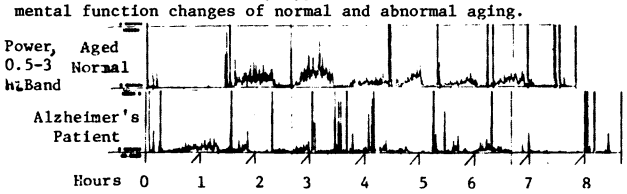
Senile dementia of Alzheimer's type is accompanied by a number of brain changes, including an accumulation of neurofibrillary tangles in the neuronal cytoplasm, and a progressive dying back of the dendritic tree. Elevated levels of aluminum cause a somewhat similar accumulation of neurofillamentous tangles in some species, and as such has been used as a model for the human condition. Crapper has found elevated levels of aluminum in the brains of senile patients and has hypothesized that this element may play a critical role in the etiology of the disease. To further determine the possible role of aluminum in that disease, it is important to systematically discern the consequences of increased brain aluminum content. Aluminum tartrate (5μM in 100μl water) or physiological saline was infused into the left lateral ventricle of adult male New Zealand white rabbits. All rabbits were trained 10 days post-operative in a step-down active avoidance task, and retested on post-operative day 13. At the first onset of neurological symptoms (14-21 days post-op), or at 21 days post-op for control animals, the rabbits were sacrificed. Sensori-motor neocortex was examined with electromicroscopy for evidence of aluminum induced neurofibrillary tangles. For light microscopy, brains were stained with the Golgi-Cox stain, layer V giant pyramidal cells were drawn from the dorsal sensorimotor cerebral cortex, and dendritic morphology analyzed by the use of the Scholl method. Aluminum treated animals were deficient on both original learning on day 10 ($p<.01$) and retention on day 13 ($p<.05$) of the step-down active avoidance task. Electron microscopic analysis indicated the presence of neurofibrillary tangles in the soma and dendrites of neurons of aluminum treated animals. The Scholl analysis revealed that there was a sharp and progressive drop off in the number of dendritic branches with increasing distance from the cell body in the aluminum animals. This progressive reduction of dendritic branches as one proceeds toward the periphery of the dendritic field would be the pattern expected from a dying back process. Westrum reported a loss of dendritic spines, dendritic beading and degneration after topical alumina cream application. Such dendritic degeneration may represent the resulting course of the dendritic dying back reported here, and may be homologous to that observed in brains from the senile human.

30 EEG AND SLEEP CHANGES IN NORMAL AGING AND ALZHEIMER'S DISEASE. Pat Prinz, Murray Raskind* and Carl Gerber.* GRECC, Seattle/Tacoma VA Hospitals and Dept. Psychiatry, U. W., Seattle, Wa.

Sleep and waking EEGs from 12 healthy elderly and from 12 inpatients (drug free) diagnosed as having senile dementia of the Alzheimer's type* (i.e., primary neuronal degeneration) were monitored in the subject's typical home or ward environment whenever the subject sat or lay down. As compared with young adults (age 20-30) aged normals (age 55-80) had less stage 3 and 4 and stage REM sleep, and more wakefulness. Napping was similar to young adults. Alzheimer's type patients (aged 55-80) had even less stage 3 sleep, no stage 4 sleep, very little REM sleep and fragmentation of diurnal sleep-wake rhythms, with frequent daytime naps and nighttime awake periods (data are based on the last 48 hours of 72 consecutive hour studies).

The degree of sleep pattern change correlated with mental function measures (Wechsler Intelligence Scale, Tomlinson Dementia Scale). Correlative neuropathological data will be available for both normal and Alzheimer's subjects to determine whether the sleep and mental function relationship is based on a common factor like neuronal degeneration. Aside from sleep pattern changes, parallel changes were also seen in the sleep and waking EEG waveforms: All-night continuous power spectra analysis on a PDP 11-34 revealed a waxing and waning of power in the delta frequency band (.5-3 Hz) that corresponded with periods of slow wave sleep (Stages 2, 3 and 4). The amount of this delta activity associated with sleep was greatest in young adults, less in healthy elderly, and least in Alzheimer's patients (see below). In addition, there appeared to be a slowing of median delta wave frequency in Alzheimer's patients, and to a lesser degree in aged normals.

Changes were also observed in spindle (11-17 Hz) and in the dominant occipital rhythm (6-11 Hz) frequency bands. These changes in rhythmic EEG activity differ from focal paroxysmal EEG activities in that they appear to better correlate with the mental function changes of normal and abnormal aging.



* Clinical diagnostic criteria: see Katzman, R. Postgrad Med, 64, 119-125, 1978.

31 AGE RELATED CHANGES IN RAT CEREBELLUM: PURKINJE CELL ELECTROPHYSIOLOGY AND CORRELATIVE ANATOMY. Joseph Rogers, Michael A. Silver*, William J. Shoemaker, and Floyd E. Bloom. The Salk Institute, P.O. Box 1809, San Diego, CA 92112.

Sprague-Dawley rats (N=16) aged 3,10,20, and 28 mos were prepared for recording under halothane anesthesia. Several penetrations of cerebellar folia 6 and 7 near the vermis with 3 M NaCl filled glass pipettes (tip diameter = 1 μ) provided extracellular recordings from at least 11 Purkinje neurons per rat. On-line computer programs generated interspike interval (ISI) histograms and extracted information about firing rates, climbing fiber evoked bursts, modal ISIs, and number of long (>75 msec) ISIs. Overall, the 3,10, and 20 mos cells appeared relatively normal. The 28 mos cells, however, had significantly lower mean discharge rates, longer modal ISIs, and greater numbers of long ISIs. In the face of this diminished activity, climbing fiber evoked bursting remained remarkably normal. Inspection of individual records from the 28 mos rats revealed that approximately 1/2 the cells fired relatively normally while the rest were highly aberrant with little activity other than climbing fiber doublets and triplets. Occasionally these cells would display more normal patterns, usually for a few seconds within 2-3 min recording epochs.

Following 3-4 hours of electrophysiological assessment, rats were perfused transcardially with 2.0% glyoxylic acid-0.5% paraformaldehyde and cerebellar samples were dissected. These tissues are presently being evaluated for catecholamine varicosities, small granular vesicles, and a number of ultrastructural correlates of aging (e.g., lipofuscin) using histofluorescent and electron microscopic methods.

Since Purkinje cells provide the final common efferent pathway of the cerebellum, their electrical activity represents a plausible test system for gauging the relevance of basic neurochemical and anatomical anomalies occurring in this structure during senescence. (Supported by a grant from the Aetna/BW Price Foundation.)

32 EFFECTS OF CHRONIC HYPOXIA ON LEVELS OF CATECHOLAMINES IN BRAIN REGIONS FROM AGING RATS. Isaac F. Roubein, Larry J. Embree and David W. Jackson*. Veterans Administration Medical Center and Department of Neurology, Louisiana State University Medical Center, Shreveport, Louisiana 71130.

Oxygen deprivation affects neural tissues earlier and with a greater degree of severity than it does other tissues, and behavioral changes may be induced by hypoxia in man and animals. While there are published studies concerning the effect of hypoxia on monoamine levels in mature mammalian brain, information is lacking on the effect of chronic hypoxia on catecholamine levels in aging mammalian brain; hence this study was undertaken. Further, in an attempt to correlate neurotransmitter levels, functional anatomy and the aging process, seven discrete brain regions were selected for investigation.

Male Sprague-Dawley rats at early senescence (21-22 months old) were exposed to a mixture of 10% oxygen - 90% nitrogen in a sealed plastic cage for 36 hr. The gas mixture was passed through the cage at a rate of 3.5 l/min. Simultaneously, control animals of identical age received air at the same rate. At the end of this period, the rats were decapitated, the brain excised, and immediately dissected into the following regions: cerebral cortex, hippocampus, striatum, hypothalamus, midbrain, cerebellum, pons and medulla.

Spectrofluorometric determinations of norepinephrine (NE) in cerebral cortex, hypothalamus, midbrain, cerebellum, pons and medulla, and of dopamine (DA) in striatum indicated that the levels of these monoamines in the regions examined did not differ significantly from controls.

Gross observation of the animals after 13, 19, and 35 hr showed that the animals in the hypoxic environment were less active as compared with the controls, and the hypoactivity was at its maximum at 13 hr. Whether this observed reduction in animal activity and responsivity could be related to alterations in the levels of NE or DA in the specified brain regions is currently under investigation and will be reported.

Supported by the Medical Research Service of the Veterans Administration.

33 DIFFERENCES IN STRIATAL DOPAMINE RECEPTORS IN SEVERAL MOUSE STRAINS AS A NOVEL MODEL FOR STRIATAL AGING. J. A. Severson*, P. K. Randall* and C. E. Finch* (SPON: D. F. Lindsley). Andrus Gerontology Center, USC, Los Angeles, CA 90007.

Male CBA/J mice have 25 to 50% fewer substantia nigra neurons than male BALB/cJ mice (Ross et al., Nature 264:654, 1976). Losses of nigral neurons are a possible mechanism involved in nigrostriatal aging and are undoubtedly involved in Parkinson's disease. Genetic deficits or subclinical lesions of nigral neuron number, coupled with an age-related loss of nigral neurons has been suggested as a mechanism for the age-related onset of Parkinsonian symptoms. We viewed the CBA/J mouse as having a "genetic nigrostriatal lesion" through which we could examine the effect of early losses of nigral neurons on catecholaminergic function, particularly on dopamine receptors.

Male CBA/J and C57BL/6J mice had 50% fewer specific striatal spiroperidol binding sites than male BALB/cJ mice. Binding affinity for spiroperidol was similar (Kd= 0.5 nM). CBA/J mice failed to develop striatal dopamine receptor supersensitivity following chronic haloperidol treatment, while haloperidol treated C57BL/6J and BALB/cJ mice showed 25 to 30% increases in spiroperidol binding. CBA/J mice also failed to develop supersensitivity as measured by apomorphine stereotypy.

Decreased spiroperidol binding and an inability to develop behavioral and biochemical supersensitivity of the striatal dopamine receptor in the CBA/J mouse are similar phenomena as those observed in the aged C57BL/6J mouse striatum. The CBA/J mouse may represent a novel model for striatal aging.

34 AGE RELATED DECREASE IN CNS β-RECEPTOR ACTIVATION OF THYROTROPIN SECRETION. Michael A. Silver[1] and Shirley A. Joseph.[2] (SPON: George Siggins) [1]A.V. Davis Ctr., Salk Inst., La Jolla, CA 92037 and [2]Dept. of Anatomy, Univ. of Rochester, Rochester, N.Y.

Recent studies have implicated central noradrenergic processes in the neuroendocrine regulation of thyrotropin (TSH). We recently reported that pharmacological activation of central β-adrenoreceptors, through ephedrine-HCl administration, resulted in a significant elevation of plasma TSH levels. In this study, we have examined this β-receptor mediated neuroendocrine response in rats at three different ages: 3 weeks, 4 and 19-22 months (n=8). Two hr. after ephedrine administration (10 mg/kg i.p.), plasma TSH was significantly elevated to over 500% of control values in the 3 week and 4 month old rats. In the aged rats, however, plasma TSH levels were not significantly elevated.

To clarify whether this inadequate neuroendocrine response was caused by either a decreased pituitary secretory response or by a CNS β-receptor-associated deficit, the quality of pituitary responsiveness to thyrotropin releasing hormone (TRH) was examined. TRH (30 pg/100g) was administered intravenously to rats at each age and the animals sacrificed after 2 hrs. Plasma TSH levels were found to be similarly elevated from 300% to 395% in each age group, suggesting that pituitary responsiveness was not impaired in the aged rats.

These findings indicate that the lack of neuroendocrine response to ephedrine administration in the aged rats was due to a β-receptor associted deficit. It is not known whether this effect is due to an age-related decrease in β-receptor affinities or binding sites or a loss of β-receptor containing cells.

35 AGE-RELATED ALTERATIONS IN PERIKARYAL MONOAMINES IN NON-HUMAN PRIMATES. John R. Sladek, Jr. and Celia D. Sladek. Depts. of Anatomy and Neurology, Univ. of Rochester Sch. of Medicine and Dentistry, Rochester, NY 14642.

Human aging is accompanied by alterations in a number of central functions which either are mediated or influenced by monoaminergic neurons; these include locomotion, sleep-wakefulness, mood and others. Synthetic and degradative monoamine enzymes are known to fluctuate with age in a direction consistent with an hypothesis of depressed monoamine levels in the elderly. However, the degree to which this might occur at the single cell level and the loci which might be affected are unknown.

Nine monkeys (M. nemestrina); 3 each at 4, 10, 20 years old (y.o.) were prepared together for formaldehyde-induced histofluorescence. Quantitative microspectrofluorometric analysis (MSF) was performed on individual neurons of select, monoaminergic, cell groups; i.e. the locus coeruleus (LC), substantia nigra (SN), and nucleus raphe dorsalis (Rd). The relative intensities were recorded; means and standard deviations were calculated and plotted as histograms. Intensity levels were highest in the 4 y.o., and declined progressively in the 10 y.o. and 20 y.o. Norepinephrine fluorescence intensity was depressed further in neurons of the LC which also contained autofluorescent pigment granules. Monoamine content as reflected in relative fluorescence intensity was depressed as much as 75% in Rd and SN, and 50% in LC.

These data indicate that monoamine levels are depressed in perikarya of origin of major aminergic systems. It is not known whether this is reflected also in the terminal fields supplied by these neurons; our preliminary analysis in these animals suggests that terminal fields in brain stem and hypothalamus are comparable to the 4 y.o., but quantitative MSF has not been performed. The present findings of depressed perikaryal stores might be related to decreased synthetic capabilities and/or heightened turnover of central monoamines during aging and may correlate with altered functional capabilities.

36 AGE-RELATED DECREASE IN MOUSE BRAIN CHOLINERGIC MUSCARINIC RECEPTOR BINDING. R. Strong*, L. Hsu*, P. Hicks*, and S. J. Enna (SPON: K. Campbell). Univ. Texas Med. Sch. and Texas Res. Inst. for Mental Sciences, Houston, Tx. 77025

Recent reports have indicated a number of pre- and postsynaptic alterations in neurodegenerative disorders. Of the various neurotransmitters, the brain cholinergic system appears to be particularly vulnerable with cholinergic changes reportedly occuring in Huntington's, Parkinson's and Alzheimer's diseases. In the present investigation, pre- and postsynaptic cholinergic markers were studied in the brains of mice aged 6 to 30 mos. in an attempt to determine whether alterations in this neurotransmitter system may also occur during the normal aging process.

For the study, brains of young (6 mos.) middle-aged (12 mos.) and senescent (30 mos.) male C57Bl/6J mice were removed, rapidly dissected on ice and frozen (-20°) until assayed. Cholinergic muscarinic receptor binding was studied using ^{3}H-QNB as a ligand. Brain glutamic acid decarboxylase (GAD) activity, an enzyme marker for GABAergic neurons, and choline acetyltransferase (ChAc) activity, a presynaptic marker for cholinergic neurons, were measured using standard biochemical techniques.

The results indicate that in the brains of the older (30 mos.) animals there was a significant 30% reduction in ^{3}H-QNB binding in the corpus striatum compared to either the 6 mos. or 12 mos. animals. Receptor saturation experiments revealed that the decrease in muscarinic receptor binding was due to a reduction in receptor number, with no change in binding affinity. No significant differences were detected in either GAD or ChAc activity in this brain region. While there was also a tendency for a reduction in cholinergic muscarinic receptor binding in the hippocampus, this decrease was not significant in preliminary experiments.

These findings suggest that there may be an age-related decline in striatal cholinergic function due to loss of receptors for this neurotransmitter. Furthermore, the absence of a change in GAD or ChAc activity in this brain area suggest that the GABAergic and cholinergic neurons are intact, indicating that the decrease in muscarinic receptors is not associated with a loss in either of these neuronal cell types. This loss of striatal cholinergic receptors may contribute to, or be the result of, the motor impairments that often accompany old age. 37 OPIATE RECEPTOR SUPERSENSITIVITY IN SOME BRAIN REGIONS OF AGED MALE RATS. Beatriz J. Vasquez, Rita B. Messing, Robert A. Jensen, Joe L. Martinez, Vina R. Spiehler*, Bernardo Samaniego*, and James L. McGaugh. Dept. of Psychobiology, University of California, Irvine, CA 92717, USA.

Previous work from our laboratory indicates that memory changes observed in aged rats may be mediated by endogenous opioid systems. Therefore, we compared dihydromorphine binding kinetics in five brain regions of young and aged F344 male rats. In order to characterize binding in the presence or absence of endogenous substances half of the tissue homogenate for each region was twice washed and resuspended in 0.05M tris buffer, pH 7.4. Aliquots from whole homogenates and washed membrane samples were then used for assays of stereospecific ^{3}H-dihydromorphine (DHM) binding with one of seven concentrations of the ligand (0.13 to 13 nM). The apparent dissociation constant (K_D) and receptor density (B_{max}) were calculated from Scatchard plots.

	24 Month Old		3 Month Old	
Brain Region	K_D(nM)	B_{max} (fmol/mg prot.)	K_D(nM)	B_{max} (fmol/mg prot.)
		Whole Homogenates		
frontal poles	1.83**	41.3	7.1	136.0
anterior cortex	3.84	123.1	3.47	131.9
amygdala	1.73	54.1**	3.93	138.4
striatum	1.11**	72.2	2.80	139.0
	7.73	220.2		
hippocampus	3.59	83.2	4.59	78.0
		Washed Membranes		
frontal poles	1.62*	58.3	4.7	123.0
anterior cortex	3.13	152.8	2.77	155.5
amygdala	1.14	56.0*	3.11	148.1
striatum	2.76	145.7	3.13	157.0
hippocampus	3.39	83.7	3.75	89.1

*$p < 0.05$. **$p < 0.01$ different from young.

Increased affinity for DHM accompanied by decreased receptor concentrations were observed in whole homogenates of frontal poles, amygdala, and striatum of aged as compared to young rats. In washed membranes, however, no difference between young and old rats was apparent in striatal tissue. The results suggest that receptor supersensitivity observed in brain regions of old rats may compensate for decreases in receptor number. Further, these receptor alterations may be related to *in vivo* differences in the effects of opiates in aged rats. [Supported by USPHS AG00538 and MH12526, NSF BNS 76-17370, and a grant from the McKnight Foundation (all to JLMcG)].

38 CULTURED EXPLANTS FROM AGING BRAINS: CHARACTERISTICS OF OUTGROWTH, NEUROFILAMENT PROTEIN, AND CYTOLOGY. P. L. Witte*, J. W. Fuseler*, W. S. T. Griffin and J. W. Shay* (SPON: R. M. Stewart). The University of Texas Health Science Center at Dallas, Dallas, TX 75235.

In a number of pathological disorders, the neurofilaments are tightly packed within the cellular processes of brain cells. Our hypothesis was that aging could cause similar effects. In order to test this hypothesis, we cultured brain explants from 24 month old rats and compared outgrowth, 100Å filament protein (neurofilament protein) characteristics and general cytoplasmic morphology between aged explants and brain explants from much younger animals, *viz.*, three days and three months of age. All rats were killed by decapitation and cerebral cortex was excised under sterile conditions. Explants were mechanically dissociated on coverslips which were flooded with CMRL 1066, containing 10% horse serum and 5% fetal calf serum. After 7 days, the coverslips were checked for outgrowth of cells. We found that cellular outgrowth is possible although the time of cell spreading may be prolonged. After 2 weeks in culture, the coverslips were fixed by washing with 4% neutral buffered formalin, incubated with rabbit-anti-bovine neurofilament antibody and fluoresced with FITC goat- and anti-rabbit globulin at a dilution of 1:6. Neurofilament fraction for antibody preparation was isolated from bovine spinal cord white matter and characterized by a molecular weight of 51,000. The cytological differences included an increase in the number of lipofuscin granules in cells from aged brains as well as accumulations of vacuoles which were bounded by neurofilaments. Even though cells from aged brains appeared to contain less neurofilament, that which was present was tightly packed and in tortuous bundles both in the cell periphery and surrounding the nucleus; whereas, young brain cells, especially from neonate explants, contained a filamentous network of thread-like neurofilaments in the periphery when compared by immunofluorescence.

AUDITION

39 CYTOLOGY OF PERIOLIVARY CELLS. Joe C. Adams . LNO, NINCDS,NIH Behtesda, Md. 20205.

Clusters of auditory cells located around the superior olivary nuclei are referred to as periolivary cell groups rather than nuclei because of their lack of well defined borders or neuropil. These cell groups are heterogeneous with respect to their anatomical inputs and outputs, as well as in their physiological properties. As an initial step towards a comprehensive analysis of these cells in the cat a cytological study was undertaken employing Nissl, Golgi, and reduced silver preparations. Some seventeen classes of cells were identified in Nissl material. Some cell classes were found predominantly within limited regions of the olivary complex. Cells similar to globular cells of the cochlear nucleus constitute the bulk of the medial trapezoid nucleus. Similar cells are also found in a large group caudal to the lateral superior olive and extending rostrally in a region ventro-lateral to the medial superior olive, with a few cells of the same type extending rostrally in a region dorsolateral to the dorsal tip of the medial superior olive. Multipolar cells with abundant large, dark clumps of Nissl substance are concentrated close to the caudal surface of the lateral superior olive. Cells of this type extend rostrally for a short distance dorsal to the lateral olive. Ventral to the lateral olive they extend rostrally for almost its entire extent. Pale cells are found caudally, predominantly dorso-medial to the medial olive. Ventral to the medial trapezoid nucleus many cells have only a few large, dark clumps of Nissl substance. Many cells in the lateral trapezoid region have only a few small Nissl clumps. Concentrations of large pale cells are found caudal and rostral to the medial olive and are connected by a sparse line of these cells that runs ventro-medial to the medial olive. Anterior to the olivary nuclei there are many large multipolar cells with diffuse Nissl substance. Large cells with dark Nissl clumps are scattered throughout the olivary complex. The morphology of several of these cell types as seen in Golgi and reduced silver preparations will be described. This study will provide information necessary for future studies of the ultrastructure, anatomical connections, and physiology of individual classes of periolivary cells.

40 MET-ENKEPHALIN POSITIVITY IN THE SMALL CELLS OF THE DEEP DORSAL COCHLEAR NUCLEUS AND POSTEROVENTRAL COCHLEAR NUCLEUS OF THE RAT. Richard A. Altschuler. Laboratory of NeuroOtolaryngology, NIH, NINCDS, Bethesda, MD 20205.

Cell bodies of neurons containing met-enkephalin have been noted in general mapping studies of the rat brain (Hokfelt et al. 1977). Fibers containing met-enkephalin have been localized in the dorsal cochlear nucleus (DCN) and in the ventral cochlear nucleus (Sar et al. 1978). In the present study the cochlear nuclei of rats were examined to determine the category of cells that contain met-enkephalin. Rats were pre-treated with colchicine to inhibit axonal transport. Indirect fluorescence immunohistochemistry was performed on 10 micron cryostat sections to detect met-enkephalin. Nissl stains on adjacent, or the same sections after quenching of fluorescence, were used to identify cell types and regions. A second adjacent section was used for an absorption control to test for specificity.

Met-enkephalin positive neurons in the DCN fell into the category of small cells. They were seen predominantly in the deep layer of the DCN. Only a small percentage of the small cells were met-enkephalin positive. This suggests it may be possible to subdivide the heterogeneous population of small cells on the basis of positivity for met-enkephalin. Cell bodies positive for met-enkephalin were also seen in the posteroventral cochlear nucleus near the border of the dorsal cochlear nucleus. These neurons were also categorized as small cells.

Many positive fibers were coursing through and often terminating in the DCN. Fewer fibers were seen in the postero- and anteroventral cochlear nucleus. Fibers were also seen in the dorsal and intermediate acoustic striae.

In conclusion, met-enkephalin containing cell bodies were localized in both the dorsal and posteroventral cochlear nuclei. In both cases these neurons were small cells, though only a portion of the total population of these cells.

41 CORRESPONDENCES BETWEEN STRUCTURE AND FUNCTION IN THE BULLFROG UTRICLE AND LAGENA. R. Baird. Dept. EECS, UC Berkeley, CA 94720

Previous studies have shown that the utricle and lagena are innervated by afferent axons whose diameters range from 1 to 10 μm (Dunn, R., J. Comp. Neurology 182: 621-636, 1978), that these axons can be divided functionally into several classes based on regularity of resting discharge and response to constant-velocity tilt (Blanks, R. and Precht, W., Exp. Brain Res. 25: 379-390, 1976), and that the hair cells innervated by these afferents can be divided into several classes based on surface morphology (Lewis, E. and Li, C., Brain Res. 83: 35-50, 1975).

It has been proposed that each unit with irregular resting discharge and phasic response to tilt corresponds to a thick afferent originating from a small number of hair cells in the striolar region of the sensory macula, while each unit with regular resting discharge and tonic response to tilt corresponds to a thin afferent originating from a large number of hair cells in the extrastriolar region of the macula (Fernandez, C. et al., J. Neurophysiol. 35: 978-997, 1972). To test this proposition directly, intracellular recordings were made from primary afferents in the anterior and posterior branches of the bullfrog VIIIth cranial nerve medial to the intact otic capsule. After functional characterization of each unit, Lucifer Yellow (Stewart, W., Cell 14: 741-759, 1978) was injected iontophoretically in order to trace the axon to its site(s) of termination on the sensory macula.

So far the results indicate that all hair cells contacted by a particular fiber are of the same morphological polarization and are either striolar or extrastriolar but not both. that large-diameter fibers contact greater numbers of hair cells than do small-diameter fibers, and that afferents innervating only one hair cell may exhibit regular resting discharge with a high mean firing rate, whereas afferents innervating many hair cells may exhibit irregular resting discharge with a low mean firing rate. These observations are contrary to the propositions that thick fibers tend to innervate smaller numbers of hair cells and that fibers with regular resting discharge innervate large numbers of hair cells. It is expected that this line of research will soon reveal how the branches of afferent fibers relate to the specific hair cell types defined by Lewis and Li, and whether the response properties of an afferent fiber correspond to the types of hair cells it contacts or simply the number and morphological polarizations of those hair cells.

42 CYTOARCHITECTURE IN THE TORUS SEMICIRCULARIS IN THE GOLDEN SKINK MABUYA MULTIFASCIATA. Alice M. Baruch and Robert H. Browner. Dept. Anat., New York Medical College, Valhalla, NY 10595.

The cytoarchitecture in the torus semicircularis (TS) was examined in 14 brains. After perfusion the brains were prepared for cresyl violet staining or Golgi-Kopsch impregnated Araldite-embedded sections 120um thick. The 15um cresyl violet sections were studied in the three standard planes; the Golgi-Kopsch material was analyzed in transverse and horizontal planes. The TS is a mesencephalic nucleus which is dorsally and superficially placed caudally and extends rostrally, laterally and ventrally to end at a mid-optic tectal level. Three nuclei can be seen within the TS: A central nucleus (CN), a laminar nucleus (LN) and a caudal superficial nucleus (SN).

The CN consists of concentric rings of small (6-12um) ovoid cells surrounding a core of large ovoid-triangular (14-28um) and fusiform (20-30um) cells. The ovoid neurons have scant cytoplasm and possess 2-5 dendritic trunks. Most of these processes are directed around the periphery of the CN and often dendrites can be traced into the CN. The average dendritic field covers approximately 100 x 100um mediolateral by dorsoventral. The large central cells have clumped darkly-staining Nissl, abundant cytoplasm and central nuclei. The dendritic fields have a mediolateral orientation and average 188 x 154 x 270um for the triangular cells and 285 x 183um for fusiform cells. Spine population increases distally.

The laminar nucleus is found caudally just ventral to the CN and at successively more rostral levels is medial and finally dorsomedial to it. This nucleus consists of a laminated group of fusiform (20-40um) and ovoid (8-12um) cells with scattered large ovoid-triangular cells (18-28um). Fusiform cells have pale Nissl, a central nucleus and medially and laterally directed dendrites, covering an average field of 278 x 288um. The ovoid cells have sparse cytoplasm and an eccentric or central nucleus. The arborization of both these cells is often skewed to present an orientation of caudomedial and rostrolateral. The large ovoid-triangular cells have dense clumped Nissl and at least two dendritic trees with a medial and lateral orientation, covering average fields of 325 x 355 x 268um. The rostral limit of the LN consists of two fusiform layers orthogonally arranged.

The SN is dorsal, lateral and caudal to the CN. As it extends ventrolaterally around the CN it becomes confluent with the LN, ensheathing the CN except medially. Present are fusiform (18-30um), ovoid (8-14um) and a few ovoid-triangular cells (14-24um). Their average dendritic fields measure 389 x 133 x 100um, 138 x 138 x 200um and 100 x 88 x 200um respectively. Both cell morphology and orientation of dendrites resemble those in the LN.

43 OBSERVATIONS ON UNIT ACTIVITY IN MONKEY AUDITORY CORTEX AND DORSOLATERAL FRONTAL CORTEX DURING A SOUND LOCALIZATION TASK. Dennis A. Benson, Robert D. Hienz*, and Moise H. Goldstein, Jr. Dept. Biomedical Engineering, Johns Hopkins School of Medicine, Baltimore, Md. 21205.

Behavioral studies have suggested that the auditory cortex plays an essential role in the localization of sound in space and that the dorsolateral frontal cortex may be involved in spatial discrimination tasks. In this experiment five small speakers were equally spaced in the horizontal plane from 75° left to 75° right and within arm's reach of a rhesus monkey subject. The animals were trained to locate the source of a 100-msec sound burst by pressing the key on the speaker which presented the sound (Localize). In a control condition (Detect), animals reported the onset of any sound regardless of location by pressing a single key which was not adjacent to any sound source. For each unit recorded, the sound-evoked activity during Detect was compared to the activity evoked by the same stimulus during Localize. In a third condition the same stimuli were presented without requiring any response from the animal (Non-Perform). In four animals approximately 8% of the units recorded from primary auditory cortex and surrounding secondary areas had significantly greater evoked activity ($p<.01$) during Localize than during Detect without any change in spontaneous rate or in the type of discharge pattern. Over 20% of the units had greater evoked activity in the performing conditions (Detect and Localize) than in Non-Perform.

Recordings were also made in the dorsal periarcuate area, a region of frontal cortex which receives input from auditory cortex. Although only a small proportion of frontal units responded to sound during Non-Perform, nearly 40% responded during Localize and Detect at a latency of less than 100 msec. These units also responded with similar latencies and discharge patterns to visual stimuli presented at the speaker locations, provided that the animal localized the visual stimuli by pressing a key adjacent to the light.

These results suggest that, during behavior, the responses of neurons in auditory cortex are dominated by auditory input, whereas sound-responsive neurons in frontal cortex are more likely to share visual input and to be more strongly influenced by the specific behavioral task.

44 EFFECT OF INTRACOCHLEAR KAINIC ACID ON COCHLEAR POTENTIALS IN GUINEA PIGS. Sanford C. Bledsoe, Jr., Richard P. Bobbin and Dorothy N. Morgan*, Kresge Hear. Res. Lab., Dept. Otorhinolaryngol., L.S.U. Med. Ctr., New Orleans, LA 70119.

Evidence has been presented which implicates glutamate as a possible transmitter candidate in hair cell systems of the guinea pig cochlea (Bobbin, Exp. Brain Res., 34: 389, 1979). To investigate the chemical nature of the synapses between hair cells and primary auditory neurons, we studied the effects of intracochlearly perfused kainic acid (KA) on sound evoked, as well as resting potentials in the cochlea. Experiments were performed on guinea pigs with intracochlear perfusion methods which have been previously described (Bobbin and Thompson, Ann. Otol., 87: 185, 1978). Input-output functions for the compound whole nerve action potential (CAP) and cochlear microphonic potential (CM) were obtained to a 10-kHz tone burst. Results reveal that 1 mM KA abolishes the CAP but has no effect on CM or the endocochlear potential. Perfusion with Ringer's after the KA produced no identifiable recovery of the CAP. To further evaluate this effect by KA, experiments have been performed studying the action of intracochlearly perfused 1 mM KA on spontaneous cochlear ganglion cell activity. These experiments indicate that KA produces an initial, excitatory increase in spontaneous discharge rate followed by suppression of activity. Although the mechanism and site-of-action of KA in the cochlea is unknown, the results are consistent with the hypothesis that postsynaptic membranes of the auditory nerve fibers have receptors for glutamate. Possible presynaptic actions on hair cells and supporting cells, however, can not be excluded. These results provide additional, indirect evidence that glutamate may be involved in synaptic transmission between hair cells and first-order afferent auditory neurons. (Supported by NIH, USPHS NS-11647 and NS-07058 and The Kresge Foundation)

45 ACTION OF GLUTAMATE AND RELATED SUBSTANCES ON THE SPONTANEOUS ACTIVITY OF AFFERENT NERVES IN THE TOAD LATERAL LINE. Richard P. Bobbin, Dorothy N. Morgan* and Sanford C. Bledsoe,Jr., Kresge Hear. Res. Lab., Dept. Otorhinolaryngol., L.S.U. Med. Ctr., New Orleans, LA 70119.

The purpose of this study was to extend our results which showed glutamate mimics the afferent transmitter released by hair cells in the guinea pig cochlea (Bobbin, Exp. Brain Res., 34:389, 1979) and in the lateral line (Bobbin and Morgan, Assoc. Res. Otolaryngol., Jan. 1979) by examining the actions of related chemicals, other putative transmitters, and their interactions. Spontaneous activity of a single lateral-line stitch from Xenopus laevis was studied using an isolated skin preparation. Ringer's solution was constantly washed over the inner surface of the skin, except for 5 minutes before and 7 minutes during drug testing. Drugs were applied to the end organ by ejection from a microliter syringe. Results indicate the application of several substances produced excitation, with larger concentrations producing greater excitation followed by inhibition of spontaneous activity. Ranking these according to degree of excitatory potency was as follows: kainic acid (10 μM) > L-glutamate (2 mM) ≈ D-glutamate (2 mM) > L-aspartate (2 mM). Only inhibitory activity was exhibited by DL-α-amino-adapate, ATP, tyramine, GABA and salicylate. Ranking all substances according to degree of inhibitory potency was as follows: kainic acid (10 μM) > L-glutamate (2 mM) ≈ D-glutamate (2 mM) > DL-α-aminoadapate (2 mM) > L-aspartate (2 mM) > ATP (2 mM) > tyramine (5 mM) > GABA (5 mM) > salicylate (5 mM). The excitatory action of L-glutamate was blocked when applied to the stitch during the inhibition following application of amino-adapate, kainic acid, or L-glutamate. At present, how or where the substances are acting is unknown, although results seem to be consistent with the hypothesis that glutamate is the transmitter released by the hair cells. (Supported by NIH, USPHS NS-11647 and NS-07058, and The Kresge Foundation)

46 DYNAMIC VERSUS STATIC CHARACTERISTICS OF SINGLE AUDITORY-NERVE FIBERS. M. L. Brachman* and R. L. Smith. Institute for Sensory Research, Syracuse University, Syracuse, NY 13210.

Although the operating range of an auditory-nerve fiber can be defined as the range of intensities over which changes in intensity produce changes in response, the observed operating range depends to some extent on the experimental paradigm. Firing rates averaged over intervals of 10 msec or more appear to reflect an inherently static operating characteristic with a small operating range (Smith, R. L., J. Acoust. Soc. Am. 65, 166-179, 1979). For example, in response to stimuli of constant sound intensity, a maximum firing rate occurs at the onset followed by a decay to a quasi steady-state rate within a few hundred milliseconds. The steady-state firing rate typically increases monotonically with sound intensity, and asymptotically approaches saturation within 30 dB of threshold. After subtraction of spontaneous activity, the ratio of onset to steady-state response is independent of sound intensity so that the onset and steady-state responses have the same operating range. In contrast, when the onset firing rate is measured using intervals of 2 msec or less, the ratio of onset to steady-state response increases with increasing sound intensity. In some units the increase continues into the steady-state saturation region, producing a dynamic operating characteristic with a range that exceeds the static range by more than 20 dB. Amplitude modulation by sinusoids reveals a similar increase in operating range. For modulation frequencies of about 200 Hz, period histograms synchronized to the modulating wave form have a sinusoidal shape and provide a measure of response modulation. Response modulation is a nonmonotonic function of average intensity, and the shape and location of the response modulation function can be more accurately predicted from the dynamic than from the static operating characteristic. Hence the use of sufficiently small time windows and/or sufficiently rapid changes in intensity reveals a dynamic operating range that can exceed the static operating range by several orders of magnitude.

47 RESPONSE PROPERTIES OF EI UNITS IN THE SUPERIOR OLIVARY COMPLEX OF THE DECEREBRATE CAT. William E. Brownell, Paul B. Manis*, and Louis A. Ritz. Depts. of Neuroscience and Surgery (ENT), University of Florida, Gainesville, Florida, 32610.

The response characteristics of superior olivary complex (SOC) neurons were observed in unanesthetized decerebrate cats. This report deals only with those units that were excited by best frequency (BF) stimulation to the ipsilateral ear and inhibited by contralateral ear stimulation (EI units). Ninety per cent of these units were localized to the lateral superior olive. Spontaneous activity was seen in all EI units and permitted demonstration of ipsilaterally driven inhibitory responses. The presense of inhibitory sidebands was a common feature of the ipsilateral receptive field. The contralateral receptive field was inhibitory and overlapped the ipsilateral central excitatory region, in those units for which it was determined.

Discharge rate could be a monotonically or nonmonotonically increasing function of intensity for ipsilateral BF stimulation. Contralateral BF stimulation produced a monotonically decreasing rate-intensity function as inhibition became more pronounced. Binaural rate-intensity functions were always non-monotonic. For some units it was possible to have a peak of excitation flanked by inhibition for intensities both above and below the peak.

We have recorded from some units before and after administration of anesthetic doses of sodium pentobarbitol. In the few EI units for which we carried out this procedure the most dramatic response to anesthetic was the almost total disappearance of spontaneous activity. Anesthetic also produced an increased response latency. Post-stimulus time histograms showed chopper responses, which were not observed in unanesthetized preparations. Interspike interval distributions became more symmetric. Ipsilaterally driven rate-intensity functions became monotonic, if they were not already so, and binaural rate intensity functions displayed no inhibition. Responses measured after administration of anesthetic were similar to those previously reported for SOC units in anesthetized intact preparations. Quantification of these results will be presented.

48 AN ACOUSTIC FOVEA IN THE COCHLEA OF THE HORSESHOE BAT. Volkmar Bruns* (SPON: J. A. Simmons). Dept. of Biology, Frankfurt Univ., FRG.

The greater horseshoe bat, Rhinolophus ferrumequinum, emits echolocation cries that have a long (10-100 msec) constant frequency component of about 83 kHz. The auditory system of this bat is very sharply tuned to about 83 kHz, the frequency corresp-ding to the emitted CF component. Of particular importance, the sharp tuning is created in the periphery and correlates with a number of specialized features within the cochlea. The innervation pattern of the cochlear region where the 80-86 kHz frequency band is analyzed is comparable to other mammals. 85% of all afferent fibers run to the inner hair cells and only 15% of the afferent innervation is devoted to the outer hair cells. Sixteen radial fibers converge onto one inner hair cell and one spiral fiber innervates several outer hair cells. Frequency mapping shows that the small frequency band between 80-86 kHz is widely expanded on the basilar membrane (4.1 mm of the total length of 16 mm). These frequencies are represented by 25% of the receptors and 21% of the neurons in the spiral ganglion (3,400 of the total number of 16,000). This means that dispite the normal innervation density per mm of basilar membrane the frequencies between 80 and 86 kHz are highly overrepresented (35,000 neurons/octave). This peripheral expansion of the behaviorally important narrow frequency band bears a striking analogy to the retinal fovea in the visual system. A study of the vibration pattern of the cochlear partition in the "foveal region" revealed an antiphasic motion between the inner and outer segment of the cochlear partition which supports the inner and outer hair cells respectively. Scanning EM studies of this "foveal region" demonstrated enlarged steriocilia and a spacing of the cuticular plates of the inner hair cells. This is interpreted as an additional improvement of the hydromechanical frequency analysis. The data from the studies of the vibration pattern of the basilar membrane and the fine morphological features of the cochlear partition are integrated into a model to account for the mechanical sharpening of the 80-86 kHz frequencies which respresent the "acoutic fovea".

49 GLUTAMATE AND ASPARTATE: EFFECTS ON THRESHOLD AND RESPONSE PATTERNS IN THE COCHLEAR NUCLEUS. D.M. Caspary and D.C. Havey. Division of Neurobiology, Dept. Medical Sciences, Southern Illinois University School of Medicine, Springfield, IL 62708

Recent evidence suggests that glutamate and/or aspartate may be the neurotransmitter(s) at acoustic nerve endings in the cochlear nucleus (CN). Godfrey et al. (J. Histochem. Cytochem. 25:417, 1977) have produced a map of the quantitative distribution of concentrations of these excitant amino acids in the CN. Wenthold (Brain Res. 143:544, 1978) has shown that glutamate and aspartate levels decrease in conjunction with the degeneration of auditory nerve terminals and has also described a calcium dependent release of these amino acids (Brain Res. 162:338, 1979). Bird et al. (Science 202:1087, 1979) have reported that kainic acid, which may be specifically neurotoxic to cells receiving a glutamatergic input causes degeneration of CN neurons.

The response patterns, at best frequency, of CN neurons in chinchilla were examined using poststimulus time and interspike interval histograms. Control histograms were obtained before, during, and subsequent to the application of putative neurotransmitters. Microiontophoretic application of glutamate and aspartate onto neurons in the posterior ventral cochlear nucleus (PVCN) and the dorsal cochlear nucleus (DCN) can induce changes in the response thresholds of these neurons to tone-burst stimulation at best frequency. With the iontophoretic application of glutamate or aspartate some PVCN neurons displaying "on" patterns become responsive to stimulation as much as 15 dB below control threshold. At near-threshold stimulus levels the "on" or onset pattern is observed to change from a brief, phasic response to a sustained response over the duration of the stimulus. At higher iontophoretic currents spontaneous activity may be induced in these neurons which display little or no control spontaneous activity. In response to glutamate or aspartate application, some PVCN "chopper" neurons display threshold shifts and a disruption of the chopper pattern as well as an increase in spontaneous activity. DCN "build-up" and "pauser" neurons also display threshold shifts and some changes in response pattern. These neurons display either a generalized increase in the number of responses during the early portion of the histogram or, for certain "build-up" neurons, the induction of an initial "pauser" peak. For many neurons which are sensitive to glutamate and/or aspartate, the iontophoretic application of these substances mimics the effects of increasing stimulus intensity as well as increasing the spontaneous activity. These findings in conjunction with the previously noted studies lend support to the hypothesis that glutamate and/or aspartate may be the transmitter(s) at acoustic nerve endings in the CN. 50 ASCENDING PROJECTIONS TO THE SUPERIOR OLIVARY COMPLEX OF RAT. J. Coleman, P. O'Connor, A. Wells*, B. Blatchley* and C. Brown*. Depts. of Psychol. and Physiol., Univ. of South Carolina, Columbia, SC 29208.

Basic connectional patterns between various divisions of the rat ventral cochlear nucleus and the superior olivary nucleus have been resolved by anterograde degeneration and Golgi techniques (Harrison and Irving, J. Comp. Neurol., 1966, 126, 51; Harrison and Feldman, Contrib. Sens. Physiol., 1970, 4, 95). The present study was undertaken to examine aspects of neuronal systems providing input to the superior olivary complex of the albino rat using the horseradish peroxidase (HRP) transport technique. Unilateral microiontophoretic injections of HRP into portions of the superior olivary complex were followed by 18-24 hr survival and processing of tissue for HRP histochemistry.

Fibers transporting label could be traced from sites of injection to the ipsilateral and contralateral cochlear nuclei. Although most injections were not confined solely to a single nucleus of the superior olivary complex there was evidence of some specificity of projections. Injections of the medial superior olive resulted in bilateral labelling of large spherical cells of the anteroventral cochlear nucleus (region III of Harrison and Irving). Within the densest foci of labelling, most, but not nearly all of the large spherical cells exhibited reaction product. Little or no reaction product was observed in this area and in other divisions of the cochlear nuclei after control HRP injections in nonauditory areas or in tissue processed without HRP injection. Injections of the medial nucleus of the trapezoid body produced labelled globular cells in contralateral region II of Harrison and Irving. Many globular cells within the most densely labelled clusters of these cells were void of reaction product. In addition, medium sized spherical cells of region I were labelled after injections in the vicinity of the medial nucleus of the trapezoid body. Larger injections of the superior olivary complex resulted in extensive labelling of multipolar neurons of region IV; no labelled cells appeared in region V following any injection of the superior olivary complex. (Supported by NIH Biomedical Research Support Grant 5 S07 RR07160 and the Deafness Research Foundation.)

51 HEARING SENSITIVITY IN AN OSTEOGLOSSOMORPH FISH. S. Coombs. Dept. Anat., Georgetown Univ. Sch. Med. & Dent., Washington, D.C. 20007.

Auditory sensitivity as a function of frequency has been determined using shock avoidance techniques for several specimens of clown knifefish, Notopterus chitala (Family: Notopteridae). The frequency range of hearing is from 100 Hz to over 1500 Hz, with best sensitivity occurring around 500 Hz, where the threshold reaches -50 dB re: 1 dyne/cm^2.

Thresholds as low as -50 dB have been reported for only a few other fish in the teleostean infraclass: several species (including the goldfish, Carassius auratus) all belonging to the superorder Ostariophysii and one other species, Myripristis kuntee, from the squirrelfish family Holocentridae. Best thresholds reported here are at least 20-30 dB lower than those reported for most other teleost fishes. While the frequency range of hearing for N. chitala also extends beyond the high frequency end reported for most teleosts (800-1000 Hz), it does not extend as high as those reported for M. kuntee (3000 Hz) or for ostariophysan species (2000-5000 Hz).

Fish from these three taxonomically unrelated groups, Notopterus, Myripristis, and Ostariophysii, all have in common a non-homologous specialization of the peripheral auditory system: an anatomical connection between the swimbladder and the inner ear. Since for many teleost species the swimbladder has a known sound amplification function, the exceptional threshold sensitivity of fishes from these groups can be attributed to the functional relationship between the swimbladder and inner ear. It is not clear at this time, however, what determines the frequency range of hearing in these fishes. It is possible that characteristics of the swimbladder coupling system and/or properties of the inner ear may play a role in this determination. (Supported by an NIMH predoctoral fellowship and NINCDS Grant NS-15090).

52 IONIC BASIS OF THE RECEPTOR CURRENT IN A VERTEBRATE HAIR CELL. D. P. Corey* and A. J. Hudspeth, Division of Biology, California Institute of Technology, Pasadena, CA 91125

The unusually high K^+ concentration of the endolymph facing the apical surfaces of virtually all vertebrate hair cells suggests that K^+ carries the receptor current in these cells (Russell and Sellick {1976}, J. Physiol. 257: 245). Yet large intracellular receptor potentials can be recorded in frog saccular hair cells in vitro when a standard saline solution bathes both apical and basal cell surfaces, and thus when the electrochemical gradient for K^+ is near zero (Hudspeth and Corey {1977}, Proc. Natl. Acad. Sci. U.S.A. 74: 2407). Calcium ion has also been proposed as carrying the receptor current (Sand {1975}, J. Comp. Physiol. 102:27), yet its concentration is extremely low in the endolymph of some species, including the bullfrog.

We have measured the voltage dependence of the receptor current in frog saccular hair cells by voltage-clamping single cells with two microelectrodes, while mechanically stimulating individual hair bundles. The reversal potential for the receptor current, with standard saline on both cell surfaces, is - 2 ± 4 mV. This suggests that the transducer channel permits both Na^+ influx and K^+ efflux: it is relatively nonspecific. In vivo, with endolymph on the apical cell surface, K^+ must, in fact, carry most of the receptor current.

A number of monovalent cations were consequently tested with an in vitro microphonic preparation (Corey and Hudspeth {1979}, Biophys. J. 26: 499), in which the fluid facing the apical hair cell surface may be changed independently of that facing the basal surface. The microphonic potential is maintained when endolymph in the apical chamber is replaced with salines containing 130 mM Li^+, Na^+, K^+, Rb^+, Cs^+, or NH_4^+. The response is reduced with tetramethylammonium, choline, or carbamylcholine ion, and is small but measurable with glucosamine, triethanolamine, or tris(hydroxymethyl)aminomethane ion. If the channel is a pore, the largest of these ions would require a minimal pore diameter of ∿ 0.7 nm. In addition, the receptor current measured under voltage-clamp varies non-linearly with voltage, and the current-voltage relation can be adequately fitted by a model which posits a single energy barrier to ion permeation placed about 40% of the way through the membrane. We suggest that the transducer channel of hair cells is a large, water-filled pore with a "tight spot" near the middle.

(Supported by NIH Grants NS-13154 and GM-07616.)

53 AUTORADIOGRAPHIC DEMONSTRATION OF AUDITORY AND VESTIBULAR PATHWAYS IN THE PIGEON BY MEANS OF ANTEROGRADE TRANSNEURAL TRANSPORT. M.J. Correia, A.R. Eden, K.N. Westlund, and J.D. Coulter. Depts. of Otolaryng., Physiol. & Biophys., Psychiat. & Behav. Sci., and the Marine Biomed. Inst., Univ. Tex. Med. Br., Galveston, TX 77550

An equal parts mixture of L-[^{3}H] proline and 1-[6-^{3}H] fucose (50 µCi/µl) was injected into the endolymphatic space of the left membranous labyrinth of each of two White King pigeons. A total amount of 1 µl of the above solution was injected through a micropipette glued into a transsected anterior semicircular duct over a period of 1 hr. Following injection, the cut ends of the ducts were sealed by cauterization and the animals were allowed to survive 15 days. The brain, spinal cord, and labyrinths were fixed with 10% buffered formalin delivered by bilateral transcardiac intracarotid catheterization. Serial paraffin sections (15 µm) were prepared by standard autoradiographic techniques.

Auditory structures, ipsilateral to the side of injection, which were labeled were the: cochlear nerve, angular nucleus, magnocellular nucleus, superior olive, lateral lemniscus, laminar nucleus, and ventral nucleus of the lateral lemniscus. Labeled structures, contralateral to the side of injection, included the: laminar nucleus, superior olive, lateral lemniscus, and ventral nucleus of the lateral lemniscus.

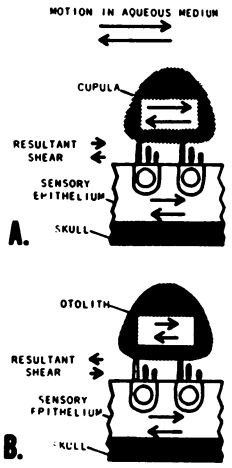
Vestibular structures, ipsilateral to the side of injection, which were heavily labeled were: the vestibular nerve, all six vestibular nuclei, and the cerebello-vestibular lateral process. Less heavily labeled ipsilateral structures included: the medial longitudinal fasciculus, terminations on motoneurons in the medial and lateral part of the ventral grey of the spinal cord and the abducens, oculomotor, and trochlear nuclei. Contralateral vestibular structures which were heavily labeled were: the medial longitudinal fasciculus, terminations on motoneurons in the medial and lateral part of the ventral grey of the spinal cord, and the oculomotor, trochlear, and abducens nuclei.

Different densities of labeling were found within the oculomotor nuclei. The lateral half of the dorsal part and the majority of the ventral part of the contralateral oculomotor nucleus showed heaviest labeling; whereas, the medial half of the dorsal part of the ipsilateral oculomotor nucleus was labeled the heaviest.

Structures which were also labeled bilaterally were: the quinto-frontal tract, the septomesencephalic tract, and a region in the ventro-medial part of the primitive paleostriatum. (This work was supported in part by grants from the Deaf. Res. Fdn., NASA, NAS9-14641, and NIH, NS-12481.)

54 PARALLEL CHANNELS FOR SOUND DETECTION IN THE FISH EAR. Jeffrey T. Corwin Dept. Neurosci., Sch. Med., UCSD, La Jolla, CA 92093.

Most studies of fish hearing seek to explain behavioral performance only in terms of sound detection by the otolithic maculae of the ear. These are presumably the primary sound detectors in many species, but they may not be the only ones. Many authors overlook the potential contribution of the macula neglecta, a non-otolithic sensory complex found almost universally in fishes. In its most characteristic form this macula is composed of two patches of sensory epithelium that contain oppositely polarized populations of hair cells. A gelatinous cupula lies over these hair cells and in cases where there is acoustic coupling to the external medium the cupula presumably causes hair cell stimulation by being well matched to the acoustic impedance of the aqueous sound transmitting medium that surrounds the fish (Fig.A). In contrast the hair cells of the otolithic maculae are covered by dense masses believed to act as inertial elements poorly matched to the impedance of the surrounding medium (Fig.B).



In the present study unit and population responses in nerve VIII have been evoked by acoustic stimulation of relatively intact sharks. The initial population response to a click is composed of a series of brief high amplitude peaks lasting 5-10 msec. Certain peaks are believed to originate at the macula neglecta, as they are reversibly altered by covering the fenestra ovalis, a sound portal important in macula neglecta stimulation. Other peaks are believed to originate at otolithic maculae, as they are unaffected by this manipulation. The response characteristics and the anatomical distribution of units within the VIIIth nerve also suggest origins at different detectors. Thus parallel channels may be active in audition by sharks, and as a result of their dissimilar modes of stimulation they may provide different types of information concerning the nature of acoustic stimuli.

(Supported by grants to Dr. T.H. Bullock from NSF and NIH.)

55 RESPONSES TO THE DIFFERENCE TONE IN THE ANTEROVENTRAL COCHLEAR NUCLEUS OF THE CAT. John Dickson, Robert Wickesberg* and Mary Morton Gibson, Dept. of Neurophysiology, Univ. of Wisconsin, Madison, Wisconsin, 53706.

We have studied the responses of anteroventral cochlear nucleus neurons to the difference tone, f_2-f_1 (f_1<f_2). Single cell activity was recorded extracellularly in anesthetized cats. The lower primary frequency, f_1, was varied stepwise from slightly above the response area to 20 KHz or more. The higher primary, f_2, was chosen to maintain f_2-f_1 equal to the neuron's characteristic frequency. We measured discharge rate and strength of phase locking to the difference tone at three to six stimulus levels for each pair of primary frequencies. The sound pressure level of f_1 was always equal to that of f_2.

With the difference tone frequency and the levels of the two primaries held constant, one might expect that the discharge rate would be independent of the primary frequencies. This, however, is not the case: the response varies with primary frequency, sometimes from a negligible response to saturation. Both enhancement and diminution of the response could be accounted for by production by the primaries of other combination tones such as $2f_1$-f_2, $3f_1$-$2f_2$, etc. Thus enhancement could result when a combination tone falls within the response area of the neuron, while reduction could result when it falls within the suppression region. It seems unlikely, though, that increases and decreases in responsiveness at higher primary frequencies could be altogether accounted for by interference with higher order distortion products. In some cases, there is an overall decrease in response with increasing stimulus frequency which may be the result of middle ear filtering. (Supported by grant NS-12732).

56 ULTRASTRUCTURE OF NEURONS AND NEUROPIL IN THE ACOUSTIC TUBERCLE OF THE RED-EARED TURTLE. A.B. Drakontides and R.H. Browner. Dept. of Anat., New York Medical College, Valhalla, NY 10595.

Audition is dependent upon the presence of a minimal core auditory pathway. Essential auditory structures, such as the cochlear duct and basilar membrane are first evident in reptiles. Since reptiles are also the stem stock for all amniotes, the study of the auditory system in this Class has proven to be of increasing significance in the understanding of the hearing mechanism.

The present study presents a preliminary morphological characterization of auditory nuclei located in the acoustic tubercle (rostral end of the posterior root of incoming eighth nerve fibers) of the red-eared turtle (Chrysemys scripta elegans). At the LM level with cresyl violet or toluidine blue staining, the most easily identifiable cells are large (19-23 um) pale staining "clear" cells with eccentric nuclei and prominent nucleoli. These cells may be representative of the nucleus magnocellularis and are located between bundles of axons. The somata are found in the medullary portion of the acoustic tubercle in close proximity to the ependymal layer. Although other types of cells are present, in this report our attention is directed to the large "clear" cells and surrounding neuropil.

The cytoplasm of "clear" cells has a diffuse Nissl substance, the rough endoplasmic reticulum appearing in single, isolated rows. Mitochondria are small (270 nm diam.) and dispersed throughout the cytoplasm; numerous lysosomes (900 nm) are usually present. The Golgi complex is present characteristically around the circumference of the nucleus. The eccentric nucleus lacks chromatin particles and has a clear vesicular appearance, while the nucleolus appears as a typical dense, spherical mass. Portions of the periphery of these "clear" cells are often encased by lamellae. This is especially evident when the cell abuts on another cell body. Axo-somatic and dendro-somatic synapses are seen, often surrounded by astrocytic processes. In addition to a dense concentration of mitochondria within dendritic terminals, mitochondrial clusters are also present within dendritic spines. The apposing synaptic membranes present an array of various specializations which have been previously described in a number of species. The majority of sampled synaptic morphology indicates a chemical means of transmission. At least 20% of axon terminals contain large dense-cored vesicles (1300Å), in addition to clear-core vesicles (500Å diam.). These dense-cored vesicles are usually described as neurosecretory. Still to be determined are the cells of origin of these terminals and their synaptic relations.

57 ADAPTATION IN A VERTEBRATE HAIR CELL: STIMULUS-INDUCED SHIFT OF THE OPERATING RANGE. R. A. Eatock*, D. P. Corey* and A. J. Hudspeth, Division of Biology, California Institute of Technology, Pasadena, CA 91125

The operating range of hair cells in the bullfrog sacculus, measured as the hair bundle displacement which brings the receptor current from its minimal to its maximal value, is only 0.3 μm, or 2° of hair bundle bend. Larger displacements might thus be expected to move the cells out of their sensitive range, rendering them unresponsive to further stimuli. Instead, we observe that the hair cell's operating range shifts in such a way as to restore sensitivity during maintained displacement, and that this form of adaptation involves calcium ion.

The operating range of hair cells was determined in vitro by giving step displacements to the otolithic membrane, which is attached to the cells' hair bundles, and measuring the resultant transepithelial currents. For small regions of sacculus that encompass hair cells of nearly uniform orientation, the operating range is about 0.4 μm. Adapting steps of various amplitudes and durations were delivered, and the shift in operating range measured by giving another set of test steps at various times during or after the adapting step. For a displacement that increases the receptor current, the adaptive shift in operating range is such as to reduce it; a step in the opposite direction, which initially eliminates the receptor current, causes a shift such that responsiveness returns. The sigmoidal shape of the operating curve is largely unaffected. For displacements in either direction, the time course of the adaptive process is approximately exponential with a time constant of 10 - 50 ms. This process thus acts as a high-pass filter with a rolloff frequency around 5 Hz. The rate of adaptation varies with Ca^{++} concentration at the apical surface of the preparation, being greater for higher Ca^{++} concentrations and small if Ca^{++} is replaced with Sr^{++}.

These observations have been extended with intracellular recordings in which the operating ranges of individual cells were determined with 10-Hz stimulation of their hair bundles. The tips of the bundles were displaced by as much as 4 μm, held until the response returned, and fixed in situ. Scanning electron microscopy confirmed that individual cells, once adapted, can respond to stimuli even with their hair bundles bent by as much as 30° in either direction.

Thus, by shifting their operating range, hair cells are able to adapt to saturating static stimuli in such a way as to maintain high sensitivity to small, superimposed stimuli.

58 PRENATAL OTOTOXICITY OF KANAMYCIN IN THE CHICK. C. D. Fermin and G. M. Cohen. Department of Biological Sciences, Florida Institute of Technology, Melbourne, Florida 32901.

Recently several investigators showed that kanamycin exerts similar ototoxic actions during intrauterine life as in the adult. In order to compare the avian ototoxic response to the mammalian, we injected kanamycin sulfate into the yolk sac of White Leghorn embryos on the 7th day (stage 31) of the 21 day incubation period. Cytoplasmic damage, though widely varying and often extensive, occurred in all lagenar cells. By the 15th day (stage 41), tall hair cells, which morphologically resemble mammalian outer hair cells, frequently show severe damage but the short hair cells display little, if any, damage. The cytoplasmic texture, which is pocked by exploded mitochondria and empty spaces, alternates between coarse and clear areas. Organelles lose their usual arrangement and regroup. Osmiophilic granules, believed to be lysosomes, lie below the cuticular cone and are occasionally incarcerated within it; the stereocilia show no evidence of damage. The synaptic vesicles that normally form a symmetrical ringlet around the synaptic bar largely disappear. The pre- and post-synaptic membranes lose density, as does the subsynaptic web; the intersynaptic material disperses. Depending upon whether their terminals are mildly or severely damaged, afferent nerves either bloat or explode; efferent nerves, which form synaptic contacts several days later than afferent, show negligible evidence of intoxication. Throughout intoxicated supporting cells, circular zones of clear cytoplasm that are usually bounded by membranes or dense borders presage the empty holes. In the basal region, the endoplasmic reticula (ER) are irregularly arranged and do not form coiled patterns as in normal cells. In the neck, the Golgi complexes lose their concentric arrangement and disperse. Kanamycin, which apparently intoxicates along a gradient, damages tegmental cells above the inferior fibrocartilaginous plate more severely than those above the superior. Tegmental dark cells leave a mosaic of large spaces as they withdraw their tangle of snugly fitting cytoplasmic processes; in light cells the sequence precedes similarly but less conspicuously because of their limited processal number. In intoxicated cells of both types, levels of glycogen increase, though to a greater extent in dark cells. The tightly stacked columnar cells pull apart when intoxicated, leaving large intercellular spaces that occasionally contain cellular debris and blind processes filled with glycogen and fragments of rough ER. Because damaged columnar cells retain their fibrillar matrix, cytoplasmic organelles remain fixed at the sides, basal, and luminal ends. The tectorial membrane does not detach from the relatively undamaged luminal end. In necrosing columnar cells, the fibrillar matrix congeals to form dense spicules.

59 RESPONSE PROPERTIES OF SINGLE AUDITORY UNITS IN THE OYSTER TOADFISH (OPSANUS TAU). Michael L. Fine, Robert R. Capranica, Section of Neurobiol. & Behavior, Cornell Univ., Ithaca, NY 14850.

To date, no studies have compared the response properties of auditory units with the parameters of communicatory sounds produced by any fish. Because of the large body of descriptive and experimental studies on sound production in the toadfish Opsanus tau, it is an ideal species for such a study. Single units were isolated extracellularly from saccular branches of the auditory nerve in submerged toadfish in response to underwater sounds. Tuning curves are complex and variable, and best frequencies (BFs) range from 25 to 90 Hz. There is a strong modal peak at 40 Hz and 83% of the units have BFs between 25 and 40 Hz. The thresholds of the most sensitive units are below -23 dB (re: 1 dyne/cm^2) at 40 and 90 Hz. The upper tails of tuning curves vary from ones that increase monotonically with frequency to others that exhibit plateaus or even regain sensitivity. These secondary regions of sensitivity often occur at 200-250 Hz, where most sensitive thresholds are near 0 dB. Above 250 Hz sensitivity falls off rapidly.

The response properties of a unit do not depend on its BF. Maximal spike rate and slope of spike-rate curves increase and latency to tone bursts decreases with increasing frequency regardless of a unit's BF, and dynamic range is not necessarily greatest at BF. At BF, units are tonically active and phase locked with no short-term adaptation during a 300 ms stimulus. After stimulus termination, units with high rates of spontaneous activity exhibit momentary suppression, while those with low spontaneous rates (37 spikes/sec or fewer) can remain suppressed for periods exceeding half a second.

No information exists on how the toadfish utilizes sound of 40 Hz and below. The grunt, an agonistic call produced by both sexes, has a fundamental frequency of 90 Hz and is matched to the upper end of the fish's most sensitive auditory region. The sound pressure level of the male's mating call, the boatwhistle, is 40 dB at 1 meter, and its fundamental frequency varies from under 150 Hz to over 250 Hz, depending on temperature and assumed hormonal state. Even though the toadfish has no neurons primarily tuned to the boatwhistle, behavioral and single-unit data indicate the fish is quite capable of hearing it. This mismatch may enable toadfish to respond preferentially to the relatively loud boatwhistle of nearby callers, since it is difficult to localize distant sounds underwater.

60 EFFECTS OF MIDLINE BRAIN STEM LESIONS ON THE SHORT-LATENCY AUDITORY EVOKED RESPONSES. B.C. Fullerton and H.L. Hosford*, Eaton-Peabody Laboratory, Massachusetts Eye and Ear Infirmary, Boston, MA 02114.

Short-latency (< 8 msec) auditory evoked responses (AER) to clicks were recorded with a vertex electrode referenced to one ear canal in 10 adult cats anesthetized with Dial. Ten per second clicks were presented first monaurally to each ear and then binaurally. Recordings were amplified, filtered (1.5Hz-8kHz), and averaged during an intensity series of 5 dB steps up to 60 dB above threshold. An example of a monaural response is shown by the solid line in Fig. 1. We assessed the binaural interaction in the AER by subtracting the binaural (B) responses from the sum of the monaural responses (L+R) to obtain a binaural difference trace (BD), seen in Fig. 2. We found little difference between B and L+R through the time of wave 3. After wave 3, B was generally smaller than L+R with the greatest binaural difference appearing during waves 4 and 5. Binaural interaction apparently occurs for these later waves, but not for the earlier waves.

We examined the acute effects of midline lesions on the binaural interaction seen in the AER. Six cats received lesions intended to sever the crossing fibers in the dorsal, intermediate, and ventral acoustic striae. The greater the involvement of the ventral stria (trapezoid body), the greater the effect on the BD. In one case with a lesion severing the fibers of all 3 tracts, the remaining binaural interaction was negligible (Fig. 2), except for high stimulus levels when acoustic cross-talk becomes significant. The waves showing a binaural interaction are significantly affected by this lesion because they almost certainly involve activity from binaurally innervated brain stem regions. In addition, wave 3, which shows no binaural interaction, was also affected by the lesion (Fig. 1). This wave may reflect activity from a region such as the medial nucleus of the trapezoid body which receives virtually only contralateral monaural inputs.

61 A PRELIMINARY REPORT ON THE ORIGIN(S) OF THE BINAURAL-INTERACTION COMPONENT OF THE BSER IN THE GUINEA PIG. John N. Gardi* and Charles I. Berlin* (Spon: C. Norris). Kresge Hear. Res. Lab, Dept. Otorhinolaryngol., LSU Med. School, New Orleans, LA 70119.

An ablation technique under visual control was used to clarify the possible sites of origin of the binaural-interaction-component of the brainstem auditory evoked response in guinea pigs (BIC-BSER). The BIC is obtained by summing BSERs elicited by monaural clicks to each ear and subtracting this sum from the BSER elicited by binaural clicks. Typically, the BIC waveform is biphasic (negative - positive). At stimulus intensities of 80 dB SPL, latency values are 3.5-4.0 ms and 4.5-5.0 ms, respectively (Dobie and Berlin, Arch. Otolaryngol. in press and Clopton, personal communication).

Under urethane anesthesia (20%, I-P injections), the scalp and skull were removed. Cortex overlying the inferior and superior colliculi was aspirated to give a clear, unobstructed view of the colliculi. Scalp-recorded monaural and binaural BSERs were collected at this point and compared to pre-surgical controls. If no change in the waveforms was observed, the ablation procedure was continued. After the colliculi had been bilaterally aspirated, a series of final recordings was made.

Among the results were the following: 1. The BSER remained virtually unchanged following collicular aspiration. 2. The binaural-interaction-component, likewise, was not significantly affected or distorted by this direct ablation procedure.

These results suggest that although the inferior colliculus is a powerful integration center for the processing of binaural signals, the neural structures necessary for the maintenance of the BIC must be located caudal to the colliculi yet rostral to the cochlear nuclei. Based on a myriad of previous micro-electrode binaural-interaction studies, the nuclei of the superior olive are to be expected to be most vital to the maintenance of the scalp-recorded binaural-interaction components. Future investigations will attempt to pinpoint these sources. (This research was supported by NIH NS-11647 and NS- 07058. Laboratory facilities were provided by the Kresge Foundation.

62 RELATIONSHIP BETWEEN TONE DURATION AND THRESHOLD FOR NEURONS IN THE ANTEROVENTRAL COCHLEAR NUCLEUS OF THE CAT. Mary Morton Gibson, John W. Dickson, Robert E. Wickesberg* Department of Neurophysiology, University of Wisconsin, Madison, Wisconsin, 53706.

It is well known from human psychoacoustic observations that the threshold for detection of a tone is lowered when the duration of the tone burst is increased. This change in threshold is generally thought to be due to temporal integration in higher centers. However, previous physiological experiments suggest that the dependence of threshold on tone duration is detectable in the activity of anteroventral cochlear nucleus neurons and seems to result from the probabilistic nature of the discharges of auditory nerve fibers.

The responses of single cells with low spontaneous firing rates were recorded extracellularly in the anteroventral cochlear nucleus of barbiturate anesthetized cats. The stimulus generally consisted of 500 msec. best-frequency tone bursts presented once per second. The sound pressure level (SPL) was varied in 1dB steps from below threshold to 10 or 20 dB above threshold with 100 presentations at each SPL.

We define threshold as that SPL at which 50% of the tone presentations evoke at least one spike. When so defined the SPL at threshold is an orderly monotonic function of the duration of the sampling time, i.e., the time following stimulus onset during which the spike is accepted as a response. Within limits, the longer the sampling time, the lower the threshold. The magnitude of the effect seems commensurate with the psychoacoustic observations.

63 DISTRIBUTION OF ENZYMES OF ACETYLCHOLINE METABOLISM IN THE RAT COCHLEAR NUCLEUS. D.A. Godfrey and F.M. Matschinsky*. Dept. Pharmacol., Washington U. Sch. Med., St. Louis, MO 63110.

The involvement of acetylcholine as a neurotransmitter in the rat cochlear nucleus was assessed by measuring the activities of the enzymes responsible for its synthesis and degradation: choline acetyltransferase (ChAc) and acetylcholinesterase (AChE). Application of radiometric assays for samples of freeze-dried tissue weighing less than one microgram, and quantitative histochemical mapping procedures, provided maps of the distributions of the enzyme activities within the cochlear nucleus and other nearby locations. Averaged data are presented in table form as mean ± SEM (no. of rats). (DCN, PVCN, AVCN: dorsal, posteroventral, anteroventral cochlear nucleus; CbF: cerebellar flocculus.)

	Enzyme activity in amt./kg dry wt./min.	
Region	ChAc (μmoles)	AChE (mmoles)
Granular region, DCN	311 ± 91 (3)	54 ± 11 (3)
Granular region, PVCN	214 ± 42 (4)	44 ± 2 (4)
Granular region, AVCN	319 ± 35 (3)	52 ± 2 (3)
DCN molecular layer	214 ± 29 (4)	42 ± 3 (4)
DCN fusiform-cell layer	375 ± 34 (4)	62 ± 3 (4)
DCN deep region	295 ± 18 (3)	42 ± 5 (4)
PVCN	292 ± 44 (4)	25 ± 1 (4)
AVCN caudoventral part	450 (1)	28 (2)
AVCN caudodorsal part	611 (1)	39 (2)
AVCN rostral part	351 ± 41 (4)	39 ± 5 (3)
Auditory nerve root	30 (2)	2.5 (2)
Trapezoid body	125 ± 33 (4)	4.8 ± 0.4 (3)
Acoustic striae	216 ± 30 (3)	25 ± 4 (4)
CbF molecular layer	27 ± 4 (4)	5.4 ± 0.7 (3)
CbF granular layer	93 ± 25 (4)	62 (2)
CbF white matter	95 (2)	30 ± 9 (3)
Facial nucleus	4735 ± 376 (3)	169 ± 13 (3)
Facial nerve root	6619 ± 1035 (4)	46 (2)
Spinal trigeminal tract	5.1 (2)	2.2 ± 0.4 (3)

Comparison of the data for auditory nerve root, trapezoid body and acoustic striae with that for facial nerve root implies that axons in the first- and second- order auditory pathways are overwhelmingly non-cholinergic. Within the cochlear nucleus, relatively high activities of both enzymes were found in the fusiform-cell layer, but these activities are much lower than those in the facial nucleus. On a quantitative basis, the distributions of choline acetyltransferase and acetylcholinesterase activities differ considerably from those reported previously for cat cochlear nucleus. The results are consistent with a function of acetylcholine as a neurotransmitter in the rat cochlear nucleus, probably mostly at synapses of interneurons and/or feedback pathways.

64 INTRACELLULAR AND EXTRACELLULAR POTENTIALS IN THE ORGAN OF CORTI OF THE MONGOLIAN GERBIL. David A. Goodman* and Robert L. Smith (SPON: J. J. Zwislocki). Institute for Sensory Research, Syracuse University, Syracuse, NY 13210.

Glass microelectrodes were inserted through scala tympani into the organ of Corti of anesthetized Mongolian gerbils and aimed toward the inner hair cells. The resting and sound-evoked potentials encountered were consistent with those reported by Russell and Sellick (J. Physiol. 284, 261-290, 1978) in the guinea pig with respect to resting potentials and response magnitude, polarity, and frequency-selectivity. As in that study two classes of cells were encountered. Cells contacted first in a penetration, presumably supporting cells, had large resting potentials of -70 to -100 mV. In these cells the depolarizations in response to sound (summating potentials) were less than 3 mV. The second class, presumably inner hair cells, had smaller resting potentials of -15 to -45 mV and large summating potentials of 5 to 15 mV. The extracellular summating potential increased as the electrode advanced and reached up to 3 mV in the vicinity of the inner hair cells where it exhibited a frequency-selectivity comparable to that of auditory nerve fibers. With further small advances of the electrode, scala media was entered as evidenced by the positive endolymphatic potential and a polarity reversal of the summating potential. The magnitude of the summating potential measured in the extracellular space near a supporting cell was generally smaller than that measured in the cell. A possible explanation for this inequality is that the summating potential spreads passively through electrically coupled supporting cells with a space constant exceeding that of the extracellular space.

65 PHYSIOLOGY OF MNTB NEURONS RECEIVING LARGE ENDINGS John J. Guinan Jr.* (SPON: N. Y. S. Kiang). Eaton-Peabody Laboratory of Auditory Physiology, Mass. Eye and Ear Infirmary, Boston, MA. 02114.

In the medial nucleus of the trapezoid body (MNTB) each principal neuron receives one large ending (calyx of Held), and many small endings. MNTB units often have unusual waveforms, typically with a positive first component (C1) followed 0.5 ms later by a negative second component (C2). Electric shocks in the region of the axons that give rise to calyces in the contralateral trapezoid body (CTB) evoke C1+C2 responses in which the latency of C1 is between 0.1 and 0.3 ms. Because these latencies are too short for there to be an intervening synapse, C1 must represent activity in a presynaptic element, presumably a calyx of Held (the only large ending nearby). Electric shocks in the ipsilateral nucleus of the lateral superior olive (LSO), a region to which MNTB neurons project, evoke a spike with a latency of 0.1 to 0.3 ms. This "A spike" must be an antidromic activation of the same neural element as a C2 spike because they have similar waveshapes and mutually interact showing refractory effects when LSO and CTB shocks are combined. C2 almost certainly represents activity from a postsynaptic element such as the soma of the principal neuron because C2 can be evoked antidromically (in the form of an A spike) but normally follows C1 by a time appropriate for a synaptic delay. In dozens of cats under the effects of Dial-urethane and in two under ketamine, both spontaneous and sound-evoked responses in units with C1+C2 waveshapes never had C1 or C2 components alone. Occasionally CTB shocks evoked a long latency (1-3 ms) "LL spike" which, by refractoriness and waveshape, is from the same neural element as C2 and A spikes. Since LL spikes do not follow every shock and have long variable latencies, it seems likely that a synapse is interposed between the axons stimulated and the elements producing LL spikes. Thus an LL spike appears to be an orthodromic, postsynaptic spike from a neuron which receives a large ending. Since LL spikes are not preceeded by C1 spikes, LL spikes most likely are mediated through small endings. Further work is needed to determine the significance of LL responses and small synapses on principal neurons in acoustic signal processing.

66 PHYSIOLOGY AND ANATOMY OF SINGLE CELLS IN THE CAT INFERIOR COLLICULUS STUDIED WITH THE TECHNIQUE OF INTRACELLULAR RECORDING AND INJECTION OF HORSERADISH PEROXIDASE. L.B. Haberly, S. Kuwada*, T.C.T. Yin, and D.C. Mountain. Depts. of Neurophysiology and Anatomy, Univ. of Wisconsin Medical School, Madison, Wis. 53706

We report here preliminary data on the morphology and physiology of neurons in the inferior colliculus of the cat. Single cells were impaled with beveled glass micropipettes filled with a buffered HRP solution. Intracellular potentials in response to auditory stimulation were recorded followed by iontophoresis of HRP. Cats were perfused and frozen sections (80μm) processed by the $CoCl_2$-DAB procedure. A small number of neurons has thus far been studied physiologically and injected successfully with no visible traces of extracellular leakage of HRP or damage to the neuron, but with an apparently complete labeling of dendritic trees and extensive labeling of axonal arborizations.

There is a marked variation in the morphology of neurons injected. Cell somas ranged in size from approximately 12-35 μm in diameter. Dendritic trees conforming to Rockel and Jones' (JCN 147:11) fusiform, bitufted, large, and multipolar categories have been labeled. In most cases these dendritic trees appear considerably more extensive than in previous Golgi studies, presumably since serial reconstruction through many sections could be readily performed on the present material. An interesting feature of the dendrites of all neurons studied was the presence of varicosities. The extent to which these varicosities are artifactual is unknown, although pyramidal cells injected and processed with identical techniques show no evidence of dendritic beading. Many dendrites are of extremely small diameter. Dendritic shafts between varicosities (often widely spaced) can be less than 0.5μm in diameter for distances of 100μm or more. Dendritic spines are always present but their morphology and numbers vary greatly in different neurons.

Extensive axonal arbors within the colliculus were found for all neurons injected. In one case the local arborization of a large cell, whose axon entered the brachium of the inferior colliculus, gave rise to more than 2000 presumed terminal swellings within the central nucleus.

In all cases the physiological properties of the cells were characterized by their intracellular responses to sinusoidal tone bursts delivered dichotically at the cell's characteristic frequency before injection. Some cells were found to be sensitive to the interaural phase difference. The spike discharge properties of the cells could sometimes be inferred from the postsynaptic membrane potentials. However, our sample of cells in which both the physiology and morphology are well-studied is still too small to draw correlations between structure and function.

67 ACOUSTIC ANALYSIS OF MATERNAL RETRIEVAL TO KITTEN STRESS CALL. J.B. Harrison*, J.S. Buchwald, and R.J. Norman, C. Hinman*, Dept. Physiology, Mental Retardation Research Center, Brain Research Institute, University of California, Los Angeles, California.

Maternal retrieval in response to kitten stress calls has been used as a means of determining significant features of this complex stimulus. The test subject was placed in a cylindrical chamber in which there were two wall apertures of approximately 6 x 6 cm covered by opaque curtains. Experimental sessions consisted of twelve 2 min trials separated by inter-trial intervals of 5 min with no more than 2 sessions per week per subject. During each 2 min trial, one of 5 test stimuli was continously delivered: stress calls from a vocalizing kitten within one of the wall-mounted boxes, tape-recorded stress calls from one of the two speakers, or synthesized components of the stress call. These stimuli were delivered pseudo-randomly so that presentations of the vocalizing kitten always occurred throughout the session to mitigate against habituation effects. "Retrieval" responses were scored when the test subject's head contacted the curtain of the box from which the call originated. Twenty-two adult females were tested with these stimuli during the month immediately before and after parturition. None of the animals retrieved in the absence of a call stimulus. The highest levels of retrieval occured post-natally to the vocalizing kitten. A response gradient to the kitten, the taped kitten call, and the synthesized components was consistently seen in all animals. There was no difference in retrieval levels to a sequence of taped stress calls compared to their digitized version. A single repeated call was also an effective stimulus. To determine what aspects of the call were most effective, digitized components of the call were played forward or backward, spectrally altered by high pass and low-pass filtering, or temporally blocked into FM and sustained epochs.

Taken together, our results indicated that the kitten stress call seems preeminent over visual, olfactory or thermal cues as a trigger for maternal retrival, since retrievals persisted at relatively high levels when tape recorded calls were substituted for the kitten. On the other hand, synthetic, stimuli which lacked certain aspects of harmonic structure, resonance and band width in the tape recorded calls induced little or no retrieval. (Supported by USPHS HD-05958 and HD-04612).

68 NEURONAL RESPONSES TO THE KITTEN STRESS CALL IN CAT MEDIAL GENICULATE NUCLEUS. C. Hinman*, J. Buchwald, J. Harrison*, and R. Norman, Dept. of Physiology, Mental Retardation Research Center, Brain Research Institute, University of California Medical Center, CA.

Anatomical studies in the cat have demonstrated direct connectivity between the medical geniculate body (MGB) and several cortical areas. While the ventral nucleus of the MGB projects to primary auditory cortex, the dorsal nucleus projects primarily to the insulo-temporal cortical area. Insulo-temporal cortex in the cat appears to be necessary for some kinds of complex acoustic processing which do not require primary auditory cortex (Dewson, J.H., Science 144: 555, 1964). Moreover, regions within the dorsal MGB are relatively unresponsive to clicks or pure tones. Thus, different kinds of ascending acoustic information may be transmitted by the dorsal MGB-insulo-temporal system and the ventral MGB-primary auditory cortex system. In order to investigate this problem, we have been recording MGB single unit responses in the awake, unanesthetized cat to species-specific vocalizations which are known to produce behavioral responses in the cat. A maternal retrieval assay of the kitten stress call has been used to determine which aspects of the call have behavioral significance. (See Harrison et al, this volume) Forward and reverse time segments extracted from the call were used as stimuli in addition to filtered calls (high/low, band-pass/reject) and individual FM call components. Responses to these complex stimuli were compared with responses of the same units to clicks and to pure tone bursts at several intensities. Preliminary data suggest that correlations can be made between gross MGB anatomical subdivisions and unit response selectivity for isolation call components. Examples will be presented from different classes of responsive units, and their implications for central auditory processing discussed. (This work supported by USPHS grants HD-05958 and HD-04612).

69 PATTERNS OF IPSILATERAL AND CONTRALATERAL CORTICOCORTICAL INPUT TO AI ARE RELATED TO BINAURAL AND BEST FREQUENCY MAPS. Thomas J. Imig and Richard A. Reale. Department of Neurophysiology and Waisman Center on Mental Retardation and Human Development, University of Wisconsin Medical School, Madison, WI 53706.

The primary auditory cortical field in cat receives input from a number of other cortical areas in the same and opposite hemispheres. Using the axoplasmic transport of tritiated amino acids we have studied the crossed projection from the anterior (A) auditory field and the ipsilateral projections from the anterior and posterior (P) auditory fields upon AI. In each experiment best frequency maps were obtained to serve as guides for placement of isotope injections. Labeling of each of these pathways produces dense aggregates of silver grains in several locations within AI which are separated from each other by areas of less dense labeling. These projections connect similar portions of the best frequency representations in each field. In tissue sections cut parallel to the flattened cortical surface dense aggregates of silver grains could often be seen which occupied patches of cortex elongated along the low-to-high best frequency gradient. Thus the patchy distribution of corticocortical input and the elongation of the patches appears similar to the terminal patterns formed by callosal fibers interconnecting the primary auditory fields in each hemisphere (Imig and Brugge, JCN, 182:637-60, '78).

We have studied the relation between the ipsilateral projection patterns from field A and the binaural organization of AI. In some experiments each physiologically defined suppression column corresponds with a region of dense labeling and each physiologically defined summation column corresponds with a region of sparse labeling. This is exactly opposite to the pattern formed by terminals of callosal fibers which interconnect the primary fields (ibid.). However more complex patterns of labeling were seen in other experiments in which suppression columns still appeared to be the major recipients of the projection but in addition dense projections were also seen to some summation columns.

Variation was also seen in the pattern of projection from field P upon AI. Injections into the same isofrequency strip produced dense elongated bands of label in the center of AI in some experiments while in others labeling was confined to regions near the dorsal and ventral borders. This variability in labeling suggests that neurons which differ in location along an isofrequency strip in field A or P may also differ in their pattern of projection upon field AI. (NSF 76-19893, HD-03352)

70 PLASTICITY OF BINAURAL INPUT TO NEURONS IN CAT INFERIOR COLLICULUS. D. R. F. Irvine* and D. R. Moore* (SPON: J. F. Brugge). Neuropsychology Lab., Dept. Psych., Monash Univ., Clayton, VIC 3168, Australia.

The effects of a period of unilateral input attenuation on the responses of central auditory neurons to binaural stimulation have been examined. Input attenuation was produced by ligation of the external auditory meatus in 13 neonatal (12-48 hr) and 5 adult cats. After survival periods of 80-100 days the ligature was removed under barbiturate anesthesia and the status of the peripheral auditory system was assessed by auditory - nerve action - potential audiometry. In those animals with normal peripheral sensitivity, the responses to binaural stimulation of neurons in the central nucleus of the inferior colliculus contralateral to the previously-ligated ear were examined by conventional extracellular recording techniques. Observations were restricted to that class of neuron commonly sensitive to interaural intensity difference (IID) in normal cats, viz. those receiving predominantly excitatory input from the contralateral ear and inhibitory input from the ipsilateral ear. Detailed quantitative observations have been made on 32 neurons in neonatally-ligated animals and 24 neurons in adult-ligated animals. Excitatory input from the contralateral (previously - ligated) ear, as reflected in threshold and discharge rate at best frequency, did not differ significantly from that in normal cats. However, ipsilateral inhibition, as reflected in the steepness of IID functions, was considerably reduced in both neonatally - and adult - ligated animals. This reduction in inhibition was particularly apparent in the sustained component of the discharge pattern.

These preliminary results suggest that the auditory system is characterized by a form of plasticity quite different from that observed in the visual system following the analogous procedure of monocular eyelid suture. It appears that binaural components of the auditory system, confronted with attenuated input from one ear, somehow reduce the input from the other (normal) ear so as to maintain a balance of input from the two sides. Such a mechanism would have the consequence that important binaural functions - notably localization - would not be totally impaired by unilateral input attenuation. This "balance of input" hypothesis provides an explanation of the clinical observation that humans with unilateral hearing loss achieve midline lateralization with equal or near-equal intensities at the two ears.

71 VISUALIZING THE RABBIT AUDITORY PATHWAY WITH ^{14}C 2-DEOXY-D-GLUCOSE. L. Sargent Jones and J.F. Disterhoft, Department of Anatomy, Northwestern Univ. Med. Sch., Chicago, Ill. 60611.

Previous work in mice has shown that the ^{14}C 2-deoxy-D-glucose (2-DG) technique can be applied to studies of the auditory pathway (Jones and Disterhoft, '79). The present work in rabbit is part of an examination of metabolic changes which may be evident during tone signalled nictitating membrane conditioning in rabbit. Male albino rabbits were restrained with their heads non-traumatically immobilized in an IAC single walled acoustic chamber. A silastic earmold fitted to the rabbit's left ear positioned the earphone, sound measuring microphone and calibrated probe tube assembly close to the eardrum. 50 msec. tone pulses with 10 msec. rise fall times were presented one per sec. at 2, 8 and 20 KHz, 30 dB above the rabbit's behavioral threshold (Martin et al., '77). 45 min. after an IV injection of 2-DG the brain was removed and sectioned as previously described for mice.

All of the auditory nuclei caudal to the medial geniculate nucleus (MGN) were labeled by the 2-DG in all three conditions. Differences between them were seen as differences in the overall pattern of 2-DG uptake rather than in the amount. Cochlear nucleus (CN), lateral superior olive (LSO), medial superior olive (MSO), medial nucleus of the trapezoid body (MNTB), nuclei of the lateral lemniscus (LL), and the inferior colliculus (IC) all demonstrated relatively high metabolic levels in the control. The dorsal CN always showed the highest uptake in the CN. The lateral curve of the LSO was more heavily labeled than the rest of the nucleus; this was less noticeable in the control. The MSO and the LL were labeled less than the other auditory brainstem nuclei under all conditions, while the MNTB was always highly labeled. The IC pattern of activation varied among conditions. In the control, metabolic activity was high in the ventromedial portion of the IC as was shown in mouse. White noise stimulation activated the whole central and external nuclei, particularly contralaterally. Although the entire central nucleus was activated, bands of greater uptake, usually three in number, ran dorsomedial to ventrolateral. They were particularly marked after pure tone stimulation when densely labeled bands with adjacent bands of reduced activity were seen. This pattern may have been the metabolic result of concentrations of excitatory and inhibitory neuronal activity caused by repeated pure tone presentations. MGN was labeled more heavily than surrounding thalamic regions but there was no striking difference among conditions. As in mouse, rabbit auditory cortex showed no substantial nor organized labeling.

Supported by NIH Grant No. 5 RO1 NS12317 and NIMH Grant No. F31 MH07870.

72 CYTOARCHITECTURE OF THE DORSAL NUCLEUS OF THE LATERAL LEMNISCUS (DNLL) OF CATS. Eileen S. Kane. Dept of Anat., Univ. of Mass. Med. Sch., Worcester, MA 01605.

The boundaries, nerve cell types and neuronal distributions in the dorsal nucleus of the lateral lemniscus (DNLL) were studied in several sets of Nissl-stained or Golgi-impregnated mature cat brains, cut in one of the three standard planes. Maps of DNLL neurons and their orientations in Nissl sections showed a nearly cubical nucleus with maximal dimensions of 1.1 mm (dorsoventral) X 1.1 mm (mediolateral) X 1.5 mm (rostrocaudal). DNLL neurons are clustered with individual clusters separated by thick fascicles of lemniscal axons. The width:length (W:L) ratios of single neurons provided three classes based on somatic shape: elongate (E) = W:L ratio $\leq$ 0.65, ovoid (O) = 0.65 < W:L ratio <0.80, and round (R)=W:L ratio $\geq$ 0.80. Three somatic size categories were present within each shape category such that large cells (L) were 21-30 µm X 26-45 µm, medium (M) cells were 11-20 µm X 16-25 µm, and small (S) cells were 5-10 µm X 10-15 µm. Counts of DNLL neurons within each of the resulting nine classes showed the following percent distributions: LR = 12%, LO = 24.5%, LE = 13.5%, MR = 17.5%, MO = 17%, ME = 14%, SR = 1%, SO = 0.5%, and SE = 0%. Dendritic orientations of Golgi-impregnated neurons were defined for six of the nine categories and showed a preferred horizontal orientation for LR, LO, ME and MO cells, preferred vertical orientation for most LE neurons, and a radiate orientation of neuronal dendrites in the MR class. The tendency toward horizontal vectors of both large and medium-sized neuron receptive fields suggests possible divergent inputs from lemniscal axons of several frequencies. Our findings suggest an additional horizontal organization to the DNLL that may be superimposed upon the dorsoventral tonotopic organization shown in other studies. That horizontal component may reflect known phase sensitivity or broad tuning of individual DNLL neurons.

73 DEVELOPMENT OF CENTRAL AUDITORY FUNCTION IN THE RAT: A [^{14}C] DEOXYGLUCOSE STUDY. Jack Kelly and Leslie C. Skeen. Department of Psychology, Carleton University, Ottawa, Ontario, K1S 5B6, and Department of Psychology, University of Delaware, 19711.

The [^{14}C]-deoxyglucose method was used to examine the course of development of the auditory system in the rat. The distribution of labeled deoxyglucose in the brain was determined following auditory stimulation of infant rats at ages 8, 11, 14, 17 and 20 days. These ages were selected to cover the period of most rapid development of auditory function as estimated from physiological and behavioral studies. In addition 30 and 60 day animals were included to provide reference points for post weaning ages. Following either intraperitoneal or intravenous injections of deoxyglucose the animals were placed inside a small cage in a sound-proofed room and were stimulated for 45 minutes from an overhead loudspeaker with an 80 dB SPL noise containing frequencies from 2 to 40 kHz. Frontal sections were taken through all levels of the auditory pathway and autoradiographs were made on X-ray film. Cresyl violet stains of selected sections provided histological verification of auditory structures. For control purposes, cases with ear blocks and without auditory stimulation were also examined. The results showed no stimulus-related response in the central auditory system of 8 or 11 day animals although a distinctive pattern of activity could be seen in auditory structures even without stimulation. The earliest response to auditory stimulation was found in 14 day animals, and was most noticeable in the cochlear nucleus and inferior colliculus. The superior olivary nucleus was very active in both stimulated and non-stimulated conditions and did not provide a reliable basis for determining the onset of auditory function. Stimulus-related responses in the cochlear nucleus and midbrain auditory areas were more pronounced at older ages, but again activity in the superior olive was high without stimulation. At all ages forebrain responses were less clear than brainstem responses and little contrast was found between stimulated and non-stimulated conditions. Evoked potential studies of auditory sensitivity and behavioral studies of auditory spatial orientation were carried out to complement the anatomical studies with deoxyglucose. Generally, the results of the deoxyglucose study corresponded closely with both behavioral and physiological indices of the onset and development of hearing in the rat.

Supported by NRC grant 7654 and NIH grant NS 14535.

74 THE TORUS SEMICIRCULARIS IN THE TOKAY GECKO, GEKKO GECKO. M.C. KENNEDY AND R.H. BROWNER. Dept. Biol., New York Univ., New York, NY 10003; Dept. Anat., New York Med. Coll., Valhalla, NY 10595.

The cytoarchitecture of the torus semicircularis in the Tokay gecko was examined in Nissl and fiber stained brains (Klüver-Barrera method) sectioned in the three standard planes. Tissue impregnated using a modified Golgi-Kopsch technique was embedded in Araldite and sectioned in the three standard planes at 120-160 um for use in the analysis of neuronal morphology.

From a superficial position under the cerebellum, the torus semicircularis continues rostrally, extending under the caudal half of the optic tectum and causing a distinct bulge in the floor of the tectal ventricle. Caudally, the two tori abut upon one another; as they proceed rostrally, they diverge. The torus semicircularis is composed of a central nucleus, a laminar nucleus and a superficial nucleus.

The central nucleus is an ovoid mass of pyriform, fusiform, triangular and oval neurons. These neurons exhibit dendritic arrays which ramify mainly within the central nucleus. The complexity of the dendritic branching increases at more caudal levels, as does the incidence of dendritic spines. At its center, the central nucleus includes a number of large neurons with extensive dendritic fields and numerous dendritic spines. Some of the cells of the central nucleus have dendrites which project ventrally into the tegmentum.

The laminar nucleus is a sheet, 3-5 cells thick, which bounds the central nucleus on its medial, ventral and dorsomedial aspects. The nucleus is populated mainly by fusiform neurons with dendrites oriented parallel to the boundaries of the central nucleus. These processes exhibit a paucity of dendritic spines.

The caudal superficial nucleus is present dorsal, dorsolateral and caudal to the central nucleus. It is of variable width and is widest at its lateral margins. The superficial nucleus is sparsely populated and is traversed by fibers apparently derived from the lateral lemniscus.

75 EAR OCCLUSION CAUSES SYSTEMATIC SHIFTS IN THE RECEPTIVE FIELDS OF AUDITORY UNITS. Eric I. Knudsen and Masakazu Konishi. Div. of Biology, Calif. Inst. of Technology, Pasadena, CA 91125

The ear openings of the barn owl (Tyto alba) are asymmetrically located on the head: the left ear is higher than the right. A consequence of this asymmetry is that the left ear is more sensitive to areas of space below the horizontal plane and the right ear is more sensitive above. Behavioral experiments show that ear occlusion causes systematic errors in the owl's ability to localize sounds: when the left ear is plugged, the owl localizes above and to the right of the sound target; when the right ear is plugged, it localizes below and to the left of the target.

A specialized region in the midbrain (MLD) of the owl has been implicated in spatial analysis of sound. Units in this region only respond to sounds from restricted areas of space (receptive fields) and are inhibited by sounds originating outside these areas. Furthermore, the units are arranged within this brain region according to the locations of their receptive fields so that they form a physiological map of auditory space.

We used a movable sound source to map the receptive fields of these units before and after plugging one ear. All units were affected in the same way. Plugging the left ear caused receptive fields to move down and to the left. Plugging the right ear caused fields to move up and to the right.

If the activity of a unit coded the location of a sound source in space, then an induced receptive field shift down and to the left, for example, would cause the owl to make a localization error above and to the right of the sound source - the effect that was, in fact, observed. These results support the contention that neurons in this specialized region of MLD are involved with spatial analysis of sounds.

76 CYCLIC RESPONSE PROPERTIES OF CAT INFERIOR COLLICULUS NEURONS AS A FUNCTION OF INTERAURAL DELAY: EFFECTS OF TIME AND INTENSITY. S. Kuwada*, T.C.T. Yin, and R.E. Wickesberg (SPON: D. Oertel). Dept. of Neurophysiology, Univ. of Wisconsin Medical School, Madison, Wis. 53706.

When a low frequency sinusoid (<3000 Hz) is presented dichotically, the response of many inferior colliculus neurons will vary cyclically as a function of the interaural delay. The interval between peaks of the interaural delay curve corresponds to the period of the stimulating frequency. The present study describes a small number of neurons in the inferior colliculus of the cat with unusual response properties: the cycling nature of their interaural delay curves was altered as a function of stimulus off time and/or interaural intensity.

Cats were anesthetized with sodium pentobarbital and single cell activity was monitored extracellularly with platinum-gold plated indium microelectrodes. A computer was employed for controlled stimulus delivery, data collection and subsequent off-line data analysis.

The following effects due to varying stimulus off time and/or interaural intensity have been observed in these neurons. 1) As stimulus off time was decreased, the degree of modulation of the cycling could markedly increase. This effect can be relatively independent of the stimulus duration. 2) As the stimulus off time was increased, the symmetry of the interaural delay curve could be altered considerably. For example, at longer off times the cyclic behavior of the interaural delay curve was abolished when the stimulus to the contralateral ear was delayed, but was preserved when the stimulus to the ipsilateral ear was delayed. 3) These asymmetrical effects due to stimulus off time could sometimes be offset and/or reversed by varying interaural intensity. Neurons which exhibited one or more of these properties were similar in that the neural response to a monaural stimulus was of an onset type to at least one of the ears.

Such manipulations are helpful in understanding the time course and interactions of the activity generated by each ear. For example, the effect of stimulus off time on the degree of modulation of the cycling can be understood in terms of a time dependent inhibition. These results suggest that some inferior colliculus neurons may be sensitive to particular stimulus attributes.

77 POSTNATAL DEVELOPMENT OF THE DORSAL COCHLEAR NUCLEUS. S.A. Larsen. Department of Neurophysiology and Waisman Center on Mental Retardation and Human Development, University of Wisconsin, Madison, Wisconsin.

Maturation of cells of the dorsal cochlear nucleus (DCN) was studied in kittens ranging in age from 2 to 81 days and adult cats using Nissl (thionin) stained serial sections. At selected developmental stages, Nissl-stained cells were drawn using a Zeiss microscope equipped with a camera lucida and a Talos cybergraphic tablet interfaced to a Harris 6024/5 computer. The cochlear nucleus doubles in size from birth to adulthood. The fusiform cell layer is 5-6 cells thick; cells are small, densely packed and poorly differentiated at birth. The central DCN is shallow and poorly developed. Cells in the central DCN are small and not well differentiated at birth. Many signs of immaturity are observed: (1) cells which appear to be migrating (2) large cells with eccentrically placed nuclei and with Nissl material congregating at the periphery of the cytoplasmic membrane (3) cells with two nucleoli and (4) many cells with heavily clumped Nissl material. Cells of the fusiform cell layer increase from 761 cells at 2 days to 1355 cells in the adult. Cells found in central DCN also increase from 715 cells/mm^3 at 2 days to 1057 cells/mm^3 in the adult. Two types of fusiform cells are recognized in Nissl-stained material as early as 2 days postpartum. These types are (1) fusiform cells with pale-staining cytoplasm and nucleus and with an adult Nissl pattern of clumped Nissl arranged along the longitudinal axis of the cell and (2) fusiform cells with dark-staining cytoplasm, lightly stained nucleus and with an adult Nissl pattern of finely dispersed Nissl material distributed evenly throughout the cytoplasm. Pale-staining fusiform cells tend to group in the ventral half of the fusiform cell layer with dark cells grouped in the dorsal half. Cell growth is a nonlinear function of postnatal age. Both types of fusiform cells are approximately 35% of adult size at 2 days and follow a similar growth rate although the pale-staining cells are larger at all ages. Pale-staining cells increase 186% and dark-staining cells increase 172% in size from 2 days postpartum to adulthood; both are approximately 90% of adult size at 81 days postpartum. Both types develop adult cytoplasmic patterns by 34 days postpartum. Cells of central DCN are 50% of adult size at 2 days increasing 70% in size by adulthood. These cells are 99% of adult size by 81 days postpartum. Nuclei of fusiform cells are 43-45% of adult size at 2 days postpartum increasing 121-131% by adulthood. The nuclei of cells of central DCN are 92% at 2 days and 98% at 81 days postpartum. Microneurons are found scattered throughout the DCN. These microneurons show little change in cytoplasmic pattern or size with age. The microneurons of DCN are larger than microneurons located in other areas of the cochlear nucleus.

78 DICHOTING LISTENING IN CHILDREN SUFFERING FROM AGENESIS OF THE CORPUS CALLOSUM. Maryse C. Lassonde, Jean Lortie* and Maurice Ptito. Lab. de Neuropsychologie expérimentale, Univ. du Québec, C.P. 500, Trois-Rivières, P.Q. Can., G9A 5H7.

Numerous studies have established beyond question the existence of functional asymetries between the two cerebral hemispheres in man. Dichotic listening proved to be a powerful tool for investigating such asymetries. This technique has often been used to study hemispheric specialization in normals and commissurotomized subjects. However, very few studies have been conducted in order to assess functional asysmetries in patients suffering from a congenital absence of the corpus callosum. The purpose of the prescut study is therefore to investigate hemispheric specialization in patients suffering from callosal agenesis using the dichotic paradigm. Two subjects were included in the experimental group; MG, age 8 and LG age 16 had a complete callosal agenesis as revealed by CT scan. The patients were matched with two control groups: a. subjects with normal IQ, b. subjects with an IQ comparable to the acallosal patients ($\simeq$75). Each was right handed and had bilaterally normal hearing at the speech frequencies. All subjects were tested in an auditory recognition task under dichoting listening and their performances (mean errors and reaction time) were compared. Verbal (common words and nonsense syllables) and non verbal (pure tones) stimuli were binaurally presented to the subjects through earphones. Results have shown that 1) in the normal and matched IQ groups, the right hemisphere is superior when confronted with the non verbal stimuli whereas the left hemisphere performed better with the verbal stimuli 2) in the acallosal patients, the right hemisphere is always superior independantly of the nature of the stimuli (verbal vs non-verbal). Moreover, the reaction times recorded from the acallosal patients are three times longer than the other groups. These results tend to show that acallosal patients acquire during their development a brain asymetry different from normal.

79 BRAINSTEM AUDITORY EVOKED POTENTIALS AND AUDITORY RADIATION ACTIVITY IN THE MONKEY. Alan D. Legatt, Joseph Arezzo*, and Herbert G. Vaughan, Jr. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461.

Short latency or brainstem auditory evoked potentials (BAEPs), recorded during the first few msec following a click stimulus, are believed to reflect activity in the brainstem auditory pathways. The BAEP waveform recorded in the monkey resembles that seen in man, although more components can be identified. We have examined the relationship between evoked activity in the geniculocortical radiations and the far-field BAEP in the monkey.

100 usec 95 dBSPL clicks were delivered monaurally at a rate of 2 or 10 per second to an alert monkey which had been implanted with arrays of vertically-oriented guide tubes for depth electrodes. Depth passes were made through contralateral auditory cortex and into the underlying white matter. Three-dimensional field mapping delineated primary auditory cortex on the basis of potential gradients, polarity inversions, and multiple unit activity (MUA) maxima.

The same components were identifiable in the depth recordings in and around primary auditory cortex as in the simultaneously-recorded BAEPs at the vertex up through wave 7, which had a peak latency of 3.7-4.0 msec. An additional positivity, peaking at 4.2-4.4 msec and larger than wave 7, was seen in these depth recordings; it was not seen as a distinct component at the vertex.

Wave 8 at the vertex peaked at 4.9-5.3 msec. The corresponding depth-recorded potential was much larger; it could be traced upwards from auditory cortex into its far field. It did not invert in polarity beneath auditory cortex, as did the cortical AEP. MUA in the deeper layers of primary auditory cortex showed two bursts preceding the cortical MUA increase, peaking at 4.5-4.6 and 5.5-5.6 msec.

A depth pass penetrating the auditory radiations recorded a MUA burst, peaking at 5.5-6.0 msec, restricted to a distance of approximately 0.5 mm. Its gross potential correlate was a positive-negative-positive waveform with onset at 4.5 msec and peaks at 5.5, 6.0, and 6.2 msec. The initial positivity could be traced upwards, its latency gradually approaching that of wave 8. A small MUA burst with an onset at 4.3 msec and a peak at 4.5 msec was recorded nearby, but over a smaller distance.

Thus it appears that wave 8 at the surface to a large degree reflects propagating action potentials in the geniculocortical radiations. The activity reflected in the earlier MUA burst and additional positivity in the depth recordings involves only a small part of the radiations and cortical projection areas, and is not seen as an individual wave at the scalp.

81 TERMINAL PORTIONS OF AFFERENT FIBERS TO INNER HAIR CELLS IN THE CAT AS STUDIED IN SERIAL ULTRATHIN SECTIONS. M. Charles Liberman* (SPON: T. F. Weiss). Dept. Anat., Harvard Med. School, Boston, MA 02115.

Recent electrophysiological data from single auditory-nerve fibers suggest that three unit types can be differentiated on the basis of thresholds for tones and rates of spontaneous discharges (Liberman, J. acoust. Soc. Amer. 63: 442, 1979). Anatomical data show that at least 95% of the auditory-nerve fibers comprising these physiological samples are radial fibers innervating inner hair cells (Spoendlin, Acta Oto-Laryngol. 67: 239, 1969). The purpose of the present study was to search for morphological differences among the fibers innervating inner hair cells which might be related to the observed unit types in the auditory nerve.

Cochlear tissue was taken from a young animal born and raised in a low-noise environment. Single units recorded from this animal were exceptionally sensitive to acoustic stimuli. Serial sections were cut (in a plane parallel to the endolymphatic surface of the hair cells) from the habenula perforata to the supranuclear region of the hair cells. These sections included the entire unmyelinated portions and terminations of the afferent fibers in a small cochlear region.

The complete afferent innervation of two adjacent inner hair cells (including 56 afferent fibers) was reconstructed. Particular attention was paid to the following morphological features: 1) branching patterns, 2) fiber diameters, 3) sizes and shapes of the synaptic complexes, 4) axoplasmic contents, and 5) number, type and position of synaptic contacts with efferent fibers. All the afferent fibers were unbranched with a single synaptic complex situated less than a micron from the fiber terminus. Several types of synaptic complexes could be differentiated among the fibers contacting each hair cell. Differences in the synaptic morphology could be correlated with neuron size and with the position and number of synaptic interactions between efferent fibers and these afferents. Possible classification schemes will be discussed.

80 DIRECT EVIDENCE FOR AN AUDITORY PLACE MECHANISM IN THE FROG AMPHIBIAN PAPILLA. Edwin R. Lewis and Ellen L. Leverenz*. Biophysics Group, Univ. of California, Berkeley, CA 94720.

A place mechanism whereby low-frequency sensitivity is confined to the anterior region and high-frequency sensitivity is confined to the posterior region has been postulated for a single auditory organ, the amphibian papilla, in the ear of the frog (E.R. Lewis, Scan. Electr. Microsc./1977, Chicago:IITRI, 429-436). This hypothesis was based on comparative physiological results of Capranica and his colleagues (Frog Neurobiol., Berlin: Springer-Verlag, 551-575, 1976) considered in the light of comparative morphological studies carried out in our laboratory on the same species. More recently, on the basis of click response latencies, Yano et al. (J. acoust. Soc. Am. 64: s85, 1978) proposed the converse- high-frequency sensitivity in the anterior region, low-frequency sensitivity in the posterior region.

In order to obtain direct evidence on this matter, intracellular recordings were made from primary afferents of the bullfrog amphibian papilla. These afferents were penetrated in the posterior branch of the VIIIth cranial nerve medial to its emergence from the intact otic capsule with intact circulation. After characterization of the frequency response properties of each unit, we attempted to fill the axon by iontophoretic injection of Lucifer Yellow (W.W. Stewart, Cell 14: 741-759, 1978) and trace it to its origins on the papillar sensory surface. Those units that have been filled so far corroborate our version of the place mechanism hypothesis. Low-frequency units originate in the anterior region of the papilla; high-frequency units originate in the posterior region. It is expected that this line of research soon will yield a complete tonotopic map of the amphibian papilla.

In addition to tonotopic organization in the amphibian papilla, this method has confirmed the observations by Capranica and others that some high-frequency units originate at the basilar papilla. Furthermore, the method reveals innervation patterns at the sensory surface. Afferent axons from the basilar papilla and those from the high-frequency region of the amphibian papilla exhibit very confined patterns of innervation, contacting at most four or five neighboring hair cells. Afferent axons from the low-frequency region of the amphibian papilla have been found with branches innervating separate groups of hair cells quite remote from one another. It is expected that this line of research soon will yield a more complete picture of afferent branching patterns and their possible relationship to function.

Research sponsored by the National Institutes of Health, Grant No. 1R01 NS12359 from NINCDS. The authors gratefully acknowledge the kindness of Dr. W.W. Stewart, who provided the Lucifer Yellow used in this research.

82 PHYSIOLOGICAL ANALYSIS OF EIGHTH NERVE INPUT TO CAT DORSAL COCHLEAR NUCLEUS. Paul B. Manis* and William E. Brownell (SPON: D. C. Teas). Depts. of Neuroscience and Surgery (ENT) University of Florida College of Medicine, Gainesville, Florida 32610.

The dorsal cochlear nucleus (DCN) is divisible into a molecular layer (ML), fusiform cell layer, and deep or polymorphic layer (DL). The primary efferent cells of the DCN, the fusiform cells, have their apical dendrites in ML, and their basal dendrites in the superficial region of DL. The lamination of the DCN has permitted us to electrophysiologically assess the distribution of eighth nerve terminals on fusiform cells. Field potentials in response to eighth nerve shock were collected from unanesthetized, decerebrate cats at successive 50 micrometer depth increments. The current source density (CSD) at each point along the electrode track was then calculated from the field potentials.

Field potential depth profiles are relatively independent of the electrode placement over the DCN. This suggests that there is no significant net lateral current flow resulting from eighth nerve stimulation, a condition necessary to perform a one-dimensional CSD analysis. CSD calculations reveal a current sink in the region of the fusiform cell basal dendrites and a current source of approximately equal magnitude in the ML. We believe that this source-sink distribution reflects primarily the dendritic currents of fusiform cells.

Excitability cycle studies of the field potential in upper DL revealed no significant effects of conditioning stimuli on the test response at intervals between 10 and 200 msec, suggesting that a monosynaptic or very secure disynaptic pathway is responsible for the evoked potential. One possible disynaptic pathway originates in the anterior ventral cochlear nucleus (AVCN). In one cat, the DCN source-sink distribution and time course in response to eighth nerve shock were not modified by transection of the dorsal intranuclear association fibers from the AVCN.

Anatomical studies have shown that the eighth nerve terminates on the basal dendrites of fusiform cells. If we assume that the eighth nerve is excitatory, then the current sink in the region of the fusiform cell basal dendrites reflects activation of eighth nerve terminals. The current source in the ML would then correspond to the expected passive current flow through the apical dendrites of the fusiform cells. The observed distribution of current sources and sinks is in full accord with the known anatomical distribution of eighth nerve synapses on fusiform cells.

83 BINAURAL SUMMATION OF LOUDNESS: WIDE-BAND AND NARROW-BAND NOISE. Lawrence E. Marks. John B. Pierce Fndn. Lab. and Yale Univ., New Haven, CT 06519.

Previous work (L. E. Marks, J. Acoust. Soc. Am. 64: 107, 1978) showed that the two ears exhibit linear binaural summation of the loudness of pure tones: Total loudness equaled the sum of the loudnesses of the left-ear and right-ear components. The present series of six experiments used the method of magnitude estimation to measure binaural summation of stimuli with various spectra, presented at equal and unequal intensity to the two ears. Narrow bands of noise (one-quarter octave at 1000 Hz) behaved like pure tones, giving linear summation of loudness in sones. (Loudness in sones is proportional to the 0.6 power of sound pressure.) Wide bands (300-4800 Hz) of white noise (flat spectrum) and pink noise (spectrum declining 3 dB/octave) showed less than complete summation of loudness in sones. Two-tone complexes with narrow spacing (860 and 1160 Hz) and wide spacing (300 and 4800 Hz) gave complete summation, like single tones and narrow-band noise, whereas a complex with intermediate spacing (675 and 1475 Hz) gave incomplete summation, more like the summation found in wide-band noise. The results imply an interaction between the process of loudness summation by the two ears and the process of loudness summation across sound frequency.

84 MAPPING OF PRIMARY AUDITORY PROJECTIONS FOLLOWING INTRACOCHLEAR INJECTIONS OF HRP. Glen K. Martin*, Brenda L. Lonsbury-Martin, Ben M. Clopton*, and Renee P. Wise*. Depts. Otolaryngol. and Physiol. & Biophys., Sch. Med., U. of Washington, Seattle, WA 98195.

The axonal projections of spiral ganglion neurons which provide the primary afferent innervation to the ipsilateral cochlear nucleus were investigated by the technique of orthograde axonal transport of HRP to obtain information about its organization for experimental studies. Young adult guinea pigs received intracochlear injections of 50% chromatographically-purified HRP (Worthington) dissolved in 5 ul of physiological saline. Following post-injection times of 24 hrs, the animals were perfused with a 2% glutaraldehyde in phosphate-buffered fixative and the brainstems post-fixed for one day in a 2% glutaraldehyde in 15% sucrose solution and for an additional day in a 30% sucrose solution. After fixation, the brain was prepared for frozen sectioning and cut at 40 um. The unmounted tissues were then reacted with tetramethylbenzidine (TMB, Sigma) following a procedure similar to that described by Mesulam (J. Histochem. Cytochem., 26:106, 1978). Sections were subsequently mounted and stained with neutral red.

Recent studies using intracochlear HRP injections and subsequent histochemical processing with diaminobenzidine (Ross et al. Acta Otolaryngol., 84:187, 1977) have suggested that HRP is not actively transported to brainstem auditory nuclei, but rather results from diffusion processes. In contrast, our results using the TMB-reaction procedure appear to indicate that anterograde transport from the cochlea to cochlear nucleus can be demonstrated. Specifically, the morphologically-distinct regions of anteroventral and posteroventral cochlear nuclei were heavily labelled with reaction product, while only the deep layers of the dorsocochlear nucleus showed dense accumulations of reaction material. These results indicate a specificity similar to that demonstrated by tritiated amino acids known to be actively transported from the cochlea to the cochlear nucleus. Additional evidence in support of these conclusions will be presented based upon injections of HRP following ototoxic insults to the cochlea.

85 THE EFFECTS OF APOMORPHINE ON ACOUSTIC STARTLE IN MICE. Michael D. McGinn* and Kenneth R. Henry. (SPON: L. F. Chapman). Dept. of Psych. University of California, Davis, CA 95616.

Dopamine agonists induce stereotyped motor responses and hypothermia in rodents. However, these agents may not have the same effects in different rodent species in terms of auditory responses; acoustic startle in rats is enhanced by apomorphine (APO), yet it protects mice from audiogenic seizures (AGS). Latencies of auditory brainstem evoked responses (BSER's) are increased by hypothermia, which offers a possible explanation for seizure protection. We looked for direct effects of APO on auditory afferents by obtaining BSER's while body temperature was maintained. C57BL/6 mice were anesthetized with pentobarbital and core temperature was maintained at 37.5 - 37.8°C. BSER's were recorded before and 15 min. after an injection of 3.0 mg/kg APO. [Dose and post-injection time are those which affect acoustic startle and AGS.] Latencies and amplitudes were virtually the same before and after the injection. In order to assess the relative motor and hypothermic contributions to the APO effect, we tested acoustic startle in C57BL/6 mice with and without body temperature maintained and compared these groups with saline injected controls. Startle was evaluated by averaging latencies and amplitudes of responses to a 112 dB click stimulus. Due to rapid habituation of startle to repeated stimuli, we used only 5 stimulus presentations before and another 5 after injection. When compared to saline injected controls, APO mice which were hypothermic had startle response latencies increased by 5.4 msec ($p < .01$) and response amplitudes reduced by 84% ($p < .01$). The APO injected mice whose temperature was maintained had latencies increased by 1.9 msec ($p < .01$) with a 49% amplitude reduction ($p < .01$). The two APO groups also differed from each other, with the hypothermic subjects having longer latencies ($p < .01$) and smaller amplitudes ($p < .01$). These data are in contrast to those obtained in the rat. However, the APO induced depression of acoustic startle in mice does correlate with the protection from AGS's that APO affords.

Supported by PHS grant AG01018-01.

86 RABBIT AUDITORY CORTEX: ELECTROPHYSIOLOGICAL EVIDENCE FOR TONOTOPIC ORGANIZATION. N.T. McMullen and E.M. Glaser, Dept. of Physiology, Univ. of Maryland School of Med., Baltimore, MD. 21201

The lissencephalic cortex of the rabbit provides opportunities for the correlative study of its functional and architectonic features, opportunities that are not available when studying gyrate brains. Using multiunit and evoked potential activity, we have studied the auditory cortex of urethane anesthetized Dutch Belted and New Zealand rabbits. Glass-coated tungsten microelectrodes were advanced tangentially through the auditory cortex in a direction perpendicular to the horizontal plane. With this technique, several parallel tracks can explore a large portion of the auditory cortex. The electrode tracks were placed so as to pass as much as possible through lamina III and IV. As much as an 8 mm extent of temporal cortex has been found to be responsive to auditory stimulation along a single track. Both amplitude discriminated multiunit activity and averaged evoked potentials (AEPs) were recorded in response to tone bursts, white noise and clicks monaurally delivered to the contralateral ear. Sound pressure levels were monitored. Electrolytic lesions were placed at selected sites and the electrode tracks were histologically verified from Nissl stained sections. Some of the brains have been processed by the Golgi-Cox method to permit subsequent analysis of the spatial orientation of the dendrite systems (Glaser et. al, Exp. Brain Res., 1979, in press). The AEPs have been found to be useful "signposts" of the electrode's location. The AEPs were often observed well before responsive unit activity was encountered. In the regions where the AEP was observed earliest, it exhibited an initially positive component. The electrode's initial invasion of the region yielding acoustically-responsive unit activity was accompanied by AEPs that were multiphasic and initially positive. At the electrode sites within this active zone, large amplitude negative AEPs predominated. Once within the active zone, the electrode was advanced in 250 µm steps and the best frequencies of neuron clusters were determined at lowest thresholds. Neurons within the active zone were found to be responsive to tones ranging from 0.4 to 35 KHz. Although some neurons were found which had no apparent best frequency, our results indicate that higher frequencies (15-35 KHz) are represented dorsally and lower frequencies (0.4-10 KHz) ventrally in the temporal cortex. These findings provide evidence for the tonotopic organization of rabbit auditory cortex, and are in agreement with the organization of the auditory fields observed by others in squirrel and guinea pig. The orientation of the isofrequency contours and the possible existence of several auditory fields are presently under investigation. Supported by NSF Grant BNS 78-05502.

87 OTOTOXIC ACTIONS OF AMINOGLYCOSIDES IN COCHLEAR PERFUSIONS CORRELATE WITH IN VITRO EFFECTS ON POLYPHOSPHOINOSITIDES. Iris N. Mechigian*, Shahid Lodhi*, Norman D. Weiner*, and Jochen Schacht. Kresge Hearing Research Institute and College of Pharmacy, Univ. of Michigan, Ann Arbor, MI 48109.

The cochlea of the guinea pig is a suitable organ for the biochemical investigation of hearing because it is readily accessible under preservation of its function. The perilymph-filled spaces surrounding the inner ear tissues lend themselves to the perfusion with solutions containing radiotracers for the labeling of tissue metabolites or with drugs which affect hearing. These fluids are perfused through capillaries implanted into the scalae vestibuli and tympani. During these perfusions, sound can be introduced by an earphone seated in the external meatus, and the cochlear microphonic potential (CM) is obtained via an electrode in the inlet capillary. In addition to monitoring the integrity of the inner ear, these simultaneous CM measurements allow correlations of biochemical reactions with the physiological state of the cochlea which can be manipulated, e.g. by exposure to ototoxic drugs.

Aminoglycoside antibiotics have specific toxicity against the inner ear and the kidney. The ototoxicity of seven aminoglycoside antibiotics and fragments was measured quantitatively by cochlear perfusion: artificial perilymph was perfused for one half hour allowing a stable CM to be achieved, followed by 10 mM drug in artificial perilymph for one hour. Continuous measurements of CM were made throughout the perfusions. Kanamycin B and neomycin caused the most rapid decline of CM followed by gentamicin C_{1a}, ribostamicin and kanamycin A. Neamine and methylneobiosamine did not show significant ototoxicity.

We have previously shown that aminoglycoside antibiotics inhibit the turnover of polyphosphoinositides in the inner ear and the kidney in vivo as well as in vitro. Furthermore, these drugs were shown to interact directly and specifically with polyphosphoinositides in monomolecular films of these lipids, implicating polyphosphoinositides as possible receptors for the ototoxic drugs. To test further this hypothesis, we measured the interactions of the above seven antibiotics with monomolecular films of polyphosphoinositides. Neomycin and kanamycin B induced the largest increases in surface pressure, followed by the other drugs in the same order as seen for ototoxicity. The correlation between the in vivo and in vitro action of the drugs was r=0.91. These results support the hypothesis that binding to polyphosphoinositides is an important part in the mechanism of aminoglycoside ototoxicity. Furthermore, an in vitro assay system seems possible for the assessment of this drug toxicity.

88 COMPARATIVE STUDIES OF SHORT-TERM AUDITORY ADAPTATION AND UNIT RESPONSE PATTERNS IN THE EIGHTH NERVE OF ANURANS. Andrea L. Megela and Robert R. Capranica, Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853.

Previous studies have indicated that the two peripheral auditory organs of anurans, the amphibian and basilar papillae, differ in their frequency sensitivities and in mechanisms of frequency analysis. The amphibian papilla likely operates by a place mechanism and is sensitive to low (100 to 500 Hz) and mid (500 to 1200 Hz) frequencies. The basilar papilla appears to be a simply tuned resonant organ which is maximally sensitive to higher frequencies. The mid- and high-frequency ranges are species-specific while the low-frequency range is similar in all species. We now report that fibers from the amphibian and basilar papillae differ in their sensitivities to the effects of short-term auditory adaptation and in their firing patterns as determined from PST histograms.

Over 200 single fibers from the eighth nerve of the leopard frog, Rana pipiens, and the green treefrog, Hyla cinerea, were studied. In both species, the number of spikes to short probe tones was decreased by prior exposure to longer adapting tones (with both tones at a fiber's best excitatory frequency). The magnitude of response reduction and the time course of recovery varied with the interval between the adapting and probe tones. Basilar papilla units exhibited less response reduction at all interstimulus intervals than did amphibian papilla units. Within the amphibian papilla, low-frequency-sensitive fibers showed less response reduction than mid-frequency-sensitive fibers.

Firing patterns of units from the amphibian papilla formed a continuum from very flat or "tonic" to very peaked or "phasic" onset-type responses. Units from the basilar papilla tended to show more homogeneous firing patterns. The effects of short-term adaptation were more pronounced in units with more peaked PST histograms. Shapes of the histograms were related to each fiber's best excitatory frequency and to spontaneous activity, but not to threshold or to sharpness of tuning.

Different adaptation rates and unit response patterns were found in R. pipiens and H. cinerea that were consistent with the differences in vocal signals produced by these two species. These results suggest that adaptation may be important in the communicative behavior of these animals.

89 A COMPARISON OF THE SUMMATING POTENTIALS TO RESISTANCE CHANGES MEASURED IN SCALA MEDIA OF THE GUINEA PIG COCHLEA. D. C. Mountain* and C. D. Geisler (SPON: L. Roth). Dept. of Neurophysiology, Univ. of Wisconsin, Madison, WI 53706.

The summating potential (SP) and the input resistance of scala media were measured simultaneously during the presentation of tone bursts. A resistance decrease was observed during the tone burst in response to a wide range of frequencies and intensities. The most effective acoustic frequency was the same for both the negative SP and the resistance change. Little or no resistance change was observed for stimuli that elecited a positive SP. The frequency tuning of the resistance change was broader than that of the negative SP but narrower than that of the cochlear microphonic (CM). The data indicate that the positive and negative summating potentials originate from different sources, one of which has a resistance change associated with it (the negative SP). This same pattern of two sources has been observed in the harmonic distortion of the CM (Mountain, Geisler, and Hubbard, J. Acoust. Soc. Am., 63:s43, 1978 and Hubbard, Mountain, and Geisler, J. Acoust. Soc. Am., in press). The negative SP may be due to an assymetrical response at or before the transduction stage and the positive SP may be due to a voltage dependent channel in the hair cell membrane which rectifies the cochlear microphonic. (work supported by NIH)

90 COCHLEAR NUCLEUS PROJECTIONS TO THE INFERIOR COLLICULUS OF THE CAT STUDIED WITH LIGHT AND ELECTRON MICROSCOPIC AUTORADIOGRAPHY. Douglas L. Oliver and D. Kent Morest, Department of Anatomy, Univ. Conn. Health Center, Farmington, CT 06032.

In this study we have begun to identify the axons of cochlear nucleus neurons which terminate in the inferior colliculus. Despite the fact that many of these neurons have been recognized with retrograde tracing techniques, many details of their axonal terminations remain unresolved.

Using highly concentrated tritiated leucine and/or proline solutions (50-200 μCi/μl), we made injections in the dorsal cochlear nucleus. After a survival time of 2-3 days, the experimental animals were perfused for electron microscopy. The midbrains were then tissue-chopped or Vibratome-sectioned and alternate sections were prepared for electron microscopy. The remaining sections were prepared for light autoradiography. In selected cases, EM autoradiographs were prepared according to the method of Kopriwa ('73). Most injections included the entire dorsal cochlear nucleus as well as parts of the underlying posteroventral cochlear nucleus and sometimes the small cell cap. In the light microscope, intensely labeled axons were found to ascend to the contralateral inferior colliculus primarily via the dorsal acoustic stria, medial to the lateral lemniscus. Within the inferior colliculus they terminate chiefly in the pars medialis and pars centralis of the central nucleus. Significant numbers of labeled axons were also located in the ventrolateral nucleus and in layer IV of the dorsal cortex, in continuity with the labeled axons of the central nucleus. Little or no labeling of axons was found in pars lateralis. The lateral portion of pars centralis also had little label, particularly in the rostral half of the colliculus. In these autoradiographs bands of labeled axons, which parallel the dendritic laminae of the central nucleus, were often seen. These bands are wider than the dendritic laminae and are separated by less intensely labeled regions of similar width. In the ipsilateral colliculus only very sparse label was found in the homotopic regions.

Our initial results of the electron microscopic autoradiography came from pars medialis of the central nucleus. After 8-12 weeks exposure, the majority of grains appeared to lie over myelinated axons or terminals. Most profiles of the labeled terminals were 1.5-3 μm in average diameter and contained medium-sized, round synaptic vesicles. These terminals formed asymmetric synaptic contacts usually on small-to-medium-sized dendrites. Similar terminals, forming axosomatic contacts and terminals with pleomorphic or flat vesicles, did not tend to be labeled.

91 THE STRUCTURE AND CORTICAL PROJECTIONS OF THE MEDIAL GENICULATE BODY OF THE RAT. Hugh A. Patterson* and W. Bruce Warr. Department of Anatomy, School of Medicine, UCSF, San Francisco, CA., and Human Communication Laboratories, Boys Town Institute for Communication Disorders in Children, Omaha, NE.

The structure of the rat medial geniculate body (MGB) was studied in photographic reconstructions from normal material stained with Nissl, myelin and reduced silver methods. Largely consistent with previous work in various species, the rat MGB is best described as consisting of two longitudinally adjacent principal cell groups, a medial (magnocellular) and a larger laterally adjacent ventral division, the latter of which is enveloped by a shell-like surface cap of lesser cell groups. These groups include a large dorsal division, a caudal division, a laterally placed marginal zone and a ventrolateral nucleus. In addition, a small-celled group occupying a niche between the ventral, medial and dorsal divisions, here termed the supragenículate nucleus, was recognized.

The cortical projections of these nuclei were studied by both the HRP and Fink-Heimer methods. All parts of the MGB have cortical projections and these projections complement the structural parcellation just described. The ventral division projects topographically to a core area of koniocortex, area 41 of Krieg. Terminal degeneration was localized primarily in layers IV and III. The medial division projects diffusely to both area 41 and to extensive areas dorsally and anteriorly contiguous to it. This projection appeared to involve all layers of cortex, but with heaviest concentrations in layer VI. The shell-like cap of nuclei, which partially surrounds the ventral division, projects topographically to a C-shaped belt of cortex centered caudoventral to Area 41, comprized by areas 36 and 20. This projection terminates primarily in layers IV and III. The projections of the supragenículate nucleus to belt cortex were demonstrable by the HRP technique, but its laminar distribution remains to be determined.

Taken together, these findings support the notion that at least three distinct projection systems originate from comparably distinct structural regions of the rat MGB, and that the possibility of convergent interaction of two of these in area 41 must be considered.

92 RESPONSE PLASTICITY OF AUDITORY CORTEX NEURONS DURING TONE - SIGNALLED CONDITIONING. N. Kraus Perkins and J.F. Disterhoft. Dept. Anat., Med. Sch., Northwestern Univ., Chicago, Ill. 60611

The activity of single neurons in auditory cortex of rabbit was monitored continuously throughout the acquisition of a classically conditioned, nictitating-membrane response to an auditory stimulus at the characteristic frequency of each unit. Stimulation and recording techniques were previously described (Perkins and Disterhoft,'79). Stimulus-evoked and spontaneous activity recorded during initial conditioning trials, in which the animal was behaviorally naive, was compared with that occurring during the later trials in which the conditioned response was established. Pseudoconditioning - random, non-paired presentations of the CS and UCS - was used as a control for general arousal, sensory habituation and random fluctuation of unit activity over time. In addition, the cell's response to selected, repetitive acoustic stimuli was assessed before and after behavioral manipulations.

Alterations in unit response to both the CS and UCS were prevalent in conditioned animals. Response plasticity was most frequently expressed as an increase in unit activity, although decreases also occurred. Subcomponents of a response pattern could change independently of each other. New responses, absent prior to conditioning, emerged after training. Shifts in spontaneous rate did not necessarily occur in the same direction as changes in stimulus-evoked activity. In pseudoconditioned animals, response patterns remained predominantly unchanged, or became attenuated over time. Some of the changes described above also occurred, but to a lesser extent, in this group.

Both conditioned and control animals showed response alterations to auditory stimuli presented prior to and following the behavioral trial series. This is consistent with previous reports of labile response properties of auditory cortex neurons to repetitive sound stimuli (Miller et al., '72). However, some features of these changes could be attributed specifically to auditory conditioning.

This study supports previous work in which multiple unit activity was shown to vary systematically with the acquisition of a behavioral response to an auditory stimulus (Buchwald et al., '66, Oleson et al., '75, Disterhoft and Stuart,'76). The fact that changes did not occur in all of the units studied, suggests that these changes are specific to a sub-population of neurons in auditory cortex. The variety of response changes observed reflects the heterogeneous response properties characteristic of single neurons in auditory cortex.

93 COCHLEAR MICROPHONIC POTENTIALS FROM INNER AND OUTER HAIR CELLS? Martha G. Pierson* and Aage Møller* (SPON: Maryanna Henkart). Neurobiology Department, Armed Forces Radiobiology Research Institute, Bethesda MD 20014; Dept. of Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213

Generally it is not considered feasible to distinguish the cochlear microphonic (CM) originating from outer hair cells from that originating from inner hair cells in extracellular recordings. The large number of contributing hair cells, their stimulated phase distribution, and the finding that there is a 40-dB difference in their sensitivities has promoted this notion. In the present study it is reported that within a narrow window defined by intensity and frequency, two types of CM can be discerned simultaneously. Specifically, within a quarter octave band, 1/5 to 1/2 octave above the best frequency of a differential electrode pair, the CM intensity function displays a feature suggestive of a dual origin: it has two maxima separated by a cancellation notch at about 70 dB SPL.

The stimuli used in the present study consisted of 120-msec pure-tone pulses with linear rates of rise and fall, obtained by using analogue multipliers and trapezoidal control signals. The rise-fall times were generally 40 msec, the on time was less than 120 msec, and the period was 1 sec. The CM was band passed with a 1/3 octave-band filter tuned according to the stimulating frequency. The amplitude measurements were obtained by the full wave rectification of the CM, followed by a low pass filtering (470 Hz) and subsequent averaging. In experiments testing the influence of basilar membrane position, CM responses were processed as above except that the stimuli consisted of continuous pure tones. Basilar membrane position was modulated sinusoidally by presenting a 100-Hz signal together with the continuous high-frequency probe signal. Cycle histograms of the relative amplitude of the CM were then generated when the averager was triggered by the 100-Hz signal.

On the basis of these experiments it is proposed that the CM originating in outer hair cells has a lower threshold, a smaller dynamic range, is more subject to acoustic fatigue, and is more labile due to metabolic impairment (hypoxia). The magnitude of this type of CM is enhanced by a movement of the basilar membrane toward the scala tympani. On the other hand, the CM presumed to arise from inner hair cells is insensitive, has a vast linear operating range, and is almost unassailable by intense acoustic exposure or by hypoxia. This latter type of CM is enhanced by movement of the basilar membrane toward the scala vestibuli.

94 DISPROPORTIONATE FREQUENCY REPRESENTATION IN THE INFERIOR COLLICULUS OF HORSESHOE BATS:EVIDENCE FOR AN ACOUSTIC FOVEA. George Pollak and Gerd Schuller*. Dept. Zoology, Frankfurt Univ., FRG.

The horseshoe bat, Rhinolophus ferrumequinum, identifies and tracks its prey by emitting loud orientation cries and listening to the returning echoes. Each echolocation sound is composed of a constant frequency (CF) component of about 83 kHz lasting for 10-100 msec followed by a brief terminal frequency modulated part. While hunting, the CF component of the echo will have a higher frequency than the emitted CF due to a Doppler-shifting of the echo caused by the bat's approach towards its target. In response to the increase in echo frequency horseshoe bats lower the emitted CF by an amount almost equal to the Doppler-shift in the echo. As a result of the Doppler-compensation, subsequent echoes are stabilized and actively held at a frequency called the reference frequency. The reference frequencies of the bats studied by us were between 83.6-84.1 kHz.

By recording the best frequencies (BF) of several hundred neurons it was found that the inferior colliculus is functionally divided into two regions: one dorsal and one ventral. In the dorsal region, extending to a depth of about 800 microns, the BFs increase systematically with depth from 9 kHz to about 77 kHz. In marked contrast, the BFs in the ventral regionare nearly constant along a particular dorsoventral axis with neurons having similar BFs being arranged in cortical-like columns. The range of BFs in the ventral region extends from about 78-88 kHz along the anterioposterior axis with columns tuned to 78 kHz located most anteriorly and columns tuned to 88 kHz being situated most posteriorly. Thus, the neurons in the ventral region are tuned to the full range of frequencies that the emitted and echo CF components can assume during echolocation.

There also exists a pronounced disproportionate representation of frequencies within the ventral region where 33% of the neuronal population have BFs between 83-84.5 kHz. This small frequency band corresponds closely to the frequencies at which these bats stabilize the echo CF components during echolocation. This suggests that the over-represented frequency region of the brain is analogous to the foveal regions in the visual system.

The auditory system of horseshoe bats appears to be similar to the visual system is several respects. Instead of eye movements, these bats manipulate their voices (compensate for Doppler-shifts) in order to stabilize echoes within a frequency region to which a disproportionately large number of neurons are tuned and in this way enhance the resolving power for fine target features.

95 INNER EAR AUDITORY RECEPTORS IN OSTEOGLOSSOMORPH FISHES. Arthur N. Popper, Department of Anatomy, Georgetown University, Sch. Med.& Dent., Washington, D.C. 20007

Scanning electron micrographic studies of the ears in four species of osteoglossomorph (Division II) fishes show considerable diversity in a number of features which may be associated with differences in auditory mechanisms or capabilities. Variation is particularly great in the hair cell orientation patterns on the sensory maculae. Species studied were the butterfly fish (Pantodon bucholzi), a mormyrid (Gnathonemus sp.), an African knifefish (Notopterus chitala), and the arawana (Osteoglossum bicirrosum).

Typically, the caudal part of the saccular macula in nonostariophysan teleosts has a group of dorsally oriented hair cells (kinocilium on the dorsal side of the cell) above a group of ventrally oriented cells. The rostral macula region has posteriorly oriented cells above a group of anteriorly oriented cells. Variants on this basic pattern are found in each osteoglossid except Osteoglossum. Pantodon has alternating anteriorly and posteriorly oriented cells on the rostral macula region. Gnathonemus is unique in having only vertically oriented cells on the saccular macula. This pattern has heretofore only been known for the saccular maculae in Ostariophysi and terrestrial vertebrates. The saccular pattern in Notopterus also differs from that seen in previous studies of fishes. The saccular macula is essentially tripartate, and thin 'bridges' connect each of the three regions. The most anterior macular region contains a group of anteriorly oriented cells at the rostral tip, followed by a continuation of the anteriorly oriented cells ventral to a posteriorly oriented cell group. The middle part of the macula contains a group of ventrally oriented cells rostral to a group of dorsally oriented cells while the third part contains dorsally oriented cells above ventrally oriented cells.

The lagenar macula in Osteoglossum, Pantodon, and Notopterus is typical of most nonostariophysans in having a dorsally oriented group of hair cells located anterior to a group of ventrally oriented cells. However, the macula in Gnathonemus more nearly resembles the pattern in Ostariophysi and has hair cells oriented in a wide range of directions.

The functional and taxonomic significance of these observations are not yet clear, particularly with regard to the mormyrids. It is possible that the diversity in saccular ultrastructure is indicative of there being striking differences in the way that each of these species detects or processes acoustic information. (Supported by NSF and by an RCDA from NINCDS).

96 RATE-INTENSITY FUNCTIONS OF SINGLE NEURONS LOCATED WITHIN BINAURAL SUPPRESSION COLUMNS OF CAT PRIMARY AUDITORY CORTEX. Richard A. Reale, Thomas J. Imig and Donal G. Sinex*. Dept. of Neurophys., Waisman Cntr. on Mental Retard. and Human Dev., Univ. of Wisconsin Medical School, Madison, WI 53706.

In addition to the tonotopic organization, the primary auditory field (AI) of the cat also contains a binaural representation in which neurons with similar binaural properties form functional columns within the high-frequency representation of the field (Imig, T.J. and Adrian, H.O., Brain Res. 138:241-257, 1977). We have mapped the best frequencies and binaural sensitivities of neuron clusters within AI to define binaural columns. The response of single neurons to tone-burst stimuli were then quantified during microelectrode penetrations directed into mapped suppression columns. Neuron clusters displaying suppression are excited by stimulation to the contralateral ear and inhibited by simultaneous stimulation to the ipsilateral ear. Monaural and binaural rate-intensity functions were determined for each isolated neuron at its best frequency. Neurons were driven by contralateral monaural stimulation, whereas stimulation of the ipsilateral ear alone was ineffective in eliciting discharges regardless of stimulus intensity. Binaural rate functions were obtained by holding the intensity to the contralateral ear constant while varying the intensity to the ipsilateral ear. With few exceptions, the average discharge rate produced by a contralateral stimulus at any chosen intensity could be significantly reduced when paired with a higher intensity tone delivered to the ipsilateral ear. In some experiments, several suppression columns were examined within a selected isofrequency strip. The majority neurons isolated within suppression columns located on the most ventral portion of an isofrequency strip exhibited non-monotonic rate-intensity functions for monaural stimulation. Plots of discharge rate versus stimulus intensity produce a Λ-shaped curve in which near zero discharge rates occur at both the low and high ends of the effective intensity range. The maximum rates elicited from these neurons were usually obtained within 30 dB of threshold. By comparison, high contralateral intensity rarely reduced the monaural discharge rates of neurons located within suppression columns nearest the dorsal end of an isofrequency strip by more than 50% relative to their maximum rates. Additionally, the discharge rates of several neurons increased monotonically over a 30-to-80 dB range. Taken together these data suggest that many neurons in a binaural column exhibit similar rate-intensity functions and that spatially separate groups of neurons with similar best frequencies and binaural properties possess dissimilar intensity sensitivities to monaural stimulation. (NS-05459, NSF76-19893, HD-03352)

97 SINGLE UNIT ANALYSIS OF THE POSTEROVENTIAL COCHLEAR NUCLEUS OF THE DECEREBRATE CAT. Louis A. Ritz and William E. Brownell. Depts. of Neuroscience and Surgery (ENT), Univ. of Florida, Gainesville, Florida, 32610.

Recent studies have shown that several lower auditory system structures are effected by barbiturate anesthetics. Use of the unanesthetized, decerebrate preparation has revealed differences in spontaneous rates, in inhibitory response areas and in firing patterns, as compared to the anesthetized, intact animal.

We have studied the posteroventral cochlear nucleus (PVCN), within the cochlear nucleus complex, of the anesthetic-free cat. The PVCN consists of two major regions; an anterior multipolar cell area (MCA) and a posterior octopus cell area (OCA). Multipolar cells are believed to receive most of their eighth nerve input on the dendrites. A chopper response is most frequently recorded in this region of the anesthetized cat. The OCA is made up almost entirely of octopus cells, which receive massive eighth nerve input onto their somas and proximal dendrites. It has been reported that octopus cells receive two different types of synapses from the same eighth nerve fiber. Single unit recordings in the OCA of anesthetized cats have displayed onset responses to tone bursts, and little or no spontaneous activity.

Within the MCA of decerebrate cats, the most frequently recorded response is the chopper pattern, with less than 5 msec. between peaks. This response seems to be independent of the units spontaneous rate and interspike interval distribution. Chopping intervals greater than 5 msec. have not been observed.

Within the OCA of the unanesthetized cat, the spontaneous rates range from 0 to 135, with a mean of 34 spikes/sec. Approximately 80% of the responses recorded from the OCA are of an onset type. One response consists of an onset, followed by a profound inhibition for the remainder of the tone burst. A second response type consists of an onset, followed by a low level of excitation for the remainder of the tone burst. These onset units have tuning curves that are generally broader than those from eighth nerve fibers. These data will be compared to other findings from the auditory system of decerebrate cats.
(Supported by USPHS Grants NS12209 and MH10320.)

98 CHANGES IN AUDITORY THRESHOLD SENSITIVITY AND FREQUENCY SELECTIVITY AFTER NOISE EXPOSURE IN NEONATAL C57BL/6J MICE. James C. Saunders and Linda L. Restifo*. Dept. Otorhinolaryngol. and Human Communication, and Human Genetics, University of Pennsylvania, Philadelphia, Pa. 19104.

Eighteen day old mice were exposed to noise for 90-seconds at 110 dB SPL (bandwidth, 8.7-13.3 kHz). At 23 days a bipolar concentric electrode was placed in the cochlear nucleus (CN) of anesthetized mice and two measures of auditory function were sought in animals exposed to the noise and in non-noise exposed control subjects. First, tone-burst evoked response threshold sensitivity was measured at 8 test frequencies between 1.0 and 39.0 kHz. Next , a simultaneous two-tone masking procedure was introduced to define evoked-response tuning curves at each of 6 center frequencies. The results showed a loss in threshold sensitivity in the noise exposed animals that was between 12 and 20 dB for test frequencies from 10.0 to 26.0 kHz. At other frequencies no threshold loss was noted. The frequency selectivity (i.e. the sharpness) of tuning curves in the region of maximum threshold loss was the same in both control and noise exposed animals. However, the sensitivity of the tuning curve, in noise exposed mice, showed a reduction that was equal to the threshold loss. These results are similar to data reported by other investigators that show a relation between cochlear trauma and changes in threshold sensitivity and frequency selectivity, and suggest that the effects of noise in the present experiment may be damage confined to the outer hair cells of the organ of Corti. The C57BL/6J mouse strain exhibits a critical period of heightened susceptibility to acoustic trauma at 18 days of age and the present data contribute to our understanding of this phenomena.

99 DIFFERENTIAL DISTRIBUTION OF GLUTAMIC ACID, ASPARTIC ACID AND GLYCINE UPTAKE IN THE COCHLEAR NUCLEUS. Ilsa R. Schwartz. Department of Surgery/Head & Neck, School of Medicine, UCLA, Los Angeles, CA 90024.

Recent biochemical and histochemical studies of the cochlear nuclei (CN) in normal, genetically deaf and surgically deafened guinea pigs have shown a correlation between levels of glutamic and aspartic acid and the presence of normal primary auditory endings (Wenthold & Gulley, Br. Res. 138:111-123, 1977; Wenthold, Br. Res. 143:544-548, 1978). This study sought to demonstrate the presence and localization of high affinity uptake systems for these substances morphologically.

Cats and C57BL/6 mice were perfused with cold saline-nitrite solutions. The brain stems were rapidly removed, sliced transversely at 235μ and the CN dissected out in the cold. Tissue was preincubated at room temperature in oxygenated Ringer's bicarbonate solution (RBS) for 10 minutes, transferred to oxygenated RBS containing approximately 10^{-8}M tritiated amino acids (100μCi/ml) for 20 minutes, rinsed in RBS, fixed with 1% paraformaldehyde and 1.25% glutaraldehyde in 0.12M phosphate buffer, pH 7.2, and processed for autoradiography with standard methods (Schwartz & Bok, J. Neurocytol. 8:53-66, 1979).

Preliminary results indicate that following incubation with aspartic acid, glutamic acid or glycine, intense labelling is present over many small structures in the granule cell and molecular layers. Synaptic terminals appear to be the major structures labeled, and the pattern differs with the amino acid. Most neurons throughout the CN are contacted by a few terminals which label with glycine. With glutamic acid fewer perisomatic and peridendritic terminals and small structures (presumably terminals) are labeled. Concentrations of label are observed in the ventral CN and the intermediate acoustic stria, with less intense labelling in the dorsal CN. Aspartic acid produced intense labelling of terminals in the mouse ventral CN which had a similar distribution to that of primary auditory terminals. Electron microscopic autoradiography is underway to identify the labeled structures.

Supported by USPHS Grants NS 09823 & 14503.

100 QUANTITATIVE [^{3}H] AND [^{14}C]-2-DEOXYGLUCOSE MAPPING OF THE AUDITORY CENTRAL NERVOUS SYSTEM IN XENOPUS LAEVIS. T. J. Sejnowski, D. B. Kelley, J. A. Paton and M. L. Yodlowski. Princeton University, Princeton, N. J., 08544 and The Rockefeller University, New York.

The 2-deoxyglucose (2DG) technique was used to study CNS activity of male South African clawed frogs during acoustic stimulation. Five μCi [^{14}C]-2DG or 50 μCi [^{3}H]-2DG was injected into the dorsal lymph sacs of 20 males; frogs were then presented with 2 hours of taped conspecific vocalizations. Half of the frogs were transcardially perfused with saline followed by 10% formalin. The [^{14}C]-2DG brains were processed as described in Sokoloff et al., J. Neurochem. 28: 897, 1977. The [^{3}H]-2DG brains were sectioned at -22°C on a cryostat in a darkroom. Sections were picked up on slides precoated with NTB-3 emulsion and dried at room temperature. Slides were developed after 4 weeks and some were counterstained with cresyl violet to identify the labelled areas. Optical densities of 125μ spots were measured with a photodensitometer. The measurements were normalized against a standard region of the dorsal optic tectum in each animal.

The following regions were consistently labelled: dorsal auditory medulla (MED), superior olive, anterior and posterior thalamus, caudal torus semicircularis (CTOR) and laminar nucleus of the torus (LTOR). A ^{14}C autoradiogram of a section through the torus and dorsal medulla is shown below. Unilateral removal of the middle ear bones decreased uptake in contralateral LTOR but not in CTOR. The 2DG labelling in the torus was used to quantitatively compare perfused with nonperfused tissue and [^{14}C]- with [^{3}H]-2DG autoradiograms. The table below gives the mean and standard deviation of the maximum optical density for [^{14}C] perfused and nonperfused autoradiograms. Perfusion did not reduce the label densities in LTOR or CTOR. The pattern of labelling using [^{3}H]-2DG was the same as that seen with [^{14}C]-2DG; optical densities were, however, more variable.

These results indicate that the 2DG method can be used to functionally map the auditory system in an anuran amphibian, that autoradiograms can be successfully prepared using perfused tissue and that [^{3}H]-2DG is an alternative but less reliable method for obtaining 2DG autoradiograms.

101 A NEW BIODETECTOR OF AUDITORY NERVE ACTIVATING SUBSTANCE (ANAS). William F. Sewell, and Paul S. Guth. Dept. of Pharmacology, Tulane University School of Medicine, New Orleans, La. 70112.

Auditory nerve activating substance (ANAS) (which may be the primary afferent transmitter of audition) is found in the perilymph of the frog or the guinea pig following appropriate stimulation with sound. ANAS was originally detected by the increase in firing rate of single afferent units serving the amphibian papilla of the bull frog. This means of biodetection although originally useful proved extremely clumsy and therefore a major impediment to the isolation and characterization of ANAS, the ultimate goal of this research. The major drawbacks of the original biodetection preparation were the seasonal variations and the small number of samples assayable per preparation. We therefore attempted to discover and develop new and better means of detecting ANAS. To this end we tried: single units of the toad lateral line afferents, the goldfish saccule-saccular nerve preparation, guinea pig auditory nerve single unit and bull frog saccule-saccular nerve preparation. Only the last mentioned preparation responds regularly to the presence of ANAS. Bull frogs of either sex are double-pithed and the saccule and saccular nerve exposed by drilling through the otic ridge. The perilymphatic sac is opened and a pipette used to deliver substances to be assayed is placed over the saccule. Glass micropipette electrodes are used to record single unit activity in the saccular nerve. This preparation responds not only to small volumes of ANAS but to glutamate (5 μl of 3 mM glutamate) in a reliable manner and allows the assay of many samples per preparation. (This work supported by grants from the U.S.P.H.S., NS 11647 to the Kresge Hearing Research Lab. of the South and from the Veteran's Administration.)

102 DEOXYGLUCOSE DEMONSTRATION OF A NEW AUDITORY PROJECTION FIELD WITHIN THE INFERIOR COLLICULUS. Martin S. Silverman* (SPON: Russell L. Snyder). Dept. Phys., Univ. of Calif., San Francisco, Ca. 94143.

A new auditory projection field with unique functional characteristics has been located within the inferior colliculus using the ^{14}C-2-Deoxyglucose metabolic mapping technique, (Science, 187: 850, '75). This field consists of a band of highly active elements located at the ventromedial extremity of the central nucleus of the inferior colliculus. In barbiturate anesthetized preparations receiving no acoustic stimulation, this projection area (VM) is seen autoradiographically as a dense band of about 200μ in width that rings the ventromedial extent of the central nucleus of the inferior colliculi, bilaterally. In similar preparations that received pure tone stimulation to one ear, this ventromedial projection area is seen in the colliculus contralateral to the stimulated ear, but is substantially diminished in density, or altogether absent in the colliculus ipsilateral to the intact ear. A variety of tones spanning at least 3 octaves located in the center of the rat's auditory range suppressed activity in the VM ipsilateral to the stimulated ear, indicating that ipsilateral suppression of activity in the VM is broadly tuned. To further investigate the effects of unequal auditory activity on the labeling of the VM band, some animals were unilaterally labyrinthectomized with the intact ear left acoustically unstimulated. Again, dense labeling was seen in the VM contralateral to the intact ear with no such labeling seen ipsilaterally. This result indicates that even the unequal binaural activity condition achieved by the elimination of the spontaneous 8th nerve activity on one side can eliminate VM labeling ipsilateral to the intact ear. The above results demonstrate that the VM can be strongly inhibited ipsilaterally by unequal sound-evoked, or spontaneous activity eminating from the 8th nerve. These cases by themselves alternatively do not show that activity within the auditory system is necessary for VM activity, (i.e., the VM could in itself be spontaneously active, and/or receive a facilatory input from extra-auditory sources). That the VM area requires auditory input for its substantial activity was demonstrated in preparations in which the spontaneous activity in the 8th nerves was eliminated by bilateral cochlear destruction. In these cases the labeling in the VM area was bilaterally eliminated, indicating that cochlear activity is necessary for VM activity. In summary, these experiments show the existance of a new and discrete collicular projection field having unique functional characteristics that are different from auditory projection areas so far reported.

103 RESPONSE OF SECOND AND THIRD ORDER AVIAN AUDITORY NEURONS TO DEAFFERENTATION. Anthony N. van den Pol, Michel Kliot*, Richard Kuritzkes*. Sect. Neurosurg., Yale Sch. Med., New Haven, Ct. 06510.

Nucleus magnocellularis (NM) and nucleus laminaris (NL) second and third order avian auditory nuclei, respectively, were examined in 43 six to ten day hatchling chickens at several time intervals after unilateral cochlea removal combined with ganglion cell aspiration, and in controls. NM receives afferent input from the ipsilateral cochlea, and NL dorsally from the ipsilateral NM and ventrally from the contralateral NM. Two days after cochlea removal, degeneration is found with EM and LM in primary afferents and NM somata ipsilaterally. Furthermore, early signs of axonal degeneration are found dorsal to the ipsilateral NL, and ventral to the contralateral NL; both axon swelling and collapse are more evident ($p<.05$) here than in the normally innervated NL. As a recent report (Parks & Rubel, JCN 180, 439, 1978) found no direct projections from cochlea to NL in chicks, and since we find degeneration of axons in NL occurring simultaneous with cell death in NM, the degenerating axons in NL two days after cochlea removal are probably secondary, and from NM. Similar results were obtained with a three day post-surgery survival. Seven days after unilateral cochlea removal, many collapsed osmiophilic axons were found in the ipsilateral NM, dorsal ipsilateral NL, and contralateral ventral NL; only a few swollen axons were seen at this time. Eight hours after cochlea removal we find no qualitative signs of axonal degeneration in NM or NL. In a parallel series of experiments with ^{14}C 2 deoxyglucose (2DG) autoradiography in unanesthetized chicks, relative to the surrounding neuropil, 2DG uptake appeared high in the synaptic region of NL, and also in the non-synaptic region of myelinated fibers and glial cells ventral and dorsal to NL. Unilateral cochlea removal caused a statistically significant ($p<.05$) decrease in 2DG uptake, as measured with microdensitometry, in the ipsilateral NM, ipsilateral dorsal NL, and contralateral ventral NL 5, 24, and 48 hours after surgery. This was true at low and high sound levels (45-92dB). In a third set of experiments, uptake of tritiated amino acid was examined in NM after unilateral cochlea removal in four chicks. Three days after surgery, ^{3}H-lysine uptake 45 minutes after intraperitoneal injection was decreased in NM on the side from which the cochlea was removed by 45% compared to the contralateral side. Since dying cells can be found in the ipsilateral NM after unilateral cochlea removal at this time interval, grains were counted only over normal appearing neurons. The use of converging techniques to analyze structure, synthesis (amino acid incorporation), and energy demand (2DG) in the auditory system may lead to a better understanding of the relationships between morphological and functional response to deafferentation.

104 RESPONSES OF SINGLE COCHLEAR NUCLEUS NEURONS OF HORSESHOE BATS TO SINUSOIDALLY FREQUENCY AND AMPLITUDE MODULATED SIGNALS. Marianne Vater* (SPON: W.J. THOMPSON). Dept. of Biology, Frankfurt Universitat, FRG.

The greater horseshoe bat, Rhinolophus ferrumequinum, emits a long constant frequency component (CF) of about 83 kHz during echolocation. The echoes are Doppler-shifted upward in frequency due to the relative movement between the bat and target. The bat compensates for these deviations in the echo frequency by lowering the frequency of its emitted calls so that the echo frequency remains constant within a narrow frequency band. The wing beats of prey insects result in periodic frequency and amplitude modulations of this carrier frequency which can be used by the bat as clues for detection and probably for the identification of moving prey objects. In order to examine the neuronal encoding characterisitcs of these complex time varying singals within the ascending auditory pathway of horseshoe bats, recordings were made from single cochlear nucleus (CN) neurons. The sample comprises neurons from all subdivisions of the CN-complex. Variable parameters of the sinusoidal frequency and amplitude modulated (SFM and SAM) stimuli were presented. The discharge patterns of most tonic units faithfully reproduced the time course of the periodic modulations. It can therefore be expected that signals with more complex temporal patterns, as for example generated by the wing beats of insects, are also processed with only little distortion and are relayed as input information to higher centers. Phasic neurons did not preserve the stimulus time structure: they reponded with a transient discharge activity to distinct portions of the modulation cycle. Synchronization was present over a wide range of signal intensities and modulation depths, important parameters for evaluations of the target distance and size. The sharply tuned CN "filter" neurons, tuned to 78-88 kHz, are able to encode modulation depths as small as +50 Hz. Neurons of the different subdivisions of the CN differ in the response properties to SFM signals. This becomes clear in the responses to different modulation rates. Primary-like neurons in the anteroventral CN are able to synchronize to rates as high as 900 Hz. The stimulus coding in the time domain therefore far exceeds the frequencies of prey insect wing beat frequencies (i. e., between 30 and 100 Hz). Build up neurons in the dorsal CN were unable to follow the periodic modulations in the frequency range tested (minimum modulation rate of 20 Hz). Phasic neurons in the dorsal CN typically lock only at modulation rates below 300 Hz, a behavior also reported for inferior collicular neurons, but a range largely covering the biologically important range of insect wing beat frequencies.

105 EVIDENCE OF INHIBITORY INTERACTIONS BETWEEN NEURONS IN DORSAL COCHLEAR NUCLEUS. Herbert F. Voigt* and Eric D. Young, Dept. of Biomedical Engineering, Johns Hopkins School of Medicine, Baltimore, MD. 21205.

Neurons in the dorsal cochlear nucleus (DCN) of unanesthetized, decerebrate cats can be classified as Type II/III (excited at all levels by best-frequency (BF) tones) or Type IV (inhibited by moderate and high level BF tones). The properties of Type II/III neurons are all consistent with the hypothesis that they are interneurons which inhibit the activity of Type IV cells. We have obtained further evidence of such a connection by studying the functional relationships between pairs of neurons in the DCN. Recordings from pairs of neurons that were physically close together were obtained by using a single microelectrode. The spike trains of the two neurons were separated on-line using a template matching technique. Each neuron was classified as Type II/III or Type IV and cross correlograms of spontaneous or acoustically-driven activity were computed. Where recording time allowed, complete frequency-intensity response maps were also obtained. For 12 of 17 Type II/III-Type IV pairs, the cross correlograms showed statistically significant decreases in the Type IV's discharge rate following spikes in the Type II/III unit. In these cases, the excitatory region of the Type II/III unit's response map was within the inhibitory region of the Type IV unit's response map. The remaining five pairs showed no signs of inhibitory interaction in their cross correlograms. In four of these cases, there was extensive overlap of the excitatory regions of the cells' response maps. A portion of the inhibitory region of the response map of one Type IV neuron was converted to an excitatory area after injury discharge and disappearence of an accompanying Type II/III unit whose discharge had shown an inhibitory correlation with that of the Type IV unit. The region in which the change occurred was centered on the BF of the Type II/III neuron. Cross correlograms of the spontaneous activity of Type IV-Type IV pairs were featureless in 10 of 20 cases, displayed signs of shared input in 7 cases, and were complex in the remaining 3 cases. There was extensive overlap of the response maps in all Type IV-Type IV pairs. (Supported by NIH grant NS-12524).

106 SPIRAL GANGLION NEURONS FOLLOWING DRUG-INDUCED ORGAN OF CORTI LOSS. Molly Webster* and Douglas B. Webster. Kresge Hear. Res. Lab., Dept. Otorhinolaryngol., L.S.U. Med. Ctr., New Orleans, LA 70119.

The guinea pig organ of Corti was destroyed by a single treatment of the ototoxic combination of kanamycin followed by ethacrynic acid (West et al., Arch. Otolaryngol., 98:32-37, 1973). The resulting loss of spiral ganglion neurons was quantitatively studied in 10-µm serial sections of 23 ears from 15 animals, including 2 normals and 13 with post-treatment survivals from 2 weeks to 15 months. For each ear, mid-modiolar sections were selected for the first half-turn (above the hook), designated as turn 0.5, and for half-turns 1.0, 1.5, 2.0, 2.5, and turn 3-4. For each turn or half-turn, all neurons were counted in the selected section and in the second sections before and after, and the three counts averaged. The cross-sectional areas of Rosenthal's canal were measured in the same sections and averaged, and the number of neurons per 10,000 μm^2 was calculated to correct for differences in orientation of the ears. By 2 months the organ of Corti has degenerated and the spiral ganglion population is greatly depleted. Neurons continue to disappear between 4 and 8 months. A small and apparently stable population of neurons is reached by 8 months.

107 DUAL POPULATIONS OF EFFERENT AND AFFERENT FIBERS OF THE BASILAR PAPILLA IN THE CHICKEN. Mark Whitehead and D. Kent Morest. Department of Anatomy, University of Connecticut Health Center, Farmington, Connecticut 06032.

Neurons with cochlear efferent fibers have been localized in adult chickens by the axonal transport of horseradish peroxidase. Injections of peroxidase into the inner ear resulted in diffuse filling of cells associated with the cochlear nerve.

Labelled efferent (olivocochlear) neurons were scattered bilaterally in the reticular formation, lateral to the abducens nerve root, and medial and ventromedial to the superior olive. Ventrally situated cells were located among the trapezoid fibers. Some cells were characterized by stellate dendrites, while others were fusiform. Axons of contralateral efferent neurons extend dorsally adjacent to 6th nerve fibers, cross beneath the ventricle, course ventrolaterally mingled with fibers of the facial genu, and exit with the ipsilateral axons through the vestibular nerve root as thick and thin fibers. In plastic-embedded preparations of the inner ear, thin, beaded, labelled fibers, resembling Golgi-impregnated efferent axons (Whitehead & Morest, Soc. Neuroscience Abstracts 4: 397, 1978), were traced to endings on hair cells of the basilar papilla. These labelled axons form large, cup-shaped endings on short hair cells, while smaller terminals contact the tall hair cells, which thus resemble outer and inner mammalian hair cells, respectively.

Afferent components of the cochlear nerve also exhibited Golgi-like filling. Primary afferents bifurcate into lateral and medial branches. The lateral branch gives rise to thin, wavy terminals in nucleus angularis. The medial branch contains mostly thick fibers forming end-bulbs in nucleus magnocellularis, where, in addition, there is a thin, heavily varicose type of primary afferent which is branched and tortuous. These latter axons may represent a class of ganglion cells different from that forming end-bulbs; or, these fibers could be collaterals of the thick primary afferents. Similar delicate, beaded fibers have been seen in Golgi impregnations. In the ear, peripheral processes of ganglion cells appeared in one case to be filled with granules of reaction product, ending on hair cells of all heights. In another case, in which no efferent neurons were diffusely labelled, a few diffusely filled, presumably afferent fibers were seen to make large, foot-shaped contacts with tall hair cells.

In conclusion, as in mammals, the avian olivocochlear neurons form at least two populations; likewise there may be two types of sensory neurons.

108 CORTICAL ABLATION AND PITCH GENERALIZATION OF COMPLEX TONES. I. C. Whitfield. Neurocommunications Research Unit, Univ. Birmingham, Birmingham 15 U.K.

A combination of overtones e.g. 1600, 2000, 2400 Hz (a) has an apparent pitch equivalent to a simple tone of 400 Hz (missing fundamental). The combinations 1600, 1942, 2284 Hz (b) and 1716, 2058, 2400 Hz (c) have lower pitches than (a), while 1600, 2058, 2516 Hz (d) and 1484, 1942, 2400 Hz (e) have higher pitches (about a minor third) in each case.

Cats were first trained to withhold a lick response when a falling pair of tones, 400-342 Hz (safe), was replaced by a rising pair, 400-458 Hz (warning). The animals transferred readily to the complex tone sequences ab (safe) and ad (warning). Animals were overtrained on this paradigm and the absolute frequencies randomly varied 10% to ensure that the response was to direction rather than spot frequency. The cats were then tested on a combination of ab, ad, ac, and ae. They treated ac like ab (safe) and ae like ad (warning) indicating that it was the direction of the fundamental pitch change that was significant, and not that of the harmonics (Heffner & Whitfield, J. acoust. Soc. Amer. 59, 915-919, 1976). The cats were then given a bilateral cortical ablation involving AI, AII, Ep. After recovery the initial training was found to have been lost. However response to the simple tones was rapidly relearned, and the response to the complex pair ab/ad somewhat less rapidly. After retraining on ab/ad, the test programme ab, ad, ac, ae was presented. Unlike the unoperated cats, the operated animals now failed to distinguish between ac and ae. Furthermore one cat, which was presented with the complex ad, but with frequencies all changed by 200 Hz, failed to treat it as warning. It is concluded that while bilaterally decorticate cats can be trained to discriminate specific complex tones; pitch generalization between different complexes of the same pitch is lost.

109 WIENER KERNEL ANALYSIS OF THE RESPONSES OF CAT ANTEROVENTRAL COCHLEAR NUCLEUS NEURONS.
Robert Wickesberg*, John Dickson, and Mary Morton Gibson, (SPON: C. Daniel Geisler) Dept. of Neurophysiology, Univ. of Wisconsin, Madison, Wisconsin 53706.

In order to determine the usefulness of Wiener kernel analysis in the estimation of second-order distortion products encoded in the peripheral auditory system, we have compared second-order Wiener kernels with neural responses to pairs of clicks. In addition, we have compared the Fourier transforms of the second kernels with neural responses to a specific distortion product, the f2-f1 difference tone (f2>f1).

Responses to pseudo-random Gaussian white noise were recorded extracellularly from anteroventral cochlear nucleus neurons in barbiturate anesthetized cats. A 8192-point noise sequence with 40 μsec. resolution and the same sequence with polarities reversed were presented alternately. For each noise sequence a peri-stimulus time (PST) histogram was made from the recorded spike times and normalized for the number of presentations and the binwidth. To calculate the first-order kernel, the PST histogram made for the noise sequence with polarities reversed was subtracted from the histogram made for the other noise sequence. To calculate the second kernel, the two PST histograms were added together. This method of kernel calculation reduces errors due to the finite length of the noise sequence and the approximation to a Gaussian distribution. The subtraction for the first kernel calculation eliminates errors contributed by even-order terms, and the addition for the second kernel calculation eliminates errors from the odd-order terms.

Preliminary results indicate that this analysis might provide insights into processes involved in the neural encoding of second-order distortion products. (Supported by NIH grant NS-12732).

110 PROPRANOLOL REDUCES AUDITORY NERVE AND BRAIN STEM RESPONSES TO CLICK STIMULI. Michael L. Wiederhold and Helen E. Savaki*. Neurobiology Department, Armed Forces Radiobiology Research Institute and Laboratory of Cerebral Metabolism, National Institute of Mental Health, Bethesda, MD 20014.

Intravenous administration of beta-adrenergic-blocking agents has been shown to decrease glucose metabolism in nuclei throughout the auditory CNS (Savaki et al., Nature 276: 521-523, 1978). In an attempt to determine where this effect might be exerted, we have recorded click-evoked electrical responses generated in the cochlea (cochlear microphonic, CM), auditory nerve (N_1), and brain stem (BSER recording). All potentials were recorded simultaneously from the external ear canal of barbiturate-anesthetized cats before, during, and after intravenous infusion of propranolol for 1 hour. Dose rates from 0.01 to 1.0 mg/kg/min were used. The amplitudes of both N_1 and BSER in response to clicks approximately 40 dB above threshold were reduced by up to 70% in a dose-dependent manner by propranolol. A half-maximal effect was obtained at approximately 0.3 mg/kg/min. Maximal effects were generally seen about 10 minutes after infusion was stopped. Recovery began immediately thereafter but was never complete within 2 hours. No consistent dose-dependent effects on CM were seen. Since comparable reductions of N_1 and BSER responses were obtained at all dose rates, a major portion of the effects of propranolol in these experiments must be mediated within the cochlea. Although most of the effect on brain stem responses can be accounted for by a reduction in auditory nerve input to the CNS, the data do indicate some additional response reduction within the brain stem.

111 EXTERNAL NUCLEUS OF THE INFERIOR COLLICULUS: A SITE OF OVERLAP FOR ASCENDING AUDITORY AND SOMATOSENSORY PROJECTIONS IN THE MOUSE. F.H. Willard* and D.K. Ryugo. Depts. Anatomy, Univ. Vermont, Burlington, VT 05401 and Harvard Med. Sch., Boston, MA 02115; and Eaton Peabody Lab., Mass. Eye and Ear Infirmary, Boston, MA 02114.

We have examined second-order auditory and somatosensory pathways which project to the external nucleus(EN) of the inferior colliculus(IC). The cells of origin that project to EN have been identified consequent to horseradish peroxidase(HRP) injections into EN. In the contralateral dorsal cochlear nucleus(DCN), HRP-labelled fusiform cells of the fusiform cell layer, and elongate, horizontal and pyramidal cells of the polymorphic layer could be distinguished. In addition, HRP-labelled fusiform cells were concentrated around the margins of the contralateral dorsal column nuclei(NG&C); large, round HRP-labelled cells were also occasionally observed within these nuclei. Finally, HRP-labelled fusiform cells were localized along the lateral border of pars interpolaris in the contralateral spinal trigeminal nucleus.

In order to evaluate the extent of terminal-field overlap from these auditory and somatosensory projections, and to confirm that our HRP data are not due to HRP diffusion into adjacent IC subdivisions, we have examined the projections from DCN and NG&C using the Fink-Heimer method for anterograde degeneration. (Analysis of the trigeminal projection to EN is still in progress.) Lesions of DCN or sections of the dorsal acoustic stria produced dense fiber and terminal degeneration in the central nucleus(CN) and moderate degeneration in EN. Peak argyrophilia occurred 24 hr after the lesions, appearing uniform in density throughout EN. Many degenerating fiber profiles were seen to bifurcate and then collateralize in both CN and EN; the overlying dorsal cortex was free of degeneration. Lesions of NG&C produced a complex pattern of degeneration within EN. At short survival times (24-48 hrs), terminal degeneration was clustered into patches, separated by degeneration-free zones. It appeared that such terminal degeneration was associated with islands of cell-dense regions; the degeneration-free zones were associated with the intervening cell-sparse areas. At longer survival times, degenerating fibers filled the spaces between the terminal fields. Degeneration was heaviest rostrally, and gradually thinned out caudally. The adjacent CN and dorsal cortex were free of degeneration.

In summary, EN of the mouse may be characterized not only by its cytoarchitecture, but by the pattern of afferent input from DCN and NG&C as well. Although neither the density nor spatial distribution of these projections are identical, their terminal fields overlap within EN. Whether the heterotypic terminals actually synapse on the same EN neurons remains to be determined.

(Supported by NIH Grant NS 13126)

112 COMPARISON OF INFERIOR COLLICULUS NEURONAL RESPONSE PROPERTIES IN C57BL/6 AND DBA/2 INBRED MOUSE STRAINS. James F. Willott and Gregory P. Urban*. Dept. Psychol. Northern Illinois Univ., DeKalb, IL 60115.

Response properties of neurons in the inferior colliculus (IC) were studied in mice of two inbred strains--DBA/2 mice, which are innately susceptible to audiogenic seizures and nonsusceptible C57BL/6 mice. The IC was chosen for study since it appears from lesion studies to play a critical role in audiogenic seizures. Using tranquilized mice, extracellular records were obtained throughout units' response areas with intensities of up to 80 dB SPL. More than 100 neurons from mice of each strain were thoroughly studied.

For most neurons, comparison of various response parameters (e.g., frequency range, intensity functions, discharge patterns, response latencies, response to 10 sec. duration tones) showed surprisingly little difference between the two strains. There was generally poorer representation of high frequencies and slightly reduced overall threshold sensitivity in IC neurons of DBA/2 mice. However, a small proportion of neurons in the latter strain displayed dramatically abnormal response properties. These neurons showed sustained discharges with prolonged afterdischarges when stimulated with 200 ms tones of relatively high intensities. In some cases, increased levels of neural activity lasting for up to several seconds were associated with exposure to tones of 80 dB SPL. Most neurons with abnormal responses were located deep in the ventrolateral nucleus of the IC and were usually most effectively driven by tones of 15-20 kHz. Since similar abnormal responses have been reported in IC neurons of C57BL/6 mice made susceptible to audiogenic seizures by acoustic priming (Urban and Willott, EXPER NEUROL 63: 229-243, 1979), it seems likely that such responses are correlated with susceptibility to audiogenic seizures. This suggests that a relatively small population of neurons having hyperexcitable responses to high intensity sound may be responsible for audiogenic seizure susceptibility.

113 LAMINAR CONNECTIONS IN THE CAT'S AUDITORY CORTEX (AI). D. Wong* and J.P. Kelly*. (SPON.: D. Toran-Allerand). Department of Anatomy, P&S, Columbia University, N.Y., New York 10032.

Neurons in all areas of the cerebral cortex are organized in layers and this laminar pattern is related directly to the connections established by a given area. To examine the connections of layers in the cat's primary auditory cortex (AI), we have used horseradish peroxidase (HRP) for retrograde mapping and autoradiography for anterograde mapping of neuronal connections. Micropipettes filled with a solution of HRP (30%) or ^{3}H-proline (.25mCi/ul) were used to record the responses of neurons in anesthetized cats to auditory stimuli presented in the free field of a sound isolation booth. After the responses of several single units were documented, thereby localizing the injection site physiologically, the tracer was injected with pressure. Tetramethyl benzidine (TMB) was used to demonstrate HRP. Autoradiographs were prepared from frozen sections of the brain after injections of ^{3}H-proline. The results from the autoradiographic experiments indicate that the vast majority of axons from the medial geniculate body (MGB) terminate within AI in a broad band (500-675 um thick) that encompasses layers III and IV. Callosal axons, originating in the contralateral AI, terminate in irregular "patches" ranging in width from 400-800 um. These patches are found principally in layers I, II and III, but it is also possible that some callosal terminals are found in layers V and VI among the fibers of passage ascending to higher layers. HRP experiments show that these callosal axons arise from pyramidal cells in layer III, in the inner rim of layer V, and in layer VI of the contralateral AI. The cells with callosal axons in layer III are grouped in clusters, each spanning about 1100 um along the horizontal axis of the layer. The dense cellular clusters are separated by smaller spaces, $\sim$ 500 um wide, that contain only a few or no callosal neurons. Interestingly, the callosal neurons in layers V and VI are not found in distinct clusters, but rather have a homogeneous distribution along the horizontal axes of these layers. HRP experiments also show that there is a separation in the projections from layers V and VI of AI to the midbrain and the thalamus. After injection of HRP into the inferior colliculus, labeled cells in AI are found exclusively in the outer rim of layer V. These cells are the largest pyramidal neurons of the layer. After HRP injection into the MGB labeled cells are found principally in layer VI, but some are also found in the outer rim of layer V. It remains to be determined whether separate populations of neurons generate the differential projections that may arise from an individual layer in the auditory cortex. (Supported by NIH Grant NS13403 and by the Sloan Foundation).

114 BINAURAL INTERACTION IN THE CAT INFERIOR COLLICULUS STUDIED WITH INTERAURAL DELAYS AND BINAURAL BEATS. T.C.T. Yin, S. Kuwada*, and R.E. Wickesberg. Dept. of Neurophysiology, Univ. of Wisconsin Medical School, Madison, Wis. 53706.

Most cells in the inferior colliculus receive binaural input and many of the low frequency cells (<3000 Hz) have been shown to be sensitive to differences in the time of arrival of the sound to the two ears, thereby suggesting that they are involved in sound localization. Most studies of these cells have employed dichotically presented sine wave signals with variable delays in the onset of the tone to one ear with respect to the other. The repetitive cycling nature of the interaural delay curves suggests that the neurons are sensitive to the interaural phase difference. An orderly and continuously changing phase difference can also be generated by delivering sinusoids of slightly different frequencies to the two ears, i.e. a stimulus which evokes the well-known sensation of binaural beats. We have used this "binaural beat stimulus" and the traditional interaural delay paradigm to study the phase sensitivity of neurons in the cat inferior colliculus.

Platinum-gold plated indium microelectrodes were used to record single cell activity extracellularly in cats anesthetized with sodium pentobarbital. We have recorded the responses of low frequency cells that receive binaural input to the interaural delay and binaural beat stimuli. Over 90% of the cells that show phase sensitivity will respond reliably to both stimuli. With the binaural beat stimulus the neurons responded cyclically at a period corresponding to the beat frequency and maximally at a particular interaural phase difference. There is a high correlation between the values of the optimal interaural phase found with the two stimuli. In addition there was usually qualitative agreement between the shapes of the curves obtained at low beat frequencies. Thus, the binaural beat provides a means for gathering the same information as the interaural delay paradigm. The binaural beat stimulus has the additional benefit that it simulates the phase relationship obtained from a sound source moving in space. By changing the beat frequency or by interchanging the frequencies delivered to the two ears, we could also study the sensitivity of the neurons to speed and direction of movement, respectively. We have found cells that will follow up to beat frequencies of at least 80 Hz. We have also observed a few cells that show marked sensitivity to movement in a particular direction or to different speeds. Thus, the binaural beat stimulus is a very effective and efficient means for gathering information concerning binaural interaction that is not available with the traditional interaural delay stimulus.

115 REGENERATION OF THE AUDITORY NERVE IN ANURANS: AN ANATOMICAL AND PHYSIOLOGICAL STUDY. H. Zakon and R.R. Capranica, Section of Neurobiology & Behavior, Cornell University, Ithaca, NY 14853.

Anurans (frogs and toads) are particularly useful for studies of the specificity of neural connections in the auditory system. Their two auditory organs, the amphibian and basilar papillae, are sensitive to distinct frequency ranges and project onto separate populations of postsynaptic cells in the central auditory system. When the eighth nerve is severed, the axons regenerate and re-enter the brainstem. As part of a set of experiments concerning specificity of reinnervation, we have studied the response properties of regenerated auditory nerve fibers and their course through the central nervous system to their target sites.

The eighth nerve was severed unilaterally and the animals (Bufo americanus and Rana pipiens) were allowed to recover. At postoperative periods of 3 months or more, the responses to acoustic stimuli were recorded from the regenerated auditory nerve fibers by means of fluid-filled microelectrodes. Following the recording session the inner ear was opened, the posterior branch of the eighth nerve was cut, and horseradish peroxidase (HRP) was applied to the stump. The animals were perfused 2 days later and their brains processed for HRP labeling.

Fibers from both the amphibian and basilar papillae were encountered in the regenerated eighth nerve, indicating that neurons innervating both organs are capable of survival after axotomy and subsequent regeneration. Thresholds, latencies and tuning curves of the regenerated fibers appear to be normal. Histological analyses of the HRP-filled axons in the posterior branch (which contained fibers from the two auditory organs and the posterior semicircular canal) of control animals indicates that this branch normally runs only in the dorsal portion of the nerve as it approaches the medulla. In regenerated nerves, even though there is substantial twisting in the regrowth process, the fibers from the posterior branch remain in proximity to each other; these fibers are capable of regeneration to their original target neuropil even if they penetrate the brain via aberrant entry points. Once the fibers re-enter the vicinity of their postsynaptic cells, they display axonal varicosities (presumptive loci of synaptic terminals) typical of normal eighth nerve fibers. Preliminary recordings in the brainstem demonstrate that central auditory neurons can be driven by acoustic stimuli via the regenerated nerve, thus verifying that its auditory fibers remake functional connections.

116 CONNECTIONS OF THE NUCLEI OF THE LATERAL LEMNISCUS IN THE MUSTACHE BAT, PTERONOTUS PARNELLII PARNELLII. J. M. Zook and J. H. Casseday, Depts. Psychology and Surgery (Otolaryngology), Duke University, Durham, NC 27710.

In the mustache bat the nuclei of the lateral lemniscus stand out as three large and cytoarchitecturally distinct areas, called here dorsal (DNLL), intermediate (INLL), and ventral (VNLL) nuclei of the lateral lemniscus. The cytoarchitectural appearance of DNLL and VNLL suggests that these nuclei have homologues in other mammals, but INLL appears so cytoarchitecturally unique as to question whether it is really part of the auditory pathway. We studied the connections of these nuclei by placing electrophoretic deposits of horseradish perixidase (HRP) or [^{3}H]-leucine in these nuclei or in subdivisions of the cochlear nucleus, superior olivary complex or inferior colliculus. Evidence from anterograde transport shows that the anteroventral cochlear nucleus supplies the main ascending projection to both VNLL and INLL, but there are little or no projections from the cochlear nucleus to DNLL. Deposit of HRP within the borders of VNLL reveal large numbers of labeled cells in the anteroventral cochlear nucleus; in the posteroventral cochlear nucleus only octopus cells were labeled. Deposits of HRP within INLL also revealed labeled cells throughout the anteroventral cochlear nucleus; in the posteroventral cochlear nucleus, octopus cells were not labeled, but other types of cells were. Very few labeled cells were found in the dorsal cochlear nucleus after deposit of HRP in any part of the lateral lemniscus.

Anterograde transport of [^{3}H]-leucine shows that the superior olivary complex projects ipsilaterally to all three nuclei in the lateral lemniscus and contralaterally to DNLL. The HRP evidence shows that the cells of origin of projections to VNLL and INLL are located in periolivary cell groups and in the medial nucleus of the trapezoid body. The lateral nucleus of the trapezoid body projects almost exclusively to INLL. The medial and lateral superior olives appear to project mainly to DNLL. Finally, all three nuclei project to the ipsilateral inferior colliculus, mainly to the central nucleus, and DNLL sends a major projection to DNLL and inferior colliculus of the contralateral side; INLL and DNLL project to the medial geniculate body.

We conclude first that all three nuclei of the lateral lemniscus in the mustache bat are major components in auditory pathways ascending to the inferior colliculus and thalamus and, second, that each of these nuclei can be distinguished one from another on the basis of their connections.

AUTONOMIC FUNCTION

117 SYMPATHETIC NERVE RHYTHM OF BRAIN STEM ORIGIN. Susan M. Barman and Gerard L. Gebber. Dept. Pharmacol. & Toxicol., Michigan State University, East Lansing, MI 48824.

A study was made to determine the origin of the 2-6 c/s rhythm in preganglionic splanchnic and postganglionic renal sympathetic nerve discharge (SND) in the chloralose anesthetized, baroreceptor denervated cat. Specifically, it was of interest to learn whether the rhythm is inherent to the brain stem network responsible for basal SND or whether, as suggested by the work of Camerer et al. (Pflügers Arch. 370: 221-225, 1977), it is dependent upon the integrity of interconnections between the forebrain and brainstem. For this purpose, the frequency characteristics of SND and cortical activity (parietal-frontal EEG) were compared using crosscorrelation and power spectral analyses before and after baroreceptor denervation and after midcollicular decerebration. Crosscorrelation analysis failed to reveal a relationship between SND and cortical activity before baroreceptor denervation. At this time, the predominant frequency in power spectra of SND was that of the heart rate, while the frequency of EEG activity varied between 2-6 c/s. Following bilateral section of the carotid sinus, aortic depressor and vagus nerves, crosscorrelation analysis revealed a weak relationship between SND and EEG. SND lagged cortical activity by an average of 30 ms. Power spectral analysis showed complex rhythms in the 2-6 c/s range for both SND and EEG (i.e., the frequency of slow wave occurrence varied between 2-6 c/s). Although no longer related after decerebration, complex rhythms in the 2-6 c/s range persisted in both SND and EEG. The complex rhythm in SND of the baroreceptor denervated and decerebrate cat was transformed into a simple rhythm (i.e., constant interburst intervals) which approached the upper limit of the 2-6 c/s band during short periods (15-30 s) of asphyxia. Furthermore, the rhythm was synchronized to single shocks applied to cardiovascular reactive sites in the medulla and to afferents in the sciatic nerve. These data indicate that although normally entrained to each other, the 2-6 c/s rhythms in SND and EEG are independently generated. That is, the 2-6 c/s rhythm in SND is not dependent upon the integrity of interconnections between the forebrain and brain stem. Rather, the results, in conjunction with an earlier report (McCall and Gebber, Brain Research 89: 139-143, 1975) which eliminated the spinal cord as the site of origin of the 2-6 c/s rhythm in SND, indicate that the rhythm is generated in the brain stem. (Supported by PHS Grant HL-13187.)

118 PARTICIPATION OF AUTONOMIC EFFECTOR PATHWAYS IN THE CARDIOVASCULAR EFFECTS OF ELECTRICAL STIMULATION OF THE CANINE AREA POSTREMA. Karen L. Barnes and Carlos M. Ferrario. Research Division, Cleveland Clinic Foundation, Cleveland, Ohio 44106.

We have shown that electrical stimulation of the dog's area postrema (AP) mimics the pressor response produced by intravertebral infusion of low-dose angiotensin II, producing an increase in mean arterial pressure associated with onset tachycardia and increased peripheral resistance (Barnes et al. Circ. Res., in press). In order to determine the effector pathways mediating the increases in mean arterial pressure and heart rate during AP stimulation, this structure was stimulated in 12 dogs anesthetized with morphine-chloralose before and after selective blockade of parasympathetic and cardiac or peripheral sympathetic nervous systems. The maximal increases in mean arterial pressure (+30 ± 5 mm Hg) and heart rate (+22 ± 9 bpm) were not significantly changed after bilateral cervical vagotomy (+32 ± 3 mm Hg; +21 ± 8 bpm). Beta-adrenergic blockade with propranolol (10 mg iv) eliminated the initial tachycardia and slowed the rise in arterial blood pressure without reducing significantly the final magnitude of the pressor response (+23 ± 3 mm Hg). Sympathetic ganglionic blockade with either pentolinium (3 mg/kg im) or hexamethonium (10 mg/kg iv) completely abolished the pressor effects of AP stimulation.

These data reveal that the sympathetic rather than the parasympathetic division of the autonomic nervous system was responsible for the cardiovascular effects of electrical stimulation of the canine AP, since vagotomy did not affect the response. Because the sympathetically mediated onset tachycardia was not necessary for the occurrence of the rise in mean arterial pressure, we conclude that central activation of peripheral sympathetic vasoconstriction is the essential component of the AP pressor response. These results provide additional support for our view that the area postrema participates in the central adrenergic control of arterial blood pressure.

These studies were supported in part by grants from NHLBI #HL-6835 and American Heart - HANEO.

119 EVIDENCE FOR PRE-SYNAPTIC α-ADRENERGIC INHIBITION OF A SYMPATHETIC-CHOLINERGIC SYSTEM. Patricia J. Bernthal*, Joanne L. Moore and Michael C. Koss. Dept. Pharmacology, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

As early as 1920, Billigheimer proposed that epinephrine has a modulatory effect on the sympathetic-cholinergic electrodermal system in humans (Billigheimer, Naunyn-Schmiedebergs Arch. exp. Path. Pharmak., 1920, 88, 172). Previous studies in our laboratory have indicated that systemic administration of epinephrine depresses the amplitude of postganglionically evoked electrodermal responses in cats. This effect was antagonized by 10 mg/kg phentolamine (Koss, Davison and Bernthal, Psychopharmacology, 1976, 50, 149). The present studies were undertaken to determine if systemic administration of epinephrine would inhibit reflexly evoked electrodermal responses in a similar fashion, and if this inhibition could also be produced by endogenous release of catecholamines. Cats were anesthetized with pentobarbital (36 mg/kg, ip) or a combination of α-chloralose (30 mg/kg, ip) and urethane (300-500 mg/kg,ip). Reflex electrodermal responses were evoked by stimulating the proximal portion of a ligated peroneal nerve once every 60 sec with a 10-30V, 6-12 Hz train of 1 sec duration. Graded doses of epinephrine (0.3-10.0 ug/kg, iv) depressed the amplitude of electrodermal reflexes in a manner that was quantitatively equivalent to that observed with the peripherally evoked response. Asphyxia (5 min) also resulted in an inhibition of both the reflexly and peripherally evoked responses which was antagonized by bilateral adrenalectomy. In order to further elucidate the mechanism of this effect, epinephrine was administered to cats before and after phenoxybenzamine or yohimbine. Yohimbine (0.5 mg/kg, iv), an α-adrenergic blocker which is postulated to act preferentially at pre-synaptic sites, effectively antagonized the inhibitory action of epinephrine on peripherally evoked electrodermal responses. Phenoxybenzamine (2.5 mg/kg, iv), an α-adrenergic blocker considered to act mainly at post-synaptic sites, did not antagonize epinephrine's inhibition. As expected, the pupillary effects of epinephrine, which have been shown to be post-synaptic in nature, were strongly antagonized by phenoxybenzamine, but not by yohimbine. The results of these studies demonstrate that systemically administered epinephrine, as well as endogenously released catecholamines, act to depress the amplitude of both reflexly and peripherally evoked electrodermal responses. The relative degree of antagonism of this effect by yohimbine and phenoxybenzamine suggests that catecholaminergic modulation of this sympathetic-cholinergic sudomotor system may occur at pre-synaptic sites.

120 SYNAPTIC HYPERFUNCTION IN A SYMPATHETIC GANGLION AND ITS POTENTIAL SIGNIFICANCE IN ESSENTIAL HYPERTENSION. R.I. Birks, Physiology Department, McGill University, Montreal, Canada H3G 1Y6.

Patterning of the preganglionic neural input to the cat superior cervical ganglion into brief high frequency trains causes a progressive and maintained increase in ganglionic acetylcholine (ACh) stores of up to 170% over those of the contralateral control ganglion. It was proposed that the effect might be related to accelerated sodium pump activity resulting from the rise in internal nerve ending sodium during the trains (Birks, R.I., J. Physiol. 280, 559-572, 1978).

It has now been found that the ACh stores increase to the same extent as with patterned stimulation during perfusion with normal K^+ following sodium-loading of the ganglia by removal of extracellular K^+. Since no increase in ACh occurred during sodium loading when the pump was inhibited, but only during accelerated pumping in the recovery period, it is concluded that the effect is related to accelerated sodium pumping, rather than to a direct effect of the raised intracellular Na^+ at the nerve terminals.

ACh output was found to increase 2.5-3.0 fold during 60 min activation by patterned stimulation, or by equally spaced low frequency pulses during recovery in normal K^+ following pump inhibition. These effects on ACh output are greater than can be accounted for by the increases in ACh stores (Birks, R.I., J. Physiol. 271, 847-862, 1977). Because ACh release is known to be increased by raised $[Na]_i$ (Birks, R.I. and Cohen, M.W. Proc. Roy. Soc. B. 170, 401-421, 1968; Charlton, M.P. and Atwood, H.L. Br. Res. 134, 367-371, 1977) it is proposed that the extra effect of patterned stimulation on ACh output is related to the increase in $[Na]_i$ and perhaps also to the hyperpolarization which accompanies accelerated sodium pumping. The general conclusion that arises from this work is that the internal sodium load at synapsing preganglionic nerve endings modulates ACh output and thus effector activity.

Recent work indicates that an abnormally high passive permeability to Na^+ is an important genetically determined defect in essential hypertension (see Garay, R.P. and Meyer, P., Lancet, Feb. 17, p. 349-353, 1979 for ref.). This membrane defect imposes an increased intracellular sodium load on affected cells, and if present at sympathetic neurons, would be expected to promote excessive sympathetic activity and thus increase vascular smooth muscle tone thereby contributing to hypertension (Birks, R.I. and Levine, S.S. in preparation).

121 A NONINVASIVE LASER-DOPPLER AND RADIOMETRIC MONITOR OF CUTANEOUS AND SKELETAL MUSCLE MICROCIRCULATION. R.F. Bonner*, P.D. Bowen*, R.L. Bowman*, A.J. Tahmoush, and W. King Engel (SPON: R. Curtis Graeber). NIH, Bethesda, MD 20205

A laser-Doppler, blood flow monitor and an LED-phototransistor reflection radiometer have been simultaneously used to measure the dynamics of the microvasculature in skin of human finger and forearm and exposed rat muscle. These noninvasive techniques measure changes in blood flow, blood volume, and red blood cell velocity within small (mm^3), superficial regions of the microvasculature. The Doppler-broadening of laser light scattered by moving red blood cells is analyzed in real-time by an analogue processor which has been shown to be linearly correlated with flow (Am. J. Physiol. 232:H441-8, 1977). The radiometric technique employs a calibrated near-infrared light source and phototransistor to detect light backscattered from underlying tissue (Techniques in Psychophysiology,1979). The radiometric signal is inversely related to tissue blood volume.

In six male subjects during basal condition, the results (1-4) were obtained. 1) Maximum laser-Doppler flow values were 2.7 ± 1 with a fractional pulsatile component of 11 ± 3% from the fingertip and .05 ± .01 with a pulsatile component of 20 ± 7% from the forearm skin. The corresponding radiometric values were 15 ± 5 μ W with a fractional pulsatile componentof 0.4 ± .1% from the fingertip and 28 ± 1 μ W with 0.04 ± .03% pulsations from the forearm skin. 2) During the Valsalva maneuver, the laser-Doppler blood flow value from the fingertip was transiently reduced to less than 10% of the resting value with an associated 5-7% increase in radiometric signal suggesting a decrease in local blood volume. 3) During graded, externally-applied pressure increases, the laser flow values decreased in a sigmoidal manner with a corresponding increase in pulsatile flow. The radiometer showed a corresponding increase in average blood volume but a decrease in pulsatile changes. 4) Following total occulsion, a 6-fold increase in laser flow values was observed in the forearm skin. The magnitude of this observed hyperemic response increased with occlusion duration from 15 to 120 sec. In the rat muscle, autoregulation of blood flow was observed with partial aortic compression and hyperemic responses were measured following total occlusion.

These results demonstrate the applicability of the laser-Doppler and radiometric techniques for continuous, noninvasive measurement of microvascular dynamics in normal and diseased tissues. By providing a rapid, continuous, indirect index of those dynamics, the techniques should prove useful in the assessment of disorders of the adrenergic sympathetic nervous system, and of intrinsic vascular and local regulatory factors.

122 THE RATIO OF PREGANGLIONIC AXONS TO POSTGANGLIONIC CELLS IN THE SYMPATHETIC NERVOUS SYSTEM. Rebecca Brooks-Fournier* and Richard E. Coggeshall. (SPON: A.E. Applebaum). Departments of Anatomy and of Physiology and Biophysics and the Marine Biomedical Institute, The University of Texas Medical Branch, Galveston, Texas 77550.

It is widely believed that the postganglionic cells outnumber the preganglionic axons in the sympathetic division of the autonomic nervous system by at least 11 to 1. This figure is usually contrasted to the parasympathetic innervation where the ratio is felt to be approximately 2 to 1. These figures give rise to the idea that the sympathetic system has a "diffuse" innervation as compared to the "precise" parasympathetic innervation. There are two major difficulties with the studies that established these ratios, however, First, the preganglionic axons were counted using the light microscope which does not allow an adequate assessment of the numbers of unmyelinated axons. Second, the axons were counted in the sympathetic chain just caudal to the superior cervical ganglion and there was no attempt made to prove that all the axons in this location were preganglionic in nature; it was assumed that there were no sensory or postganglionic axons present to contaminate the counts. To take account of these difficulties, the number of axons in the sympathetic chain was reassessed by using the electron microscope and found that the ratio of preganglionic axons to postganglionic neurons was 1 to 1.9, which is far higher than reported in the classic literature. The second part of the study, to check for the presence of sensory and/or postganglionic fibers in the chain is reported here. Ventral roots C8 - T4 were transected in rats. This operation would remove the preganglionic fibers. The remaining fibers were counted and in three rats, the average number of surviving axons was approximately 600 out of a total population of approximately 4500. If further work confirms these preliminary observations, then two conclusions are possible; 1) that the ratio of preganglionic to postganglionic axons in the sympathetic system is approximately 1 to 2.5, which is much higher than previously reported and 2) that there are a significant number of postganglionic and/or sensory fibers in the cervical sympathetic trunk. This work is partially supported by NIH grants NS 07377 and NS 10161 and a teaching and research assistantship of the University of Texas Medical Branch.

123 CENTRAL AND PERIPHERAL CATECHOLAMINERGIC ACTIVITY DURING SODIUM DEPLETION. K. Bridget Brosnihan, Julianna E. Szilagyi* and Carlos M. Ferrario. Research Division, Cleveland Clinic Foundation, Cleveland, Ohio 44106.

Reduction of sodium intake affects both the renin-angiotensin and sympathetic nervous systems, but the effects on the latter are less well understood. During sodium depletion it has been demonstrated histochemically that the adrenergic nerve terminals are depleted of neural transmitter (Ljundqvist et al. Acta path. microbiol. scand. 83:661,1975). Others (Rocchini et al. Am. J. Physiol. 233: 196, 1977) have shown the presence of depressed sympatnetic reflexes which they attributed to a decreased ability to release norepinephrine from peripheral sympathetic nerve endings.

In order to assess whether these alterations in sympathetic activity could originate centrally, samples of cerebrospinal fluid (CSF) from the cisterna magna and plasma were simultaneously taken to assess differences in the peripheral and central levels of catecholaminergic activity in mongrel dogs placed first on a diet of normal followed by a diet of low sodium content (40 mEq sodium/day vs. 4 mEq sodium/day respectively). Animals on the low sodium diet received furosemide (40 mg/day i.m.) during the last three days of the 21-day period of dietary sodium depletion. Samples were taken under pentobrabital anesthesia. Catecholamines [norepinephrine (NE), epinephrine (EPI), and dopamine] were measured by the radioenzymatic method.

After sodium depletion plasma NE rose from 127 ± 19 to 223 ± 28 pg/ml ($p< 0.01$) but EPI and dopamine did not change (111 ± 3 vs. 193 ± 43 pg/ml and 90 ± 43 vs 50 ± 6 pg/ml respectively). In CSF, NE rose from 87 ± 10 to 121 ± 14 pg/ml ($p< 0.05$) while EPI and dopamine levels remained unchanged (9 ± 3 vs 6 ± 1 pg/ml and 53 ± 10 vs. 63 ± 27 pg/ml respectively). Plasma sodium decreased from 151.3 ± 2.4 to 143.8 ± 1.1 mEq/l ($p< 0.05$) and similarly CSF sodium decreased from 154.3 ± 4.0 to 146.8 ± 2.3 mEq/l ($p< 0.05$). No correlation was found in plasma between sodium and NE levels, but in CSF the levels of sodium appears to be inversely correlated to the levels of NE.

Our findings of an inverse correlation between CSF sodium and NE suggests the possibility of a sodium-mediated effect influencing central noradrenergic activity. Such augmented central noradrenergic activity indicates that the previously reported alterations of the sympathetic nervous system are not confined to the peripheral site but may originate centrally. The presence of elevated plasma NE levels may result secondarily from the elevated plasma renin activity or depleted plasma volume, factors which are both known to be associated with sodium depletion.

124 REDUCED PRESSOR RESPONSE TO INTRACAROTID ANGIOTENSIN INFUSION AFTER SUBFORNICAL ORGAN LESION IN RATS. J. Buggy, W.E. Wells, W.J. Bryan* and G.D. Fink*. Department of Physiology, University of South Carolina, Columbia, South Carolina 29208, and Department of Pharmacology and Toxicology, Michigan State University, East Lansing, Michigan, 48824.

Blood-borne angiotensin (AII) may rapidly increase arterial pressure not only by its direct vasoconstrictor action on vascular smooth muscle but also by activation of central nervous system mediated pressor mechanisms. Although some evidence also implicates more rostral brain structures, AII sensitive brainstem sites (area postrema, subnucleus medialis) have been identified in dog, cat, and rabbit which initiate the centrally mediated component of the pressor effect of circulating AII. In the rat however, intracarotid but not intravertebral artery infusion of AII produces an exaggerated pressor response suggesting that in this species, AII sensitive brain sites mediating the central component of the pressor effect are located in the forebrain region rather than brainstem. Consistent with this view is the finding of no change in pressor response to circulating or intraventricular AII after area postrema ablation in rat. Previous stimulation and ablation studies have demonstrated the importance of preoptic-hypothalamic periventricular tissue surrounding the anteroventral third ventricle (AV3V) for centrally mediated pressor, dipsogenic, and antidiuretic effects of AII in the rat. An adjacent circumventricular structure, the subfornical organ (SFO), is also exceptionally sensitive for pressor and dipsogenic responses to AII. The supraoptic nucleus, site of cell bodies synthesizing antidiuretic hormone, has been reported to receive projections from both AV3V and SFO. This study assessed the effect of SFO ablation on drinking and pressor responses elicited by intracarotid (IC) or intraabdominal aortic (IA) infusions of AII in conscious rats with chronic indwelling catheters. SFO ablation did not affect body weight, basal blood pressure or heart rate but compared to rats with control lesions, SFO lesioned rats showed a reduced drinking response to IC AII infusion. SFO lesioned rats also had reduced pressor responses to IC but not IA infusion of 25, 50, or 100 ng AII/min. The reduced pressor response to IC AII infusion is not an exclusive property of SFO ablation since the same effect has been reported after AV3V ablation. The finding that SFO ablation abolished the increased pressor sensitivity to IC infusion of AII is consistent with the hypothesis that both SFO and AV3V are part of an AII sensitive periventricular system in rat forebrain which mediates the central component of the pressor action of blood-borne AII. (This work was supported by a grant in aid from the American Heart Association and with funds contributed in part by the SC Heart Association.)

125 THE INVOLVEMENT OF MEDIAL MEDULLARY RETICULAR FORMATION IN CARDIOVASCULAR EFFECTS OF CLONIDINE IN EXPERIMENTALLY-INDUCED HYPERTENSIVE CATS. Yih Huey Chen and Samuel H.H. Chan. Dept. Life Sci., Indiana State Univ., Terre Haute, IN 47809.

Clonidine, a potent antihypertensive agent, has been demonstrated in our laboratory to exert its hypotensive and bradycardiac actions via the activation of α-adrenoceptors in the medial medullary reticular formation (MMRF) (Chen and Chan, Neuroscience Abst. 4:18, 1978) in normotensive cats, actions that require the presence of vagus nerve. In addition, the MMRF has been identified in the rat to be at least one of the central sites of clonidine induced actions (Chan and Koo, Neuropharmacol. 17:367, 1978). The present study was undertaken to further investigate the cardiovascular effects of clonidine in experimentally-induced hypertensive cats and the involvement of MMRF in these actions.

Cats that were lightly anesthetized with pentobarbital sodium (35 mg/Kg, i.p.) or precollicularly decerebrated were used. Cannulations of left carotid artery and left femoral vein were performed for measurement of arterial blood pressure (ABP) and injection of drug. Heart rate (HR) was determined by conventional EKG. Experimental hypertension was induced at the beginning of the recording session by common carotid occlusion, which elicited a maintained elevation of ABP without a significant change in HR.

Systemic injection of clonidine (10 μg/Kg, i.v.) in the experimentally-induced hypertensive cat produced an initial, transient increase in ABP (mean, systolic, and diastolic), followed by a significant decrease of the same parameters and a prolonged suppression of HR for 60 min. Apart from the transient hypertension, which represents a peripheral vascular effect of clonidine, depression of ABP and HR by this imidazoline compound was eliminated after bilateral vagotomy, indicating that these circulatory events were mediated by the vagus nerve. Likewise, bilateral focal electrolytic lesions of MMRF (three 1 mm apart lesions on each side) resulted only in the transient hypertension without the subsequent hypotension and bradycardia after systemic injection of clonidine (10 μg/Kg). Preliminary results indicated that unilateral microinjection of clonidine (1 μl in vol.) directly into three 1 mm apart loci in MMRF at an ineffective dose (0.2 μg/Kg) when administered systemically produced a significant decrease of ABP and HR without the preceding hypertension, while control microinjections of saline (vehicle) did not produce any cardiovascular changes.

It is concluded that clonidine may exert its central actions in experimentally-induced hypertensive cats via activation of medial medullary reticular neurons to produce depression of ABP and HR, an action that would require the presence of vagus nerve.

126 EFFERENT PROJECTIONS OF THE CANINE AREA POSTREMA. C.L. Chernicky,** K.L. Barnes, J.P. Conomy and C.M. Ferrario. Division of Research and Dept. of Neurology, Cleveland Clinic Foundation, Cleveland, Ohio 44106.

The canine area postrema (AP) has been shown by Barnes et al. (Circ. Res., in press) to be the site of a physiological pressor pathway. We have previously described the morphological composition of this structure (Chernicky et al., Neurosci. Abstr. 4: 13, 1978). In order to demonstrate the anatomic pathway from the canine AP, efferent projections were studied by the Fink-Heimer and Wiitanen modifications of the Nauta-Gygax silver degeneration technique. Discrete electrocoagulation lesions were placed in the AP under direct vision with the aid of an operating microscope. Following survival times of 2-5 days, animals were perfused with isotonic saline followed by 10% buffered formalin. After 4-8 weeks storage in 10% formalin, the brainstems were serially sectioned at 25 μm in the sagittal, horizontal, or transverse plane. Every fifth section was stained with luxol fast blue and/or cresyl violet for both anatomic orientation and establishment of the extent of the lesion. Adjacent sections were silver stained for degenerating axons and terminals.

The most prominent projection from the canine AP was through the ipsilateral dorsolateral fiber bundle previously described in the cat by Morest (Am. J. Anat. 107: 291-303, 1960). The amount of degeneration seen in this bundle was constant throughout its length from the obex to the most rostral portions of the AP. A sparse projection was seen to terminate in the subadjacent medial portion of the ipsilateral nucleus tractus solitarii (NTS). A small bundle of degenerating fibers crossed the nucleus commissuralis of Cajal, entering the region of the contralateral NTS just caudal to the obex. A few scattered terminals were observed in the contralateral AP-NTS junctional zone and in the dorsolateral corner of the AP.

The observation of terminal degeneration in the AP-NTS junctional zone confirms the finding in Golgi studies of AP neurons with short axons projecting into this region. The present study also demonstrates an efferent projection from the AP to the medial NTS. The degenerating fibers seen crossing the midline in the nucleus commissuralis of Cajal provide evidence for bilateral interconnectedness of the two halves of the AP. This study suggests that the AP projects only to the closely adjacent medullary structures, and implies that the pathways which mediate its facilitative effects on the sympathetic vasomotor outflow are multisynaptic.

Supported by grants from NIH, HL-6835; American Heart, #76 646; and the Reinberger Foundation.

127 ADRENERGIC AND CARDIOVASCULAR RESPONSIVENESS OF 28-MONTH OLD FISHER-344 RATS FOLLOWING STRESS. C.C. Chiueh and S.I. Rapoport. Lab. Neuro Sci., NIA, NIH, Balto City Hosp. Balto.,MD 21224.

The blood pressure and heart rate of freely moving or restrained male Fisher-344 rats at 3 months (young), 12 months (adult) and 28 months (old) of age were monitored through a chronic indwelling catheter which was implanted in the ventral tail artery at least 20 hrs before the experiment (Chiueh and Kopin, Amer. J. Physiol. 234:H690-H695, 1978). The sympathetic activities of the animal were determined by radioenzymatically measuring the catecholamines in 50 μl of plasma. Conscious and unrestrained Fisher-344 rats undergo a decrease in heart rate and an increase in diastolic blood pressure with increasing age. The heart rate of old rats, 369±12 bpm, was significantly lower than those of young (396±6 bpm) or adult (385±5 bpm) rats. The systolic and diastolic blood pressure of unrestrained young, adult and old rats were 124±5/71±4, 141±3/78±2 and 120±4/92±4 mm Hg, respectively.A 3 min or 30 min forced immobilization was applied to the animals and used as physical and emotional stressors in order to investigate the effect of the aging process on the amplitude and rate of responsiveness in the sympathetic and cardiovascular systems. Three minutes of stress failed to increase the blood pressure and heart rate of old rats, but increased cardiovascular responses in young and adult rats. Following 30 min of stress, the heart rate of aged rats increased slightly (Δ29±9 bpm), approximately 1/3 to 1/2 of the increase seen in young rats. The immobilized rats had slightly lower blood pressures than unrestrained controls because of their massive release of epinephrine following the 30 minute stress. The resting plasma levels of norepinephrine in unrestrained Fisher-344 rats ranged from 0.4 to 1.1 ng/ml and increased slightly with increasing age. Aged rats showed no decrease in the maximal adrenergic release due to stress, but had a prominent delay in the cathecholamine release. The respective increments of plasma norepinephrine after 3 min and 30 min stresses were 1.8±0.5 and 3.5±0.4 ng/ml. The delay of norephinephrine release may be responsible for the lack of blood pressure change after 3 min stress. A decrease in the activity of adrenergic receptors, especially β receptors, in the target organs was evident because the 30 min stress induced a greater increase in plasma epinephrine in old rats (Δ7.3±1.1 ng/ml) than in adult rats (Δ4.3±0.6 ng/ml) while producing a decrease in β-adrenergic responses; i.e., heart rate (old = Δ29± 9 vs adult = Δ88±6 bpm) and blood sugar (old = 141±3 vs adult = 217±5 mg%). The present results indicate that the release mechanism of the sympathoadrenal medullary system of aged Fisher-344 rats can respond maximally but not efficiently to stress due to a decline in the rates of catecholamine release and a decrease in the activities of adrenergic receptors or effectors in the target organs.

128 DIRECT PROJECTIONS FROM THE NUCLEUS TRACTUS SOLITARIUS TO THE HYPOTHALAMUS IN THE CAT. J. Ciriello and F. R. Calaresu, Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

Although it is known that the function of the hypothalamus can be affected by cardiovascular afferent information in the buffer nerves the course and distribution of these afferent fibers from the first relay in the n. tractus solitarius (NTS) to the hypothalamus is not known. The traditional view is that the NTS relays afferent information to the hypothalamus via numerous connections in the brain stem reticular formation, but recent evidence obtained in the rat suggests a direct connection. Two series of experiments were done in cats in an attempt to obtain anatomical and electrophysiological evidence concerning this issue. In the first series, small injections (20-40 μl) of a mixture of tritiated amino acids were made in the caudal NTS of 11 cats and after 1-15 days' survival the brains were processed for autoradiography. Fibers from the NTS appeared to project rostrally, through the lateral periaqueductal gray matter and medial lemniscus bilaterally, to several hypothalamic regions: the periventricular hypothalamic area, the paraventricular hypothalamic n. (PAH), the dorsomedial hypothalamic area (DMH), and the subcommissural part of the bed n. of the stria terminalis (BST). In three animals in which the injection missed the NTS and was mainly confined to dorsal column nn., no label was seen in the hypothalamus although the contralateral medial lemniscus was heavily labeled. In the second series, the electrical activity of 84 single units widely distributed in the hypothalamus was monitored in chloralosed cats for changes in firing frequency during stimulation of the carotid sinus nerve (CSN) and NTS. CSN stimulation excited 46 of the 84 units, 23 in the PAH (mean latency, 27.1 ± 3.0 ms), 14 in the DMH (mean latency, 19.2 ± 3.2 ms), and 9 in the BST (mean latency, 14.9 ± 1.0 ms). These units were also excited by NTS stimulation with significantly shorter latencies (mean latencies, 13.1 ± 2.1 ms, 9.5 ± 2.0 ms, 6.9 ± 1.2 ms, respectively). These results demonstrate the existence of a fiber tract originating in the NTS conducting at 2.3 to 4.4 m/s and carrying cardiovascular afferent information directly to the hypothalamus.

129 REGIONAL CEREBRAL BLOOD FLOW IN MIGRAINE SUBJECTS DURING SELF-REGULATION OF SKIN TEMPERATURE. James L. Claghorn, Roy J. Mathew*, John W. Largen*, John S. Meyer*. TRIMS, Houston, Tx. 77030

A study was undertaken to compare regional cerebral blood flow in normal subjects and migraineurs experiencing the effects of biofeedback induced skin temperature changes. Also we investigated the specific and nonspecific effects of such training on the frequency, intensity and duration of migraine headaches.

A typical classic migraine attack is characterized by a biphasic pattern of vasomotor behavior. The prodrome stage involves the reduction of intracranial blood flow followed by a reactive dilatation of the intracranial and extracranial arteries. It has been hypothesized that hand-warming through biofeedback training may result in a decrease in sympathetic outflow, thereby, interrupting the vasomotor pattern of change in a migraine headache.

Normal subjects were 12 right handed women and they were compared to 12 right handed female migraineurs. Age ranges for the normal group were 18 to 35 and for the migraine group 27-52. Migraineurs were selected on the basis of the following characteristics: manifesting either classic or common migraine and having a minimum of two migraine attacks per month. Each volunteer was randomly assigned to either a hand-warming or a hand-cooling temperature biofeedback group and given extensive training in skin temperature self-regulation in a series of 12-15 sessions.

Each subject was subsequently given 2 measures of regional cerebral blood flow (rCBF) utilizing the non-invasive ^{133}Xe inhilation technique. One rCBF run was given during a relaxation steady-state condition and a second while subjects were attempting to manipulate their skin temperature in the trained direction.

Results show small, statistically non significant, changes in blood flow for normals irrespective of whether they cool or warm their hands. In contrast migraineurs increase the non-dominant left hemisphere flow 8% with suggestive increases regionally distributed. Examination of headache data show specific and non specific effects on frequency, severity and duration of headache. This study confirms autonomic peculiarities in migraineurs which result in novel changes in blood flow during warming and cooling of the dominant hand. It is proposed these changes explain the reported salutary effects of hand-warming in migraine.

The presence of non specific effects of biofeedback training emphasizes that placebo effects play an important part in relieving symptoms of migraine.

130 THE EFFECT OF LEFT CARDIAC SYMPATHECTOMY ON CARDIAC CHANGES DURING BEHAVIORAL STRESS IN DOGS. Lewis K. Clarke* and Richard A. Galosy. Dept. of Cell Biology, Univ. of Texas Hea. Sci. Ctr. at Dallas, TX 75235.

Alterations in heart rate (HR), left ventricular systolic pressure (LVP), and maximum rate of left ventricular pressure development (LV dp/dt max) during a 13 day Sidman shock avoidance task were studied in 3 groups of four chronically prepared dogs. In one group of animals the left dorsal and ventral ansa subclavian nerves were transected between the stellate and the caudal cervical ganglia resulting in a denervation of the left cardiac sympathetic nerves. The second group of dogs was a neurologically intact, experimental stress group, and the third group was a neurologically intact, nonstress control. The intact stress group demonstrated phasic increases in HR, LVP, and LV dp/dt max during the avoidance period of each day as well as tonic increases in HR, LVP, and LV dp/dt max during the 13 days of the experiment. In the denervated animals there was no evidence of phasic increases in any of the parameters during the avoidance period. Tonic levels of LVP and LV dp/dt max in the denervated group were not significantly different from controls, but tonic levels of HR remained elevated. These results suggest that the integrity of the left cardiac sympathetic nerves is necessary for stress induced change in LVP, LV dp/dt max, and phasic increases in HR during the avoidance period of each day. However, right cardiac sympathetic and/or vagal influences are apparently responsible for stress induced tonic changes in HR.

131 CELLS OF ORIGIN OF MOTOR AXONS AND AFFERENT DISTRIBUTION OF THE SUBDIAPHRAGMATIC VAGUS IN THE RAT. Janet D. Coil*and Ralph Norgren. The Rockefeller University, New York, NY 10021.

The neurons of origin of preganglionic motor axons that travel in the subdiaphragmatic segment of the vagus nerve classically have been ascribed to the dorsal motor nucleus of the vagus (DMX) in the medulla. To re-examine the central cell groups that give rise to such axons in rats, the ventral or dorsal branch of the subdiaphragmatic vagus was transected near the stomach and incubated in crystalline horseradish peroxidase (HRP) for 6 to 8 hours. After 48 hours post-operative survival, the animals were killed and their brains processed according to standard HRP histochemical technique, using tetramethyl benzidine as the chromagen. After counterstaining with neutral red, the tissue sections were examined under bright- and dark-field illumination for the presence of HRP-positive somata. As expected, numerous retrogradely labeled cells were present in DMX, distributed throughout the rostro-caudal extent of the nucleus. HRP-positive cells were also observed bilaterally in the rostral portion of the nucleus ambiguus. This finding is in contrast to previous accounts in which motor fibers of the nucleus ambiguus were considered to project only to the larynx, pharynx and cervical esophagus (Lawn, J. Comp. Neurol. 127, 1966, p. 293), but support functional evidence that suggests DMX is not the exclusive source of subdiaphragmatic vagal motor fibers (Kerr, J. Physiol., 202, 1969, p. 755; Lawn, J. Physiol., 174, 1964, p. 232.) Different patterns of cell-labeling were observed in DMX which could be correlated with one or the other of the two vagal branches. Incubation of the ventral branch resulted in labeled cells in only the left DMX, while incubation of the dorsal branch labeled cells on both sides, although more extensively on the right. The extent of the retrograde labeling in DMX indicates that its rostro-caudal limits extend somewhat further than is usually assumed on the basis of cytoarchitecture alone. The incubation procedure also resulted in anterograde transport of HRP in vagal afferent axons which could be traced to a circumscribed portion of the nucleus tractus solitarius immediately ventral and rostrolateral to the area postrema.

132 EFFECT OF BILATERAL CERVICAL VAGOTOMY IN SQUIRREL MONKEYS. K.C. Corley, H.P. Mauck* and F.O'M. Shiel*. Dept. of Physiol., Pediat and Path. Med. Coll. of Virginia, VCU, Richmond, VA 23298.

Stress-induced cardiac arrest and myocardial pathology observed in squirrel monkeys has been suggested to be mediated by the autonomic nervous system (Psychophysiol. 14: 322, 1977). The involvement of parasympathetic cardiac input was studied by bilateral cervical vagotomy. This procedure in 27 monkeys was accomplished in one operation. While 9 monkeys succumbed suddenly within 24-48 hrs, no additional deaths over 35±13 days (M±SE) occurred. Lethargy and apnea were noted only during the first week. A weight loss also occurred, but body weight stabilized at a lower level by the second week. Mortality, lethargy and apnea were almost totally eliminated by vagotomy in two operations with weight stabilization used to indicate readiness for second operation. Since the only mortalities were two monkeys that had a left followed by right section, the sequence of vagi section was important. Because the right vagal input is greater than the left, the effect of a right-left denervation was more evenly distributed between the two operations than a left-right denervation. This observation suggested autonomic imbalance may be a factor in vagotomy deaths. Seventeen monkeys after the two stage vagotomy were studied for 40±8 days before stress with no other mortalities. While resting heart rate (335±4 bpm; N=28) was greater than that of intact monkeys (300±8 bpm; N=28; $p > .01$), blood pressure did not differ (vagotomy: 151/120mm Hg; N=3 and intact: 149/108mm Hg; N=6). Vagotomy monkeys subjected to shock stress (1 sec.; 4mA; 60Hz) showed the same heart rate or blood pressure changes as intact monkeys. Tachycardia was followed by bradycardia with cardiac arrest which had an incidence comparable to that of intact monkeys stressed for similar periods of time. While acute myocardial pathology was like that of intact monkeys, myocardial fibrosis was also observed in 5 vagotomy monkeys sacrificed after a single 24-hr. stress session. Since no fibrosis occurred in intact monkeys after a 24-hr. stress, cardiomyopathy was attributed to vagotomy per se and enhanced sympathetic activity after the abrupt removal of vagal restraint. Thus, squirrel monkeys survived vagotomy, and reaction to stress was comparable to that of intact monkeys. The immediate effects of vagotomy indicated autonomic involvement, but failure to affect stress-induced bradycardia and cardiac arrest suggested that parasympathetic input was not necessary for these cardiovascular changes (Supported by HE-13454).

133 PROJECTION OF SPLANCHNIC, PNEUMOGASTRIC AND SINUS NERVE AT SUPRAMEDULLARY LEVELS.

Bernard Delbarre, Alain Chatelus*, Danielle Senon* - Laboratoire de Chirurgie Expérimentale, Faculté de Médecine, 37032 TOURS FRANCE.

Projection of sinus nerve afferents are also located at supramedullary levels in structures in which autonomous and emotional events are connected. CHATELUS and al., 7 Int. Congress Pharmac. Abstracts, 1978, 2921. We have investigated the projection of splanchnic and pneumogastric nerve by using the technique of averaged evoked potential (EP) in chloralozed cats.

The projection of carotid sinus nerve, pneumogastric and splanchnic nerve are located at the same place in anterior and posterior hypothalamus, amygdala, cortex SI SII and ansate sulcus. Stimulation of these areas induces modifications of blood pressure and heart rate.

Destruction of nucleus tractus solitarii induces an increase of blood pressure, decrease of systemic hypertension evoked by norepinephrine and suppression of EP sinus nerve at supramedullary levels. Amplitude of evoked potentials of splanchnic and pneumogastric nerve are diminished.

These results suggest that a supramedullary level in some areas, there is projections of sinus nerve, sympathetic and parasympathetic nerve at the same place.

134 REPEATED RESTRAINT STRESS AND PLASMA CATECHOLAMINES IN RATS. Kathryn H. DeTurck* and Wolfgang H. Vogel, Dept. Pharmacol., Thomas Jefferson Univ., Philadelphia, PA 19107.

The right external jugular vein of five male Wistar rats was catheterized to permit repeated sampling of small volumes of blood from freely-moving rats. The flexible silastic catheter was encased in a protective steel wire spring suspended by a pulley to allow for relatively free movement. Plasma norepinephrine (NE) and epinephrine (E) concentrations were determined by the radioenzymatic assay from Upjohn. The animals were restrained 3 times and each experiment was separated by one day of rest. Restraint was done by securely taping the animal to the workbench for 30 min. Blood samples were drawn at 0 min in the home cage, at 1, 5, 15 and 30 min during restraint and at 60 minutes (30 minutes after the animal was released and returned to its home cage).

Animals differed behaviorally; excitement ranged from mild to severe during the first stress period and this behavior declined noticeably during the next two restraint periods. Levels of NE and E were similar in all animals at the beginning of the experiments, 186.6±40 and 101±29 pg/ml, respectively; baseline values at 0 time did not change for the next two experiments. Restraint stress markedly increased NE and E levels during the first exposure with peak levels of NE (1264±333 pg/ml; 576% as compared to 0 min) and E (1230±500 pg/ml; 1118%) occurring at 5 min during the first restraint period. Levels of NE (355±58 pg/ml) and E (288±137 pg/ml) were still significantly elevated 30 min after the stressor had been removed. Increases in E (about 1000%) were greater than those seen with NE (about 500%). The second restraint period showed a decrease in peak NE (250%; $p < 0.1$) and E (300% ; $p < 0.05$) levels. The third experiment demonstrated further adaptation since peak levels of NE (260%; $p < 0.05$) and E (235%; $p < 0.05$) continued to decline slightly. Studies of the effects of various drugs on the stress response are planned.

135 HYPERTENSIVE EFFECTS OF CEREBELLAR LESIONS IN THE FASTIGIAL NUCLEUS. Kenneth J. Dormer, Dept. of Physiology and Biophysics, Univ. of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

Colony-bred beagles were selected for long-term studies of arterial blood pressure (AP) both prior and subsequent to bilateral lesions in the rostral fastigial nucleus (FN) as an effort to examine the autonomic role of the nucleus in the conscious animal. Previous studies with dogs in my laboratory have described the hypertensive response to electrical stimulation of the FN in anesthetized and conscious dogs. The objective of the study was to verify the absence of mean AP changes following ablation of rostral FN. Four beagles (2 male, 2 female) were implanted under sterile procedure with solid state pressure transducers in descending aortae and AP and heart rate (HR) recorded on a monthly basis, for 24 hour sessions, up to 9 months following surgery. Animals were acclimated (1 month) to the laboratory environment and recording apparatus prior to chest surgery. The 24 hour studies were performed 2-3 months prior to lesioning and 1-4 months post-lesion. The 24 hr mean ± S.D. of all the mean AP's for 4 dogs was 102.6 ± 4.7 mmHg and HR was 69 ± 10.5 beats/min (ten-24 hr records). Next, the dogs were anesthetized with alpha-chloralose (110 mg/kg i.v.) and the regions of the rostral FN were stereotaxically implanted under sterile surgery with concentric bipolar electrodes. When the maximal pressor response was obtained, the site was then lesioned with RF current until the response could no longer be elicited. The 24 hr mean ± S.D. for 3 dogs beginning 1 month following surgery was 122 ± 5.1 mm Hg and heart rate was 81 ± 11.5 beats/min. All 4 dogs showed elevated mean AP and the fourth dog post-lesioning exhibited waking mean AP of 110 to 160 mm Hg, a pulse pressure of 175/110 and 100 mm Hg mean AP during sleep but the 24 hr mean was not yet available. These results were totally unexpected, however, a plausible explanation for the induced hypertension is that a chronic FN inhibitory tone to the reticular formation is removed which is only observable over a long time period. Nevertheless, these results are in conflict with the pressor response obtained by electrical stimulation in cats and dogs. This work was supported by NIH grant HL22747.

136 SOMATOSTATIN AND SOMATOSTATIN ANALOGS INHIBIT SYMPATHETIC NERVOUS SYSTEM ACTIVITY. David Fisher*, Wylie Vale and Marvin Brown (SPON: Jon Lindstrom). Peptide Biology Laboratory, The Salk Institute, La Jolla, CA 92037.

Somatostatin (SS) and SS analogs, e.g. des-AA^{1,2,4,5,12,13}-[D-Trp^{8}]-SS (ODT8-SS) placed intracisternally (ic) or intracerebroventricularly (icv) have been demonstrated to prevent the hyperglycemia, hyperglucagonemia, and hypoinsulinemia induced by bombesin given ic or icv. SS and SS analogs inhibit these humoral changes by preventing bombesin induced adrenomedullary epinephrine secretion. These experiments suggest that SS and SS analogs may act within the brain to decrease sympathetic nervous system (SNS) activity. Therefore, we have carried out studies to determine whether SS and SS analogs prevent activation of the SNS by other neural stimuli. Plasma epinephrine (E) and norepinephrine (NE) were measured using a radioenzymatic assay, i.e. enzymatic conversion of the catecholamines to their respective 3-methoxy derivatives in the presence of [^{3}H-methyl]S-adenosyl methionine. Treatments were administered icv to rats via chronic indwelling lateral ventricular cannulas, and blood samples taken from venous jugular catheters. Human β-endorphin (20μg) and carbachol (10μg) given icv, intravenous insulin (1.5U), and handling stress induce a significant rise in plasma glucose, glucagon and epinephrine. These humoral changes were completely prevented by simultaneous administration of ODT8-SS (1μg) icv. OTD8-SS (1μg) alone did not significantly lower basal catecholamines; however, a rise of E and NE occurs 60 minutes following treatment suggesting a post-inhibitory rebound. Further evidence that ODT8-SS acts to decrease SNS activity is based on the observation that it prevents the rise in NE following icv carbachol (10μg). Recent studies have suggested that spontaneously hypertensive rats (SHR) may have an overactive SNS. Administration of ODT8-SS (1μg) ic to SHR reduces systolic blood pressure from ca. 170 mmHg to ca. 100 mmHg for at least 60 minutes. These data provide strong pharmacologic evidence that SS and SS analogs, particularaly ODT8-SS, act within the CNS to modulate SNS activity. SS's role in normal and abnormal physiology of the SNS remains to be determined.

137 EFFECTS OF CENTRAL ADMINISTRATION OF ANGIOTENSIN II ON NOREPINEPHRINE INDUCED REFLEX BRADYCARDIA AND BARORECEPTOR PRESSOR RESPONSES IN CATS. J.S. Francis, A.S. Tadepalli and J.P. Buckley.* Inst. for Cardiovascular Studies, Univ. of Houston, Houston, Texas 77004.

Experiments were performed on cats anesthetized with chloralose-urethane, and artifically ventilated. Reflex bradycardia was induced by intravenous (I.V.) pressor doses of norepinephrine. Intraventricular (IVT) infusion of angiotensin II (AII) or its antagonist saralasin (SAR) was performed through a cannula in the lateral ventricle and the fluid exited through the cisterna magna. Infusion of AII (2-4 µg) produced a 20-40 mmHg increase in arterial pressure (AP) and slight increase in heart rate (HR). During the infusion of AII and for 30-40 min after, the reflex bradycardia induced by i.v. norepinephrine was significantly enhanced by 2-4 fold but the pressor responses to i.v. norepinephrine were not altered. Also during this time the HR and AP increases normally seen during bilateral carotid occlusions (BCO) were enhanced by 53% and 46% respectively. Infusion of the AII antagonist SAR (30-60 µg) IVT produced a significant lowering of AP but no change in HR. Pre-infusion of SAR blocked the AII induced increase in AP, and the enhancement of both the norepinephrine induced reflex bradycardia and the BCO pressor response. Systemic administration of AII or vasopressin which induced an equal rise in AP as that seen with IVT administrated AII, produced little change in the reflex bradycardia and no change in the BCO response. These results suggest that AII enhances the reflex bradycardia and BCO response by an action in the central nervous system and that SAR can prevent these effects.

138 BASIS FOR COMPLEX RHYTHM IN SYMPATHETIC NERVE DISCHARGE (SND). Gerard L. Gebber and Susan M. Barman. Dept. Pharmacol. & Toxicol., Michigan State Univeristy, East Lansing, MI 48824.

The cardiac-related rhythm in SND is transformed into a complex rhythm of brain stem origin (i.e., frequency of sympathetic nerve slow wave occurrence varies between 2-6 c/s) after baroreceptor denervation. The present study was designed to determine the basis for the complex rhythm. For this purpose, discharges recorded simultaneously from different postganglionic sympathetic nerves were compared before and after baroreceptor denervation (i.e., bilateral section of carotid sinus, aortic depressor and vagus nerves). The phase relations between slow waves in postganglionic nerves (e.g., internal and external carotid) which exit from the same sympathetic ganglion (i.e., intraganglionic recording) were fixed before and after baroreceptor denervation. As a consequence, crosscorrelation functions approached a value of one. Crosscorrelation analysis revealed a weaker relationship between slow wave activity recorded from postganglionic nerves (e.g., external carotid and renal) which exit from different sympathetic ganglia (i.e., interganglionic recording). The weaker relationship in the experiments with interganglionic recording was explained by marked shifts in the phase relations between slow wave activity from cycle to cycle of SND. Regarding this point, the distribution of intervals between the peaks of slow waves recorded from the external carotid and renal postganglionic nerves in 100 consecutive cycles of SND was 80±7 ms before baroreceptor denervation and 132±6 ms after baroreceptor denervation (6 experiments). Importantly, the shifts in phase relations between slow wave activity in the experiments with interganglionic recording far exceeded the range of conduction times in pathways from the brain stem to the external carotid and renal nerves (as determined from the range of onset latencies of sympathetic nerve potentials evoked by electrical stimulation of medullary pressor sites). These observations have led us to propose that the brain stem sympathetic network is comprised of a number of coupled oscillators, each of which is inherently capable of producing a 2-6 c/s rhythm in a separate group of postganglionic sympathetic neurons. Variations in the phase relations between slow wave activity in the interganglionic recording experiments further suggest that the complex form of the 2-6 c/s rhythm in SND results as the consequence of changes in the sequence of activation of coupled brain stem oscillators. That is, the leading brain stem focus is believed to shift from cycle to cycle of SND. (Supported by PHS Grant HL-13187.)

139 CENTRAL PHYSIOLOGICAL ORGANIZATION OF THE CARDIAC VAGUS. G. Steven Geis and Robert D. Wurster. Department of Physiology, Loyola University of Chicago, Stritch School of Medicine, Maywood, Illinois 60153.

Previous studies in this laboratory localized cardiac vagal preganglionic somata in the dorsal motor nucleus of the vagus (DMN) and the nucleus ambiguus (NA) in the cat (Neuroscience Abstracts 4: 20, 1978). The present study was designed to investigate the role of each nucleus in cardiac control.

Occipital craniotomies were performed in anesthetized cats and stimulating electrodes were inserted into the DMN or NA on either side of the neuraxis. A strain gauge arch was sutured to the right ventricle and catheters were inserted into the left and right ventricular chambers for monitoring left and right ventricular pressures, respectively. The strain gauge output and the rate of rise of the left ventricular pressure curves (dP/dt) served as indices of ventricular contractility (VC). Pacing electrodes were placed in the right ventricle. The DMN and NA were stimulated with and without cardiac pacing; before and after ipsilateral vagotomy. Electrode tip locations were histologically verified.

DMN stimulation produced decreases in mean arterial blood pressure (MABP), dP/dt and strain gauge output; no change in heart rate (HR) and increases in left and right ventricular end-diastolic pressures (LVEDP, RVEDP). NA stimulation produced decreases in HR and MABP and increases in dP/dt, strain gauge output, LVEDP and RVEDP. The responses to NA stimulation were abolished by ventricular pacing. The responses to stimulation of either nucleus were abolished by ipsilateral vagotomy.

VC changes could be secondary to HR, LVEDP or RVEDP alterations. Yet, LVEDP and RVEDP increases could not produce the VC decreases observed with DMN stimulation. Since the VC changes during NA stimulation were abolished by cardiac pacing, the responses were secondary to bradycardia.

The data suggest cardiac vagal preganglionic somata are organized according to physiological function. Cell bodies of the DMN control VC while NA somata are involved in HR regulation. (Supported by NIH Grant HL08682.)

140 EVIDENCE FOR INVOLVEMENT OF A CNS GABAergic MECHANISM IN REFLEX-INDUCED VAGAL BRADYCARDIA IN THE CAT. Richard A. Gillis* and Daniel J. Williford* (SPON: R. McGee). Dept. of Pharmacol., Schs. Med. & Dent., Georgetown Univ., Washington, D.C. 20007.

Previous studies have demonstrated that blockade of GABA receptors in nucleus ambiguus with microinjections of bicuculline in the cat increases central vagal tone to the heart (DiMicco et al.: Proceed International Congress of Pharmacol., p. 755, 1978). This effect was reversed by the GABA receptor agonist muscimol. These data suggested the existence of a GABAergic synaptic mechanism for the regulation of central vagal tone. To determine the physiological importance of this GABAergic system, the effects of drugs that modify CNS GABAergic synaptic transmission were tested on reflex-induced vagal bradycardia produced by activation of baroreceptors with i.v. bolus injections of phenylephrine. Chloralose-anesthetized cats were used and all drugs were administered into the fourth cerebroventricle. Administration of the GABA receptor agonist muscimol (2.5 to 12.5 ug) to six cats prevented approximately 85% of the reflex-induced vagal bradycardia produced by phenylephrine. This blockade was not due to antagonism of the pressor response of phenylephrine. Once blockade was present, administration of the GABA receptor antagonist bicuculline (25-30 ug) restored the reflex vagal bradycardia response to near normal. This occurred without alteration in the phenylephrine-induced pressor response. Administration of bicuculline alone (1-5 ug) enhanced reflex-induced vagal bradycardia. These results suggest that a CNS GABAergic synapse comprises part of the reflex vagal pathway in the cat.

141 DISCHARGE PROPERTIES OF VAGAL CARDIAC NEURONS DURING CONDITIONED HEART RATE CHANGE. Michael R. Gold and David H. Cohen. Dept. Physiol., Univ. of Virginia, Charlottesville, VA 22908.

Classically conditioned heart rate change in the pigeon has both vagal and sympathetic components. As part of a comprehensive effort to describe the discharge characteristics of the motoneurons mediating this response, the activity of vagal cardiac neurons was recorded in trained animals. As previously reported (Fed. Proc., 38, 1200), these neurons show a sustained decrease in discharge during the conditioned stimulus. This report now describes the discharge properties of such neurons during acquisition of the conditioned heart rate change.

Single cell activity was recorded from the intermediate rostrocaudal (cardiac) zone of the right dorsal motor nucleus in immobilized, artifically ventilated pigeons. Units were identified as cardiac efferents by previously established criteria based upon antidromic activation and conduction velocity (Brain Res., 147, 79-90). Thirteen animals were given 40 trials of conditioning training where a 6-sec light presentation was immediately followed by foot-shock. Ten sensitization control animals received 40 unpaired stimuli. The light initially evoked a small cardioacceleration that was differentially affected by training ($p<.02$), being enhanced by conditioning and attenuated by sensitization.

Regarding neuronal activity, the groups did not differ with respect to maintained discharge, and such discharge did not change significantly over training. The initial light presentation elicited a decrease in discharge that was most prominent during the initial 500 msec (phasic period) but persisted throughout the remaining 5500 msec of the light period (tonic period). In the conditioning group (10 cells) the phasic reduction in discharge increased in magnitude from 33% to 68% over training. The tonic decrease in discharge increased from 27% to 46%. In contrast, in the sensitization group (8 cells) the phasic response was attenuated from 35% to 18% and the tonic response from 33% to 8%. Thus, the groups changed differentially ($p<.001$). Further analysis indicated that the latency of the decrease in discharge was 120-160 msec for both groups early in training. However, in the conditioning group this latency shortened to less than 100 msec, while in the sensitization group it increased to almost 200 msec.

These results clearly indicate vagal involvement in conditioned cardioacceleration. Moreover, the vagal contribution is synergistic with that of the sympathetic cardiac innervation which shows phasic and tonic increases in discharge during conditioned stimulus presentation. (Supported by NSF grant BNS 75-20537 and NIH grants P01 NS14620 and T32 HL07284)

142 MODIFICATION BY LIGHT HALOTHANE ANESTHESIA OF THE CARDIOVASCULAR CHANGES ASSOCIATED WITH REM SLEEP IN THE CAT. Richard E. Hall, Eduardo H. Rubinstein and Richard W. Patterson.* Depts. of Physiology and Anesthesiology, Sch. Med., UCLA, Los Angeles, CA 90024.

Anesthetic sleep induced by the inhalation agent halothane is manifest by a persistent high voltage EEG pattern superimposed on a background of 10-14/sec low voltage activity. We have observed in chronic instrumented cats that light stages of halothane anesthesia were associated with the EEG desynchronization and rapid eye movement bursts characteristic of REM sleep. These changes occurred together with a marked drop in arterial pressure and heart rate that persisted for the duration of the REM episode. The cardiovascular responses differed from those observed during natural REM episodes, especially the extent and direction of the heart rate changes. Commonly, the transition to the REM stage is marked by an initial bradycardia followed by transient episodes of cardioacceleration that are associated with the REM bursts. The variability of the heart rate changes during natural REM sleep may depend on the superimposition of a tonic inhibition of cardiac sympathetic activity with a phasic inhibition of vagal activity. This assumption was based on work by others and on the effects of pharmacological agents on heart rate changes during natural REM sleep. Typically, propranolol, a beta blocking agent (0.2 mg/kg) decreased resting heart rate, prevented the REM associated bradycardia but did not block the phasic cardioacceleration associated with the REM bursts. Conversely, atropine (0.06 mg/kg), at a dose sufficient to block cardiac cholinergic receptors without altering the EEG, increased resting heart rate but did not affect the bradycardia associated with the onset of the REM stage and prevented the display of the transient episodes of tachycardia. The effect of light halothane anesthesia on heart control during REM sleep resembled that of atropine, in that the phasic tachycardia was abolished with preservation of the tonic decrease in heart rate. This apparently selective effect of halothane blocking phasic vagal control may be exerted on the CNS area that couples the phasic somatic changes displayed during REM sleep (REM bursts, tachypnea) with the vagal control. The present observations indicate that light halothane anesthesia may have differential effects on central autonomic control and on sleep mechanisms and that the detection of EEG desynchronization during clinical light halothane anesthesia may correspond to REM sleep and not to an arousal response.

143 RESPIRATORY DYSFUNCTION IN IDIOPATHIC ORTHOSTATIC HYPOTENSION, Robert W. Hamill, Carol K. Petito* and Ira B. Black. Depts. of Neurol. and Pathol., Cornell Univ. Med. Col., New York, N.Y. 10021.

The Shy-Drager variant of Idiopathic Orthostatic Hypotension (IOH) is a progressive multisystem degenerative disorder which begins during middle age and is associated with autonomic and extrapyramidal system dysfunction. Recently, respiratory abnormalities such as periodic respirations and sleep apnea have been described, but the occurrence of laryngeal stridor has received little attention. We report three patients with Shy-Drager syndrome in whom laryngeal stridor developed. The clinical picture and correlative neuropathological findings will be presented.

Laryngeal stridor presented a variable clinical picture in our patients. The first patient developed acute stridor, vocal cord paralysis and esophageal dysfunction early in the course of his disease and required intubation and tracheostomy. The second patient developed acute stridor with irregular respiration late during the course of his disease. The third patient developed intermittent stridor and irregular respirations.

To define the histological substrate of these respiratory abnormalities, lower cranial nerve nuclei and brain stem respiratory areas were examined in autopsy material obtained from these patients. Similar brainstem areas were examined in autopsies of 30 age-matched control patients. In the first patient, microscopic examination showed gliosis in the nucleus ambiguus (NA), tractus solitarius (TS), and nucleus of tractus solitarius (NTS). Pathological examination of the second patient revealed gliosis in the NA, and gliosis, dystrophic axons and one area of phagocytosis in the TS and NTS. In the third patient, microscopic studies showed focal neuronal phagocytosis with a glial nodule in the NA, and diffuse gliosis in the medullary tegmentum.

Control patients, aged 40-80, exhibited mild gliosis in the medullary tegmentum with only one patient exhibiting increased gliosis in the NA and NTS. These observations suggest that laryngeal stridor is associated with degenerative changes in the NA, and possibly NTS, in the Shy-Drager variant of IOH.

144 GABA CONTENT AND SPECIFIC BINDING IN A NUCLEUS ASSOCIATED WITH CENTRAL VAGAL OUTFLOW IN THE CAT. Betty L. Hamilton, Sandra C. Brown*, Wesley P. Norman*, Janette Dias Souza*, Karen Gale*, & Richard A. Gillis*. Depts. Pharmacol. & Anat., Schs. Med. & Dent., Georgetown Univ., Washington, D.C. 20007.

In previous studies (DiMicco et al.: Proceed. 7th International Congress Pharmacol., p. 755, 1978), blockade of GABA receptor function by direct microinjection of bicuculline into the nucleus ambiguus (NA) of cats produced a marked dose-related depression of heart rate which was mediated by the vagus. This effect was not obtained in other regions of the brainstem and was reversed by the GABA receptor agonist muscimol. These data suggested that the NA may be the site of a GABA receptor mediated inhibition of vagal outflow. The purpose of the present study was to determine (1) whether GABA is present in the NA, and (2) whether there are receptors for GABA in the NA. GABA content and specific binding for tritiated GABA was measured in NA as well as in several other CNS regions. To determine GABA levels, an enzymatic spectrophotofluorometric method was used. [^{3}H]-GABA binding was done on frozen and Triton X-100 treated membrane preparations. GABA content of NA was 24.4 nmol/mg protein. This level was similar to that found in caudate nucleus (28.4 nmol/mg protein), and was approximately 2.5-fold higher than the level found in surrounding reticular nuclei. Specific [^{3}H]-GABA binding in NA (120 femtomoles/mg protein measured at a concentration of 30 nmol [^{3}H]-GABA) was slightly lower than that in substantia nigra (180 femtomoles/mg protein), and was approximately 3-fold higher than the specific [^{3}H]-GABA binding obtained in tissue from surrounding reticular nuclei. This demonstration of the presence of GABA and specific binding sites for GABA in NA provides further evidence for GABAergic synaptic regulation of neural activity in nucleus ambiguus.

145 CHANGES IN CENTRAL CHOLINERGIC NEURONS IN SPONTANEOUSLY HYPERTENSIVE RATS (SHR). Cinda J. Helke, Eric A. Muth* and David M. Jacobowitz. Lab. Clin. Sci., NIMH, Bethesda, Md. 20205.

Recent pharmacological studies demonstrate that CNS cholinergic mechanisms which may be involved in blood pressure control (Europ. J. Pharm. 29:262, 1974; Clin. & Exptl. Hypertension 1: 219, 1978) are altered in SHR (JPET 206: 644, 1978). In order to investigate whether biochemical differences in cholinergic neurons of discrete brain nuclei exist between 4, 8 and 12 wk old SHR and aged matched Wistar Kyoto (WKY) control rats, the activity of choline acetyltransferase (ChAT) was measured in numerous microdissected brain nuclei. ChAT activity is a specific marker for cholinergic nerves and changes in its activity have been correlated with changes in impulse flow in cholinergic neurons (Experientia 34: 1247, 1978). The acetylcholine (ACh) concentration was also measured in hindbrain nuclei of 12 wk old SHR and WKY.

Changes in ChAT activity of several nuclei were observed in SHR of all three age groups. The greatest alteration (79% increase) was found in the ChAT activity of the locus coeruleus of 12 wk old SHR rats. A 31% increase in ACh content was also detected. No differences were found in this nucleus in 4 or 8 wk old SHR. Other nuclei known to be involved in blood pressure control which showed differences in ChAT activity in SHR compared to WKY rats were the paraventricular nucleus (36% decrease in 4 wk SHR), dorsomedial nucleus of the hypothalamus (19% and 23% decrease in 8 and 12 wk SHR, respectively), posterior hypothalamus (25% decrease in 12 wk SHR) and the nucleus reticularis gigantocellularis (28% increase and 18% decrease in 4 and 8 wk SHR, respectively). A significant increase in the ChAT activity of the anterior ventral thalamus was detected in 4 and 8 wk SHR.

The data from this study demonstrate that cholinergic nerves in certain rat brain areas, several of which play a role in cardiovascular control, are altered in SHR. Of particular interest is the change in the cholinergic input to the locus coeruleus of 12 wk but not 4 or 8 wk old SHR. The fact that the 4 wk SHR are not hypertensive and the 8 wk SHR are still in the developmental stages of BP elevation compared to the 12 wk SHR suggests secondary changes in the nucleus in response to the hypertension. Kawamura et al. (Brain Res. 140: 137, 1978) suggest on the basis of their findings of alterated BP response to electrical stimulation of the locus coeruleus in SHR that the locus coeruleus may sensitize the descending depressor systems in an attempt to combat the hypertension. In view of the wide distribution of noradrenergic nerves of the locus coeruleus in the brain and spinal cord, further exploration of this cholinergic noradrenergic connection is warranted.

146 SMALL, INTENSELY FLUORESCENT CELLS OF SUPERIOR SYMPATHETIC GANGLION CONTRASTED IN GUINEA PIG AND RABBIT. Jean Jew. Dept. Anat., Coll. Med., Univ. of Iowa, Iowa City, IA 52242.

Dopamine, released from the small, intensely fluorescent (SIF) cell, is believed to elicit the slow inhibitory postsynaptic potential (s-IPSP) identified in the rabbit principal ganglionic neuron (PGN). The schema postulated involves an interneuron, possibly the type I SIF cell (Williams et al., in SIF Cells, Fogarty International Center Symposium, O. Eränkö, ed., pp. 143-162, 1977) which is solitary and has long processes directed among the PGNs.

The guinea pig superior sympathetic ganglion differs from the rabbit in being almost devoid of type I SIF cells. SIF cells in the guinea pig ganglion are much more numerous and, in addition, norepinephrine instead of dopamine has been identified as the transmitter present in the SIF cells. The guinea pig also lacks a dopamine receptor-adenylate cyclase complex, which is present in the rabbit. Since no s-IPSP has been found in the guinea pig, it was hypothesized that the interneuron (assumed to mediate this hyperpolarizing membrane change in the rabbit) would be absent.

5-OH-DA (100mg/kg dissolved in saline with 0.1% ascorbic acid) was administered i.p. to guinea pig and rabbit to mark catecholamine-containing vesicles for electronmicroscopy. After perfusion with a solution of 2.5% glutaraldehyde/1% paraformaldehyde in 0.1M Sorensen's phosphate buffer (pH 7.3), the superior cervical ganglia were removed and processed for electronmicroscopy. After localization of SIF cells using semithin sections, thin sections were stained with uranyl acetate and lead citrate and surveyed in a Philips 201 electronmicroscope.

The ultrastructural characteristics of the SIF cells and their connections are summarized as follows: Rabbit: Clustered and solitary SIF cells were distinguished by their conspicuous and large electron-dense vesicles. Presumptive SIF cell processes containing large and small dense vesicles could seldom be traced directly from the cell of origin (leaving the possibility that some were recurrent collaterals of PGNs). Terminals of cholinergic type synapsed on the SIF cells. SIF cell processes synapsed on presumed PGN dendrites. Guinea pig: Intraganglionic SIF cells received cholinergic inputs. However, their processes made synaptic contact with cell bodies and processes of other SIF cells. Thus there are associative synaptic connections between SIF cells in the guinea pig ganglion. Some of the smallest processes receiving SIF cell efferents were not identifiable. (Supported by HL 21914.)

147 Chemically Sensitive Vagal Endings in the Airways: Their Stimulation by Bradykinin. M.P. Kaufman, H.M. Coleridge*, J.C.G. Coleridge* & D.G. Baker*. Cardiovas. Res. Inst., UCSF, San Francisco, CA 94143.

Bradykinin (BK) is a potent algesic substance released in the lung in asthma and pulmonary anaphylaxis. Inhalation of BK aerosol causes cough and retrosternal irritation in normal subjects, and reflex bronchoconstriction in asthmatics and in some normal subjects also; it has little or no direct bronchoconstrictor effect in humans or dogs. We recorded activity in afferent vagal fibers in anesthetized dogs, in order to determine which lung receptors were stimulated by BK. We injected 20 ug BK into the right or left atrium, and examined its effects on pulmonary C fiber endings (J receptors), rapidly adapting receptors with myelinated fibers (irritant receptors) and bronchial C fiber endings. We also injected 1.5 ug BK directly into the bronchial circulation, and examined its effects on rapidly adapting receptors and bronchial C fiber endings, since both are in airways supplied by the bronchial arteries. Right atrial injection of BK had little effect on pulmonary C fibers, although their endings are directly accessible from the pulmonary circulation. Left atrial or bronchial arterial injection of BK stimulated 13/23 rapidly adapting receptors; the maximum increase in activity was from 3 to 6 impulses/sec; effects were usually brief, and if more prolonged, receptors fired with each cardiac cycle, suggesting that stimulation was secondary to the vasodilator properties of BK. (Rapidly adapting receptors in dogs fire up to 40-50 impulses/sec in response to bronchoconstrictor agents or to hyperinflation of the lung.) BK stimulated 13/14 bronchial C fibers. In 3 dogs (7 fibers) activity increased from less than 1 to 7-15 impulses/sec, and remained elevated for 1 min or more; in 4 dogs (6/7 fibers) the response consisted of brief bursts of spikes with several seconds of silence between. We conclude that there may be individual differences in afferent susceptibility to BK in dogs, as in humans, but that stimulation of bronchial C fibers probably accounts for its irritant effects on the respiratory tract. (Supported by NIH grants HL-06285 and HL-07192.)

148 PHASE SHIFTING OF THE RESPIRATORY CYCLE PRODUCED BY ELECTRICAL STIMULATION OF THE MEDIAL PONTINE RETICULAR FORMATION. C.K. Knox, Laboratory of Neurophysiology, Department of Physiology, University of Minnesota Medical School, Minneapolis, MN 55455

The pathways and mechanisms underlying the effects of reticular stimulation on respiration are not well understood. It is possible that such stimulation affects respiration directly at the brainstem level, or, as Anderson and Sears (J. Physiol., London 209) have suggested, only indirectly at the spinal level via reticulospinal pathways separate from those conveying respiratory rhythm. To test the first possibility, the medial pontine reticular formation of decerebrate spontaneously breathing cats was stimulated with short bursts of rectangular pulses (100μsec, 10 pulses at 100 pps), while noting the stimulus strength required to cause inspiratory to expiratory (I→E) or expiratory to inspiratory (E→I) phase switching of the phrenic discharge. Within medial pons, two regions could be identified from which I→E or E→I switching could be obtained: An I inhibitory region dorsally situated in the gigantocellular tegmental field, and an I facilatory region in the ventral magnocellular tegmental field. Depth/switching threshold profiles were defined for stimuli delivered halfway into inspiration or expiration. Throughout the medial pons, two depths were found at which thresholds for either I→E or E→I switching were at a minimum, with the thresholds increasing in the dorsal and ventral directions from these positions. When delivered to minimum threshold I→E switching sites at various times in inspiration, stimuli of greater strength were required for switching early as compared to late in the phase. Bivagotomy lengthened the time course of this threshold curve but did not alter its magnitude. Stimuli delivered to minimum threshold E→I switching sites at different times in expiration, revealed a similar time-dependent decrease in stimulus strength for phase switching. Stimulus bursts which caused I→E switching resulted in a decrease of the ensueing expiratory time; whereas, stimuli which caused E→I switching brought on a normal phrenic discharge. From these results it is concluded that medial pontine reticular structures can affect the respiratory phase switching mechanisms directly at the brainstem level. (NIH Grant #HL16430)

149 MECHANISM OF REGIONAL VASCULAR RESISTANCE CHANGES PRODUCED BY ACTIVATION OF A PERIVENTRICULAR-PERIAQUEDUCTAL DESCENDING PATHWAY. Mark M. Knuepfer*, A.K. Johnson*, and M.J. Brody* (SPON: R.K. Bhatnagar) Depts. Pharmacology and Psychology and Cardiovascular Ctr., The University of Iowa, Iowa City, IA 52242.

Our laboratory has reported that the integrity of the anteroventral third ventricle (AV3V) region is necessary for the manifestation of many forms of experimental hypertension. We have also reported that descending neuronal tracts from this region pass through the central gray since a lesion in this area will significantly attenuate the hemodynamic changes seen with AV3V stimulation. This study was designed to examine the effects of adrenalectomy and peripheral adrenergic blockade on regional vascular responses to central stimulation of the pathway. Bipolar electrodes were placed in the AV3V region and the rostral central gray (CG) a minimum of two days before experimentation. Rats were anesthetized and cannulated for arterial pressure determinations and for intravenous administration of drugs. Regional blood flows were determined using miniaturized pulsed Doppler flow probes placed on the renal and mesenteric arteries and the lower abdominal aorta. Electrical stimulation of the AV3V and the CG was done using 14V, 0.5 msec pulses at varying frequencies. Stimulation of the AV3V or the CG region elicited a frequency-dependent decrease in hindlimb vascular resistance and mesenteric and renal vasoconstriction. After bilateral adrenalectomy, the mesenteric and renal responses to both AV3V and CG stimulation were significantly attenuated. The hindlimb vasodilator response was attenuated by adrenalectomy for CG stimulation but not for AV3V stimulation. Intravenous infusion of epinephrine (1-2 μg/kg/min) resulted in vascular resistance changes similar to those produced by central stimulation of these two sites. After adrenalectomy, blockade (using phentolamine or guanethidine) further reduced vascular responses to central stimulation. In summary, catecholamines released from the adrenal medulla appear to play a role in vasoconstrictor responses elicited by AV3V and CG stimulation. In addition, adrenal catecholamines appear to be a significant factor in CG-induced hindlimb vasodilation. We conclude that electrical activation of the descending pathway between AV3V and CG produces complex integrated regional vascular responses mediated by both efferent sympathetic innervation and circulating catecholamines released by central activation of the adrenal medulla. 150 CNS EFFECTS OF α-METHYLDOPA ON TWO NONCARDIOVASCULAR AUTONOMIC SYSTEMS. Michael C. Koss. Departments of Pharmacology and of Ophthalmology and McGee Eye Institute, Univ. of Okla. Health Sciences Center, Okla. City, OK 73190.

In addition to well established CNS sympatho-inhibitory effects on the cardiovascular system, clonidine has also been shown to exert actions on other autonomic systems. For example, clonidine inhibits centrally evoked electrodermal responses (Europ. J. Pharmacol. 37: 71, 1976) and produces pupillary dilation in cats primarily by means of inhibition of central parasympathetic outflow to the iris (Invest. Ophthal. 15:566, 1976). Both of these noncardiovascular effects of clonidine are antagonized by CNS α-adrenergic antagonists such as yohimbine. α-Methyldopa (α-MD) has also been shown to exert a therapeutically effective hypotension and, like clonidine, it is suggested that this agent also acts (indirectly) to stimulate CNS α-adrenergic receptors. The present study was undertaken to determine if α-MD also causes clonidine-like effects on the sympathetic-cholinergic electrodermal system and pupil.

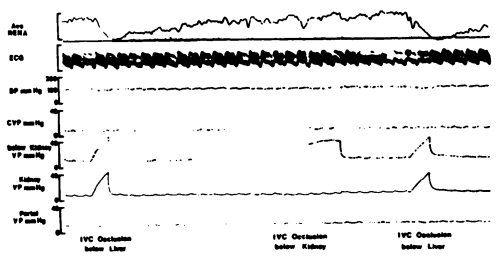
Experiments were performed on cats anesthetized with α-chloralose (60 mg/kg, i.p.) or pentobarbital (36 mg/kg, i.p.). Intravenous administration of α-MD (30 and 100 mg/kg, i.v.) caused a dose related decrease in the amplitude of electrodermal responses evoked by stimulation of the posterior hypothalamus. The peak effects were observed approximately 3 hr after injection. Administration of yohimbine hydrochloride (0.5 mg/kg, i.v.) partially reversed this α-MD sympatho-inhibition. With respect to the pupil, α-MD also caused a dose related mydriasis which was antagonized by yohimbine. Again the peak effects were not observed for 2.5-3 hr after administration. Yohimbine pretreatment abolished the α-MD-induced pupillary dilation but did not prevent mydriasis in response to epinephrine. In contrast, phenoxybenzamine pretreatment (2 mg/kg, i.v.) blocked the epinephrine but not the α-MD pupillary actions. These results were confirmed in experiments utilizing direct ciliary nerve recordings.

The present observations suggest that α-MD acts in a manner similar to clonidine on these two noncardiovascular systems and that an α-adrenergic inhibitory mechanism may be involved. The long time course to reach the maximal effects suggests that α-MD is converted to an active metabolite (i.e. α-methyldopamine or α-methylnorepinephrine).

(Supported by USPHS Grant NS 14039)

151 RENAL VENOUS CONGESTION RECEPTORS THAT CAN REFLEXLY ALTER RENAL AND CARDIAC SYMPATHETIC EFFERENT NERVE ACTIVITY. David R. Kostreva, Angel Castaner*, and John P. Kampine*. Depts. of Anesthesiology and Physiology, Medical College of Wisconsin and Wood VA Medical Center, Milwaukee, WI 53193.

Occlusion of either the left or right renal vein in open chested dogs resulted in a short latency inhibition of renal (RSENA) and cardiopulmonary (CPSENA) sympathetic efferent nerve activity before and after bilateral vagotomy. Mongrel dogs, 20-30 kg, were anesthetized using sodium pentobarbital, 35 mg/kg i.v. The animals were intubated and placed on positive pressure ventilation. The chest was split transversely to allow access to both stellate ganglia and the ansae subclaviae, CPSENA was recorded from the cut central end of either the left or right ansae. RSENA was recorded from the cut central end of a renal nerve. The SENA was amplified, filtered and time averaged using a half-wave rectifier. Central venous pressure, and renal venous pressure were monitored from catheters inserted into the femoral veins. Systemic blood pressure and left ventricular pressure were monitored from catheters inserted into the femoral arteries. The electrocardiogram (ECG) was monitored from leads placed in a lead II configuration. Heart rate was measured using a tachograph. The averaged RSENA, CPSENA, ECG, heart rate, and pressures were recorded using a polygraph. Occlusion of either the left or right renal vein, or as shown in the figure below, occlusion of the inferior vena cava (IVC) below the liver but just above the renal veins resulted in a marked increase in renal venous pressure and a reflex inhibition of RSENA and CPSENA. Heart rate, left ventricular pressure



and systemic blood pressure all decreased during occlusion of one renal vein or the IVC above the kidney. IVC occlusion below the renal veins did not alter RSENA or CPSENA. (Supported by NIH HLBI Young Investigator Research Award HL 21042 and Grant 16511, and the Med. Research Service of the VA).

152 DO SYMPATHETIC NERVES CONTROL CARDIAC GROWTH? C. Lau*, R. Morgan*, D.L. Bareis* and T.A. Slotkin. Dept. Pharmacol., Duke Univ. Med. Ctr., Durham, N.C. 27710

Development of the rat heart involves two growth phases: (1) in the first 2-3 weeks of postnatal development rapid replication of myocardial cells occurs, associated with high rates of DNA synthesis, (2) thereafter, DNA synthesis and cell replication terminate and further growth occurs by cardiac muscle hypertrophy involving RNA and protein synthesis. Previous studies have implicated involvement of sympathetic tone in both growth phases. Exposure of the neonatal rat heart to sympathetic neurotransmitters elicits a decline in DNA synthesis and an elevation in protein synthesis (Claycomb, J. Biol. Chem. 251, 6082, 1976) and in adults, sympathomimetics have long been known to cause cardiac hypertrophy. These data, together with the progressive developmental increase in endogenous stores and uptake of norepinephrine (NE) prompted the proposal that adrenergic innervation might control cardiac muscle differentiation and growth. In the present study, this hypothesis was tested by giving the neurotoxic adrenergic neuron blocking agent, guanethidine (50 mg/kg s.c.) daily to rats for 21 consecutive days to produce long-term peripheral sympathectomy in both neonatal and mature rats. Heart growth of sympathectomized animals was monitored by developmental increases in organ weight, RNA and protein synthesis. Ontogeny of the sympathetic nerve terminal was measured by the ability of synaptic vesicle preparations to take up radiolabeled NE. A 3-fold developmental increase in vesicular uptake was obtained in control rats from 2 to 40 days of age. In contrast, guanethidine treated rats did not show nerve development beyond the level reached at 2 days of age. Physiological response (heart rate change) to tyramine, which acts by displacement of NE from the sympathetic terminal, was deficient in guanethidine-treated rats, and postsynaptic supersensitivity of cardiac β-receptors (isoproterenol-induced tachycardia) was present throughout development. These biochemical and physiological indices show that sympathetic nerve destruction by guanethidine was taking place and that a sufficient lesion was obtained to interfere with basal sympathetic function. Despite the clearcut effectiveness of guanethidine to prevent formation of functional adrenergic innervation of the heart, no significant alterations in heart growth were observed in the developing rats. Results similar to those seen in the developing neonate were obtained in mature rats after chronic guanethidine treatment, i.e. no effect of sympathectomy on heart growth. These results suggest that the presence of sympathetic innervation is not obligatory for normal growth of the heart to occur. (Supported by USPHS HD-09713 and DA-00006).

153 FOUR CENTRAL NERVOUS SYSTEM SITES PROJECT TO THE PANCREAS. W. Laughton* and T.L. Powley* (SPON: Lynda Uphouse). Dept. Psychol., Yale University, New Haven, CT 06520.

Central nervous system sites projecting to the rat pancreas were identified and mapped using retrograde axonal transport of horseradish peroxidase (HRP). A total of 50ul of 30% (w/v) HRP (Sigma, Type VI) was injected into the pancreas of each animal (n=12). After 48 hours, the animals were sacrificed, and their brains and spinal cords were processed for HRP with the tetramethylbenzidine procedure (Mesulam, J. Histochem. & Cytochem. 26: 106-117, 1978). Serial 42u sections of the tissue from the sacral cord to the caudal pons were saved and systematically analyzed for HRP reaction product.

Four well organized cell groups--two in the medulla and two in the spinal cord--were found to project to the pancreas. The largest number of cells with HRP reaction product formed a coherent group occupying the medial two-thirds of the dorsal motor nucleus (DMV) bilaterally at the rostrocaudal level of the area postrema. Another tightly clustered, smaller population of cells was identified in the rostral pole of the nucleus ambiguus (NA). Thus, consistent with some degree of topographic organization, the labeled neurons were confined to specific regions of both the DMV and the NA. Labeled cells in the spinal cord were organized in two columns. One column occurred bilaterally in the cervical cord (C2 to C3), and the other bilaterally in the lower thoracic region (approximately T5 to L1); both spinal cell groups were located in the ventral horn, not the classic autonomic nucleus of the lateral horn. With the exception of a few isolated cells that were found along the intra medullary course of the vagal fibers (and that appeared to be "displaced" DMV neurons), no other CNS cell populations projecting to the pancreas were identified. In additional animals, HRP treatment of the proximal cut end of the cervical vagus high in the neck labeled the two pancreas cell groups in the medulla as well as the remainder of the neurons in the DMV and NA (virtually all ipsilateral to the nerve soak), but not the two columns in the spinal cord.

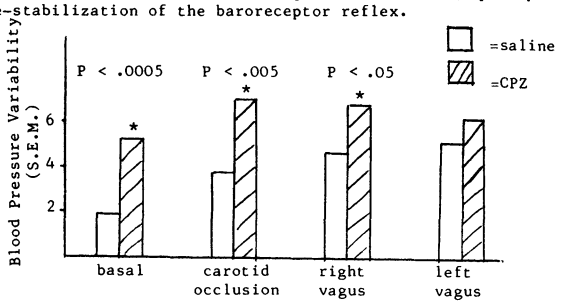
154 EFFECTS OF CHLORPROMAZINE ON BLOOD PRESSURE AND THE BARORECEPTOR RELFEX. A. L. Loeb* and R.J. Anderson. Dept. Pharmacol., Geo. Washington U., Washington, D.C. 20037.

The baroreceptor reflex in α-chloralose anesthetized cats was stimulated by (1) complete carotid occlusion and electrical stimulation of the (2) right and (3) left vagus nerves. Chlorpromazine (CPZ) was administered in cumulative doses of 0.0156, 0.0313, 0.0625, 0.125, 0.25, 0.50, 1.0, 2.0, and 4.0 mg/kg over an approximately 4-hour time period. CPZ produced no significant change in basal heart rate or blood pressure over time. The mean blood pressure response to each of the 3 test stimuli was not affected in a dose related fashion. Also, the latency between carotid occlusion and maximum increase in blood pressure was not significantly affected by CPZ.

However, in nearly all animals CPZ (n=8) produced a more variable basal blood pressure ($p < .0005$) than in control animals (n=8). In some cases CPZ caused a repetitive oscillation in blood presure (frequency=.7/min) whose duration was dose-dependent. CPZ also resulted in a more variable blood pressure response to carotid occlusion ($p < .005$) and to right vagal stimulation ($p < .05$). The response to left vagal stimulation was not significantly affected by CPZ. These effects are shown below.

In three additional cats, each receiving single rather than cumulative doses of CPZ, the drug produced marked decreases in blood pressure. In two of these, the blood pressure returned toward the pre-drug value within 30 min.

The results show that although mean blood pressure and the baroreceptor reflex are not depressed by CPZ, the drug results in more variable blood pressure control, perhaps by de-stabilization of the baroreceptor reflex.



155 ANATOMICAL EVIDENCE THAT THE A5 CATECHOLAMINE CELL GROUP IS A VASOMOTOR CENTER. A.D. Loewy, S. McKellar, and C.B. Saper. Dept. Anat. and Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

The A5 catecholamine cell group (Dahlström and Fuxe, '64) lies dorsal and lateral to the superior olive and medial to the root of the VIIth cranial nerve.

Two lines of anatomical evidence indicate that the A5 cell group projects to medullary and spinal vasomotor centers. First, stereotaxic injections of ^3H amino acids were made in the A5 cell group in rats. As demonstrated by autoradiography, a spinal projection from this area descends via the dorsolateral funiculus to the intermediolateral and intercalated sympathetic cell groups of the thoracic and upper lumbar spinal cord. There are also descending projections to the medial and paramedian reticular formation, the medial and parvocellular regions of the solitary complex, and the dorsal motor nucleus of the vagus. After similar injections in animals pretreated with 6-hydroxydopamine (2x250 µg, intraventricularly), there was no evidence of a spinal projection. Second, we used the combined histofluorescence-retrograde cell labeling technique of Blessing et al. ('78) to show that the A5 catecholamine cells are retrogradely labeled after injections of HRP into the T1-T2 spinal cord. Control injections of HRP into the femoral vein or subarachnoid space at the T1 levels failed to label the A5 neurons. To provide further evidence, we studied the retrograde labeling pattern in the A5 cell group of rats that had received 6-hydroxydopamine injections in the lateral ventricle and this treatment abolished virtually all retrograde cell labeling in this area from HRP injections in the spinal cord.

These observations indicate that the A5 cell group is one source of the noradrenergic input to vasomotor centers of the medulla and spinal cord.

Supported by USPHS grant NS 12751 and American Heart Association grant 77 797.

156 SPECTRAL ANALYSIS OF HEART RATE DURING DEPRESSOR NERVE STIMULATION: THE VALIDATION OF A NON-INVASIVE ESTIMATE OF VAGAL TONE. Philip M. McCabe*, Stephen W. Porges*, and Brandon G. Yongue* (SPON: C. S. Carter-Porges). Neural and Behavioral Biol. Prog. and Dept. Psych., Univ. Illinois, Urbana, IL, 61801.

An experiment is described which addresses the potential for non-invasive assessment of vagal tone to the heart. Previous research has demonstrated that respiratory sinus arrhythmia (RSA) is mediated primarily through the vagus and that quantitiative evaluation of the magnitude of RSA provides an accurate estimate of vagal tone in the anesthesized preparation. This research focuses on the validation of a statistical method of detecting shifts in vagal tone based on the heart rate variance (HRV) which is associated with respiratory influences. In the preparation used in this study, respiratory influences are the primary source of HRV. In unanesthetized preparations behavioral and physiological influences may affect the variability of heart rate. Therefore, it is necessary to partition the respiratory influence on HRV from the total HRV. Spectral analysis, applied to heart rate, can decompose the HRV into its constituent frequencies. Thus, the HRV distributed across the respiratory frequencies may be used to quantify a component of HRV which may be sensitive to shifts in the vagal tone to the heart.

To assess this method, the aortic depressor nerve (ADN) of anesthetized rabbits was stimulated for 30 seconds (.1 msec pulse duration, 100 pps, .05-2mA). The stimulation, independent of current level, produced a reflex bradycardia. Since stimulation of ADN increases vagal efferent activity to the heart, spectral analysis was applied before and during stimulation. ADN stimulation increased HRV associated with the respiratory frequencies in all animals at all currents tested. This supports the contention that the spectral estimate of this component of HRV is sensitive to increases in vagal tone to the heart.

β-adrenergic blockade (propranolol, i.v., 2 mg/kg) did not decrease the change in the spectral estimate of vagal tone during stimulation. Cholinergic blockade (atropine methyl nitrate, i.v., 2 mg/kg) decreased the spectral estimate of vagal tone and eliminated the bradycardia response to aortic nerve stimulation. During the β-adrenergic blockade there was an apparent current intensity-vagal tone relationship. This implies that differing amounts of vagal stimulation will be manifested in a monotonic fashion in the spectral estimate of vagal tone. Subsequent research will investigate the applicability of non-invasive recording and spectral analysis in the unanesthetized, freely moving preparation. These data suggest that the spectral analysis of heart rate may provide a method for the non-invasive estimation of vagal tone to the heart. 157 ANALYSIS OF THE ROLE OF CALCIUM IN RHYTHMIC HYPERPOLARIZATIONS INDUCED BY THEOPHYLLINE IN BULLFROG SYMPATHETIC NEURONS. S.M. McCort* and F.F. Weight. Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, Md. 20852

In previous investigations, theophylline was found to prolong the duration of a calcium sensitive potassium conductance in the spike after hyperpolarization (Busis & Weight, Nature 263, 434, 1976). In that study, using sucrose gap recording, theophylline also produced an increase in baseline noise. In this study we investigated the cellular origin of that "noise" by recording intracellularly from neurons in the ninth or tenth paravertebral sympathetic ganglion of the bullfrog. Superfusion with a Ringer's solution containing 5 mM theophylline induced a slow depolarization of the membrane. The depolarization occured over 5-15 min. and was usually 10-15 mV in amplitude. In addition, spontaneous hyperpolarizations were observed in approximately 60% of the neurons. The amplitude of these hyperpolarizations varied between 5-20 mV and the duration between approximately 30 sec. - 45 sec. The hyperpolarizations reoccured rhythmically approximately every 3-6 min. During the spontaneous hyperpolarizations membrane resistance was decreased.

Since theophylline potentiates a calcium sensitive potassium conductance in the spike after hyperpolarization of these neurons, we analyzed the role of calcium in the spontaneous hyperpolarizations. Superfusing the ganglia with a calcium-free Ringer's solution resulted in a decreased frequency or a complete abolition of the rhythmic hyperpolarizations. Dantrolene also decreased the frequency or completely abolished the occurance of the rhythmic hyperpolarizations. In muscle, dantrolene has been found to block the intracellular release of calcium ions (Desmedt and Hainaut, J. Physiol., 265 565, 1977). These data suggest involvement of both extracellular and intracellular release of calcium ions in the generation of theophylline induced rhythmic hyperpolarizations.

158 CHANGES IN THE ORGANIZATION OF THE MICTURITION REFLEX PATHWAY (MRP) IN THE CAT FOLLOWING TRANSECTION OF THE SPINAL CORD. Richard J. Milne* and William C. deGroat, Dept. Pharmacol., Univ. of Pittsburgh, Pittsburgh, PA 15261

Previous studies showed that micturition in cats with an intact neuraxis was dependent upon a sacral spinobulbospinal reflex. This report describes the changes in the MRP in chronic spinal cats 1 to 14 weeks after spinal cord transection at T_{13}. Reflexes were recorded from postganglionic fibers on the surface of the bladder in response to stimulation of afferents in the pelvic nerve. In chronic spinal cats, reflexes occurred at long latency (150-180 msec) and only at stimulus intensities which activated C fiber afferents. The reflex, which was usually sufficiently intense to evoke bladder contractions, could be elicited when the bladder was distended with fluid or completely empty. It occurred only ipsilateral to the site of stimulation and was not affected by bilateral transection of the hypogastric nerves or the sympathetic chain. The reflex was abolished by mechanical stimulation of the anal canal.

In cats with an intact neuraxis reflexes were detected at shorter latencies (95 to 140 msec) contralateral as well as ipsilateral to the site of stimulation at stimulus intensities which activated Aδ fibers. In 60% of these animals (7 of 11 experiments) a longer latency reflex (180-200 msec) was also observed when the stimulus intensity was increased above the threshold for C-fiber afferents, at least 7 times the threshold for A-fiber afferents. This late reflex was also observed contralateral as well as ipsilateral to the site of stimulation. Neither the early nor the late reflex could be elicited when the bladder was empty. Neither reflex was affected by bilateral transection of hypogastric nerves and sympathetic chain, but both were abolished by spinal section at T_{10}. 24 to 48 hours after cord transection at T_{13} a very weak reflex which corresponded in latency and threshold to the C-fiber reflex could be elicited with trains of stimuli to the pelvic nerve.

We conclude that in chronic spinal cats the MRP undergoes a reorganization which is characterized by: (1) functional disconnection of the A-fiber component of the peripheral afferent limb, and (2) a change in the central pathway from a primarily supraspinal reflex distributed bilaterally to a spinal reflex distributed ipsilaterally. The reemergence of a strong spinal reflex one week after cord transection accounts for the development of automatic micturition in chronic spinal animals. 159 HYPOTHALAMIC AND SPINAL ACTIVATION OF PRE-CELIAC SYMPATHETIC ACTIVITY:Time Analysis and Influence of Hexamethonium. S.M. Morrison* and D. Whitehorn. Dept. of Physiology, Univ. of Vermont, Burlington, VT 05405

In earlier work we found that three second stimulation of the perifornical posterior hypothalamus (PFPH) produces activity in the splanchnic nerve, proximal to the celiac ganglion (PCSA) which rises rapidly during the first, and declines steadily during the second and third second of stimulation. The decline represents inhibitory influences of the baroreceptor reflex activated by the evoked rise in blood pressure and can be blocked by sinoaortic denervation, or by preventing the pressure rise with hexamethonium (HEX).

In the present work we have applied a similar analysis to the PCSA response to stimulation of the dorsolateral spinal cord (DLC) at C1. In 250-300 gm., male rats (SHR and WKY), anesthetized with 100mg/kg alpha-chloralose, paralyzed with Flaxedil and artifically respired, a portion of the greater splanchnic nerve, proximal to the celiac ganglion was placed on bipolar platinum hooks. Activity was filtered(300-3K) and digitally integrated.

In most preparations DLC stimulation produced a time course of PCSA similar to that evoked from PFPH; a decline in PCSA occuring during the 2nd and 3rd seconds of DLC stimulation as blood pressure rose.

When HEX (25 mg/kg) was given i.v., resting pressure fell to about 70 mm Hg. and evoked pressure changes from PFPH or DLC were eliminated. In most animals, spontaneous PCSA increased (10-30%). Evoked activity in the first second of PFPH or DLC stimulation was relatively unchanged while activity in the 2nd and 3rd seconds increased as compared with pre-HEX responses. Since evoked activity in the 2nd and 3rd seconds of DLC stimulation remained after ipsilateral hemisection of the cord rostral to C1, the decline in PCSA in the 2nd and 3rd seconds in pre-HEX responses probably is due to baroreceptor reflex influences acting at the spinal level.

In some preparations, HEX produced a fall in spontaneous PCSA and the entire response to DLC stimulation was reduced by 30-70%. Pre-HEX PCSA response levels could be restored by increasing the intensity of DLC stimulation.

We conclude that time course analysis can be applied to PCSA responses obtained with DLC stimulation, allowing measurement of both sympatho-excitation and reflex inhibition acting at the spinal level.

160 SUPERIOR CERVICAL GANGLION DECENTRALIZATION IN THE ADULT RAT. ITS LONG TERM EFFECTS ON THE IRIS NERVE TERMINALS. Catherine Mytilineou and Maria C. Papaconstantinou*. Dept. of Neurology, Mt. Sinai School of Medicine, New York, N.Y. 10029.

Adult rats (70-80 days old) were subjected to unilateral superior cervical ganglion decentralization and the effects on the adrenergic nerve terminals were studied in the iris. There was no change in the norepinephrine (NE) content of the iris up to 8 weeks after decentralization. The number of the nerve terminals in the iris did not change and their uptake properties remained normal as determined by the ^{3}H-NE uptake by the irides from untreated and reserpine pretreated animals. However when irides innervated by a decentralized ganglion were depolarized in vitro by high extraneuronal K^+ concentration (100 mM), they released significantly higher amounts of previously accumulated ^{3}H-NE than the control irides. This effect was not evident until two weeks after decentralization but remained present up to 16 weeks, the longest time studied. Catecholamine histofluorescence of the irides indicated a change in the distribution of NE with an increase in the fluorescence intensity of the varicosities and a decrease in the intensity of the inervaricose spaces in the nerve plexus of the decentralized irides.

Our results demonstrate that, in the rat, prolonged isolation of the peripheral adrenergic neurons from the central nervous system and interruption of firing does not affect the NE content or uptake properties of the nerve terminals. However, decentralization does induce changes, possibly in the distribution of the neurotransmitter inside the nerve terminals, which result in increased release of ^{3}H-NE by K^+ depolarization. (Supported by United States Public Health Grant NS11631).

161 RELATIONSHIP OF PLASMA EPINEPHRINE AND NOREPINEPHRINE LEVELS IN RECUMBENT HUMANS. Benjamin H. Natelson and Barry E. Levin. VA Medical Center and Dept. of Neurosciences, CMDNJ-New Jersey Medical School, East Orange, NJ 07018.

If changes in epinephrine (E) and norepinephrine (NE) reflect some common central mechanism of autonomic function, plasma levels of the 2 catecholamines should relate well with each other under a variety of different conditions. To examine this issue, we sampled plasma from an indwelling intravenous line in recumbent humans every 15 min for either 4 hr (n=9) or 8 hr (n=3). Subjects in the first group arrived in the laboratory 1 hr before the start of sampling while subjects in the second group slept overnight in the laboratory. Deproteinated plasma was frozen and subsequently assayed for norepinephrine and epinephrine by a radioenzymatic method. NE and E levels in the first group both decreased in a similar fashion over time (median r of log transformed data = .75, $p < .01$). Because this pattern of relatively high early values was seen in subjects studied in both the morning and afternoon, we concluded that the downward tendency was related to our experimental procedure. This was verified in our second group of subjects who showed no consistent changes in NE and E over time. To further study the relation between NE and E, we detrended data by computing deviations from a linear regression cast through each subject's log-transformed E or NE values. Correlations between NE and E residuals fell in 2 groups: those with a poor relation (r ranging from .10 to .43, n = 6), and those with a strong relation (r ranging from .60 to .88, $p < .01$, n = 6). Time series statistics were then applied to both NE and E residuals in the group studied for 4 hr. Peak power ranged from frequencies of 34-188 min (median = 107 min) for NE and from frequencies of 50-188 min (median = 94 min) for E. Our conclusions from these results are that (a) some common process is responsible for tonic stimulation of E and NE because of the invariable downward slope in both substances over time, probably related to our experimental design; (b) superimposed on this tonic factor are phasic fluctuations in both neuro-humors with a median ultradian rhythm of about 1.5 hr; and (c) humans can be divided into 2 groups based on whether or not their ultradian rhythms of E and NE correlate tightly. Thus E and NE correlate well with each other in some but not all conditions; this suggests that central control of release of these neuro-humors may be due to activation of anatomically discrete but interrelated areas.

162 MULTIPLE SPINAL PATHWAYS DESCENDING FROM THE FASTIGIAL NUCLEUS. Carl A. Ohata, Robert D. Foreman and Kenneth J. Dormer, Dept. of Physiology and Biophysics, Univ. of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma 73190.

Electrical stimulation of the fastigial nucleus (FN) in the cerebellum of dogs results in the widespread activation of sympathetic efferents. FN-evoked potentials are present in preganglionic fibers of the T_2 white ramus communicans and the splanchnic nerve. FN stimulation evokes a marked pressor response, an initial tachycardia which is buffered by baroreceptors, and an increase in plasma renin activity. The object of this study was to determine the effects of spinal lesions on evoked potentials in the splanchnic nerve and on the pressor response. The right or left FN was located with a stimulating electrode in dogs anesthetized with chloralose (115 mg/kg). The splanchnic nerve was cut and evoked potentials were recorded from multifiber units in the central end. Lesions were made successively in different segments of the spinal cord. The fastigial pressor response was unaffected by L_1 spinal transection, moderately attenuated by lesions placed in the T_5 dorsolateral funiculi and T_6 spinal transection, and abolished by C_8 transection. This indicates that sympathetic efferents affecting blood pressure leave the spinal cord primarily in the upper thoracic segments (T_1 to T_5). FN stimulation also increased the activity of multifiber units in the splanchnic nerve. At the end of pressor stimulation, the spontaneous discharge of some splanchnic units was inhibited during maximal and declining pressure presumably via the baroreflex. This inhibition was attenuated or abolished by transection of the T_6 cord. The splanchnic potentials were relatively unaffected by L_1 transections although sometimes the spontaneous activity and evoked response were attenuated but without changes in the conduction latency. The effect of subsequent spinal lesions on the FN-evoked response indicate multiple pathways of splanchnic preganglionic fibers. Some units were unaffected by mid-thoracic lesions suggesting that the preganglionic fibers leave the cord in the upper white rami then descend in the sympathetic chain. The evoked response of other units was abolished after mid-thoracic lesions suggesting that splanchnic fibers also leave the lower thoracic cord. Still other multifiber units were attenuated by mid-thoracic lesions suggesting that fibers exit from the upper and lower thoracic segments. All evoked responses were abolished after C_8 transection. In conclusion the fastigial pressor response is conveyed primarily by fibers departing from the upper thoracic cord. Splanchnic fibers may depart from various segments of the thoracic spinal cord. Splanchnic multifiber units were excited by FN stimulation and sometimes inhibited by a convergent descending baroreceptor pathway. (Supported by NIH grant HL05670 and the Oklahoma Heart Association).

163 SOCIAL INTERACTION, STRESS AND CATECHOLAMINES IN RATS S. PASHKO, K. DETURCK* and W.H. VOGEL
Thomas Jefferson University, Department of Pharmacology, Philadelphia, PA 19107 USA

Male wistar rats were catheterized in the jugular vein and the silastic tubing protected with a steel spring which was supported by a swivel pulley and counterweight. The animal could move relatively freely and blood could be drawn without disturbing the animal. Plasma norepinephrine (NE) and epinephrine (E) were measured daily and found to vary only slightly over a 5 day period following surgery (range 200-400 and 150-300 pg/ml plasma, respectively). Repeated drawing of five samples of 0.25 ml blood over one hr did not significantly affect hematocrit and plasma NE and E. Isolated catheterized rats were placed together with male rats, female diestrous rats, amphetamine-treated rats (5 mg/kg, IP, 15 min prior to experiment) or mice for one hour and blood was drawn after 1, 5, 15, 30 and 60 min. The catheter was found not to draw unusual attention by the second animal. The presence of the male or female rat produced no marked behavioral changes and had no effects on plasma NE or E in the experimental animal. The presence of a mouse or amphetamine-treated rat produced aggressive and excited behavior in the catheterized rat. In the case of the amphetamine-treated rat, NE levels were significantly elevated at all times (from 194 pg/ml to 540, 523, 429, 425 and 418 pg/ml, respectively) with no change in E levels. In the case of the mouse, NE levels were significantly elevated at 1 and 15 min (from 218 pg/ml to 325 and 371 pg/ml, respectively). No change in E levels was found. This model seems quite suitable to study blood catecholamines (and other chemicals) during social interactions.

164 EVIDENCE FOR INVOLVEMENT OF A CNS CHOLINERGIC MECHANISM IN REFLEX-INDUCED VAGAL BRADYCARDIA IN THE CAT. Christine A. Petti,* Thomas P. Williams*, Cinda J. Helke, and Richard A. Gillis*. (SPON: F.G. Standaert). Dept. Pharmacol., Schs. Med. & Dent., Georgetown Univ., Washington, D.C. 20007.

To confirm earlier findings of others that a CNS cholinergic mechanism is involved in reflex-induced vagal bradycardia (e.g., Rozear et al.: Int. J. Neuropharmacol. 7: 1, 1968), experiments using chloralose-anesthetized cats were performed whereby baroreceptors were activated with i.v. bolus injections of phenylephrine and the effects of drugs that modify CNS cholinergic synaptic transmission were observed. Drugs tested were propantheline, neostigmine, and hexamethonium, and were all administered into the fourth cerebroventricle. Propantheline (0.2-0.5 mg), a muscarinic receptor blocking agent, administered to six animals exhibiting reflex vagal bradycardia prevented approximately 70% of the response without altering either the rise in arterial pressure induced by phenylephrine or the responsiveness of peripheral muscarinic receptors. Neostigmine (0.2-1.2 mg), an inhibitor of cholinesterase, administered to five animals exhibiting reflex vagal bradycardia significantly enhanced the response without altering either the pressor effect of phenylephrine or the responsiveness of peripheral muscarinic receptors. Central administration of propantheline counteracted the enhancing effect of neostigmine. Administration of an agent known to block nicotininc receptors (hexamethonium) had no effect on phenylephrine-induced bradycardia. These results suggest that a CNS cholinergic synapse comprises part of the reflex vagal pathway, and that muscarinic receptors mediate transmission at this synapse.

165 LOCALIZATION OF NEURONS IN THE RAT SPINAL CORD WHICH PROJECT TO THE SUPERIOR CERVICAL GANGLION. T.R. Rando*, C.W. Bowers*, and R.E. Zigmond. Dept. Pharmacol., Harvard Med. Sch., Boston, MA 02115

Horseradish peroxidase (HRP) was applied to the proximal cut end of the cervical sympathetic trunk several millimeters caudal to the superior cervical ganglion in the rat. After survival times of two, three, six or nine days, the animals were sacrificed and the spinal cords processed to visualize the HRP using either diaminobenzidine or benzidine hydrochloride. The results from experiments at two, three, and six days were similar. All labeled neurons found in the spinal cord were in segments C8-T5 with 90% of the neurons in segments T1-T3. The total number of labeled neurons found in 6 experiments at a survival time of 6 days ranged from 1583-2129 (mean ± S.E.M. was 1842 ± 83). At nine days the mean number of labeled cells and the density of label per cell were reduced and the most caudal, labeled neurons were in segment T4. Labeled neurons were distributed among four areas of the spinal cord: the intermediolateral nucleus (76.5%), the lateral funiculus (20.8%), the central autonomic region (2.3%) and the intercalated nucleus (0.5%). The cells of the intermediolateral nucleus did not form a continuous column, but instead were found in clusters, several clusters being present per root. (Supported by U.S. Public Health Service Grant NS 12651).

166 MEDIAL POSTERIOR HYPOTHALAMIC LESIONS INHIBIT HYPERTENSION IN SPONTANEOUSLY HYPERTENSIVE RATS. Elinor Riley*, Kazuo Takeda*, and Ruben Bunag. Dept. of Pharmacology, Univ. of Kansas Medical Center, Kansas City, Kansas 66103.

Although evidence exists for autonomic hyperactivity and endocrine involvement in the etiology of hypertension in the Kyoto Wistar rat (SHR), the exact role of the nervous system is unknown.

Bilateral lesions (stainless steel electrodes, 0.2 x 0.5 mm exposed length, 2 mA x 5 sec DC anodal current, rectal cathode) or sham operations (electrode placement without current passage) were made in 55-day-old female SHR and their normotensive Kyoto Wistar-derived counterparts (WKY, both from Charles River Laboratories).

Systolic blood pressure, heart rate, and body weight were recorded weekly up to 16 weeks of age (9 weeks after lesion). The rats were housed in a limited access room (lights on 0700-1900 h) where measurements were also made (AM) using a tail cuff method with preheating and a 25 mm cuff.

Blood pressure did not change in WKY but was significantly lower in lesioned than in sham operated SHR throughout the experiment. Heart rate was reduced in both WKY and SHR. Although an initial weight loss in lesioned SHR was followed by normal weekly gain, body weights remained lower than those of controls.

	9 Weeks after Lesion		
Group (n)	Blood pressure	Heart rate	Weight
WKY sham (6)	108±11	431±8	202±6
lesion (6)	107±5	385±11+	200±6
SHR sham (9)	167±4	458±7	173±4
lesion (9)	127±7*	388±13*	151±4*

+ = p <.01 * = p <.001 t-test

When sympathetic nerve activity (splanchnic nerve) was recorded in sham and lesion SHR groups (urethane anesthesia) 10 weeks after lesion, basal nerve activity and changes in blood pressure and nerve activity in response to anterior hypothalamic stimulation were significantly reduced in lesioned SHR.

Our results suggest that hypothalamic lesions inhibit the rapid blood pressure elevation that normally occurs in SHR at the age of about 5-12 weeks and that this inhibition is possibly due to reduced sympathetic output. (Supported by NIH Grant HL 14560.)

167 DESCENDING CONNECTIONS FROM THE BRAIN TO THE SPINAL CORD IN THE RAT, AS STUDIED WITH HORSERADISH PEROXIDASE. Christopher Ross, David A. Ruggiero*and Donald J. Reis. Lab. of Neurobiol., Dept. Neurol., Cornell Univ. Med. College, New York, NY 10021.

With the objective of defining descending central autonomic pathways in the rat, we have injected horseradish peroxidase (HRP) into thoracic segments of the spinal cord and compared the distribution of retrogradely transported enzyme with that following injections at other levels. HRP (0.2 microliters of a 50% saline solution) was unilaterally injected into cervical, upper or lower thoracic, lumbar, or sacral levels of rat spinal cord. Following 48-hr survival, brains were sectioned and processed using diamino- or tetramethyl benzidine.

Injections at all levels resulted in HRP-labelled perikarya located in the solitary complex, the spinal trigeminal nucleus, the periphery of nucleus cuneatus, vestibular and perihypoglossal complex, raphe nuclei, reticular nuclei ventralis, dorsalis, gigantocellularis (NGC), pontis caudalis et oralis, the locus coeruleus, subcoeruleus, parabrachial, dorsal tegmental, and pedunculo pontine (PPN) nuclei, red nucleus, nuclei of Darkschewitsch and the posterior commissure, zona incerta, perifornical area, entopeduncular and paraventricular nuclei, lateral hypothalamus and cerebral cortex. Labelled neurons in the locus ceruleus were restricted primarily to ventral regions, suggesting a topographic organization of this nucleus's efferent connections. The existence of labelled cells in the paraventricular and lateral hypothalamus confirms the previous report of direct hypothalamo-spinal connections in the rat (Saper et al, Brain Res. 117, 305). In contrast to other species, few if any afferents from fastigial nucleus and tectum project to spinal cord in the rat.

A striking connection (previously undescribed) from PPN to the cord, especially the cervical and lumbar enlargements, appears significant when related to the importance of PPN as a terminus of pallidal and precentral cortical efferents, and may represent a direct extra-pyramidal channel for signals derived from the basal ganglia to the spinal cord.

Projections predominantly to thoracic levels of the cord were observed from the lateral reticular nucleus, the paramedian reticular nucleus, portions of the nucleus gigantocellularis (pars dorsalis), and the nucleus parvocellularis, supporting physiological evidence that these nuclei may be of particular importance in central autonomic regulation.

(Supported by NIH grants HL 18974, HL 07379, and the N.Y. Heart Association.)

168 SEGMENTAL ORIGIN OF PREGANGLIONIC SYMPATHETIC AXONS EMERGING IN PARTICULAR RAMI OF THE GUINEA-PIG THORACIC CHAIN. Eric Rubin* and Dale Purves. Dept. of Physiol. and Biophys., Washington Univ. Sch. of Med., St. Louis, MO 63110

Sympathetic ganglion cells in the guinea-pig are selectively innervated in that each neuron is contacted by preganglionic axons arising from a preferred subset of the spinal cord segments that innervate the ganglion as a whole (Njå and Purves, 1977). Since selective innervation is a function of the segmental level of preganglionic axon emergence, a distinguishing feature of preganglionic neurons may be the rostro-caudal position of their cell bodies within the spinal cord. To examine this idea we have used the retrograde marker horseradish peroxidase (HRP) to identify the preganglionic neurons whose axons emerge from the cord at a particular level. About 1 mg of crystalline HRP was applied to a single cut ramus of one of the mid-thoracic sympathetic chain ganglia (T4-7) in adult guinea-pigs. After survival times of 2-3 days, transverse or longitudinal frozen sections of the spinal cord were cut, and the HRP reaction product developed with DAB or TMB. Transverse sections taken from the mid-portion of the segments above and below the one corresponding to the cut ramus failed to show any labeled cells (8 animals), while labeled preganglionic neurons were present in nearly every section from the segment whose ramus had been exposed to HRP. Serial longitudinal sections of the thoracic spinal cord confirmed that the retrogradely labeled cells were almost completely confined to a region approximately one segment long, which in each case was at the level of the cut ramus (9 animals). About 500-700 neurons were labeled in each animal (uncorrected counts). We conclude that preganglionic sympathetic axons in the guinea-pig emerge from the cord at the level of their parent cell bodies. Our finding conflicts with several recent reports, and possible reasons for this discrepancy will be discussed.

Njå, A. and Purves, D. J. Physiol. (Lond.) 264:565-583, 1977.

169 CENTRAL PROJECTIONS TO A MEDULLARY TONIC VASOMOTOR CENTER IN RABBIT, DEMONSTRATED BY TRANSPORT OF HORSERADISH PEROXIDASE. David A. Ruggiero*, Mamoru Kumada, and Donald J. Reis (SPON: C.R. Noback). Lab. of Neurobiol., Dept. Neurol., Cornell Univ. Med. College, New York, NY 10021.

The pressor response to cerebral ischemia or to brainstem distortion (Cushing reflex) appears mediated by a restricted region of dorsal medulla overlapping, in part, the parvocellular (NPvc) and dorsal gigantocellular (NGCpd) reticular nuclei. Since lesions of caudal portions of this area result in a profound hypotension (Kumada et al, 1979 in press), we have proposed it represents the so-called tonic vasomotor center. We sought to establish afferent projections to this region by use of a modified horseradish peroxidase (HRP) technique (Ruggiero et al, 1977). HRP was injected into sites of medulla (NPvc and NGCpd) of rabbits from which low intensity electrical stimulation elicited an appropriate cardiovascular response. In general, there was a differentiation of afferent projections into these structures; several projections, however, overlap both nuclei. Afferents to NPvc derive predominantly from dorsolateral frontal cortex (FC), central amygdala, lateral hypothalamic area (LHA) (dorsomedial to the peduncular portion of the internal capsule), ventral tegmental area, substantia nigra pars reticularis (SNpr), ventromedial zona incerta, ventral central grey (CG), nuclei of Darkschewitsch and the posterior commissure, cuneiform nucleus (CuN), lateral perirubral field (PRF), locus ceruleus (LC), dorsal subceruleus (SCd), ventral medial parabrachial nucleus (PBN), group h, nucleus pontis oralis, NPvc and reticularis dorsalis (RD), vestibular complex (VC), spinal trigeminal (STN) and mesencephalic nucleus of V, and lamina VII of cervical spinal cord (CSC). Afferents to NGCpd derive from dorsal FC, LHA, posterior hypothalamic area, perifornical nucleus, CG, Edinger-Westphal and anterior median complex, interstitial nucleus of Cajal, ventromedial LC, SCd, dorsal tegmental nucleus, VC, STN, nucleus pontis caudalis, NPvc, RD, reticularis ventralis, fastigial nucleus and lamina VIII of CSC. Minor projections to both or either of these nuclei arise from bed nuclei of stria terminalis and anterior commissure, lateral preoptic, dorsomedial and entopeduncular nuclei, SN pars compacta, medial PRF, sub-CuN, lateral PBN, Köllicker-Fuse nucleus, solitary complex and most lamina of CSC. The medullary vasomotor area therefore appears as a site of convergence of afferent fibers from widely dispersed segments of CNS. While many are from regions known to influence cardiovascular activity, projections from somatomotor, general sensory and limbic regions are present as well. Such convergence would be consistent with the view that the region is a focus for integrating cardiovascular activity with movement and behavior.

170 ADRENAL CATECHOLAMINES IN THE SODIUM SENSITIVE, HYPERTENSIVE RATS (DAHL RATS). J.M. Saavedra, R. Del Carmine*, R. McCarty*, V. Weise*, and J. Iwai* (SPON: G. Gilad) National Institute of Mental Health, Bethesda, Md. 20205.

The effects of high (8%) and low (0.4%) sodium diet in adrenal catecholamines (CA) have been studied in the sodium resistant and the sodium sensitive Dahl Rats.

When kept under low sodium diet, the sodium sensitive rats have increased dopamine-ß-hydroxylase (DBH) and phenylethanolamine-N-methyltransferase (PNMT) activities with respect to the sodium resistant animals, indicating an increased synthesis of CA.

The effects of a high sodium diet were opposite in both strains. High sodium resulted in a decrease in the synthesis of CA in the sodium resistant rats (decreased tyrosine hydroxylase (TH), DBH and CA). In contrast, the sodium sensitive rats responded with increased CA synthesis (increased TH, PNMT and CA).

These results show that there are genetic differences in the CA metabolism in adrenal glands, between both strains, and also in the response of adrenal CA metabolism in each strain after a high sodium load.

The increase in CA synthesis in sodium sensitive rats after high sodium diet, coincides with clinical hypertension. These results suggest that adrenomedullary catecholamines may be implicated in the development and maintenance of the hypertension in the Dahl rats.

171 VAGAL CARDIAC INNERVATION: COMPARATIVE CONTRIBUTIONS OF THE DORSAL MOTOR NUCLEUS AND THE NUCLEUS AMBIGUUS DETERMINED BY LIQUID SCINTILLATION COUNTING. James Schwaber, Susan Wray*, and Gerald Higgins*. Department of Anatomy, The University of Vermont College of Medicine, Burlington, Vermont 05405.

Vagal cardiac efferents have been reported by different laboratories to have their central origin in either the dorsal motor nucleus (DMN) or the nucleus ambiguus (NA), the location apparently depending upon the species. Alternatively, subpopulations of cardiomotor cells may be present in both nuclei, each potentially having different projections and functions. We have approached this question by injecting ^{3}H proline into each nucleus and assaying the heart by liquid scintillation counting for significant levels of axonally transported radioactivity.

First, to locate each nucleus, vagal efferent neurons were retrogradely labeled with HRP. Small injections were then stereotaxically placed in 19 rats and 10 cats. Following survival times of 2-17 days the medulla was processed using the autoradiographic method to determine the injection sites. The vagus nerve and its branches and cardiac terminals were dissected and processed for counting.

Bilateral injections of both nuclei revealed the vagus to have an extensive cardiac innervation, including: the major vessels rostral to the heart, the left atrium rostrally near the aorta and pulmonary arteries and on the posterior surface, the right atrium along the SA node, the interatrial septum extending to the vicinity of the AV node, and some areas of the ventricles. The innervation of the major vessels and left atrium appears to remain largely superficial to the myocardium in the layer of visceral epicardium, whereas the innervation to the regions of the SA and AV nodes and the interatrial septum extends more deeply into adjacent planes of connective tissue.

Injections confined to a single nucleus show that the DMN and NA both contribute to the cardiac innervation in the cat and the rat. There are differences in the cardiac termination of each nucleus, the DMN of the rat, for example, predominantly projecting to the regions around the major vessels and the left atrium, and to a much lesser extent to the region of the SA node. In contrast the right nucleus ambiguus appears to preferentially innervate the region of the SA node. We conclude that both the DMN and the NA may project to the heart as distinct subsets of cardiomotor neurons in the rat and the cat. (Supported by VHA Grant 5-26528).

172 CARDIAC-RELATED DISCHARGE OF NEURONS IN THE MEDIAL PARABRACHIAL NUCLEUS OF THE CAT DURING SLEEP-WAKING STATES. Gary C. Sieck* and Ronald M. Harper (SPON: Thelma Estrin). Department of Anatomy and Brain Research Institute, University of California School of Medicine, Los Angeles, CA 90024.

The discharge of single neurons in the nucleus parabrachialis medialis (NPBM) was examined in unanesthetized, unrestrained cats across sleep-waking states. Adult cats were anesthetized with sodium pentobarbital, and electrodes were implanted for monitoring EEG, EOG, EKG, lateral geniculate nucleus EEG, and dorsal hippocampal EEG. A bundle of 10 fine-wire electrodes (62 µ insulated nichrome), together with a miniature microdrive, were implanted stereotaxically in the NPBM. Recordings were initiated in a total of six cats after they had recovered from these surgical procedures. Sleep-waking states were assessed using standard physiological and behavioral measures. Cardiac relations in NPBM neuronal activity during each sleep-waking state were determined by calculating cross-correlation functions between neuronal discharge and a reference event at the peak of the 'R' wave of the EKG. Different bin widths were used in the cross-correlations to assess phase relationships between the neuronal spike train and the EKG reference. Cardiac relations were observed in approximately 25% of the 60 NPBM neurons examined. The extent of the phasic cardiac modulation of NPBM neuronal activity varied between cells and sometimes across states for individual cells. In some NPBM neurons, cardiac relationships in discharge appeared during only 1 or 2 sleep-waking states. Generally, cardiac relationships in neuronal activity during quiet sleep (QS) were absent or reduced compared to waking (AW) and REM sleep states. Most NPBM neurons that showed cardiac relations increased their discharge 0-50 msec after the peak of the 'R' wave. In other NPBM cells, an increase in activity occurred 200-250 msec after the 'R' wave. Compared to waking, mean discharge rates of NPBM neurons decreased slightly during QS, and increased during REM sleep. Mean heart rates were comparable during AW and REM sleep states, and were reduced during QS. We propose that cardiac modulation of NPBM neuronal discharge may reflect the influence of cardiac afferent feedback, possibly via the n. tractus solitarius (NTS). The reduced phasic modulation of NPBM neuronal activity during QS may result from forebrain inhibitory influences on this area.

173 BRAINSTEM AREAS MEDIATING THE HYPOTENSIVE EFFECTS OF MUSCIMOL. D. W. Snyder, J. A. Boccagno* and M. J. Antonaccio. Squibb Inst. Med. Res., Dept. Pharmacol., Princeton, NJ 08540 USA

Muscimol (M) a GABA receptor agonist, acts centrally to decrease blood pressure (BP), heart rate (HR) and sympathetic renal nerve discharge (RND) (Antonaccio and Taylor: Eur. J. Pharmacol. 46: 283, 1977). The present study defines the areas within the brain that are mediating the hypotensive effects of M. In chloralose anesthetized cats, M was perfused into the lateral ventricle and the perfusate was collected from either the cisterna magna (ICV) or the cerebral aqueduct (supramedullary area SMA). To differentiate the sites of action in the medullary region, M was administered into either the caudal or anterior region of the 4th ventricle. Administration of M (0.003-0.03 µg/kg/min) for 30 min ICV produced dose related decreases in BP, HR and RND with the highest dose of M producing maximum reductions of 40%, 30% and 80%, respectively. When the largest dose of M was prevented from reaching the 4th ventricle, (perfusion of SMA) a reduction in BP and HR of <15% occurred. Administration of M (0.03 µg/kg/min) into the caudal region of the 4th ventricle failed to alter BP, HR or RND. However, administration of clonidine (1.0 µg/kg/min) for 10 min, an α agonist, to the same area of the medulla led to a 30% fall in BP and 20% fall in HR. In contrast to the lack of effect of M in the caudal region of the medulla, perfusion of M (0.03 µg/kg/min) into the anterior region of the 4th ventricle produced maximum decreases in BP and HR. Pretreatment with the GABA receptor antagonist, bicuculline methiodide administered into the cerebral aqueduct in a dose which produced virtually no change in BP, HR or RND (0.5 µg/kg/min) blocked or markedly reduced the effects of M administered ICV. These results indicate that the major sites mediating the hypotensive actions of M are localized in the anterior region of the medulla and/or on the anterioventral surface of the medulla. The actions of M were blocked by pretreatment with the GABA receptor antagonist bicuculline suggesting the hypotensive effects are mediated by activation of GABA receptors. Furthermore, the medullary site of action of M is markedly different from that of clonidine which lowers BP and HR by activating central α adrenergic receptors. There appears to be a supramedullary site which contributes to the hypotensive effects of M.

174 EFFECT OF SYMPATHETIC BACKGROUND ON THE NEGATIVE CHRONOTROPIC RESPONSE TO VAGAL STIMULATION. Sherry L. Stuesse, Mathew N. Levy*, and Harrison Zieske*. Division of Investigative Medicine Mt. Sinai Hospital, Cleveland, Ohio 44106.

The time in the cardiac cycle at which a vagal stimulus is delivered is an important determinent of the chronotropic response. Thus, at some point in the cardiac cycle, a vagal stimulus will be maximally effective; at another point in the cardiac cycle it will be minimally effective. The effect of sympathetic stimulation on the sinus node chronotropic response to vagal stimulation was determined in open-chest, anesthesized dogs. Both stellate ganglia and the cervical vagi were decentralized and stimulated distal to the ligations. A factorial experimental design was used. The stellates were stimulated at one of three constant frequencies while one burst of stimulation was delivered to the vagi each cardiac cycle. The time of vagal stimulation was varied.

A background level of stellate stimulation significantly affected the following parameters ($P<.01$): the maximum and minimum amounts of slowing during vagal stimulation and the times in the cardiac cycle at which the vagal stimulus was maximally or minimally effective. However, stellate stimulation did not significantly alter the range over which a negative chronotropic vagal response could be produced nor did it shift the time from the minimum chronotropic response to the subsequent P wave (St to P interval) even though the total cardiac cycle was shortened.

175 A POSSIBLE ROLE OF OPIATE RECEPTORS IN THE PRESSOR RESPONSE TO ANGIOTENSIN II. J.E. Szilagyi* and C.M. Ferrario. Research Division, Cleveland Clinic Foundation, Cleveland, Ohio 44106.

Previous inability to produce a differential effect of angiotensin II (AII) infused via the vertebral arteries (VA) when compared to the intravenous (i.v.) route of administration was attributed to the depressant effects of pentobarbital anesthesia. A centrally mediated pressor response (PR), however, was unmasked when chloralose anesthesia was used in combination with morphine. The recent demonstration of opiate receptors in the same regions of the medulla where AII acts to facilitate central sympathetic activity caused us to wonder whether the action of morphine in facilitating the PR to AII represented some interaction between the hormone and this opiate system. The following study was designed to investigate a possible interrelationship between central effects of AII and opiate receptors in the brain by observing the central and peripheral pressor effects of AII and norepinephrine (NE) before and after treatment with naloxone (NX). Eight male mongrel dogs were anesthetized with chloralose (60 mg/kg, i.v.) after pre-medication with morphine (2 mg/kg, i.m.). Arterial pressure (MAP) was monitored via a femoral artery catheter. For infusions, a jugular vein (i.v.) was cannulated, while small catheters were placed in both vertebral arteries (VA) without interruption of blood flow. AII (10,20 ng/kg/min) and NE (100,200 ng/kg/min) in 0.9% saline were infused in random order for 3 minutes into the VA or jugular vein. The dogs were then injected with 0.8 mg NX i.v. and the response to AII and NE determined again. At the largest dose treated AII (20 ng/kg/min) infused VA caused a 22.1 ± 3.5 (SE) % increase in MAP. The same dose given i.v. produces a 18.6 ± 3.5% increase in MAP. NE (200 ng/kg/min) infused VA and i.v. caused a 13.5 ± 2.4% and a 17.2 ± 4.8% increase in MAP respectively. Ten minutes after a dose of NX the PR to AII VA (20 ng/kg/min) was reduced by 61 ± 5.1 % ($p < 0.01$) while those to NE were unchanged. The depression of PR to AII VA was not due to a generalized decrease in vascular reactivity since PR to the same dose of AII i.v. was not significantly changed after NX (18.6 ± 3.5% vs 11.9 ± 3.4%). These data show that administration of NX in previously morphinized dogs specifically antagonized the magnitude of the centrally mediated PR to AII. A specific mechanism is suggested by the lack of similar effects to central administration of NE or i.v. NE and AII. There is, thus, reason to suspect that there exists a previously unrecognized interaction of endogenous opiates in the medulla in mediating the action of AII at the level of the area postrema, the site of action of centrally administered AII.

176 FULMINATING HYPERTENSION PRODUCED BY LOCAL INJECTION OF KAINIC ACID INTO THE NUCLEUS TRACTUS SOLITAKII IN THE RAT. W. Talman*, M. H. Perrone*, N. Doba, and D. J. Reis. Laboratory of Neurobiology, Department of Neurology, Cornell University Medical College, New York, New York 10021

Kainic acid (KA) is a glutamic acid analog, which in low doses stimulates and in high doses may destroy intrinsic neurons in the brain purportedly via interaction with glutamic acid receptors. We sought to determine the effects of local administration of KA into the nuclei of the tractus solitarius (NTS), (the site of termination of baroreceptor afferents) on arterial pressure (AP) and heart rate (HR) in the rat. Rats were anesthetized with halothane and cannulas inserted in the ventral artery of the tail to record AP. Vehicle (0.3ul) containing KA (0.6-60ng) or, as control, 30ng of ascorbic acid was injected, under direct vision, bilaterally into the NTS or adjacent regions of brainstem. At the onset of injection, KA, in any dose, produced transient hypotension, bradycardia, and apnea with rapid return to baseline. After termination of anesthesia, KA elicited a dose-dependent elevation of AP, HR, and pulmonary edema (PE). At a dose of 0.6ng, KA did not change AP from control (114±2 mm Hg ; 349±24 bpm; n=5, n.s.). Modest hypertension and tachycardia followed a dose of 6ng KA. At doses of 15-60ng, hypertension and tachycardia were accompanied by PE and death within 30 minutes (e.g. 15ng: AP to 157±8 mm Hg; HR to 450 ±38 bpm; n=5 p<.01-.001). KA (80ng) injected into the nucleus gracilis or pressor areas of dorsal medulla did not alter AP or HR. Rats unilaterally injected with higher doses, while exhibiting transient hypertension and tachycardia for 3 hr, recovered and survived. No histological changes in NTS were noted 2 weeks after unilateral injection of 60ng of KA. Such injections failed to alter activity of choline acetyltransferase or tyrosine hydroxylase in microdissection of NTS. Since KA does not damage neurons in NTS, the data suggest that the drug produces hypertension by blocking activity of neurons in NTS which mediate baroreceptor reflexes. It raises the possibility that glutamate may be a neurotransmitter in the baroreceptor reflex arc.

177 PROJECTION AND CONNECTIONS OF VASCULAR AFFERENTS IN THE FELINE CENTRAL NERVOUS SYSTEM. F. J. Thompson, C. D. Barnes, K. A. Fields, D. A. Lerner, J. R. Wald. Dept. of Neuroscience, University of Florida, Gainesville, FL 32610, and Dept. of Physiology Texas Tech. School of Medicine, Lubbock, Texas.

Little is known regarding the physiology or functional connections of vascular afferents which potentially form a vast source of sensory input. Afferent fibers from a segment of femoral vein were selected to provide a model to study the properties and connections of vascular afferents. The study reported here was undertaken to examine the electrophysiology and projection pattern to the spinal cord of vascular afferents electrically activated in a segment of femoral vein. These experiments were carried out in decerebrate-spinal cats. Stimulation of the femoral venous afferents elicited potentials which were recorded from the dorsum of the ipsilateral lumbar and sacral spinal cord, and from the lumbar dorsal rootlets. These potentials enabled determination of the following findings:

1. The fibers activated in the femoral vein segment course into the spinal cord via the saphenous nerve, and the fourth, fifth, and sixth lumbar dorsal roots.
2. Transection of the spinal cord (T_{10}) "releases" venous afferent elicited synaptic activities in the spinal cord subsequent to the initial slow negative cord dorsum potential.
3. Compound action potentials recorded from the rootlets of the fifth and sixth lumbar segments were characterized by two peaks. Conduction velocity calculations in four animals produced mean values of 57.8 and 44.3 meters/sec respectively for these two peaks.
4. Strength-duration relationships of the dorsal root fibers activated by femoral venous afferent stimulation revealed a rheobase current of 130 μa and chronaxie of 210 μsec. Paired pulse stimulation revealed an absolute refractory period of 1.1 msec.
5. Stimulation of the femoral venous afferent elicited dorsal root potentials recorded from the ipsilateral and contralateral lumbar rootlets.
6. Conditioning stimulation of the femoral venous afferents elicited facilitation followed by inhibition in both flexor (common peroneal) and extensor (gastrocnemius, deep posterior) monosynaptic test reflexes.

In a subsequent series of of experiments, the distribution of femoral venous afferent projections to the sensorimotor cortex was determined. A multiple representation on the sensory and motor cortex was observed.

178 RESPIRATORY RELATED MODULATION OF HEART RATE DURING SLEEP AND WAKING STATES IN THE CAT. Robert B. Trelease*, Gary C. Sieck*, and Ronald M. Harper. Department of Anatomy and Brain Research Institute, UCLA, Los Angeles, CA 90024.

It has been observed that the magnitude of respiratory related sinus arrhythmia (RSA) in cats varies according to sleep/waking state (Baust and Bohnert, Exp. Br. Res. 7:169, 1969). Meaningful quantification of RSA has been difficult to derive, however, given the complex behavior of the heart rate in response to multiple reflex and non-reflex influences. In order to determine the magnitude and degree of respiratory coupling, we have performed spectral analysis and coherence calculations on cardiac rate variations and respiratory activity. Five adult cats were implanted with cortical EEG, EOG, LGN, hippocampal EEG, and EKG electrodes for chronic recording. Respiratory movements were monitored with a thoracic strain gauge, and continuous polygraphic recordings were made from freely-behaving animals during multiple sleep/waking periods. Quiet wakefulness (AW), quiet sleep (QS), and active sleep (REM) were identified by standard polygraphic criteria. Extent of RSA (X_r; log spectral amplitude of heart rate at minute respiratory frequency) and coherence of heart rate variation with respiration (C_r) were calculated on a minute-by-minute basis from fast Fourier transforms of respiratory activity and interpolated heart rate intervals. Paired T-tests were used to assess differences in RSA between states. X_r and C_r were greatest in QS in all cats. Although X_r during QS showed considerable variation between cats, C_r was very high (approaching 0.9) for every QS segment examined. In contrast to previous observations, we found that respiratory related sinus arrhythmia decreased during REM, with both X_r and C_r values significantly less than those of QS. Extent and coherence were also significantly less in AW than in QS. Sleep thus exerts a powerful effect on respiratory modulation of cardiac rate variation. Quiet sleep represents a state wherein the strongest coupling occurs between these two physiological variables.

179 DO SUPERFICIAL MEDULLARY NEUROVASCULAR ELEMENTS HAVE RESPIRATORY CHEMOSENSOR FUNCTION? Trouth, C.O., Patrickson, J.W., Kang, Y.H. Holloway, J.A., Moolenaar, G.M. Dept. Physiology & Biophysics, College of Medicine, and Dept. of Zoology, Howard University, Washington D.C. 20059.

The response characteristics of spontaneously firing neurons on the ventrolateral surface of the medulla oblongata in 11 cats anaesthetized with chloralose urethane were analysed in order to identify receptors involved in the chemical drive to respiration. The discharge frequency of chemosensitive units increased from 7 to 19 impulses per second when mock CSF-pH superfusing the ventral surface was changed from 7.4 to 7.0 and decreased to 2 imp/sec when pH was changed to 7.8. The activity of these same units increased as the CO_2 tension of the inspired gas was increased, however, HCl and $NaHCO_3$ administered intravenously had no effect on the activity of these neurons. Histological examination of the site at which neurons were identified which responded specifically to mock CSF-pH changes and increased inspired CO_2 revealed: 1) Thickened marginal glia with processes projecting into the subarachnoid space. 2) Neurons dispersed within the thickened glial patches - some lying less than 10 um from the surface. 3) Neurons (Neurovascular elements) within the walls of superficial arterioles (branches of the basilar artery) and venules. Are these Neurovascular elements the central respiratory chemoreceptors? (Supported by NSF Grant HES 75 - 09024 and NIGMS Grant 1 TO 2 GM 05010 - 01)

180 PREOPTIC-ANTERIOR HYPOTHALAMIC AREA AS MEDIATOR OF BRADYCARDIA RESPONSES IN RABBITS. J. Wallach, H. Ellenberger*, N. Schneiderman, D. Liskowsky*, R. Hamilton and M. Gellman*. Dept. of Psychology, Univ. of Miami, Coral Gables, Fl. 33124.

Electrical microstimulation (10 s trains, 100 pulses/s, 0.5 ms pulses, <300 μA, threshold~110 μA) of 15 sites in the preoptic-anterior hypothalamic area (PAHA) of 15 Urethane-anesthetized rabbits elicited bradycardia (M=-32bpm, SD=±9) and a depressor response (M=-12 mm Hg, SD=±3). The bradycardia was due to vagal excitation as it was abolished by bilateral vagotomy. Single-pulse (0.1 ms duration) stimulation of aortic nerve (AN) activated 14 neurons recorded extracellularly within PAHA indicating that neurons in the region receive barosensory input. Mean onset latency for cells activated by AN stimulation was 25 ms (SD=±14). In order to examine the decending pathways mediating the bradycardia responses elicited by stimulation of PAHA, extracellular recordings were made from dorsomedullary neurons that were activated by single-pulse stimulation of both PAHA and AN. Nine of the 15 neurons receiving barosensory input were also driven by single-pulse stimulation of PAHA. These units were histologically located in dorsal vagal nucleus (DVN) or nucleus tractus solitarius (NTS). Although the mean onset latency to diencephalic stimulation was relatively short (M=10 ms, SD=±2) these neurons did not follow repetitive stimuli faithfully. Therefore, the functional connections between PAHA and dorsal medulla are probably not monosynaptic. Four of the above neurons located in DVN were also antidromically-invaded by stimulation of ipsilateral vagus nerve, and therefore were preganglionic and probably cardioinhibitory. Unilateral injections of horseradish peroxidase (HRP, 30%, 0.03-0.1μl) were made in dorsomedial NTS and DVN in 17 rabbits. Following a 48 hr survival period, the brain tissue processed in 3 different chromagens displayed cell body labeling in the anterolateral hypothalamic area, paraventricular n., dorsomedial hypothalamic n., zona incerta, central n. of amygdala, and central gray. None was observed in preoptic region or anterior hypothalamic n. The anterolateral hypothalamic area revealing cell body labeling was the most caudal and lateral region of PAHA from which (a) neurons were activated by AN stimulation, (b) bradycardia and depressor responses were obtained to train stimulation and (c) cardiac-related neurons in DVN and NTS were activated by single-pulse stimulation. However, since single-pulse stimulation in anterolateral hypothalamus only activated units in the dorsal medulla oligosynaptically, it appears that the functional and anatomical pathways studied were parallel but not identical (Supported by NSF Grant BMS 78-15403 and by a grant from Florida Heart Association).

181 EVIDENCE FOR THE PRESENCE OF A TONICALLY ACTIVE FOREBRAIN GABA SYSTEM INFLUENCING CENTRAL SYMPATHETIC OUTFLOW IN CATS.

Daniel J. Williford*, Joseph A. DiMicco*, & Richard A. Gillis*. (SPON: R.J. Kellar). Dept. of Pharmacology, Schs. of Med. & Dent., Georgetown Univ., Washington, D.C. 20007.

Bicuculline administered into the lateral cerebroventricle of chloralose anesthetized cats produces increases in arterial pressure and heart rate. To determine whether this effect is localized in forebrain areas, bicuculline in doses of 1, 5 and 25 ug was administered into either the third and lateral ventricles with cannulation of the cerebral aqueduct or into the fourth ventricle of vagotomized cats. Administration into the third and lateral ventricles resulted in dose-dependent increases in pressure and rate, with the maximal response being 63 + 11 mm Hg and 44 + 9 beats/min., respectively. These same doses had no significant effect on heart rate and only a slight effect on pressure when administered into the fourth ventricle. Administration of the GABA receptor agonist, muscimol, into the third and lateral ventricle in a dose that had no effect alone on pressure and rate (10 ug) prevented the cardiovascular effects of bicuculline. In contrast, administration of the centrally active antihypertensive agent clonidine (31 ug) had no effect on bicuculline-induced increases in pressure and rate. In addition, muscimol (10 ug) when administered at the time of the peak pressure and rate responses of bicuculline restored these indices of cardiovascular function to normal. Clonidine (31 ug), however, administered in the same fashion had no effect. These results suggest that a tonically-active GABAergic system exists in the region of the forebrain and exerts inhibitory control over sympathetic activity influencing arterial pressure and heart rate.

AXONAL TRANSPORT

182 A POSSIBLE NON-NEURONAL TRANSFER OF ^{3}H-PROLINE-LABELED MOLECULES FROM THE DORSAL COLUMN NUCLEI TO THEIR TERMINAL TARGETS IN CATS. K. J. Berkley and H. H. Molinari. Dept. Psychol., Fl. St. Univ., Tallahassee, FL 32306.

Several investigators have found that ablations of the dorsal column nuclei (DCN) in cats produce degeneration in the inferior olive (IO). This projection involves neurons because degenerating synaptic terminals are observed at the ultrastructural level in IO following these ablations. It is not surprising, therefore, that injections of ^{3}H-leu into DCN produce dense labeling in IO, since neurons at the injection site are also heavily labeled.* Unexpectedly, however, ^{3}H-pro injections into DCN also produce dense labeling in IO, despite the fact that neurons at the ^{3}H-pro injection site appear to be, at best, only very lightly labeled 24 hrs after the injection.*

There are several possible explanations for these unexpected findings. (1) ^{3}H-pro-labeled neurons were missed due to insufficient sampling of IO-projecting neurons. The ^{3}H-pro samples, however, were taken from areas in DCN which are known to contain IO-projecting neurons and in which small ^{3}H-pro injections still produce heavy labeling in IO. (2) ^{3}H-pro-labeled molecules may be transported very rapidly out of the DCN neurons, precluding their visualization at a 24 hr survival time. The same labeling pattern is seen, however, even at a 20 min survival time. (3) Since the methods used here allow visualization only of bound amino acids, it may be that ^{3}H-pro is unseen in DCN neurons because it is taken up and transported from the perikaryon in its free form before being bound. It is generally agreed, however, that amino acids are incorporated into molecules within the perikaryon.

These considerations suggest that the paucity of neuronal labeling by ^{3}H-pro in DCN as seen in the present experiments does not reflect an artificial situation. If so, then some ^{3}H-pro-labeled molecules must be transferred to IO (as well as to other terminal targets of DCN) by a non-neuronal mechanism. One such mechanism might involve glial cells. Consistent with this suggestion is the fact that cells small enough to be glia are labeled in DCN when HRP is injected in IO. Both astrocytes and oligodendrocytes could be involved in this transfer mechanism. Most astrocytes and their processes are heavily labeled following ^{3}H-pro injections along with some oligodendrocytes and myelin.* Astrocytes with very long processes are known to exist and the fibers which project to IO are myelinated. Thus, it appears that molecules labeled by tritiated amino acids may be transferred from one location to another by glial as well as by neuronal mechanisms.

183 EVIDENCE FOR MULTIPLE SOMATIC POOLS OF INDIVIDUAL AXONALLY TRANSPORTED PROTEINS. Robert W. Berry. Dept. Anat., Northwestern Univ., Sch. Med., Chicago, IL 60611.

Although the existence of a large somatic storage pool of secretory material is a common characteristic of neurosecretory cells, it is not known if secretory proteins are withdrawn from this pool at random for axonal transport and secretion, or if cellular mechanisms exist that route newly-synthesized proteins either to storage or transport. These alternatives can be tested by using neurons L11 and R15 of Aplysia, which synthesize and commit to axonal transport large quantities of a specific class of low molecular weight presumptive neurosecretory proteins (LMW proteins). Pulse-chase studies in which the LMW proteins are identified by SDS gel electrophoresis indicate that they leave the soma by a biphasic process: a rapid phase of decay (halflife 1-2hr) is followed by a slower phase (halflife >10hr). These kinetics are not due to the presence of more slowly turning-over contaminating species, since the same results are obtained when the LMW proteins are identified by migration on gel systems which separate proteins by both molecular charge and molecular weight. Two additional tests indicate that total LMW protein turns over at the slow rate: Exposure to vinblastine for 6hr blocks decay without affecting synthetic rate, but has no detectable effect on somatic LMW content as assayed by Coomassie staining of SDS gels. Furthermore, the ratio of labeled LMW protein to labeled higher molecular weight species is the same after 18hr of exposure to labeled precursor as after a 2hr exposure, whereas if total LMW protein had a 1-2hr halflife, the ratio should have declined significantly over this period. These data are not consistent with the single-pool model. Rather, they indicate that following synthesis these proteins are partitioned into at least two kinetically distinguishable somatic pools, one of which is rapidly subjected to axonal transport, and the other of which represents a slowly turning-over somatic storage pool.

184 AXONAL TRANSPORT OF CHOLESTEROL. William D. Blaker*, Arrel Toews and Pierre Morell. Biol. Sci. Res. Ctr. and Dept. of Biochem., Univ. of North Carolina, Chapel Hill, NC 27514.

Twenty-two-day-old rats were injected intraocularly with [^{3}H] acetate and killed 1 hr to 35 days later. Cholesterol was isolated from the retinas, optic tracts, lateral geniculate bodies and superior colliculi. Radioactivity was rapidly incorporated into retinal cholesterol with near maximal labeling present one hour after injection. [^{3}H] cholesterol was lost from the retina with an apparent half-life of 15 days, with transported radioactivity accounting for 40% of the decrease.

Transported labeled cholesterol (contralaterally corrected for systemic background labeling) was present in the optic tract by two hours and in the superior colliculus by three hours, consistent with a fast rate of transport. Radioactive cholesterol accumulated in all visual structures throughout the 35-day period, but the rate of accumulation was maximal at about the time of arrival of the initial pulse of radioactivity and fell to low levels by 2-4 days. Colchicine treatment of the retina blocked transport of cholesterol but not its synthesis by the retina. The use of [^{3}H] mevalonate or [^{14}C] acetate also showed transported labeled cholesterol in all visual structures by 1 day.

The time course of accumulation of transported cholesterol is consistent with that of phospholipids, which are also rapidly transported (Toews, et.al., J. Neurochem. 32:1165-1173). Both showed an increase in the rate of accumulation at 4-5 days in optic tract and superior colliculus, indicating the fast transport of a phase of slowly released lipid. Differences between the transport time courses of cholesterol and phospholipid are probably due to differences in metabolism rather than differences in modes of transport. Labeled phospholipid decreased in all visual structures after 5 days while cholesterol continued to rise, reflecting the greater metabolic stability of cholesterol. Cholesterol showed a greater preferential deposition in the axons relative to nerve endings when compared to phospholipids.

185 BATRACHOTOXIN BLOCKS SLOW AND RETROGRADE AXONAL TRANSPORT IN VIVO. R.J. Boegman, R.J. Riopelle and E.X. Albuquerque. Depts. of Pharmacology and Medicine, Queen's University, Kingston, Canada, K7L 3N6, and Dept. of Pharmacology, University of Maryland, Baltimore MD 21201.

Batrachotoxin (BTX) causes membrane depolarization and has been shown to block fast axonal transport both in vivo and in vitro at concentrations of 1.86×10^{-12} and 1×10^{-9} moles respectively (Boegman and Albuquerque, Fed. Proc. 62 158 1978; Ochs and Worth, Science. 187 1087 1975). It is not clear how the toxin blocks fast axonal transport since there does not appear to be a direct relationship between membrane excitability and the transport process. In an attempt to define the site at which BTX acts in blocking axonal transport we examined slow axonal transport and retrograde axonal transport in BTX-poisoned nerves in vivo. The accumulation of cholineacetyltransferase (CAT) proximal to and Nerve Growth Factor (NGF) distal to the site of BTX (3.7×10^{-11} moles) injection was used to monitor slow and retrograde axonal transport respectively. Slow transport was blocked within 1 day and remained so for up to 7 to 10 days when recovery was evident by the decreased accumulation of CAT at the site of injection. The amount of CAT accumulating proximal to the injection site was, however, only 1/2 that observed following nerve ligation. Retrograde transport of ^{125}IβNGF was blocked within 6 hrs of injection into the foot pad with accumulation of the protein distal to the site of BTX injection. The degree of block was as complete as that observed following nerve ligation. Neither BTX nor TTX influenced uptake or transport of ^{125}IβNGF when injected into the nerve or into the foot pad 30 minutes prior to NGF injection. In contrast to BTX, Tetrodotoxin did not block either slow or retrograde axonal transport. These results suggest that BTX interacts with a component in the axon possibly tubulin or Ca++ which is required to maintain fast, slow and retrograde axonal transport.

186 NERVE SPECIFIC ENOLASE AND CREATINE PHOSPHOKINASE ARE TRANSPORTED AS PART OF THE AXOPLASMIC MATRIX (SLOW COMPONENT b). Scott T. Brady* and Raymond J. Lasek (SPON: R. Plonsey). Dept. Anat. Sch. Med., Case Western Reserve Univ., Cleveland, OH. 44106.

Slow Component b (SCb) is a complex constellation of proteins moving in the anterograde direction along the axon at a rate of 3-4 mm/day. Materials associated with SCb have been shown to move separately from the microtubule-neurofilament network (Slow Component a) and to include both actin and clathrin (Garner and Lasek 1978 Trans.Am. Soc. Neurochem. 9 200, Black and Lasek 1977 Soc. Neurosci. Abstr. 7 29). Pulse labelled SCb is known to move for weeks or months as a discrete wave. These properties of SCb suggest that it represents a distinct cellular structure which may be termed the axoplasmic matrix, although some 60% of the proteins in SCb are easily solubilized in physiologic buffer. These easily solubilized proteins are commonly thought to be diffusible proteins in the cell and may include the enzymes of glycolysis and related intermediary metabolic pathways. Marangos et al (1975 Biochim. Biophys. Acta 392 75) reported the axonal transport at 6 days but not at 6 hours of a brain specific soluble protein later found to have enolase activity. Since this nerve specific enolase (NSE) [E.C. No. 4.2.1.11] is the nerve isozyme of the glycolytic enzyme, we have examined the transport of NSE and a second enzyme associated with energy metabolism, creatine phosphokinase (CPK) [E.C. No. 2.7.3.2].

^{35}S-methionine was injected into the eyes of adult guinea pigs. The animals were sacrificed 6 days later when the only labelled proteins in the optic nerve are associated with SCb. The optic nerve was homogenized and aliquots subjected to two dimensional electrophoresis. NSE was purified by a modification of the procedure of Marangos et al (1975 J. Biol. Chem. 250 1884) and rabbit brain CPK was obtained from Sigma (St. Louis, Mo.). Fluorographs of the two dimensional gels showed at least 50 proteins transported in SCb. NSE (pI 5.5, mw 48000) and CPK (pI 6.3 mw 43000) were found to have labelled homologues in SCb which behaved identically upon two dimensional electrophoresis. We conclude that NSE and CPK are transported in SCb. It has been suggested that SCb proteins are tightly associated in a highly ordered complex because they move in a coherent manner and are associated specifically with SCb and not with any other transport components [i.e. Slow Component a and Fast Component] (Tytell and Lasek 1978 Soc. Neurosci. Abstr. 8 37). If the easily solubilized proteins NSE and CPK are associated with this complex, which we term the axoplasmic matrix, then the common view that these and other metabolic enzymes are diffusible in the axon requires reevaluation.

187 **AGRANULAR RETICULUM-LIKE CISTERNS INVOLVED IN THE NEURONAL TRANSPORT OF ACID HYDROLASES AND HORSERADISH PEROXIDASE (HRP).** **M. W. Brightman* and R. D. Broadwell (SPON: S. P. Wise). Lab. Neuropath. and Neuroanat. Sci., NINCDS, NIH, Bethesda, MD 20205.**

Studies with HRP as a tracer have suggested that the agranular reticulum is associated with the anterograde and retrograde axonal transport of peroxidase. We have reported (J. Comp. Neurol. 185:31, '79) that in the hypothalamo-neurohypophysial system of the hydrated mouse, HRP-labeled cisternal profiles with an appearance and width (400-700Å) similar to the agranular reticulum were minimally involved in the retrograde axonal transport of the HRP. Similar profiles labeled with HRP or containing acid hydrolase were more prevalent during anterograde axonal transport, but only in hyperosmotically stressed mice. We proposed that these cisterns are part of the lysosomal system and that anterograde transport of HRP is associated with the movement of acid hydrolases, presumably from perikaryal secondary lysosomes. We report here additional evidence that these organelles in the soma participate in the anterograde movement.

In supraoptic perikarya from normal, hydrated mice injected with HRP into the blood or cerebral ventricles, very few agranular reticulum-like cisterns, attached or unattached to secondary lysosomes, contained peroxidase. The number of HRP-labeled cisterns and dense bodies increased when the animals were hyperosmotically stressed by having them drink 2% NaCl 5-8 days prior to HRP injection. Supraoptic cell bodies from osmotically stressed mice not injected with HRP were incubated for acid hydrolase activity using trimetaphosphate or β-glycerophosphate as substrate . Acid hydrolase-positive lysosomes and 400-1000Å wide cisterns proliferated in these perikarya. Some of the cisterns were confluent with secondary lysosomes. Peroxidase-exposed perikarya incubated for both HRP and acid hydrolase activity from the salt-treated animals contained secondary lysosomes and a few cisterns which exhibited reaction products of both enzymes.

Our results suggest that agranular reticulum-like cisterns in the perikaryon, like those in the axon, are part of the lysosomal system of organelles and may provide the route through which acid hydrolases and other lysosomal-related substances can leave secondary lysosomes within the perikaryon for transport down the axon.

188 BATRACHOTOXIN BLOCKADE OF AXOPLASMIC TRANSPORT: STUDIES OF A DIRECT TOXIN EFFECT ON PURIFIED MICROTUBULES. George B. Brown and Lelland C. Tolbert, Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294.

Ochs and Worth (Science, 187:1087, 1975) have shown that the steroidal alkaloid batrachotoxin (BTX) is 5,000 to 10,000 times more potent than the vinca alkaloids in blocking fast axoplasmic transport in the cat, and that this effect is not due to the well-known depolarizing action of the toxin on excitable cells. We have purified tubulin from rat brain using three cycles of polymerization/depolymerization and examined the binding of a radiolabeled BTX derivative, ^{3}H-batrachotoxin benzoate (^{3}H-BTX-B), to this protein. At a concentration of 0.1 μM, ^{3}H-BTX B did not bind to tubulin in either the depolymerized or polymerized state over a time period of 2.5 hr. Ochs and Worth reported that 0.1 μM BTX produced a block of axoplasmic transport in 2.35 hr. We also conducted a pilot study to examine the effect of BTX on the polymerization of tubulin. Purified tubulin was subjected to polymerizing conditions (0.1 mM 2-(N-morpholino) ethanesulfonic acid, 1 mM EGTA, 1 mM GTP, 0.5 mM $MgCl_2$, 4 M glycerol, pH 6.4, at 37°C) either in the presence or absence of 1 μM BTX. Polymerization was allowed to continue for 1.6 hr and the amount non-polymerized protein remaining was determined. Relative to the sample without toxin, BTX inhibited polymerization by approximately 20%. The observed lack of ^{3}H-BTX-B binding to tubulin contrasts with the apparent direct action of BTX on tubulin polymerization in our initial study. Although BTX-B is known to bind at the same sodium channel site as BTX, this may not be the case with respect to toxin action on axoplasmic transport. The effect of batrachotoxin benzoate on axoplasmic transport should be tested in vitro.

189 DIFFERENTIAL UPTAKE OF HORSERADISH PEROXIDASE ISOENZYMES BY CULTURED NEUROBLASTOMA CELLS. Kwan Y. Chan, Richard H. Haschke and Ann H. Bunt. Depts. of Ophthalmology and Anesthesiology, University of Washington, Seattle, WA 98195.

Neurons of the central visual pathways of the rat have been shown to take up horseradish peroxidase (HRP) at the axon terminal and transport the protein retrogradely in a selective way (Bunt and Haschke, 1978: J. Neurocytol. 7, 655-78). Cultured mouse neuroblastoma cells (clone N18) have been used to develop an in vitro system for further studying the selectivity of protein uptake. The cells, while differentiating in serum-free medium, were incubated with HRP isoenzyme C (HRP-C) and A (HRP-A). Ultrastructural morphometry of labeled organelles was performed on cells fixed and processed for cytochemistry after incubating with 2 mg/ml of HRP for 5 min and also for 5 min followed by an hour of wash. The number of vesicles labeled by HRP-C was 1.5 times that of HRP-A during initial endocytosis, and the number of dense bodies labeled by HRP-C was 1.8 times that of HRP-A in the pulse-chase experiment. However, to overcome the limitations of morphometry the rate of uptake of HRP isoenzymes in unfixed cells was quantified by a spectrophotometric assay using o-dianisidine as substrate. To measure rates of intracellular decay of HRP activity after endocytosis, the cells were incubated with 0.5 mg/ml of HRP for 2 h and subsequently washed for various periods. After lysing the cells in 0.05% Triton X-100, HRP activity was measured directly in the lysate. The data showed that the two isoenzymes decayed at different rates inside the cells, with a half-life ($t_{½}$) of 8.7 h for HRP-C and 1.9 h for HRP-A. The decay rate constant (k) can be calculated from equation $k = \frac{\ln 0.5}{t_{½}}$. To find the rate of uptake of HRP, the cells were incubated with 0.2 mg/ml of HRP for various periods, washed 5 times and lysed. The amount of HRP internalized by the cells for a given period (t) was measured (X'_t) and corrected for lysosomal decay to obtain the initial value (X_t), by using the equation $X_t = \frac{X'_t \cdot kt}{1-e^{-kt}}$.

Over the 7-hour period studied, HRP-C was taken up by N18 cells at a rate 2.2 times that of HRP-A. Over the HRP concentration range of 0.2-0.7 mg/ml, HRP-C was incorporated into cells 2-3 times faster than HRP-A. At higher concentrations (2 to 6 mg/ml) the rate of uptake of these isoenzymes appeared to become similar. Experiments are in progress to assess the effects of various compounds on the uptake of proteins by these cells.

190 CALCIUM LOCALIZATION IN MAMMALIAN NERVE FIBERS IN RELATION TO ITS REGULATION AND AXOPLASMIC TRANSPORT. S.Y.Chan, S.Ochs, and R. Jersild,Jr.: Depts. of Physiol., Anat., and The Biophysics Prog., Indiana University Medical Center, Indianapolis, IN 46223.

A specific Ca^{2+} requirement for axoplasmic transport was shown using a desheathed cat sciatic nerve preparation (Ochs, Worth & Chan, Nature, 270: 748, 1977). A block of transport was seen following incubation of nerves in a Ca^{2+}-free or low Ca^{2+}medium with normal transport restored by adding Ca^{2+}. The block in Ca^{2+}-free media was considered due to a depletion of free Ca^{2+} from the axons. On the basis of the transport filament model, the level of free Ca^{2+} in the axon regulates a calcium binding protein (calmodulin) which activates the Ca^{2+}-Mg^{2+}-ATPase utilizing ATP needed to drive the transport filaments. The level of free Ca^{2+} in the axon is regulated by mechanisms present in the mitochondria and endoplasmic reticulum (ER) which sequester and release Ca^{2+}, keeping it close to about 10^{-7}M. To show the presence of Ca^{2+}, K^{+}-pyroantimonate which binds to Ca^{2+} to form an electron-dense deposit, was used to stain thin sections of nerve for EM. Nerves were incubated in media containing normal levels of Ca^{2+} or media with raised or lowered levels of Ca^{2+}. Incubation was carried out at 38°C, pH 6.7 and the nerves bubbled with 95% O_2 + 5% CO_2. The nerves segments were then fixed in 5% glutaldehyde and 1% osmium with 2% K-pyroantimonate added. Electron-dense granules were seen in the EM sections of nerves incubated for 3 hrs or more in normal media containing Ca^{2+}. The granules were found scattered throughout the axoplasm with some attached to the axolemma, to the surface of the mitochondria, and some within the ER. Evidence that the granules contained Ca^{2+} was obtained from their wash-out from thin sections exposed to 4 mM EGTA. Preliminary studies using X-ray microanalysis also showed Ca^{2+} present in the granules. Experiments with Na^{+} and Mg^{2+} showed very much less binding to pyroantimonate. When incubated in a Ca^{2+}-free medium for 3 hours or more, the nerves were depleted of their granular deposits. Conversely, when desheathed nerves were placed in in vitro media containing 20 mM Ca^{2+} or more, a larger number of granules was seen throughout the axoplasm, in the ER, inside the matrix and attached to the outside of the mitochondria. Granules were also seen in the nodes of Ranvier which could be related to the exchange of Ca^{2+} at the nodal membrane. The increased deposits seen in the nerves exposed to high levels of Ca^{2+} were depleted from nerves returned to a low Ca^{2+} medium for at least ½ hr. This was most marked for the mitochondria and ER. Such changes indicate that these organelles act to regulate the level of free Ca^{2+} in the axons by sequestering and releasing Ca^{2+}. 192 NEW TECHNIQUES FOR REVEALING THE CYTOSKELETON OF AXOPLASM AND THE EFFECTS OF CA^{++} UPON ITS ORGANIZATION. Mark H. Ellisman and Keith R. Porter. Dept. Neurosci., Sch. Med., UCSD, La Jolla, CA 92093.

The microtrabecular matrix of axoplasm was found to consist of an organized system of crossbridges between microtubules, neurofilaments, cisternae of the smooth ER and the plasma membrane. It is proposed that formation and deformation of this system is involved in rapid axonal transport. In order to facilitate electron microscopic visualization of the trabecular connections between elements of axoplasm the following three techniques were used: First, the addition of tannic acid to the primary fixative coupled with en bloc staining in uranyl acetate for conventional TEM. Second, embedding tissue in polyethylene glycol for thin sectioning, dissolving out the embedding media from the sections and then critical-point-drying (Wolosewick & Porter, in press). Third, visualization in freeze-etch replicas by rotary shadowing. All of these procedures yielded images of cross-linking elements between neurofilaments and organelles of the axoplasm.

Our next objective involved the determination of fixation conditions which best preserved the cross-linking trabeculae. We examined the effect of variable Ca^{++} ion concentrations and low temperature upon the form and connectivity of these structures. By incubating nerve fibers in solutions containing either no Ca^{++} with ionophore A23187 (Lilly) and EGTA, or alternatively high Ca^{++} and ionophore, we were able to determine the effect of high and low Ca^{++} ion concentrations upon the cross bridges. The results indicate that elevated Ca^{++} concentrations reduce the amount and integrity of trabecular linkages between fibrous proteins and cisternal elements, while decreased Ca^{++} availability within the axoplasm increases the amount of intact trabecular cross-links. These improvements in visualization should enable us to examine the distribution of trabecular links on motile axonal organelles.

193 TRANSNEURONAL TRANSPORT OF HORSERADISH PEROXIDASE IN THE RAT CILIARY GANGLION. P. Gomêz-Ramos*, E.L. Rodriguez-Echandia* (SPON: F. Reinoso-Suarez). Dept. Morfología, Inst. Invest.Oftalmol. Castroviejo, Fac. Medicina, Univ. Autónoma.Madrid 34.Spain.

Transneuronal transport of some macromolecules such as radioactive tetanus toxin has been shown after retrograde intraaxonal transport (Schwab and Thoenen, 1976 Brain Res 105: 213-227). However, it has not been possible to detect transneuronal transfer of other materials such as labeled nerve growth factor although it is transported retrogradely in a similar manner (Schwab and Thoenen, 1977 Brain Res. 122:459-474). These data seem to favor the concept of a specific transneuronal transport of macromolecules. We now report a transneuronal transport of HRP in the ciliary ganglion of the rat. The HRP is known to be transported mainly in the retrograde direction.

Injections of HRP (1mg/µl, Sigma type VI) were made in the ciliary body of the eye. After 24 hours the animals were perfused and the HRP activity in the brain and in the ciliary ganglion was revealed by the Graham and Karnovsky technique (1966).

In the brains no HRP positive neurons were identified neither in the Edinger-Westphal nucleus nor in any other mesencephalic structure in the 40 µ thick sections studied by light microscopy.

The electron microscopic observations on the ciliary ganglion homolateral to the injection showed HRP reaction product in the neuronal soma but the major proportion of HRP at this time interval was found at both dendritic processes and preganglionic axons. It was possible to visualize the release of the HRP reaction product from membrane-bound vesicles located in the peripheral perikarya or in the dendritic processes to the extracellular space. Also, in some cases images appeared in which vesicles containing HRP were incorporated by the preganglionic axon terminals. Such images were never observed in the synaptic cleft in our material.

Although the possibility of a trans-synaptic passage can not be ruled out, our results support the suggestion that the HRP is released from the ciliary ganglion cells to the extracellular space. This release seems not to occur at the synaptic surface. When the HRP is in the extracellular space, it is taken up by the axon terminals in the proximity but not in the region of the synaptic surface.

Supported by DCINP Grant n°78/77.

194 AXONAL TRANSPORT OF PHOSPHOLIPIDS IN RAT SCIATIC NERVE. Robert M. Gould, Raymond S. Sinatra*, Warren Spivack*, Mark Berti*, Henry M. Wisniewski*, Thomas Lindquist*, and Nicholas Ingoglia. N.Y.S. Inst. for Bas. Res. Ment. Retard., Staten Island, NY 10314, and Dept. of Physiol. and Neurosci., N.J. Med. Sch., Newark, NJ 07103.

Using EM autoradiographic techniques we have demonstrated that tritiated inositol, locally injected into mouse and rat sciatic nerve is actively incorporated into phospholipid within the axoplasm. In contrast, we have found no evidence for an axon-based incorporation of choline into phosphatidylcholine. At last years meeting we presented evidence that inositol transferase, the enzyme required for de novo phosphatidylinositol formation is axonally transported. Choline phosphotransferase required for de novo phosphatidylcholine synthesis is probably not axonally transported. Buildup of this enzyme at the site of nerve ligation was shown to be largely a result of increased metabolism of local Schwann cells, responding to the trauma.

In this present report we examine the axonal transport of the phospholipids in rat sciatic nerve following the injection of tritiated choline and inositol into the spinal cord (according to the procedure of Lindquist and Ingoglia, Brain Res. 161 (1979) 95-112). At the time of injection the left sciatic nerve was crushed at its emergence from the sciatic notch. At 6, 12, and 18 days following the injection and crush animals were sacrificed by intracardiac perfusion with 4% glutaraldehyde in Millonig's phosphate buffer. The spinal cord, ventral roots (L_4 & L_5) and both sciatic trunks were carefully dissected. Both nerves were sectioned into two mm lengths and alternate sections were taken for autoradiographic and biochemical analyses.

The distributions of radioactive lipids along the nerves varied. With both precursors a greater percentage of the label was found more distal at the longer survival times. In both normal and crushed nerves phosphatidylcholine was transported to a greater degree than phosphatidylinositol. Toews et al (J. Neurochem. 32 (1979) 1165-1173) made a similar observation with transport in rat optic nerve using ^{32}P-phosphate as precursor. There was not much difference in the distribution of lipid along the control and crushed nerves.

Grain localization in more distal segments (after 30 days exposure) is much more pronounced with choline than inositol. With choline label is localized over axons and the myelin sheaths suggesting as pointed out by Droz et al (Brain Res. 155 (1978) 342-355) that some transported lipid can enter the myelin sheaths. Some label is also present in the growing tips and regenerating fibers. (Supported by grants NS-13980, AM-20541, and NEI-02887 from NIH).

195 DYNEIN CROSSBRIDGING OF BRAIN MICROTUBULES AND ITS ATP DISSOCIATION. Leah T. Haimo* and Joel L. Rosenbaum. Dept. Biol., Yale Univ., New Haven, CT 06520.

Dynein, the ATPase enzyme responsible for flagellar beating, binds to brain microtubules and causes their ATP dependent crossbridging. When dynein, obtained from Chlamydomonas flagella, is combined with purified brain tubulin and the preparation warmed to 30 C, microtubules are immediately formed as analyzed by an increase in turbidity of the tubulin suspension and by the observation of microtubules by dark field optics. Moreover, these microtubules appear aggragated when compared to microtubules assembled in the absence of dynein. Examination of these aggragated microtubules by electron microscopy reveals them to be crossbridged by a regular array of dynein-like arms; no such arms are observed on microtubules to which dynein is not added. Moreover, the periodicity of these arms along the in vitro assembled microtubules is 23.5nm, equal to the spacing of dynein arms along flagellar microtubules. Addition of ATP to the aggragated microtubules results in an immediate decrease in turbidity of the microtubule suspension, and observation of this preparation by dark field microscopy indicates that the microtubules are no longer aggragated.

The ATPase activity of microtubules polymerized in the presence of dynein is 0.1-0.2 umole Pi/min/mg which is slightly less than that of flagellar axonemes, 0.2-0.3 umole Pi/min/mg. On the other hand, microtubules polymerized in the absence of dynein have no measureable ATPase activity. Furthermore, SDS gel electrophoresis indicates that dynein sediments with microtubules on a sucrose gradient.

In favorable electron microscopic preparations, the dynein arms are observed to bind to the in vitro assembled brain microtubules at an angle. Dynein can, therefore, be used to determine the polarity of microtubules in situ.

These observations demonstrate that dynein can bind to brain microtubules, induce their crossbridging, and result in ATP dependent microtubule sliding. These data are the first demonstration that cytoplasmic microtubules can bind dynein in a manner similar to that of flagellar microtubules and supports the notion that cytoplasmic microtubule-mediated movements might result from dynein induced crossbridging between adjacent microtubules.

196 CALMODULIN ACTIVATION OF BRAIN AND NERVE Ca^{2+}-Mg^{2+}-ATPASE. Z. Iqbal, B.P. Garg*, and S. Ochs. Depts. of Physiology, Neurology and the Medical Biophysics Program. Indiana University Medical Center, Indianapolis, Indiana 46223.

In the transport filament model for the axoplasmic transport, the energy required for the transport of materials is supplied through the hydrolysis of ATP by a calcium-dependent adenosine triphosphatase (Ca^{2+}-Mg^{2+}-ATPase) which had been found present in the nerve (Khan and Ochs, Brain Res. 81: 413-426, 1974). Calcium has also been shown to be required to maintain transport by the block of transport in desheathed nerves placed in a Ca^{2+}-free medium in vitro and the addition of Ca^{2+} reversing the block (Ochs, Chan, and Worth, Nature 270: 749-750, 1977). We have also demonstrated that Ca^{2+} is fast transported in association with a calcium binding protein (CaBP) in nerve (Iqbal and Ochs, J. Neurochem. 31: 409-418, 1978). The CaBP shows similarities to the calcium-dependent regulatory protein (CDR) as regards its electrophoretic mobility on acrylamide gels containing SDS and its isoelectric point (3.9) on isoelectrofocusing. CDR, which is now known as calmodulin, was first observed as a modulator of adenylate cyclase and cyclic nucleotide phosphodiesterase (PDE) of brain and has recently been found to activate Ca^{2+}-Mg^{2+}-ATPase isolated from RBC and sarcolemma. In this communication we now report that peripheral nerve calmodulin can stimulate microsomal Ca^{2+}-Mg^{2+}-ATPase isolated from neural tissue. Cat brains were homogenized in 0.32 M sucrose and the post-mitochondrial supernatant was centrifuged at 105,000 g for 1 hr. The microsomal pellet obtained in this preparation contains an appreciable amount of calmodulin. This was determined by; (a) electrophoresis on acrylamide gels containing SDS, (b) activation of PDE, and (c) the binding to it of ^3H-trifluoperazine (TFP). Washing the microsomes with 10 mM Tris-HCl, pH 7.5 containing 0.1 mM EGTA was not effective in releasing calmodulin from the microsomes. Incubation of the microsomes in 0.05% Triton X-100 was relatively more effective in dissociating calmodulin from the microsomes. The pellet obtained after the treatment of the microsomes with Triton X-100 had Ca^{2+}-Mg^{2+}-ATPase activity which was stimulated 1.5 - 3-fold by the calmodulin prepared from peripheral nerve. This stimulation was found to depend on the level of Ca^{2+} concentration in the incubation medium. Furthermore, addition of TFP blocked the stimulation of Ca^{2+}-Mg^{2+}-ATPase by calmodulin. Similar observations were made using the Ca^{2+}-Mg^{2+}-ATPase obtained from sciatic nerve. These results suggest that under physiological conditions where Ca^{2+} levels are low, approximately 10^{-7} M, calmodulin is required to activate Ca^{2+}-Mg^{2+}-ATPase, an integral part of the axoplasmic transport mechanism. Supported by NIH grant # RO1 8706-10 and NSF grant # BNS 77-24176.

197 EFFECT OF RESERPINE ON AXONAL TRANSPORT OF PROTEINS AND GLYCOPROTEINS IN NORADRENERGIC NEURONS IN THE RAT BRAIN. Barry E. Levin, Neurology Serv. and Dept. of Neurosciences, VA Med. Ctr., East Orange, NJ 07019 and N. J. Med. School, Newark, NJ 07103

The injection of radiolabeled precursors into the locus coeruleus (LC) of the rat is followed by the sequential appearance in the hypothalamus of 2 waves of rapidly transported glycoproteins (wave I:72-192 mm/d and wave II:24 48-mm/d), one intermediately (wave III:13-20 mm/d) and one slowly transported (wave V:1.4-2.9 mm/d) wave of proteins travelling in noradrenergic neurons. Reserpine, which disrupts storage of catecholamines and markedly affects the metabolism of LC noradrenergic neurons, also affects axonal transport and turnover of proteins in these neurons. Rats were pretreated with Serpasil phosphate (Ciba), 5 mg/kg IP, at intervals of 1-21 days prior to [^3H] fucose (waves I and II) or [^3H] leucine (waves III and V) injection into the LC. Reserpine pretreatment was associated with significant decreases to 25-40% of control LC levels in [^3H] glycoprotein and protein content during the first 2 days following injection. When axonal transport was corrected for these and subsequent changes in LC protein turnover to give a net transport value, distinctly different effects of reserpine pretreatment on the various waves were evident when compared to vehicle injected or uninjected controls. In general, axonal transport in all four waves was decreased at some point during the first four days after reserpine injections, varying from complete to partial blockade. Transient decreases in transport also occurred at 7 and 14 days after reserpine in waves I and II, while wave V was decreased from 8-10 days. Transport in wave III was significantly depressed from days 6 through 10. Transport in all waves had returned to control levels by day 21 after reserpine injection. That these changes in transport were due to decreased quantities of transported proteins rather than a change in transport rates was shown by the failure of transported [^3H] proteins to appear in serial hypothalamic sections at various times other than those at which such waves would usually have appeared in the untreated animals. The differential effects of reserpine on axonal transport of proteins and glycoproteins in these neurons appear to reflect a re-ordering of the priorities of the cell in response to the changes in the metabolism of catecholamines and their synthetic enzymes caused by reserpine.

198 IMMUNOFLUORESCENT LOCALIZATION OF AXONALLY-TRANSPORTED POLYPEPTIDES. Joel Levine* and Mark Willard*. (SPON:D.G.Amaral). Dept. Anat.&Neurobiol., Wash.Univ.Sch.Med., St. Louis, MO 63110.

We have used immunofluorescent techniques to determine the destination of two axonally-transported polypeptides. These polypeptides, designated 26 and 27, were previously shown to move down axons of rabbit and guinea pig retinal ganglion cells at a velocity of approximately 50 mm per day, i.e. slower than the most rapidly moving group of axonally transported polypeptides, but faster than at least three other groups. Twenty-six and twenty-seven (molecular weights 260,000 and 245,000, respectively) have an electrophoretic mobility similar to that of erythrocyte spectrin, smooth muscle filamin and several other actin-binding proteins.

In order to raise an antibody against 26 and 27, we purified these polypeptides from an extract (0.6M KCL) of guinea pig brain by means of gel filtration and preparative SDS gel electrophoresis and injected the denatured purified polypeptides into rabbits. The resulting antibody was specific for 26 and 27 by the criterion of immunodiffusion; in addition, it precipitated only 26 and 27 from detergent extracts of guinea pig brain and from extracts of the optic nerve and tract containing radioactively labeled transported proteins.

We used the antibody to locate 26 and 27 in frozen sections of nervous tissue by indirect immunofluorescence. In sections of guinea pig spinal cord and brainstem containing axons cut in cross-section, the major fluorescent profiles were ring-like, indicating that 26 and 27 are most concentrated near the axolemma. The fluorescent profiles probably cannot be entirely accounted for by staining of the myelin sheath since large motor neurons displayed a fine rim of fluorescence around unmyelinated structures, e.g. the perikarya, large dendrites and axon initial segment. Immunoprecipitation experiments showed that the 26 and 27 antigens are present in other tissues, including kidney, liver, cardiac muscle and cultured fibroblasts. When cultured guinea pig fibroblasts were stained with the antibody, the fluorescence appeared in linear arrays and bands across the cells. In all cases, the immunofluorescent staining was specific for the 26 and 27 antigens since similar fluorescent profiles were absent when tissues and cells were stained with pre-immune serum, pooled serum from non-immunized rabbits and serum which had been adsorbed with 26 and 27. These results strongly suggest that 26 and 27 are located peripherally in nerve cells, most likely closely associated with the plasma membrane; judging from the results with fibroblasts, they are disposed in a non-uniform, highly organized fashion.

199 A NEW PROCEDURE FOR MICROELECTROPHORETIC DELIVERTY OF HORSERADISH PEROXIDASE. E.R. Marchand and J.N. Riley. Dept. Neurosciences, Univ. California San Diego, La Jolla, CA 92093.

The horseradish peroxidase (HRP) retrograde tracing method has been used extensively as a neuroanatomical tracing technique. One of the major drawbacks of the method is the extensive diffusion of the enzyme when injected into the CNS. While more discrete deposits can be made with the microelectrophoretic procedure developed by Graybiel and Devor (1974), analysis of local connections is obscured by diffusion of the enzyme. We have developed a procedure which allows extremely small deposits of HRP to be made in which there is little secondary diffusion of the enzyme.

The basic elements of the procedure are: (a) dilute solutions (1.5%-5%, w/v) of fluorescein isothiocyanate-conjugated HRP (F-HRP, Polysciences) in 0.1 M Tris·HCl buffer, pH 8.5, are loaded in glass micropipettes having internal tip diameters of 4-12 μm; (b) constant cathodal current (2-4 μA) is passed for 10-60 min to eject the F-HRP. Unlike unlabeled HRP, F-HRP-filled electrodes will carry constant cathodal current for extended periods of time; (c) following survival times of 24-30 hrs, animals are perfused with 5% dextrose in 0.05 M phosphate buffer followed by 2% glutaraldehyde solutions containing 5% and 10% sucrose in the same buffer; (d) frozen sections are processed according to a modified benzidine dihydrochloride procedure.

We have found that the use of F-HRP has several advantages for making electrophoretic deposits compared to unconjugated HRP, such as Sigma Type VI. First, extremely small deposits are made reliably. Deposits as small as 125 μm result in detectable retrograde and anterograde transport. Second, the secondary diffusion of F-HRP is significantly less than with unconjugated HRP, even when the injection sites are of comparable size. Third, the use of a dilute F-HRP solution minimizes any potential problem from leakage along the electrode tract.

Details of the procedure will be presented as well as examples of results obtained with the method is studies of the afferents to the suprachiasmatic nucleus and arcuate nucleus of the hypothalamus of the rat.

200 THE ANTEROGRADE TRANSPORT OF HRP IS AN ACTIVE PROCESS. M-M. Mesulam and E.J. Mufson. Beth Israel Hospital, Boston, MA.

Many investigators have reported that efferent neural connections of the injection site can be demonstrated with horseradish peroxidase (HRP) histochemistry. While the retrograde transport of HRP is universally ascribed to an active process within intact neurons, the mechanisms responsible for its anterograde displacement remain controversial. For instance, some investigators consider the anterograde displacement of HRP to be insignificant and unreliable while others stress the necessity for axonal damage and subsequent passive diffusion. However, we would like to present evidence which suggests that the anterograde transport of HRP is an active and reliable process, perhaps identical to the transport of this enzyme in the retrograde direction.

Experiments with intraocular injections of HRP in rats show that the anterograde displacement of the enzyme to the suprachiasmatic nuclei, to the lateral geniculate bodies and to the superior colliculi is blocked if the eye is pretreated with colchicine or pentobarbital. No blocking occurs when the pretreatment consists of saline. Furthermore, if the pretreatment precedes the HRP injection by 10 days, the block is no longer evident. Thus, the inhibition of anterograde displacement is reversible and not due to permanent injury of the retina. These results strongly suggest that the mechanism is one of active transport, perhaps dependent on the microtubular system.

In further experiments, the brains of rats with intraocular HRP injections were processed not only for HRP histochemistry but also with the Nauta stain. The absence of degeneration-induced argyrophilia within the same areas that received anterogradely transported HRP demonstrated that retinal damage is not necessary for the occurance of anterograde transport. In addition, neither the rapid rate of the appearance of the reaction-product at anterograde termination sites nor its granularity is consistent with passive diffusion as the underlying process.

The validity of the anterograde transport of HRP can be shown in cases with combined intraocular injections of HRP and ^{3}H-amino acids by the similarity of the termination patterns demonstrated by both tracers. Furthermore, in other experiments in rats and monkeys, we have demonstrated all the known efferents of various injection sites with HRP histochemistry. However, these experiments also showed that HRP methods more sensitive than the traditional diaminobenzidine procedure are required for the reliable visualization of efferent neural connections.

In conclusion, the anterograde displacement of HRP is probably as significant and active a process as its retrograde transport. Although caveats are still applicable to its interpretation, it is clear that the active anterograde transport of HRP may be used for tracing efferent connections. (Supported by NS-09211).

201 DIFFERENCES IN GLIAL AND NEURONAL LABELING FOLLOWING ^{3}H-LEUCINE AND ^{3}H-PROLINE INJECTIONS IN THE DORSAL COLUMN NUCLEI OF CATS. H. H. Molinari and K. J. Berkley. Dept. Psychol., Fl. St. Univ., Tallahassee, FL 32306

When ^{3}H-leu is injected into the dorsal column nuclei (DCN) of cats, most large and some small cells are labeled. When ^{3}H-pro is injected, only small cells are labeled and the neuropil labeling between cells becomes heavier and more homogeneous.

In order to characterize these labeled elements more precisely, injection sites from the DCN clusters region were examined using electron microscopic autoradiography. Following ^{3}H-leu injections, most neurons were densely labeled. About 50% of the astrocytes and oligodendrocytes were also labeled with a density about equal to or less than the neurons. Scattered labeling of the rest of the neuropil was related predominantly to dendrites and axons. In contrast, following ^{3}H-pro injections, all neurons were, at best, only lightly labeled while glial cells were heavily labeled. In addition to a marked increase in the density of grains over labeled glia, there was an increase in the percent of labeled astrocytes to about 85%. These increases were reflected in the rest of the neuropil by an increase in the proportion of grains associated with astrocytic processes and myelin and a decrease in the proportion associated with dendrites and axoplasm.

Since many astrocytes are located adjacent to neurons in the DCN clusters region, it was possible that the probability of glial cell labeling might depend upon its proximity to these neurons. At both ^{3}H-pro and ^{3}H-leu injection sites, however, glial labeling did not appear to depend upon the proximity of the glial cells either to neurons, blood vessels or other glial cells.

The reasons for the preferential uptake of ^{3}H-pro by glial, and not by neuronal, elements in DCN is not yet known. Since such an uptake pattern suggests that proline might function as a neurotransmitter, various physiological manipulations which might be expected to alter the labeling patterns of neurotransmitters were performed prior to injecting ^{3}H-pro into DCN. Such manipulations included: a) depolarization of axon terminals in DCN either by increasing the K^{+} concentration or by electrically stimulating the dorsal columns (DC), b) removal of synaptic terminals by ablating DC and the somatosensory cortex, or c) antidromic activation of the cluster neurons. None of these manipulations changed the light microscopic labeling pattern. Thus, it appears that proline probably does not function as a neurotransmitter in DCN. This conclusion is supported by the fact that putative neurotransmitters in DCN, such as glycine, glutamate and GABA, all produced light microscopic labeling patterns unlike that of proline when their tritiated forms were injected into DCN.

202 COMPARISON OF PROTEINS TRANSPORTED IN DIFFERENT CNS TRACTS. Stephanie S. Padilla*, L. Jack Roger*, Arrel D. Toews, Jeffry F. Goodrum* and Pierre Morell. Biol. Sci. Res. Ctr. and Dept. of Biochem., Univ. of North Carolina, Chapel Hill, NC 27514

A comparison was made of the [^{35}S]-methionine labeled proteins axonally transported in each of three central nervous system tracts in the rat [i.e., 1. retina to superior colliculus, 2. dorsal lateral geniculate body (dlgb) to visual cortex, and 3. substantia nigra to "striatum" (nuc. caudatus, putamen, and nuc. accumbens)]. Injection of the isotope into the retina, dlgb or substantia nigra was followed by sacrifice at time points designed to coincide with the arrival of the fast (3-4 hr), intermediate (16-48 hr), and slow (6-21 days) waves of transport in the respective projection sites. After dissection of the injection and projection sites and solubilization of the tissue, proteins were fractionated on a discontinuous (3% stacking gel) 7.0-15% polyacrylamide gradient slab gel in buffers containing sodium dodecyl sulfate. The [^{35}S]-methionine labeled proteins were visualized by fluorography of the dried slab gels.

The injection site radioactive protein profiles were similar for the dlgb and substantia nigra, and differed from retinal proteins labeled by intraocular injection, especially in the intensity of labeling in the range of 35,000-45,000 daltons. During a time span from 3-4 hrs. to 6-21 days after isotope injection, the labeling pattern of the individual injection sites changed very slightly.

In contrast, time-dependent changes were observed in the projection sites; each transport wave contains characteristic proteins. In all three tracts the labeled proteins transported in each wave are very similar in electrophoretic pattern quantitatively. The only distinctive differences observed were labeled protein of MW≈27,000 (arriving in the intermediate and slow waves) absent in the superior colliculus but present in the visual cortex and striatum; and a protein MW≈53,000 (arriving in the slow wave) absent in the visual cortex but present in the striatum.

Two heavily labeled rapidly transported proteins common to the three tracts exhibit similar turnover properties: one, MW≈105,000, has disappeared by the arrival of the intermediate wave and the other, MW≈26,000, has decreased considerably by the time of arrival of the slow phase.

203 **ON THE MECHANISM OF ACTION OF PYRIDINETHIONE ON THE NERVOUS SYSTEM.** Mohammad I. Sabri* and Peter S. Spencer. Dept. Neurol. & Neurosci., Alb. Ein. Coll. Med., Bronx, NY 10461

The zinc salt of 1-hydroxy-2(1H) pyridinethione, commonly known as zinc pyridinethione (ZPT), is a broad spectrum bacteriocide and fungicide used as a antidandruff ingredient in shampoos. Oral administration of ZPT, or percutaneous absorption of the sodium salt of 1-hydroxy pyridine--2-thione (NaPT) results in a syndrome of progressive hindlimb paralysis in rodents. Mendell and Sahenk (1) have shown that ZPT interferes with the axonal transport system and produces distal axonopathy in rats. The biochemical mechanisms involved in the pathogenesis of toxic damage seen in ZPT or NaPT neuroapthy are obscure. We have proposed a working hypothesis that chemically unrelated neurotoxins producing distal axonopathy or "dying-back" might be inhib-iting enzyme systems required for the maintenance of intermediary metabolism (2). A blockade of metabolism at one of those sites would have profound effects on energy supplies, causing nerve cells with their high energy demands to undergo pathological changes.

We demonstrated earlier that neurotoxic hexacarbon compounds such as 2,5-hexanedione and methyl n-butyl ketone inhibit the glycolytic enzymes glyceraldehyde-3-phosphate dehydrogenase (DL-glyceraldehyde-3--phosphate: NAD oxidoreductase; phosphorylating; E.C. 1.2.1.12; -GAPHD)(3) and fructose-6-phosphate kinase (phosphofructokinase; ATP:D-fructose-6-phosphate-1-phosphotransferase; E.C. 2.7.1.11; PFK) (4). Acrylamide and carbon disulfide, which also produce distal axonal degeneration, inhibit glycolysis at the same sites, suggesting a common metabolic block. Data reported in this study indicate that NaPT also inhibits these enzymes in crystalline form as well as in nervous tissue. Thus 0.4mM NaPT inhibited crystalline GAPDH by about 30% after 20 min at 37°C in vitro, and at 3mM concentration about 80% activity was lost. A comparable inhibition was found when crystalline and nervous tissue PFK was preincubated with NaPT. The enzyme activities were preserved by dithiothreitol, suggesting sulfhydryl groups are the target sites of toxic action. By contrast, succinic dehydrogenase (succinate:(acceptor) oxido reductase; E.C. 1.3.99.1) activity in isolated rat brain mitochondria was not affected by 0.4mM NaPT; crystalline lactic dehydrogenase (L--lactate:NAD oxidoreductase; E.C. 1.1.1.27) remained unchanged even after preincubation with 25mM NaPT.

In summary, these data point to the causation of toxic neuropathies of the distal axonopathy type and provide a basis to test the biochemical properties of other compounds which precipitate this disease.

204 AFFERENT PROJECTIONS TO THE MEDULLA OBLONGATA IN THE CAT. Patricia M. Saxton and J. Siegel. Inst. for Neuroscience and Behavior, Univ. of Delaware, Newark, DE 19711.

The rostral to midcaudal extent of the medulla oblongata is known to mediate the integration of basic physiological processes including inhibitory motor effects and the coordination of the visual motor system. A previous report (Neurosci. Abst., Vol. III (213), 1977) described projections to the rostral gigantocellular tegmental field (FTG) using injections of 0.2 ul horseradish peroxidase (HRP) and incubating with standard diaminobenzidene (DAB) procedures.

We have since been using the more sensitive tetramethylbenzidene (TMB) chromagen for incubations after pressure injections in the FTG both rostrally at the level of the abducens n. and more caudally dorsal to the inferior olivary complex. Cells of origin are labeled bilaterally in the frontal eye fields (precruciate and lateral deep presylvian gyri), in the mesodiencephalic areas including the ipsilateral interstitial n. of Cajal and contralateral n. of the posterior commissure, contralateral superior colliculus, medial and inferior vestibular n., n. praepositus hypoglossi, n. incertus, and ventrolateral regions of the cervical spinal cord. All of these areas are closely associated with the eye-head coordination of the visual motor system. Cells of origin in the following ventral telencephalic areas are seen exclusively with the sensitive TMB procedures; bilaterally in the ventrolateral frontal cortex (ectosylvian, orbital, and coronal gyri), in the ipsilateral central n. of the amygdala throughout its rostral-caudal extent, the associated bed n. of the st. terminalis, and the substantia innominata of the rostral ventral forebrain. Labeled cells are also seen in the caudal diencephalon in the zona incerta, subthalamus, posterior and lateral hypothalamus; in the mesodiencephalic junction in the prerubral fields and ventral tegmental areas; in the mesencephalic tegmentum; and scattered through the reticular formation bilaterally throughout the medulla. This pattern of labeling is suggestive of a ventral tier of limbic behavioral inhibitory regions converging from the forebrain and other anterior regions onto cells of the caudal brainstem.

Both rostral and caudal medullary injections of 0.2 ul label similar areas of the brain, suggesting the diffuse projections from these areas throughout the extent of the FTG. However, preliminary experiments using smaller injections, 0.02 to 0.04 ul, reveal more specificity, particularly in the afferent projections from the superior colliculus and from the central n. of the amygdala and bed n. of the st. terminalis. (Supported by NSF Grant BNS 76-01652.)

205 EFFECTS OF CHANGES IN THE COMPOSITION OF EXTERNAL SOLUTIONS ON STRUCTURE AND AXONAL PARTICLE TRANSPORT IN AMPHIBIAN AXONS. Richard S. Smith. Department of Surgery, University of Alberta, Edmonton, Alberta, Canada. T6G 2G3

Desheathed sciatic nerves from *Xenopus laevis* were incubated for varying periods of time in salines with and without divalent cations. Single axons were sampled from the nerve bundles and these were viewed by darkfield microscopy to detect axonally transported particles. Nerve bundles treated similarly, but undissected, were fixed for structural studies.

Nerves incubated in salines containing (mM): NaCl, 112; KCl, 3.0; CaCl, 2.0; $MgSO_4$, 2.0, and buffer, displayed an active retrograde particle transport and a normal structure for at least 12 h. In solutions with no Ca^{2+} or Mg^{2+} and with 2 mM EGTA the axons showed, over a period of 4h, a slowing or arrest of particle transport concomittant with gross structural changes. The structural changes consisted of collapse of the axis cylinder and a beading of some of the fibers. Ultrastructural examination showed that in these fibers the axolemma contained defects which may represent holes or local deformations. Addition of 2 to 5mM Mg^{2+} to the solution protected the axons from the structural changes and particle transport continued normally.

Nerves in isotonic NaCl or Na glutamate with EGTA showed slight collapse of the axis cylinder at 4h with continued particle transport. In isotonic KCl with EGTA the fibers became beaded by 4h; the axis cylinders did not collapse and particle transport was active. Nerves in isotonic K glutamate with EGTA remained normal in structure and retrograde particle transport was observed at periods up to 24h.

It is concluded that the abnormality of particle transport in nerves bathed in conventional physiological salines from which divalent cations are omitted is secondary to the structural changes in the axons. Solutions free of divalent cations which caused no or minimal structural changes in the axons caused no abnormality of particle transport. This finding cannot, however, be interpreted to mean that divalent cations play no role in axonal transport.

206 ON THE IMPORTANCE OF PROTEINSYNTHESIS FOR AXONAL TRANSPORT
Richard E. Snyder*, T. Richard Nichols*, SPON: Richard S. Smith. Faculty of Medicine, University of Alberta, Edmonton, Alberta, T6G 2G3, Canada.

These experimental results provide evidence that protein synthesis is necessary for the loading not only of amino acids but also of nonprotein precursors onto the transport system. Dorsal root ganglia of R. catesbeinana were incubated in (32P)-phosphate, (35S)-Met, or (3H)-Leu, and transport was allowed to proceed in the attached sciatic nerve for up to 20 hours. Liquid scintillation analysis revealed that the transport of all three isotopes was blocked when the ganglia were exposed to cycloheximide or puromycin before the isotope was added. If cycloheximide or puromycin were added after the isotope, the amount of activity transported increased as the delay between the addition of isotope and of inhibitor was increased. In the case of (32P), label was found in the TCA soluble and chloroform-methanol fractions.

The multiwire proportional chamber was used to follow the movements of (32P) and (35S). When either inhibitor was added several hours after either isotope, the results were similar to those obtained when the nerve was transected close to the ganglia a while after adding the isotope. Transport velocity was unaffected, but the export of material from the ganglia ceased abruptly following the addition of the inhibitor. These results are consistent with the notion that the loading of materials onto the transport system involves the formation of a lipid-protein complex, possibly in the form of membrane .

207 IMMUNOCYTOCHEMICAL LOCALIZATION OF PLASMA PROTEINS IN NEURONAL PERIKARYA.
J.R. Sparrow and J.A. Kiernan*, Dept. Anatomy, Univ. of Western Ontario, London, Ontario N6A 5C1.

It is well known that exogenous protein tracers are transported intraaxonally to neuronal perikarya following their uptake by axonal terminals. Foreign proteins shown to be retrogradely transported include horseradish peroxidase[1] bovine albumin[2] and tetanus toxin[3] and nerve growth factor[4]. This led us to speculate that there may be movement of naturally occurring plasma proteins into axonal terminals and along axons to cell-bodies in the central nervous system. Thus we undertook to search for normal plasma proteins in the cell-bodies of neurons whose axons project outside the blood-brain barrier using the peroxidase anti-peroxidase (PAP) immunocytochemical technique[5].

The medullae of male rats were rapidly frozen in isopentane and liquid nitrogen. Cryostat sections (10 µm) were fixed for 10 minutes in 95% ethanol at room temperature. The following steps were then carried out at room temperature (1) incubation of sections for 30 mins. in rabbit antiserum to whole rat serum at various dilutions in Tris-buffered saline (TBS)(pH7.6) (2) washing in 3 changes TBS (3) application of goat antibody to rabbit IgG diluted 1:10 with TBS for 30 mins. (4) washing as above (5) treatment with rabbit PAP complex diluted 1:50 with TBS (6) washing as above (7) incubation in hydrogen peroxide and 3,3'-diaminobenzidine in Tris-buffer (pH7.6) for 15 mins. (8) finally sections were washed, dehydrated, cleared and mounted.

Reaction product, indicative of the presence of serum protein, was seen in neurons of hypoglossal nucleus, nucleus ambiguous and dorsal motor nucleus of vagus. A diffuse staining was also present in the neuropil of the area postrema, a region in which the blood-brain barrier to protein is known to be absent[6]. Appropriate control sections were unstained confirming that staining by the complete method truly demonstrated the sites of attachment of primary antiserum to antigenic proteins normally present in the serum of rats.

These results suggest that one or more of the proteins of serum is normally present in central neurons whose axons terminate outside the CNS.

208 FAST AXOPLASMIC TRANSPORT OF TUBULIN AND TRIAD PROTEINS
D.P. Stromska, Z. Iqbal, and S. Ochs; Dept. of Physiology and the Biophysics Program, Indiana University Medical Center, Indianapolis, Indiana 46223

Two axoplasmic transport mechanisms are usually considered present in nerve fibers, one giving rise to a fast, the other to a slow downflow. Alternatively, in the "unitary" view, one transport mechanism accounts for both the fast and slow rates with the slow rate resulting from those materials dissociating from the transport mechanism early on (Ochs, J. Physiol. 253:459, 1975). The L5 dorsal root ganglia or ventral cord of rats were injected with high specific activity (^{35}S)-methionine as a protein precursor, and the axoplasmic transport of labeled proteins in their sciatic nerves studied. The nerves, taken after periods of downflow of 4 hours to 33 days, were cut into 5 mm segments, each segment delipidated in chloroform: methanol (2:1) and solubilized in 8 M urea, 5% 2-mercaptoethanol, 1% SDS in 60 mM Tris-HCl, pH 6.8. The solubilized proteins of successive nerve segments were each electrophoresed on SDS polyacrylamide gels, stained, scanned and prepared for fluorautoradiography. The slow transported proteins contained the prominently labeled "triad" neurofilament proteins and α and β tubulin subunits (Hoffman and Lasek, J. Cell Biol. 66:351, 1975). Additionally, a smaller amount of tubulin and "triad" proteins were found to be fast transported in the crest, at close to 410 mm/day. The fast transported tubulin and "triad" proteins amounted to about 5% that of the slow downflow. The tubulin and "triad" proteins in the crest were higher in amount than in the plateau region just behind the crest. The difference in the specific activity of tubulin in the crest and the plateau was more pronounced when a postganglionic ligature was placed 2 hrs. after the injection of ^{3}H-leucine into L7 dorsal root ganglia of cats and sciatic nerves taken after 5-7 hrs. of downflow. The nerve portions corresponding to the crest and the plateau regions were prepared for analysis of tubulin by the temperature dependent assembly-disassembly procedure and the amount of radioactivity in tubulin determined by gel filtration, acrylamide gel electrophoresis and isoelectrofocusing. These procedures also demonstrated that a small amount of tubulin was transported at a fast rate. We consider the fast and slow transport of these proteins to be explained on the basis of the unitary concept. As the transport filaments move down the fiber, most of the tubulin and "triad" proteins dissociate from the transport system leaving only a small amount to continue further down the fiber. The pool of tubulin and "triad" proteins deposited in the axoplasm can then participate in the turnover of the subunits comprising microtubules and neurofilaments respectively. Supported by NIH grant PHS RO1 NS 8706-09, NSF grant BNS 75 03868-A03.

209 GLIA-AXON PROTEIN TRANSFER: A SELECTIVE PROCESS WHICH SUPPLEMENTS THE SUPPLY FROM THE NEURON SOMA.
M. Tytell and R. J. Lasek. Dept. of Anat., Case Western Reserve University Cleveland, Ohio 44106.

In the squid giant axon, there is considerable evidence that some of the proteins synthesized by the adaxonal glial cells are actively transferred into the axon, but little is known about these putative transferred proteins. To obtain a better understanding of their properties and functions, we compared them with the major proteins of axoplasm (AXM) and the proteins synthesized by the glial sheath and the stellate ganglion (representing proteins synthesized principally in the soma). Proteins synthesized by the sheath and ganglion were labeled by incubating 3-4 cm of ligated giant axon and the isolated ganglion in 0.3 ml of artificial seawater with 0.5 mCi ^{3}H-leucine for 60-270 min at 19-21°C. At the end of the incubation, the axon and ganglion were rinsed and the AXM, containing labeled transferred proteins, was extruded. The empty sheath, AXM, and ganglion were each homogenized in solubilization buffer (5% β-mercaptoethanol, 8 M urea, and 10mM Tris-HCl, pH 7.3). All homogenates were centrifuged at 140K x g - 30 min to remove insoluble material and frozen until analyzed by combined iso-electric focusing and SDS-polyacrylamide gel electrophoresis (2D-PAGE).

The 2D-PAGE pattern of AXM revealed more than 50 labeled proteins and was similar to the sheath pattern. However, one of the most highly labeled sheath proteins was not transferred at all, whereas other minor labeled species of the sheath appeared as prominent labeled proteins in the AXM. Thus, the transfer process is selective.

About 19 proteins in the 2D-PAGE pattern of AXM were visibly stained with Coomassie blue, indicating that they are major axonal proteins. Eleven of these stained proteins were coincident with labeled transferred proteins, which suggests that some of the transferred proteins are identical to major axonal proteins. Because the ganglion is the primary source of these major axonal proteins, we then compared the proteins synthesized in the ganglion with the transferred proteins and found that several of the transferred proteins, which were identical to major axonal proteins, were also made in the ganglion. These observations show that some of the major proteins of axoplasm, presumably supplied principally by the soma, are also selectively transferred to the axon from the adaxonal glial cells. Therefore, we propose that glia-axon protein transfer may serve to supplement a specific fraction of proteins supplied to the axon via axonal transport from the soma.

210 HORSERADISH PEROXIDASE DETERMINATION OF LATERAL PREOPTIC AREA INNERVATION. M. J. Wayner, F. C. Barone, S. L. Scharoun*, W. Woodson, Jr.*, J. E. Zrebiec*, R. Guevara-Aguilar and H. U. Aguilar-Baturoni. Brain Research Lab, Syracuse Univ., Syracuse, NY 13210 and Dept de Fisiologia, Facultad de Medicina, U.N.A.M., Mexico.

Horseradish peroxidase (HRP, Sigma Type IV, 25%) was applied microiontophoretically to the lateral preoptic area (LPA) of male hooded rats. After 24 hr animals were perfused intracardially, the brain was removed and sectioned in the frontal plane. Sections were processed with DAB for the brown reaction and were lightly counterstained with cresyl violet. Labeled neurons were identified and photographed under the microscope in light and dark fields and sequential sections were examined. The HRP ejection sites were approximately 500 μm in diameter within the LPA. Anterior to the ejection site a large number of labeled neurons and axons were located in the LPA and medial forebrain bundle (MFB). Many labeled axons and cell bodies were found along the striahypothalamic tract dorsal to the ejection site. Labeled soma were found in the globus pallidus and ventral caudate putamen. In addition, labeled axons and soma were observed along the stria terminalis and diagonal tract of Broca into the lateral septal nucleus. Axons were also labeled in the anterior commissure. Labeled neurons were located ventral and lateral to the ejection site in the olfactory terberculum. Also, cell bodies were labeled in the medial preoptic nucleus, medial to the ejection site. Similar results were observed posterior to the ejection site. Many labeled neurons and axons were located in the LPA and the lateral hypothalamus along the MFB into the mesencephalon. Labeled cell bodies were also identified in adjacent areas including the zona incerta, medial hypothalamic regions, and the amygdaloid nuclei. These results, based on the retrograde movement of HRP, indicate that the primary presynaptic inputs into the LPA are from neurons which are located along the MFB, in the striahypothalamic tract, and lateral hypothalamic area. Other significant inputs occur from the lenticular nucleus and various limbic structures including the septum, amygdala, and hypothalamic areas adjacent to the MFB.

211 THE IDENTIFICATION OF AN AXONALLY TRANSPORTED PROTEIN BY MEANS OF IMMUNE-AFFINITY ELECTRON MICROSCOPY. Mark Willard*, Carolyn Simon*, Celia Baitinger*, Joel Levine* and Pate Skene*. (SPON: B. Stanfield). Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

We have used immune-affinity electron microscopy to demonstrate that an axonally transported polypeptide (H) is associated with the 100 Å filaments of neurons. H is a 195,000 molecular weight polypeptide which, together with at least two other polypeptides (45 and 46, molecular weights = 145,000 and 73,000, respectively) is axonally transported at a velocity of 0.7-1.1 mm per day in the rabbit retinal ganglion cells. At least four other groups of proteins are transported at more rapid velocities in these neurons.

In order to determine which organelle contains H, we employed the following strategy: first, H was purified from rabbit spinal cord and an antibody directed against H was obtained by injecting the purified protein into goats. Second, Formvar-coated electron microscope grids were incubated with the anti-H IgG in order to coat the Formvar with the specific antibody. Third, the grids were incubated with polyglutamic acid to block nonspecific adsorbtion sites on the Formvar. Fourth, the resulting "immune-affinity grids" were used to specifically adsorb organelles containing H-antigens from extracts of spinal cord. Finally, the grids were negatively stained and observed by electron microscopy.

The only organelles which appeared to be specifically adsorbed to anti-H coated immune-affinity grids were filaments of approximately 100 Å diameter; in some cases the anti-H IgG-coated grids adsorbed more than 100 times as many of these filaments as did control grids which had been incubated with the same concentration of IgG from a non-immunized goat. The capacity of the anti-H IgG to adsorb filaments onto grids was completely blocked when the IgG was preincubated with H.

These experiments provide immunological evidence that H, a polypeptide which is axonally transported in the most slowly-moving transport group (group V) of the rabbit retinal ganglion cells, is associated with the 100 Å neurofilaments. Group V therefore may be largely concerned with the movement of neurofilament-associated proteins, as was originally proposed by Hoffman and Lasek for a similar transport group (SCa) in the rat sciatic nerve. Our experiments also serve to demonstrate the potential usefulness of immune-affinity electron microscope grids as a general approach for determining the organelle association of certain proteins.

BASAL GANGLIA

212 CAUDATE NUCLEUS INVOLVEMENT IN SPATIAL ORIENTATION. L. Abraham and M. Potegal. Dept. of Physical & Health Ed., Univ. of Texas, Austin, TX 78712 and N.Y. State Psychiatric Inst., New York, N.Y. 10032.

Investigation of rostral vestibular projections has led to the suggestion that the caudate nucleus may mediate egocentric spatial orientation behavior through the use of proprioceptive afference (Potegal, Acta Neurobiol. Exp. 32: 479, 1972). This hypothesis was tested with a spatial task allowing only such proprioceptive cues. Eighteen thirsty male rats (Long-Evans, 300-350g.) were trained to retrace a path leading to a water spout, following passive movement away from the spout in an opaque cart. This task required discrimination of the correct spout from eight spouts equally spaced around a chamber devoid of visual, auditory, tactile, and olfactory directional cues. All animals were trained to criterion in eight days (three consecutive successful trials over a path of five body lengths). The path contained one right angle turn, randomly assigned left or right, and the path from the spout was randomly set at one of three initial directions. Following training the animals were divided into three groups matched for performance. Two groups received bilateral radiofrequency lesions (0.1mm dia.); the third group received no lesion and served as a sham operation control group. Lesions in one group were placed in the posterior portion of the caudate nucleus, and lesions in the second group were placed in the hippocampus, an area implicated in some spatial tasks but which has not been reported to receive direct vestibular or other proprioceptive projections. Following a period of post-operative recovery, all animals were retrained for eight days. Comparison of pre-operative to post-operative scores revealed improved performance for the sham and the hippocampal groups. The caudate group, however, had significant performance deficits. These deficits were evident in maximum path length achieved and in rate of task acquisition. Analysis or righting reflexes (as a measure of vestibularly-based spatial function) revealed the caudate group was significantly different from the other groups in angle of head inclination at landing. Thus the caudate lesions apparently disrupted vestibular orientation. These findings support the hypothesis that the caudate nucleus employs vestibular afference in the performance of spatially-oriented behavior based on passive movement. Also, the involvement of the hippocampus in spatial orientation may be restricted to the use of exteroceptive cues for orientation to the environment, while the caudate mediates the use of proprioceptive cues for egocentric spatial orientation.

213 MORPHOLOGICAL EVALUATION OF NEOSTRIATAL SLICES USED FOR ELECTROPHYSIOLOGICAL EXPERIMENTS. Il Jin Bak, Ulrich Misgeld* and Molly H. Weiler*. Dept. Neurol. and Pharmacol., Sch. Med., UCLA, Los Angeles, CA 90024.

The refinement of the brain tissue slice technique for neurophysiology has made it possible to measure electrical activity including field potentials and extra and intra-cellular unit activity in the rat neostriatum. Such studies combined with neurochemical experiments indicate that relatively thin (300-400 μm thick) neostriatal slices maintain electrical activity and also a high value of acetylcholine (5.08 $\pm$ .53 n mol (mg protein)$^{-1}$ (n=3) in the slice. On the other hand relatively thick neostriatal slices (700 μm thick) showed limited electrical activity and lower concentration of acetylcholine (2.67 $\pm$ .25 n mol (mg protein)$^{-1}$(n=4) in the slice. A morphological examination of these thin and thick slices was done at the light and electron microscopic levels.

In thin slices, most of the preserved cells were localized in an inner layer which measured an average of 150 μm and was sandwiched between 75 μm thick outer layers which contained more degenerating cells. In the central zone, intact cells varied in size, measuring from 10 μm to 20 μm in diameter. No conspicuous swelling of the cells was noted. Among the numerous well preserved nerve cells there were very few degenerating cells similar to that seen in vivo. In the central zone about 90% of the nerve cells were preserved.

In contrast to the thin slice, thick slices of the neostriatum demonstrated numerous vacuoles throughout the tissue. These thick slices did not display any layering of normal and abnormal tissue. Large vacuoles which probably originated from glial cell processes often engulfed the degenerating nerve cell bodies. Many nerve cells showed signs of degeneration, including cells which had swollen cytoplasm containing large cytoplasmic vacuoles. Such swollen cells measured more than 20 μm in diameter. Among the counted neurons, almost 70% were degenerating and 30% were intact.

These results indicate that in terms of two parameters, fine structure and Ach levels, the thin slices are closer to the in vivo state.

214 LIGHT AND ELECTRON MICROSCOPIC ANALYSIS OF VARIOUS NEOSTRIATAL NEURONS INTRACELLULARLY LABELED WITH HRP: II. PATTERNS OF AXONAL DISTRIBUTION. G.A. Bishop, H.T. Chang, and S.T. Kitai, Dept. Anat., Michigan State University, E. Lansing, MI 48824.

In our previous study (Preston et al., 1979) the axons of medium spiny neurons, intracellularly stained with horseradish peroxidase (HRP), were traced from their cell of origin in the neostriatum of rats to the globus pallidus (GP) or internal capsule (IC), thus positively identifying this cell type as a striatal projection neuron. In the present study, the same technique has been used to examine specific details of the axons of several neuron types of the rat neostriatum. Recording, injection and histological processing procedures have been described previously (Preston, et al., 1979).

The axons of at least three different neostriatal neurons have been analyzed. The axons of medium spiny neurons arose from the soma or primary dendrite thinning abruptly to approximately 0.5 μm as they entered a fiber fascicle to leave the nucleus. Three to four collaterals arose from the axon within 250 μm of the soma, each of which branched repeatedly forming an extensive collateral network mainly confined to the dendritic field of the cell of origin. No further collaterals were observed to arise from the axons of these neurons until they entered GP where 1-3 fine collaterals arose from the parent axon as it coursed toward the IC. Electron microscopic analysis revealed that these axons are myelinated. A second type of medium spiny neuron (similar to the spiny II of DiFiglia et al. in monkey (1976) had an axon arising from a primary dendrite which entered a fiber fascicle and coursed caudally. It could not be followed beyond the border of the neostriatum. Six collaterals arose from the axon at distances of 100-300 μm from the soma. In contrast to the collaterals of the first type of medium spiny neuron described above, the collaterals of the latter cell branched infrequently, each branch extending for at least 500 μm away from the cell of origin. This axon is currently undergoing electron microscopic analysis. Finally the axon of a large aspiny neuron (soma diameter 35 μm), arising from the soma, became myelinated at a distance of 50 μm. This axon did not appear to give rise to local collaterals. In conclusion, different neostriatal neurons exhibit unique branching patterns of their local collaterals.

215 AUTORADIOGRAPHIC DEOXYGLUCOSE STUDIES OF APOMORPHINE EFFECTS IN HALOTHANE ANESTHETIZED RATS. Lucy L. Brown, Leslie I. Wolfson,* Dept. Neurol., Albert Einstein Coll. of Med., Bronx, N.Y. 10461.

Previous autoradiographic ^{14}C deoxyglucose (DG) studies (Brown and Wolfson, 1978) found that apomorphine increased glucose utilization (GU) in several extrapyramidal system nuclei: the substantia nigra reticulata (SNR), subthalamic nucleus (STN), globus pallidus and striatum. The substantia nigra compacta (SNC) was apparently unaffected. The localized GU increases were observed in awake rats which were either freely-moving or restrained in a plaster cast. In the present study, anesthetized rats were used to observe the effect of apomorphine on extrapyramidal system nuclei in animals with no movement and no demand for movement. Male Sprague-Dawley rats (250-300 g) were anesthetized with halothane (~1%) mixed with oxygen. Seven animals were injected with apomorphine (I.P., 5 mg/kg) and 5 minutes later were injected with 50 μCi ^{14}C DG through a previously placed femoral vein catheter. The animals were maintained with anesthesia for 30 min., decapitated, and the brains were prepared for autoradiography following the methods of Sokoloff et al. (1977). Seven animals were anesthetized with halothane but not treated with apomorphine. Autoradiographic data (both visual inspection and preliminary densitometric data) show that the anesthesia alone produced a large decrease in GU in the sensorimotor cortex and nucleus accumbens; the additional treatment with apomorphine did not change the GU of these areas. In the extrapyramidal system, the halothane treatment produced a small decrease in GU; however, the additional apomorphine treatment markedly increased GU in SN and STN, but not in globus pallidus and striatum. But of particular interest, in the halothane-treated rats without apomorphine there was a striking increase in GU over awake rats in the SNC region. This increase in the halothane rats was markedly attenuated by apomorphine. Such an attenuation with apomorphine parallels the well-documented decrease in neuronal firing rate of SNC cells with apomorphine (Bunney and Aghajanian, 1973, 1976). This effect of apomorphine to decrease GU in the compacta region only when GU is especially high may reflect a presynaptic potentiation of DA on GABA inhibition. The presynaptic action would be functional only when GABA inhibition is submaximal, in the halothane anesthesia state. However, several other interpretations are possible. In summary, under halothane anesthesia, apomorphine increases GU in the STN and SNR similarly to the awake state, but affects GU in other nuclei and subnuclei differently. Supported by NIH grant NS 09649.

216 EFFECTS OF NEONATAL MEDIAL FOREBRAIN BUNDLE (MFB) LESIONS ON DEVELOPMENT IN CATS. II. PREVENTION OF AMPHETAMINE-INDUCED SLOWING OF THE SPONTANEOUS FIRING RATES OF CAUDATE NEURONS BY NEONATAL MFB LESIONS. N.A. Buchwald, M.S. Levine, C.D. Hull, L. Erinoff* and E. Garcia-Rill. Mental Retardation Research Center, School of Medicine, UCLA, Los Angeles, CA. 90024.

We have recently described some of the behavioral, neurochemical and electrophysiological effects of neonatal MFB lesions made in kittens of 9-21 days of age (Levine et al., Neurosci. Abst. 3 (112): 1977; Levine et al., Neurosci. Abst. 5: 1979). The present experiment assessed the neurophysiological effects of amphetamine treatment on the spontaneous firing rates of caudate neurons and determined if these effects could be blocked by neonatal MFB lesions that interrupt the nigrostriatal pathway and severely deplete the caudate nucleus of dopamine. Juvenile cats of 7-12 months of age received 3 dosages of d-amphetamine sulfate (1,2,4 mg/kg i.p.). Time between injections varied from 10 days to several weeks. The spontaneous firing rates of caudate neurons were measured several weeks to several months after the last amphetamine injection. The cats were then sacrificed and the dopamine content of the caudate nuclei determined. In intact cats amphetamine produced a slowing in the spontaneous firing of caudate neurons. Average interspike interval (ISI) in amphetamine-treated cats was about 3800 msec compared to about 1800 msec in intact cats. In cats that had received neonatal MFB lesions reducing caudate dopamine content by about 75%, amphetamine treatment did not slow the firing rates of caudate neurons. Average ISI for amphetamine-treated cats with MFB lesions was about 2000 msec while that for cats with MFB lesions but no amphetamine treatment was about 2200 msec. This result was not a nonspecific effect of neonatal brain-damage since amphetamine produced a decrease in spontaneous firing rates of caudate neurons in a group of cats that had ventral thalamic lesions as neonates (Mean ISI=3900 msec). In addition to its effects on the spontaneous firing, amphetamine treatment produced a 40% depletion of caudate dopamine in unlesioned cats. These results indicate that in the developing cat, a relatively mild dosage regime of amphetamine produces long-lasting neurophysiological and neurochemical effects. Furthermore, the neurophysiological effects can be blocked by neonatal MFB lesions that interrupt the nigrostriatal pathway.

217 THE BASAL GANGLIA-TECTAL PATHWAY: ITS ROLE IN VISUALLY GUIDED BEHAVIOR IN THE PIGEON. Nellie M. Bugbee* and William Hodos. (SPON: Roger M. Brown) Department of Psychology, University of Maryland, College Park, MD 20742.

In birds, reptiles and mammals, neural output of the basal ganglia is relayed to the tectum. In birds, this prominent pathway originates in the paleostriatum primitivum (the avian equivalent of the globus pallidus) and synapses in a large diencephalic nucleus, spiriformis lateralis (SpL): SpL then projects to widespread regions of the optic tectum (Karten & Dubbeldam, J. Comp. Neur., 148, 1973; Brecha, Hunt & Karten, Neurosci. Abstr., 1976).

The present study investigated the function of this pathway in pigeons. Pre-operatively, subjects were trained to: 1) discriminate visual stimuli differing in color, intensity or pattern; 2) track a target which changed position continuously (ie, peck grain mounted on a revolving drum); 3) track a target which changed position intermittently (ie, to rapidly peck a sequence of response keys which were illuminated in a random order); and 4) peck stationary targets (grain mounted in the same positions as the response keys). Subjects were also examined on a series of neurological tests and assessments of normal locomotion patterns.

Following training, the basal ganglia-tectal pathway was interrupted in 10 subjects by placing electrolytic lesions in SpL; in 8 other subjects, control lesions were placed in nucleus rotundus, nucleus ovoidalis, or nucleus pretectalis.

Subjects with bilateral interruption of the basal ganglia-tectal pathway showed a severe and seemingly permanent deficit in their ability to track targets which changed position in space. In the task in which the target shifted position intermittently, subjects continued to peck the response keys, but took much longer to complete a response sequence than normal or control subjects. In the task in which the target moved continuously, most subjects were totally incapable of pecking the grain even when it moved at the lowest velocity (8cm/sec). These same subjects were able to detect and accurately peck stationary targets, and to discriminate visual pattern, intensity and color. Motor behavior, including flight, walking and head movements were normal in these subjects, as were neurological reflexes related to posture and locomotion. Control subjects were not impaired on any tasks.

These results indicate that in normal birds, the basal ganglia provide information to the tectum critical to the ability to respond to changes of the spatial position of visual targets. This pathway may relay information about the bird's ongoing or impending movement to the tectum so that prior to the initiation of a peck, sensory input concerning the spatial location of a target can be correlated with the subject's own body position.

218 AFFERENT CONNECTIONS TO THE SUBTHALAMIC NUCLEUS OF RAT STUDIED WITH HORSERADISH PEROXIDASE. G.A. Campbell*, M.J. Eckardt*, and F.F. Weight (Spon: G.C. Salmoiraghi). Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, Md. 20852.

Investigations using the ^{14}C-deoxy-D-glucose technique have found that the dopamine agonist apomorphine and d-amphetamine produced the greatest increase in metabolic activity in the subthalamic nucleus (STH) (Wolfson and Brown, Soc. for Neurosci. Abst. 2:510, 1976 and Wechler, et al., J. Neurochem. 32:15, 1979). In addition, iontophoretic administration of dopamine to STH neurons has indicated the presence of neurons sensitive to dopamine (Campbell and Weight, Soc. for Neurosci. Abst. 4:442, 1978). These studies suggest the possibility of dopaminergic input to STH. The current study was undertaken to identify afferent connections to the STH using the horseradish peroxidase (HRP) technique.

Male Sprague-Dawley rats (140-160 gms.) were anesthetized with sodium pentobarbital (60 mg./kg.), placed in a stereotaxic frame, and surgically prepared by removal of skull, dura, and cortex over the electrode site. In some experiments, single-barrel micropipettes were used, while in others four-barrel micropipettes were used to permit passage of a negative holding current through the HRP barrel during descent and withdrawal. Electrodes were inserted stereotaxically using the atlas of Konig and Klippel. Four percent HRP (Sigma Type VI) in pH 8.5 NaCl-Tris buffer was ejected using pulsed positive currents (1 sec. pulses, freq. 0.5 hz, amplitudes up to 500 nA for time periods of 45 to 90 min.). After survival periods of 24 to 36 hrs., the brains were processed histologically using the tetramethylbenzidene technique of Mesulam (J. Histochem. and Cytochem. 26:106, 1978).

Labelled axons were observed extending from STH to the ipsilateral cerebral peduncle running along a rostral-caudal axis, and from STH toward substantia nigra. Labelled cell bodies were observed in ipsilateral STH, zona incerta, and globus pallidus. In addition, a large percentage of cell bodies were labelled in the pars compacta region of the ipsilateral substantia nigra. Label was observed in only a few cells of the pars reticularis. No labelled cells were observed contralaterally. These observations suggest the existence of a pathway from the pars compacta region of the substantia nigra to STH. The data also further document the known pathway from the globus pallidus to the STH. These findings provide anatomical evidence consistent with a dopaminergic input to STH.

219 CELLS OF ORIGIN OF DIFFERENT PALLIDAL EFFERENTS ARE SEPARABLE. David A. Carter* and Derek van der Kooy (SPON: F. Coceani) Toronto General Hospital and Department of Anatomy, University of Toronto, Toronto, Canada

Experiments in the cat have demonstrated entopeduncular nucleus (EP) cells projecting to either ventrolateral-ventral anterior nuclei of thalamus (VAL), centromedian-parafascicular nucleus (CM-Pf), lateral habenula (HBL) or nucleus tegmentipedunculopontis (TPP). The reports showed little or no topographical specificity of these neurons within EP. Carter and Fibiger (1978) suggested that the EP projection to TPP in the rat arose from a more ventral site within the EP region than did the projection to the thalamus. In order to re-examine this problem the fluorescent retrograde double labeling technique reported by van der Kooy, Kuypers, and Catsman-Berrevoets (1978) has been utilized. Fifteen rats had 0.1-0.3 ul DAPI - Primuline injected into one EP terminal field and the same amount of Evans Blue injected into another EP terminal field. The EP terminal fields included VAL, HBL, and the TPP region. Injections into HBL labeled virtually all EP neurons within the rostral two-thirds of this nucleus, but resulted in minimal labeling in its caudal aspects. This caudal region, however, contained a circumscribed group of cells labeled after injections into VAL. The TPP region injections resulted in heavy labeling in zona incerta, lateral hypothalamus, and a band of cells which runs ventral to EP to mushroom into the central nucleus of the amygdala. These findings suggest that different pallidal outflows represent functionally and anatomically distinct basal ganglia processes.

220 LIGHT AND ELECTRON MICROSCOPIC ANALYSIS OF VARIOUS NEOSTRIATAL NEURONS INTRACELLULARLY LABELED WITH HRP: I. SOMA-DENDRITIC MORPHOLOGY. H.T. Chang, G.A. Bishop and S.T. Kitai. Dept. of Anat. Michigan State University, E. Lansing, MI 48824.

Combining the techniques of intracellular recording and intracellular labeling with horseradish peroxidase (HRP) with light and transmission electron microscopy (TEM), we have identified several neuronal types in the rat neostriatum. Intracellular records were obtained from these neurons following stimulation of the cerebral cortex (CX) and the substantia nigra (SN). Recording glass microelectrodes were filled with 4% HRP in 0.5 M KCl-Tris buffer (pH 7.6). HRP was injected by passing positive DC pulses (3-5 nA, 100-400 msec duration, frequency 2-5/sec) through the recording electrodes. After fixation and histochemical processing, the HRP labeled cells were analyzed under the light microscope and subsequently processed for TEM.

The most frequently encountered cell type was a medium spiny neuron which responded with monosynaptic excitatory postsynaptic potentials (EPSPs) to stimulation of CX and SN. The other cell types included large and medium aspiny neurons, the former responded with EPSPs to SN stimulation and the latter with monosynaptic EPSPs to both CX and SN stimulation. Under TEM, these neurons displayed differences with respect to their nuclear morphology (nucleus size, membrane invaginations and heterochromatin distribution), and the shape, size and distribution of their rough endoplasmic reticulum (ER), smooth ER, ribosomes, Golgi apparatus, lysosomes and mitochondria. For instance, the nucleus of the medium spiny neuron was round with no membrane infoldings while those of the large and medium aspiny cells had many deep membrane invaginations. These latter two aspiny neurons could be distinguished from each other on the basis of differences in the nuclear-cytoplasmic ratio and the overall soma size.

In conclusion, we have positively identified the morphological characteristics, at both the light and ultrastructural levels, of at least three different neuronal types in the rat neostriatum and recorded differences in their intracellular responses to extrinsic inputs. (Supported by USPHS Grant NS 14866 and in part by NIH BRSG RR 05772-04).

221 MODIFICATION OF CIRCLING BEHAVIOR IN SHAKER-1 MUTANT MICE WITH HALOPERIDOL AND APOMORPHINE. John M. Cooke* and M.K. Wolf, Deptartment of Anatomy, University of Massachusetts Medical School, Worcester, MA 01605

Shaker-1 mutant mice, like other "circling" mutants, lack inner ear function and have a set of abnormal behaviors including hyperactivity, vertical head-tossing and running in circles (Deol, M.S., Proc. Roy. Soc. B, 145: 206, 1956). Similar circling behavior can be elicited by administering dopaminergic agents to animals with lesions of the nigrostriatal dopamine pathway (Ungerstedt, U., Acta Physiol. Scand. Suppl., 367: 49, 1971). After determining that the baseline level of spontaneous circling activity in individual adult shaker-1 mice was relatively stable and reproducible, we tested their response to haloperidol and apomorphine, drugs which affect CNS dopamine function.

Eleven affected mice were observed in their home cages for a minimum of 15 periods of 3 or 5 minutes. The number of clockwise and counter-clockwise turns were counted manually. The average circling rate ranged from 25 to 58/min. Seven of the eleven mice exhibited a preference for counter-clockwise circling. One mouse circled preferentially counter-clockwise during all 23 observation periods with an average ratio of counter-clockwise to clockwise circles of 128:1.

Shaker-1 mice responded to injections of haloperidol with reduced rates of circling with the maximum suppression approximately 2 hours after injection. Circling was reduced to one-half the baseline rate by 0.075mg/kg, i.p., and abolished completely with doses higher than 0.2mg/kg. Mice injected with haloperidol circled with the same speed and agility observed in uninjected shaker-1 mice but simply spent less time circling. The hyperactivity and vertical head-tossing were also noticeably decreased but no attempt was made to quantify these changes. A few affected mice were injected with valium in doses ranging from 0.2 to 1.2mg/kg. Valium reduced circling but did not abolish it even at the highest dose. In addition, mice injected with the higher doses of valium showed noticeable impairment of muscular coordination during circling.

Apomorphine (0.2mg/kg, i.p.) increased the rate of circling by up to 100% with the maximal effect 45 to 60 minutes after injection. These preliminary results suggest that genetically induced circling behavior may have some features in common with the circling behavior produced by unilateral lesions of the dopaminergic nigrostriatal pathway.
(Supported by NIH Grant Number NS-11425)

222 THE POSTNATAL DEVELOPMENT OF PRECRUCIATE CORTICOSTRIATE PROJECTIONS IN KITTENS. J.A. Cospito, M.S. Levine and A.M. Adinolfi. Mental Retardation Research Center, School of Medicine, UCLA, Los Angeles, Ca. 90024.

The purpose of this study was to investigate the organization of corticostriate connectivity in kittens at early postnatal ages. We reported previously that projections from the medial and lateral precruciate cortex in young animals are prominent and differentially organized within the lateral half of the head of the caudate nucleus and dorsal aspects of the rostral putamen. Results from that study were based on Fink-Heimer staining of preterminal and terminal degeneration following selective destruction of the precruciate cortex. It was difficult to identify terminal degeneration with this argyrophilic method in young brains. Therefore, we decided to repeat the study by using the autoradiographic technique. Multiple injections of a mixture of tritiated leucine and proline (54-200 μCi) were made into the precruciate gyrus of twelve kittens, ranging in age from two to twenty-seven days. As with the Fink-Heimer technique, the precruciate projections to the head of the caudate nucleus were prominent and restricted to the lateral half. However, using autoradiographic tracing techniques, we observe that 1) the projections to the head of the caudate nucleus display a patchy distribution, 2) cortical projections extend caudally into the body of the caudate nucleus and remain patchy in character, 3) the projections to the putamen appear to be more prominent than observed with the Fink-Heimer method, and 4) contralateral corticostriate projections are organized similarly to ipsilateral projections. From the striatal areas with the greatest cortical terminal fields, cores of tissue were removed and processed for electron microscopy. The perinatal projections from the precruciate cortex to the caudate nucleus and putamen end mainly on dendritic profiles. With maturation, these projections shift to a predominantly axospinous connectivity.
Supported by HD-05958 and HD-07032.

223 PHARMACOLOGY OF KAINIC ACID LESIONED RATS. B.I. Diamond, J.E. Comaty and R.L. Borison. Mt Sinai Hosp, Chicago, Il. 60608.

The pathology of Huntington's chorea (HC) involves the degeneration of striatonigral GABA neurons and the loss of intrastriatal cholinergic neurons. It has been demonstrated that the intrastriatal administration of kainic acid (KA) produces a lesion which closely mimics the biochemical changes in HC. Although this animal paradigm provides insight into the neuropathological and biochemical changes in HC, few studies have been conducted to test whether this model may be pharmacologically analogous to the human counter part. We now report studies on the pharmacology of the KA animal model. Subjects were white male Sprague-Dawley rats which received stereotactically placed injections of KA into the caudate-putamen necleus. Animals were rated for stereotyped behavior using a five point rating scale of ascending intensity of behavior. Administration of d-amphetamine (2.0 mg/kg), in a dose per se subthreshold for eliciting stereotypy, evoked moderate stereotypy (score 2.62 ± 0.21) in KA lesioned rats. In contrast, apomorphine (0.5 mg/kg) in a dose that elicits stereotypy, produced only a slight increase in exploratory behavior. In the remainder of our studies, we compared the effects of various drugs on KA lesioned animals receiving d-amphetamine (2 mg/kg). The dopamine receptor blocker haloperidol markedly antagonized stereotypy (0.74 ± 0.08), whereas the weak dopamine blocker clozapine (10 mg/kg) potentiated stereotyped behavior. In studying the cholinergic system, the anticholinergic trihexyphenidyl markedly enhanced stereotypy to 4.12 ± 0.26. The cholinesterase inhibitor physostigmine, at 0.25 and 0.5 mg/kg, decreased stereotypy scores to 1.54 ± 0.16 and 1.00 ± 0.14 respectively. The acetylcholine precurser, choline chloride, failed to affect stereotypy at 75 mg/kg, but lowered stereotypy score to 2.00 ± 0.18 when the dose was raised to 150 mg/kg. In contrast, the muscarinic cholinomimetic arecoline markedly potentiated stereotypy at a dose of 0.1 mg/kg, while failing to affect behavior at higher dosages (0.5 and 1.0 mg/kg). The purported GABA-mimetic baclofen at 10 mg/kg significantly decreased stereotypy, whereas at 5 mg/kg this effect was less marked. The benzodiazepine diazepam, which is reported to have GABA mimetic properties, potentiated stereotypy at 2 mg/kg and markedly antagonized this behavior (1.3 ± 0.11) at higher doses (5 mg/kg). In contrast, isoniazid (20 or 40 mg/kg), which blocks GABA catabolism, potentiated stereotypy. Our results indicate that the pharmacology of the KA animal paradigm closely mimics the human pharmacological responsiveness, and may be used for preclinical drug screening of agents which may be therapeutic in HD.

224 ON THE ROLE OF GLOBUS PALLIDUS AS A SOURCE OF GABA-ERGIC PROJECTIONS TO THE NIGRA. G. Di Chiara*, M.Morelli,* M.L.Porceddu *and M.Del Fiacco* (SPON:R.Collu)
Institute of Pharmacology, University of Cagliari, Italy.

It is well known that long GABA-ergic neurons project from basal ganglia to the substantia nigra. While it is generally aggreed that this pathway originates, at least in part, from the caudate-putamen, there has been much debate on the role of the globus pallidus. Although this role has been reaffirmed by various recent studies, the evidence provided until now is either indirect or derives from non-specific pallidal lesions. In order to reexamine this problem we studied in rats the effect on nigral GAD of pallidal and striatal lesions induced by local injections of kainic acid, which destroys neuronal perikarya but spares axons "en passage". Unilateral intrapallidal injection of kainic acid (0.75 /ug/5 /ug) resulted in complete loss of neuronal perikarya in most of the pallidus, in the MFB area, in the anterior thalamus adjacent to the internal capsule (reticular nucleus) and in the most ventral part of the caudate body. The head and the dorsal 2/3 of the body of the caudate were intact. This lesion resulted in a non-significative decrease (-8%)of nigral GAD on the lesioned side. Kainic-lesions of the dorsal caudate body instead, resulted in a dramatic (-52%) reduction of nigral GAD. Kainate-lesion of the caudate head resulted in a significative (-18%) reduction of nigral GAD. Kainate-lesions of the caudate tail failed to reduce significantly nigral GAD.
These data negate the existence of a GABA-ergic pallidonigral projection but confirm that the caudate head contributes only a minor component to nigral GABA-ergic afferents as compared to the dorsal caudate body.

225 ULTRASTRUCTURE OF THE MONKEY GLOBUS PALLIDUS. Marian DiFiglia, Tauba Pasik and Pedro Pasik. Dept. of Neurol., Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029.

The neuropil of the medial and lateral segments of the globus pallidus was examined in serial sections. Results show that the dendrites of uniform diameter seen in Golgi impregnations (see Pasik et al., this volume) give rise to various types of spines which are usually postsynaptic, having either symmetric or asymmetric contacts. The largest of these elements contain multivesicular bodies, cisterns and a few dense core and small clear vesicles. Others are long and thin, and may penetrate an axonal bag which makes an asymmetric synapse covering the entire surface of the process except for the tip. In these cases there is an additional rod-like density occupying the core of the spine. Most dendrites, including those with varicosities, are covered by synapsing axon terminals and both are encapsulated by glial processes. Some dendrites are not surrounded by axons and only occasionally are postsynaptic.

At least four types of profiles containing vesicles are observed. (1) The most numerous are small boutons, about 1 µm containing large pleomorphic and dense core vesicles and forming symmetric contacts. They project fine finger-like processes, frequently devoid of vesicles, deeply inside adjacent elements of similar type. Contiguous elements of this category may show symmetric membrane densities with a widened intermembranous gap. These terminals arise from fine collaterals of small caliber myelinated axons (0.5 µm) and most likely correspond to the fibers of striatal origin seen in Golgi material. (2) Large bulbous elements, up to 3 x 4 µm, contain loosely packed small pleomorphic vesicles, cisterns and numerous mitochondria. Each bulb forms multiple symmetric contacts with a single large element or one contact with each of several smaller profiles. They are seen to emerge from large caliber myelinated axons (1-1.5 µm) which course in bundles. Such fibers may correspond to the second category of afferents seen in our Golgi material. (3) Small to medium size profiles (1-2.5 µm), have many small round vesicles and numerous mitochondria. Some emerge from myelinated axons. These elements form asymmetric synapses with thin spines (see above) and dendritic trunks. There is usually an additional band of dense material beneath the postsynaptic thickening. (4) Elements of small to medium dimensions (1-2.5 µm) have loosely packed pleomorphic vesicles and may show mitochondria, cisterns and multivesicular bodies. They can be postsynaptic to all of the above categories of axons. In addition, they participate in serial and triadic synapses, being postsynaptic to type 3 axons and presynaptic with a symmetric contact to dendrites (serial) which sometimes are also postsynaptic to the same type 3 axon (triad). 226 LOW CSF BIOPTERIN LEVELS IN INHERITED DYSTONIA. Roswell Eldridge, Adrian Williams*, Robert Levine*, and Walter Lovenberg*, NIH, Bethesda, MD 20502

The hereditary torsion dystonias are a genetically heterogeneous group of disorders whose chief or sole characteristic is dystonia. Although the pathological and neurochemical basis of these dystonic states remains unknown, abnormal dopaminergic mechanisms have been invoked as L-Dopa therapy may be helpful and similar involuntary movements can be reproduced by administration of dopamine receptor blocking agents.

Tetrahydrobiopterin (BH_4) plays a critical role in controlling the rate of tyrosine and tryptophan hydroxylation. This substance, expressed as 'hydroxylase cofactor content', can be reliably measured in the cerebrospinal fluid (CSF) by a radioenzymatic method utilizing a cofactor dependent phenylalanine hydroxylation system. We report CSF BH_4 levels in 7 members of a family with dystonia.

Four sisters developed generalized dystonia between the ages of 8 and 10. Their mother and two brothers had later onset of focal dystonia. The family was of German, English, and Irish extraction and there was no history of consanguinity or of Jewish ancestry. The mother and two daughters were taking low doses of diazepam at the time we obtained CSF but none of the others were on medication. None had had thalamotomy.

Mean CSF hydroxylase cofactor levels for those with generalized dystonia was 3.0 pmol/ml (SE±0.2). This compared to a mean of 20.2 pmol (SE±1.0) for 32 controls of similar age ($p < .001$ by 't' test). For the three family members with focal dystonia, the mean was 7.2 pmol/ml (SE±2.1).

BH_4 is synthesized in many organs of the body including brain but crosses the blood brain barrier with difficulty. Hence, CSF values are likely to reflect brain levels. Since there is no known loss of aminergic neurons in the hereditary dystonias, the low CSF BH_4 observed in these family members may reflect a primary metabolic abnormality rather than neuronal atrophy.

227 EFFECTS OF UNILATERAL DESTRUCTION OF THE NIGRO-STRIATAL DOPAMINE SYSTEM ON LOCAL CEREBRAL GLUCOSE UTILIZATION IN ADULT RAT. A. Ferron*, M.H. Des Rosiers, C. de Montigny, O. Bosler*, T.A. Reader and L. Descarries, Centre de recherche en sciences neurologiques (Département de physiologie), Université de Montréal, Montréal, Québec, H3C 3J7, Canada

In the mammalian brain, dopamine (DA) could influence glucose utilization as a neuro-hormone regulating glycogen metabolism and/or -modulator of functional neuronal activity. To explore these possibilities, local cerebral glucose utilization (LCGU) was measured by means of the [^{14}C]deoxyglucose method, in conscious male albino rats subjected, 5, 15 or 60 days earlier, to pretreatment with desmethylimipramine (25 mg/kg i.p.) and unilateral injection of 6-hydroxydopamine (6-OH-DA, 8 µg in 4 µl) into zona compacta of substantia nigra. Radioenzymatic determinations of DA content in neostriatum indicated 84% and 90% reductions on the side of the lesion, 5 and 15 days after 6-OH-DA, respectively. Histofluorescence examination revealed that this depletion was imputable to almost complete destruction of the ipsilateral nigro-striatal DA system. However, at days 5, 15 and 60, there was no side to side difference in LCGU in caudate-putamen. In contrast, striking differences were observed in globus pallidus (GP) and habenula (HA). Indeed, 15 days after 6-OH-DA, LCGU was 50% higher in GP, and 30% higher in HA, on the side of the lesion. Whereas at 5 days, an increase was already present in HA, but not in GP, none was any longer detectable after 60 days, in either structure. Twelve to 16 days after 6-OH-DA, extracellular recording of GP neuronal activity combined with glutamate microiontophoresis was carried out in urethane anesthetized as well as unanesthetized decerebrate animals. No significant side to side differences in the number and firing rate of spontaneously active units or mean threshold current of glutamate needed to activate quiescent neurons were detected in GP. Since GP is the major output of the richly DA-innervated caudate-putamen but receives little DA input, its increased rate of glucose utilization represents an effect at distance, probably due to suppression of inhibitory influences mediated by DA in neostriatum. However, in the absence of concomitant changes in neuronal firing, it cannot be ascertained at present whether such a temporary effect on LCGU actually corresponds to an increase in oxidative metabolism or rather reflects qualitative shifts in the glycolytic cycle. Radioautographic identification of the cellular elements in which deoxyglucose-6-phosphate is accumulated might help to resolve these issues.

228 PALLIDAL NEURONS BRANCHING TO THE THALAMUS AND TO THE MIDBRAIN IN THE MONKEY. M. Filion and C. Harnois*. Lab. Neurobiologie and Dept. Physiologie, Fac. Méd., Univ. Laval, Québec, Qué., Canada, G1K 7P4.

According to anatomical studies, the pallidothalamic projection is considered to be more important than the pallidotegmental projection. In a previous study[1], using antidromic activation of entopeduncular neurons in the cat, we have shown that at least 46% of these neurons branch to the thalamus and to the midbrain. We have undertaken a similar study in the monkey. Stimulation techniques were improved to activate the great majority if not all pallidofugal fibers in a given area, while minimizing current spread. Squirrel monkeys were anesthetized with sodium pentobarbital. Pallidal neurons were recorded extracellularly. Stimulation electrodes were separated by 1.5 mm and arranged in frontal stereotaxic planes. Two electrodes were placed in the rostral part of the ventral anterior thalamic nucleus and 3 others were placed 1.5 mm more caudally. A similar array of 3 electrodes was placed at the level of the midbrain pedunculopontine nucleus. Pulses of current were delivered alternatively between pairs of neighboring electrodes in the same plane and in each polarity. The arrays were moved in 0.5 mm steps in the vertical plane to map sites where pallidal neurons could be activated antidromically with weak stimulation current. Antidromic responses, identified according to criteria described previously[1], were recorded from nearly every neuron histologically located in the medial globus pallidus, but not from those located in the lateral globus pallidus. Out of 90 neurons, 76 (84%) responded to stimulation of both the thalamus and the midbrain. In these cases, the antidromic responses to successive stimulation of the two sites collided at stimulation intervals longer than the difference of the latencies of the responses plus a refractory period. This indicates that the stimulation activated two branches of a parent axon, and not the same branch at two sites. Similarly, it was shown that several pallidofugal fibers branch to at least two thalamic planes separated by 1.5 mm. Eleven neurons responded only to the thalamus and 3 responded only to the midbrain. Therefore, the great majority of medial pallidal neurons branch to both the thalamus and the midbrain.

229 EFFECTS OF INTRANIGRAL MICROINJECTION OF MORPHINE AND STRYCHNINE ON CAUDATE NEURONAL ACTIVITY IN THE RAT. Edward P. Finnerty and Samuel H.H. Chan. Department of Life Science, Indiana State University, Terre Haute, IN 47809.

Previous studies from our laboratory have implicated that suppression of caudate nucleus (CN) spontaneous activity by morphine (MO) may be achieved partly via a direct activation of the nigrostriatal dopaminergic pathway (Lee, Wong, and Chan, Neuropharmacol. 16:571, 1977) and partly through inactivation of a population of inhibitory neurons in the striato-nigral feedback loop (Finnerty and Chan, Neurosci. Abst. 4:443, 1978). Neurochemically, these inhibitory neurons, believed to be located in the substantia nigra (SN) zona reticulata, have been proposed to suppress the zona compacta (SNC) cells utilizing glycine as the transmitter agent. This work represents a further analysis of the mechanism(s) of suppressive action by MO on CN activity and the role of glycine in this process.

Experiments were performed on Charles River rats lightly anesthetized with sodium pentobarbital (50 mg/kg, i.p.). Spontaneous unitary activity was recorded from the CN via stereotaxically placed tungsten microelectrodes. Local microinjection to the SN, at a volume of 1 µl, was performed by means of a stereotaxically placed 27-gauge syringe needle attached to a microinjection device. Systemic injections were administered via a cannulated jugular vein.

MO (200 µg/kg) microinjected into the SN was found to suppress the spontaneous CN activity, which was effectively reversed by naloxone (1 mg/kg, i.v.). These results confirmed that MO may elicit its effects by directly activating the opiate receptors on the SNC cells.

Intranigral microinjection of the glycine antagonist, strychnine (STRY, 1 µg/kg), elicited two types of response in the CN in different animals. There was either an increase or a decrease in its spontaneous activity lasting 3-5 min. The presence of a tonic inhibition exerted on the SNC cells by neurons using glycine as the transmitter is at least partially implicated.

When MO (5 mg/kg) was administered intravenously immediately following the intranigral microinjection of STRY, an interesting phenomenon was unveiled. The suppressive effect of the opiate on CN activity was either abolished or greatly minimized.

It is concluded that MO may suppress CN spontaneous activity by directly activating the SNC cells. The mechanism(s) whereby MO effect is antagonized by STRY remains to be elucidated. Possibly, it may involve the inhibitory neurons in the striato-nigral feedback loop and may engage an interaction between glycine and MO in the SN.

230 ATTENUATION OF NUCLEUS ACCUMBENS INDUCED INHIBITION OF SUBSTANTIA NIGRA UNIT ACTIVITY BY BICUCULLINE

Simon J. Fung, Howard K. Strahlendorf, Jean C. Strahlendorf, and Charles D. Barnes, Department of Physiology, Texas Tech University School of Medicine, Lubbock, Texas 79430.

Lesions of the nucleus accumbens (N.Acc.) produced behavioral manifestations which tend to classify it functionally as a component of the limbic system. However, on the bases of neurogenesis and development, the N.Acc. more closely resembles the striatum. Current concepts hold that this nucleus represents a bridge between the limbic system and the basal ganglia since it has in common features typical of each. Anatomical studies have revealed efferents from the N.Acc. to the substantia nigra (SN) in monkey and rat. Recent radioautographic studies have demonstrated a projection from the N.Acc. to the SN pars reticulata (SNor) in cat. We have previously reported that stimulation of the N.Acc. evokes either inhibition or brief excitation followed by inhibition of extracellularly recorded spontaneously active or driven units in SNpr. The inhibitory period reached a peak 50-80 msec following the onset of N.Acc. stimulation and persisted for approximately 300 msec.

Pharmacological interventions designed to characterize the nature of this inhibition were performed in α-chloralose anesthetized, immobilized, and artifically ventilated cats. Stainless steel microelectrodes were used to record extracellular spontaneous or sural evoked unit activity in SNpr. Brief trains of stimuli were delivered to the N.Acc. and caudate nucleus (CN) approximately 80 to 100 msec preceding the sural shock if the unit was normally quiescent. Bicuculline, 0.01 to 0.1 mg/kg iv, consistently antagonized N.Acc. and CN elicited suppression of SNpr cells. Diazepam 0.5 mg/kg effectively reversed bicuculline actions. Inhibition of spontaneously active units as well as sural driven units was blocked by bicuculline. In contrast, strychnine, 0.1 to 0.5 mg/kg iv, failed to affect inhibition arising from either N.Acc. or CN. In one instance, strychnine enhanced CN induced suppression of a SNpr cell. These data suggest that, analogous to the GABA-ergic striatonigral pathway, inhibition of SNpr cells arising from N.Acc. utilizes GABA as its transmitter.

231 GABA RECEPTORS IN RAT SUBSTANTIA NIGRA: CHANGES IN RESPONSE TO LESIONS AND CHRONIC DRUG TREATMENT. K. Gale* (Spon: D. Stoff) Dept. Pharmacol., Georgetown U. Sch. Med & Dent, Wash. DC 20007

Changes in ^{3}HGABA binding in substantia nigra (SN) were examined after 1)discrete electrolytic lesions of striatonigral projections 2) hemitransections anterior to SN 3) hemitransections posterior to SN and 4) chronic administration of haloperidol or chlorpromazine. Specific binding of ^{3}HGABA was determined in a frozen and Triton X-100 treated crude synaptosomal-mitochondrial membrane fraction. Both high (K_D=20 nmolar) and low (K_D=120 nmolar) affinity binding sites were observed; the high affinity sites accounted for >50% of the total specific binding in SN. This was in contrast to cerebral or cerebellar cortex where high affinity sites account for < 15% of the total specific ^{3}HGABA binding. 3 weeks after striatonigral electrolytic lesions (which decreased GABA content in SN by > 65%) high affinity ^{3}HGABA binding in SN was increased by 60%, with no significant change in amount of low affinity binding sites. Hemitransections anterior to SN resulted in a similar increase in ^{3}HGABA binding in SN. In contrast, hemitransections posterior to SN resulted in a 30-40% decrease in specific ^{3}HGABA binding in SN when measured at 3 weeks postop. Chronic (8 weeks) treatment with haloperidol (1 mg/ kg/day) or chlorpromazine (20 mg/kg/day) did not alter GABA receptors in caudate-putamen but caused a significant increase (35%) in ^{3}HGABA binding in SN. An increase in nigral GABA receptors may compensate for a decrease in the function of striatonigral GABAergic neurons. This in turn may be an indirect effect of dopamine receptor blockade in the caudate. Such a compensatory mechanism may play a role in the development of tolerance to the haloperidol-induced activation of tyrosine hydroxylase.

The decrease in ^{3}HGABA binding after transections posterior to SN suggests the presence of GABA receptors on neurons connecting the SN with caudal brain regions and may include a population of GABA receptors located on serotonergic axon terminals in SN (based on studies with 5,7-dihydroxytryptamine lesions of the raphe). Nigral GABA receptor stimulation (by unilateral intranigral injection of muscimol) induced postural asymmetry and contralateral circling even after complete hemitransections between the SN and forebrain, indicating that GABA receptors located on projections descending from the nigra may be important for motor control. Thus, we postulate that a modification of nigral GABA receptor activity, produced by drug- or lesion-induced changes in striatonigral neural function, may have impact not only on dopaminergic and other ascending pathways but also on descending projections from SN.

232 EFFECTS OF CAUDATE STIMULATION ON INTRACELLULARLY RECORDED VA-VL NEURONS. E. Garcia-Rill. Dept. of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72201.

A recent study (Garcia-Rill, et al., Brain Res. 1979) described a differential distribution of motor cortex (MCX) projections to the caudate nucleus (CN). The medial MCX (axial representation) projects to the entire lateral half of the head of the CN. The lateral MCX (forelimb representation) projects to a circumscribed area adjacent to the internal capsule and within the projection area of medial MCX. The present study was undertaken to determine whether a differential distribution of CN efferent projections is maintained (via the globus pallidus) at the level of the VA-VL nuclei of the thalamus. Post-synaptic potentials were recorded intracellularly from VA-VL neurons in locally-anesthetized, paralyzed cats. Stimulating arrays were placed medially in the CN (within the medial MCX projection area), in the lateral CN (within the lateral MCX projection area) and in the internal capsule (IC). Fastigial, interpositus and dentate nuclei were also stimulated, as well as medial and lateral MCX. CN stimulation elicited responses in 13% of VA-VL neurons. All of these neurons showed EPSP responses, followed by IPSPs in most cells. (Mean latency 15.9 + 2.3 (S.E. of the mean) ms; Mean threshold 0.17 + 0.07 mA). All of these responses were elicited by medial CN stimulation and could not be replicated by lateral CN, MCX or IC stimulation. IC stimulation produced no response, pure IPSPs or lower amplitude EPSPs (1 case) in this proportion of VA-VL neurons. However, 72% of the total sample of VA-VL cells showed EPSP-IPSP or IPSP responses to IC stimulation. (Mean latency of EPSP or spikes 1.7 + 0.43 ms, mean latency of IPSPs 10.0 + 1.7 ms; mean thresholds 0.14 + 0.03 mA for EPSPs and 0.09 + 0.01 mA for IPSPs. Cerebellar stimulation produced EPSP-IPSP sequences in 27% of VA-VL neurons. (Mean latency 5.6 + 1.8 ms, mean threshold 0.12 + 0.03 mA). The interpositus was found to preferentially influence over half of these neurons, while the rest were evenly divided between preferential fastigial or dentate responses. To date, no VA-VL neurons responding to CN stimulation responded at short (< 8 ms) latency to cerebellar stimuli. VA-VL neurons responding to CN stimulation were preferentially located anteriorly, in medial VA and medio-dorsal VL.

This study reveals a preferential excitatory influence from medial CN (which in turn receives axial and proximal limb MCX input) to the anterior VA-VL nuclei. Whether lateral caudate (or pure inhibitory) influences are "filtered" by the entopeduncular nucleus remains to be determined.

233 ELECTROPHYSIOLOGICAL CHARACTERIZATION OF A PROJECTION FROM PEDUNCULOPONTINE NUCLEUS TO ENTOPEDUNCULAR NUCLEUS IN THE CAT. Teresa Gonya-Magee and Marjorie Anderson. Depts. of Physiol. and Biophys and Rehab. Med., University of Washington, Seattle, WA. 98195.

Earlier horseradish peroxidase studies in the monkey (Clausing, DeVito, and Anderson, 1977) demonstrated a potential synaptic input to the globus pallidus from neurons in the pedunculopontine nucleus (PPN). HRP injected into the globus pallidus area in cats also causes retrograde labeling of neurons in PPN. Electrophysiological experiments were designed to determine the synaptic effect of PPN stimulation on neurons in external globus pallidus (GPe) and entopeduncular nucleus (ENT), the feline homologue of the internal globus pallidus.

Chloralose-anesthetized cats were prepared for electrophysiological recording from GPe and ENTO cells, and arrays of tungsten electrodes were inserted stereotaxically for stimulation of the ventrolateral thalamus (VL) and PPN area of the brainstem. Glass micropipettes filled with potassium acetate and fast green were used for recording and marking. Antidromic activation from VL was used to determine the location of ENTO. Stimulation of PPN with trains of pulses of 300 uA or less evoked action potentials orthodromically (OD) in ENTO neurons at latencies of 6-9 msec. Antidromic (AD) responses also were noted in some neurons at latencies of 1.6 - 4 msec. Extracellular recordings from GPe neurons showed OD or AD excitation at latencies similar to those for ENTO cells. Stimulation at different positions in the midbrain-pontine tegmentum showed that excitation of ENTO and GPe neurons was evoked at lowest stimulus intensities from the PPN area, corresponding to the region containing labeled cells in HRP experiments. Both OD and AD excitation were obtained from the same general brainstem area.

Our results suggest that PPN is a source of excitatory input to the entopeduncular nucleus and globus pallidus and may be an important determinant of the activity of those neurons.

234 NEURONS IN THE RAT SUB-THALAMIC NUCLEUS SEND AXON COLLATERALS TO BOTH THE SUBSTANTIA NIGRA AND GLOBUS PALLIDUS. Toshi Hattori and Derek van der Kooy. Dept. Anat., Univ. of Toronto, Toronto, Ont., Canada.

The rat sub-thalamic nucleus (STN) is a densely packed group of deeply staining (Nissl) neurons, situated immediately dorsal to the cerebral peduncle in the caudal diencephalon. Moving from rostral to caudal, the STN shrinks in the dorsoventral plane and expands in the mediolateral direction. Both multipolar and fusiform cells are seen in the STN, and they range from 10u - 25 u in diameter. Smaller size cells are more likely to be found medially in the STN. The total number of neurons in the STN on one side of the brain was estimated to be 9,500.

Autoradiographic anterograde transport studies have revealed that the two major projections from the STN are to the substantia nigra and globus pallidus. In the present study a retrograde fluorescent double labeling technique was used to investigate the organization of the STN neurons projecting to the substantia nigra in relation to those projecting to the globus pallidus. 0.1 - 0.3 ul of 10% Evans Blue, which fluoresces red, was injected into the globus pallidus and a similar quantity of 2.5% DAPI - 10% Primuline was injected into the substantia nigra. After retrograde axonal transport of the two fluorescent tracers, over 90% of the STN neurons were double labeled with both Evans Blue and DAPI-Primuline. The smaller STN cells (previously proposed to be interneurons) were also double labeled, suggesting that the STN contains few, if any, interneurons. At the level of the caudal two-thirds of the STN a relatively small number of double labeled cells was seen extending from the mass of STN cells slightly medially into the posterio-lateral hypothalamus and laterally in a very thin strip to the far lateral edge of the cerebral peduncle. In conclusion, almost all STN axons bifurcate into ascending and descending branches, innervating the globus pallidus and substantia nigra, respectively.

235 THE RELATIONSHIP BETWEEN THE ISLANDS OF CALLEJA AND THE STRIATO-PALLIDAL COMPLEX: A HISTOCHEMICAL STUDY. Joanna M. Hill* and Robert C. Switzer, III. Laboratory of Brain Evolution and Behavior, National Institute of Mental Health, Bethesda, MD 20205

The islands of Calleja (ICal) not only have a close spatial relationship but also share some histochemical characteristics with the striatum and globus pallidus. Exploiting the high iron content of the globus pallidus, we have used Perl's method to identify the pallidal component of the olfactory tubercle (Switzer and Hill, this volume). Using the same method, we describe here iron-positive, finger-like formations of the ventral pallidum that extend rostrally from the caudal polymorph zone of the olfactory tubercle. Each formation is capped by an island of Calleja. The iron-positive pallidal-like zone extends into the cell sparse cores of the ICal, including the magna island. The neuropil around the granule cells of the ICal is heavily laden with iron.

The striatal component of the olfactory tubercle, as revealed by acetylcholinesterase (AChE) stained preparations, is distinct from the iron-positive areas, and extends from the superficial strata through cell bridges of Heimer to join the main body of the striatum. The ICal are located within this area and also contain AChE.

The intimate spatial relationship with the ventral pallidum and striatum, as well as the similarities in histochemistry to both of these areas, suggest a role for the ICal in striato-pallidal functions.

236 INCREASED DOPAMINE RECEPTOR SENSITIVITY AFTER ESTROGEN TREATMENT. R.E. Hruska and E.K. Silbergeld. Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20205.

The effect of estrogens on non-hypothalamic neurotransmitters in the central nervous system was investigated biochemically and behaviorally. Male, adult rats were chronically estrogen treated by a single subcutaneous injection of estradiol valerate (125 µg/rat) in sesame seed oil. Six days after the estrogen treatment the rats were sacrificed, the brains rapidly removed, and the caudate nuclei isolated, homogenized, and washed. The characteristics of the dopamine receptors were measured by a receptor binding assay for ^{3}H-spiroperidol. Scatchard analyses of the binding curves indicated that there was a 20% increase in the density of the dopamine receptors, with no change in their apparent receptor affinity (101% of control).

Behavioral responses were measured after the injection of 6-hydroxydopamine (6-OHDA). Male rats were injected into the caudate nucleus (A: 7.9, L: 2.6, V: -0.4 mm; Konig and Klippel) with 20 µg 6-OHDA in 2 µl of saline containing 1% ascorbate. One and two weeks after unilateral 6-OHDA injection, the transport of dopamine was reduced to 36% of the uninjected side, while choline transport was unaffected (101% of control). The rats rotated intensely (30-40 rotations/5 min) to the ipsilateral side when administered d-amphetamine (3 mg/kg). The rats also rotated to the contralateral side (10-15 rotations/5 min) when administered apomorphine (5 mg/kg). Estrogen treatment increased the duration of the rotation to d-amphetamine, suggesting an increased sensitivity of the dopamine receptors.

Male rats injected bilaterally with 6-OHDA were also tested for stereotypy after estrogen treatment. The rats treated with estrogen had an increased duration of stereotypy when injected with d-amphetamine (5 mg/kg). This again suggests that dopamine receptors are more sensitive after estrogen treatment.

These results indicate a direct effect of estrogens on dopamine receptor sensitivity as measured both biochemically and behaviorally. Biochemically, there is an increase in the number of dopamine receptors, and behaviorally, there is an increased response (rotation or stereotypy) to d-amphetamine treatment. These findings suggest an important interaction between estrogens and dopamine, which is of relevance to therapeutics and disorders involving dopamine.

237 A REGIONAL ANALYSIS OF DOPAMINE-INDUCED DEVIATION IN THE ADULT RAT. J. N. Joyce and C. Van Hartesveldt. Psychol. Dept., Univ. of Fla., Gainesville, FL 32611

An imbalance in dopaminergic (DA) activity between the caudate-putamen nuclei (CPU) is widely believed to be reflected in postural asymmetry. However, although the CPU in the rat is regionally differentiated with respect to neuroanatomy, neurochemistry, and some behaviors, the possibility that the CPU might be regionally organized with respect to DA-induced postural asymmetry had not previously been explored. In addition, since prefrontal cortex receives a heavy DA innervation it might also play a role in DA-induced asymmetries. We implanted male Sprague-Dawley hooded rats intracerebrally with permanent cannulae and administered both DA (25 ug in .25 ul) and the vehicle alone (.9% saline, .25 ul) unilaterally on separate occasions. A series of sites throughout the CPU, the prefrontal cortex, and the tissue surrounding the CPU were tested. After injection the rats were placed in a circular enclosure in a sound-attenuated chamber and observed via a television monitor. The amount of time spent in an asymmetrical posture, time spent grooming on each side, number of rotations, and locomotor activity were measured. Regional differences within the CPU were found with the vehicle alone: injection of saline into the ventral CPU produced a strong ipsilateral deviation, while injection of saline into the medial-dorsal regions had little effect. Injection of DA into both regions resulted in contralateral deviation, but while the absolute contralateral deviation scores for ventral injection were less than those for the medial-dorsal region, the difference between the effect of the saline vehicle and the effect of DA injection was greater for the ventral region. Injection of DA into prefrontal cortex also induced contralateral deviation; DA injections into other areas surrounding the CPU did not produce postural asymmetries. For both the CPU and prefrontal cortex the grooming data parallel those for postural deviation. No activity changes were produced by DA injection at any site; circling was infrequently seen.

We conclude that the CPU in the rat is regionally differentiated not only with respect to postural deviation but also with respect to other on-going activities such as grooming.

238 FUNCTIONAL PROPERTIES OF DORSAL RAPHE-SUBSTANTIA NIGRA PROJECTIONS IN THE CAT. Athanasios B. Karabelas*, and Dominick P. Purpura. (SPON: G.D. Pappas). Dept. of Neuroscience, Rose F. Kennedy Center for Research in Mental Retardation, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Intracellular recordings were obtained from substantia nigra (SN), pars compacta (p.c.) and pars reticulata (p.r.) neurons identified by antidromic stimulation of medial forebrain bundle (MFB) and thalamic VL-VM nuclei respectively in barbiturate-anesthetized, flaxadilized cats. Stimulating electrodes were also placed in the dorsal raphé nucleus (DRN) which was approached by direct visualization of upper brain stem following limited cerebellectomy. Thalamic stimulation elicited 0.8-2.8 ms latency spike potentials in nigral neurons whereas MFB stimulation evoked 1.6-2.3 ms latency spikes. Criteria for antidromic invasion were met by findings of constant latency at threshold firing level, collision with preceding spontaneous discharges and absence of underlying EPSPs. Stimulation of DRN evoked orthodromic activity in all antidromically identified nigrostriatal neurons and 80% of identified nigrothalamic neurons. Orthodromic response latencies ranged from 1.8-6.0 ms. Most orthodromic responses recorded intracellularly consisted of EPSPs with 1-3 superimposed spikes. Although IPSPs were not observed with intracellular recording DRN stimulation frequently inhibited SN extracellular unit discharges as well as elicited diphasic excitatory-inhibitory sequences. As a further aid to identification of target cells in SN HRP-staining of impaled neurons was employed. The electrophysiological data obtained in this study establish the existence of short latency excitatory synaptic inputs from a sub-population of neurons in the dorsal raphé nucleus to cells in both SN p.c. and SN p.r. While there is uncertainty concerning monosynaptic inhibitory projections from dorsal raphé to nigral neurons multisynaptic inhibitory effects of raphé stimulation on SN cells are clearly demonstrable.

239 DECREASE OF NEOCORTICAL CHOLINE ACETYLTRANSFERASE ACTIVITY BY KAINIC ACID INJECTED INTO THE BASAL GANGLIA. Peter H. Kelly and Stanley L. Hartgraves* (SPON: M. J. Cullen). Dept. of Physiol. and Biophysics, University of Southern California Sch. Med., Los Angeles, CA 90033.

Choline acetyltransferase (CAT) activity, as a marker of cholinergic neurons has been measured in the neocortex after microinjections of kainic acid into the caudate nucleus and globus pallidus of the rat. Anterior, middle and posterior neocortical regions were dissected (Kelly & Moore, 1978, Exp. Neurol. 61, 479) and analyzed separately. Five days after injection of kainic acid (1.25 µg in 1 µl of saline, 0.25 µl/min) into the caudate nucleus CAT was significantly decreased in the anterior and middle neocortical regions. The amount of kainic acid spreading to the neocortex was assessed by including 0.1 µCi of [3H] kainic acid in the injection. Five minutes after the end of the injection, radioactivity in the neocortex was less than 10% of that remaining in the striatum. Direct injection of kainic acid (1.25 µg in 1 µl of saline over 100 sec) into the neocortex did not affect neocortical CAT though experiments with [3H] kainic acid showed greater cortical retention of radioactivity by this route than by intracaudate injection. Thus spread of kainic acid up the injection cannula is not responsible for the decrease of neocortical CAT. With smaller injections of kainic acid (0.625 µg in 0.5 µl, 0.25 µl/min) into the caudate nucleus or globus pallidus, decreases of CAT in anterior and middle neocortex were observed only after the pallidal injections. The results suggest that the direct projections to neocortex from neurons in the region of the globus pallidus, demonstrated by the horseradish peroxidase technique (Divac, 1975, Brain Research 93, 385), are cholinergic and sensitive to kainic acid.

240 IMMUNOHISTOCHEMICAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE IN VARIOUS REGIONS OF HUMAN CNS. Hiroshi Kimura*, Edith G. McGeer, Patrick L. McGeer and Frank Peng. Div. Neurol. Sci., Univ. of B.C., Vancouver, B.C., Canada V6T 1W5

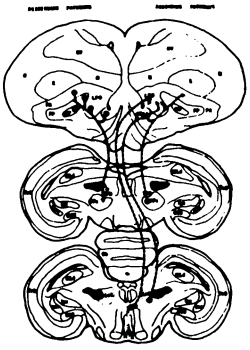
Antibodies prepared in rabbits against purified choline acetyltransferase (CAT) from human neostriatal tissue have been employed to localize CAT-containing neurons in the human CNS using the indirect (PAP) immunohistochemical method. Normal human brains, obtained from various corners' offices within 0.5-1 hr post-mortem, were removed from the skull and perfused via vertebral arteries with 6 l of 5% paraformaldehyde and 0.1% glutaraldehyde. Various brain regions were dissected out and post-fixed with 4% paraformaldehyde for 8 hr followed by washing with 15% sucrose in PBS for 48 hr. All steps were carried out at 2-4°C. Cryostat sectioned (20 µm) tissues were first treated with 0.05% Triton X-100 in PBS. Fab fragments of IgG from normal rabbit serum or from the rabbit anti-human CAT were then diluted with 0.01% Triton X in PBS and applied to the tissue for PAP immunocytochemical procedures. Specific staining of neuronal cell bodies was found in the caudate nucleus, putamen, globus pallidus, deeper layer of the cerebral cortex (the main motor area), and ventral horn motor neurons of spinal cord. CAT positive fibers were also found in the regions mentioned above as well as in the cerebellum, hippocampus, inferior olive and substantia nigra. The CAT specific staining obtained in the human spinal cord, cerebellum and hippocampus was in agreement with previous reports using other species of animals. In the neostriatal area, however, at least two different kinds of positively staining cell bodies were observed. These included some large or giant multipolar cells (> 25 µm) which possess large, roughly spherical or ovoid dendritic trees and were at one time thought to be efferent neurons but are, according to more recent evidence, very probably interneurons. Small multipolar cells (< 10 µm) with round shaped somata were also stained. The globus pallidus contained a high density of long positive fibers and a rather scattered population of large multipolar neurons.

241 DEMONSTRATION OF RECIPROCAL CONNECTIONS BETWEEN THE AVIAN PALEOSTRIATUM AND THE MIDBRAIN TEGMENTUM. Cheryl A. Kitt and Steven E. Brauth, Dept. of Psychol., Univ. of Maryland, College Park, Md.

In pigeons, equal parts mixtures of ^{3}H-leucine and ^{3}H-proline were placed in the dorsomedial paleostriatum augmentatum (PA) or lobus parolfactorius (LPO) of the paleostriatal complex. Light microscopic analysis revealed heavy silver grain accumulations over the central and dorsal portions of the pars compacta of the nucleus tegmenti pedunculo pontinus (TPc) and over the anterodorsal pars disseminata et dorsalis (TPD) of the nucleus tegmenti pedunculo pontinus.

Injections of horseradish peroxidase (HRP) into the TP area of the midbrain confirmed the existence of projections to this region from PA and LPO neurons. In addition, labeled cells were also observed in the paleostriatum primitivum (PP) and nucleus intrapeduncularis (INP) as well as the nucleus accumbens (Ac).

HRP injections placed in PA, LPO and Ac revealed that these neurons receive projections from the dopaminergic cells of TPc, the norepinephrine-containing cells of the locus ceruleus (LoC) and the serotonergic cells of the midbrain raphe (R). As found in prior studies PP and INP appear not to receive monoaminergic innervation. Taken together, these results indicate the existence of reciprocal connections between neurons of the avian paleostriatum and midbrain tegmentum comparable to those existing in mammalian forms between the striatum and substantia nigra area.



Projections from PA, LPO and Ac upon TPc and TPD appear comparable to projections of neurons in the mammalian striatal complex upon A8, A9 and A10 areas of the brainstem. TPc appears comparable to A8 and A9 and may contain components of A10 as well. The TPD regions appear most comparable to the pars reticulata of the mammalian substantia nigra. PA, LPO and Ac thus appear comparable to cells of the mammalian striatum while the larger cells of PP and INP appear most comparable to portions of the mammalian pallidal complex.

Interconnections of avian paleostriatal neurons and the midbrain tegmentum are depicted in this figure.

242 ALTERED GLUCOSE UTILIZATION OF BASAL GANGLIA CIRCUITRY FOLLOWING DEGENERATION OF ASCENDING DOPAMINERGIC NEURONS, AND APOMORPHINE-INDUCED REVERSAL. Michael R. Kozlowski* and John F. Marshall. Dept. of Psychobiology, Univ. of California, Irvine, CA 92717.

The 2-deoxy-D- ^{14}C glucose (2-DG) autoradiographic technique was used to determine (1) the effect of unilateral destruction of ascending dopamine (DA)-containing neurons on hemispheric glucose incorporation, and (2) the extent to which the DA agonist apomorphine (APO) reverses these denervation-induced changes.

Rats were given unilateral injections of 6-hydroxydopamine (6-OH-DA; 8 ug/4 ul) into the left ventral tegmental area (VTA) or lateral hypothalamus (LH), 30 min. after DMI (15 mg/kg, i.p.), which produced a 98% loss of ipsilateral neostriatal DA. One week postoperatively, 6-OH-DA-treated rats were given ^{14}C-2-DG (150 ug/kg, i.v.) 5 min. after receiving i.p. APO (0.25 mg/kg), its vehicle, or left striatal APO (5 ug). After 45 min. the rats were killed and the brains examined using X-ray autoradiography.

Six-OH-DA injected into the left VTA or LH decreased glucose incorporation into ipsilateral DA-innervated forebrain structures (neostriatum, amygdala, nucleus accumbens (NAS), olfactory tubercle (OT)). Labeling of structures receiving afferents from the neostriatum (globus pallidus (GP), entopedunclear nucleus (EN), substantia nigra pars reticulata (SNr)) as well as thalamic structures receiving afferents from EN or SNr (ventromedial nucleus (VM), ventral anterior lateral nucleus (VAL), far lateral habenula (FLH)) was increased.

Systemic or intrastriatal administration of APO attenuated or reversed most of these asymmetries. The left neostriatum was more heavily labeled, and other DA-innervated forebrain regions (amygdala, NAS, OT) showed symmetric labeling. APO administration also attenuated the denervation-induced increase in GP labeling. However, the APO further exaggerated the labeling in EN and SNr. A decreased labeling of thalamic structures receiving basal ganglia afferents (VM, VAL, FLH) was also observed. Due to the similarity in the pattern of changes observed after i.p. or striatal APO, its effect appears largely attributable to its action on denervated neostriatal cells. In confirmation, APO (i.p. or intrastriatal) increased the labeling of the ventral tip of the internal capsule, where axons of neostriatal efferents course. Most of the APO-induced changes were abolished by haloperidol (2 mg/kg, i.p.).

The ^{14}C-2-DG technique has proven a sensitive tool to study the metabolic activity of basal ganglia circuitry consequent to brain lesions and pharmacological treatments that alter neostriatal DA-ergic activity. The observed changes in labeling are largely consistent with the anatomy and electrophysiology of these structures. Further, the results provide information concerning the pathophysiology of DA-related movement disorders.

243 SENSORIMOTOR DEFICITS CAUSED BY GLOBUS PALLIDUS LESIONS. T. Labuszewski*, L.R. Edelstein, B. Federchuck*, D. Lederman*, T.I. Lidsky. Dept. Psychol., SUNY Stony Brook, N.Y. 11794.

There is a large literature demonstrating that rats with bilateral globus pallidus lesions show aphagia and adipsia lasting several days. In an attempt to understand the bases of these deficits, we used a fine-grained analysis of drinking behavior. Rats were trained to lick a spout recessed behind a plexiglass wall for 8% sucrose solution. Interlick interval, duration of tongue contact with spout, and postural adjustments were monitored. Pre-lesion, each animal showed characteristic bell-shaped lick duration and interlick interval distributions, which varied little from day to day. Globus pallidus lesions caused obvious disruptions of these rhythmic behaviors. This disturbance is in large part due to an inability to correctly position the mouth with respect to the spout and maintain that position for a burst of licks, activities which normally insure consistently efficient ingestion. After pallidal lesions, animals often miss the spout altogether. When they do find the spout, only the first few licks in a burst of licking are "on target". The head then drifts away from its "drinking position" and the animal spends much time licking at the surrounding empty space. The burst of licks is terminated after several unrewarded air-licks, the head and mouth are repositioned, and a new burst of licks initiated by the animal. The methods used by lesioned animals to find the recessed spout are reminiscent of someone finding their way in the dark by feeling. Some tap the spout with their noses, then move their heads into the proper drinking position; some tap it with their paws first. Normal animals show no obvious "spout finding" behavior. They walk up to the spout and simply begin licking. Lesioned animals will show more normal ingestion patterns, however, if ease of access to the drinking tube is greatly increased; although they often adopt bizarre head positions when they drink. This licking deficit seems to be qualitatively similar to the deficits in bar press behavior following unilateral basal ganglia lesions (Levine et al, JCPP, 1971 77: 282 293). Animals' ability to continue licking during speed controlled, smooth lateral movement of the spout was also examined. Preliminary data show that moving spout duration distributions also change after globus pallidus lesions.

These data are indicative of neither purely sensory nor purely motor deficits. Rather, basal ganglia damage seems to interfere with movements whose successful execution is dependent upon sensory feedback.

244 HETEROGENEITY WITHIN THE CAUDATE NUCLEUS OF THE CAT: BIOCHEMICAL AND HISTOCHEMICAL INVESTIGATIONS. John Lehmann H.C. Fibiger and A. Parent. Division of Neurological Sciences, University of British Columbia, Vancouver V6T 1W5, and (A.P.) Département d'Anatomie, Université Laval, Québec.

"Patchy" distributions of afferents to the caudate nucleus (CN) have been described. The recent finding (1) that acetylcholinesterase has a heterogeneous distribution in the CN emphasizes the importance of characterizing these discrete topographical units.

We report the results of assaying numerous small samples of cat caudate nucleus for tyrosine hydroxylase (TH), choline acetyltransferase (CAT), acetylcholinesterase (AChE), glutamate decarboxylase (GAD), and high-affinity glutamate uptake (Glu-up). The following significant correlations were obtained:

AChE, CAT:	r = .731	p<.001
CAT, TH:	r = .623	p<.001
AChE, TH:	r = .861	p<.001
TH, Glu-up:	r = -.650	p<.01
AChE, Glu-up:	r = -.681	p<.01

Subcellular fractionation studies have shown that all these enzymes are highly concentrated in the P_2 fraction; thus these enzyme values are interpreted as indices of terminal densities in given samples. The results suggest that dopaminergic and cholinergic terminals are concentrated in similar AChE-rich areas. AChE-poor zones appear to be preferentially innervated by corticostriatal fibers, insofar as high-affinity glutamate uptake can be considered a marker for this projection.

Since AChE is heterogeneously distributed in the caudate nucleus, it was of interest to determine if the putative cholinergic large aspiny neurons (2), which synthesize high levels of AChE, have a patchy distribution. In some coronal sections, the distribution of perikarya within squares of a superimposed grid deviate from the Poisson distribution, suggesting aggregation; however, this is not a consistent observation. More powerful stochastic methods will be presented which can be used to test for aggregation of discrete events in any histological material.

The density of AChE-positive perikarya in the CN of the cat is approximately half that of the rat; similarly, CAT activity in the CN of the cat is approximately half that of the rat. This correlation supports our previous suggestion (2) that the large aspiny neurons which stain heavily for AChE are the cholinergic interneurons of the striatum.

245 SOURCE AND TOPOGRAPHY OF THALAMIC PROJECTIONS TO THE CAUDATE-PUTAMEN IN THE RAT AS DEMONSTRATED BY THE RETROGRADE TRANSPORT OF HORSERADISH PEROXIDASE (HRP). J. F. Lentini* and G. M. Krauthamer. Dept. Anat., CMDNJ-Rutgers Medical School, Piscataway, N. J. 08854.

The posterior intralaminar thalamus, consisting of centrum medianum (CM), n. parafascicularis (Pf) and posterior n. centralis lateralis, is the source of a major projection to the caudate nucleus in the cat. There is, however, a long standing controversy with regard to the delineation of these nuclei.

In the rat, the existence of CM is not always recognized. The two most commonly used stereotaxic references for the rat differ widely in the size and location of CM and Pf. Hence, the stereotaxic coordinates defining these structures cannot be used with confidence in studies of the thalamo-striate projection system. To resolve this problem, we used HRP (TMB method) to define the intralaminar projection to the caudate-putamen. Large injections of HRP were used to define the extent of the thalamic input and small iontophoretic HRP deposits were used to determine its topographic organization. Clusters of retrogradely labeled cells were found surrounding the habenulo-interpeduncular tract (retroflex bundle) dorsally, ventrally, and laterally, but not medially. The projection was topographically organized. This delineation of CM agrees with that of the rat stereotaxic atlas of Albe-Fessard et al., but differs from that of the atlas of König and Klippel.

246 EFFECTS OF NEONATAL MEDIAL FOREBRAIN BUNDLE (MFB) LESIONS ON DEVELOPMENT IN CATS. I. RESULTS ON JUVENILE AND ADULT CATS. M.S. Levine, C.D. Hull and N.A. Buchwald. Mental Retardation Research Center, School of Medicine, UCLA, Los Angeles, CA. 90024.

We have previously described some of the effects of bilateral MFB lesions made in kittens of 9-21 days of age (Neurosci. Abst. 3 (112): 1977). These lesions interrupt many ascending and descending pathways and destroy parts of the lateral hypothalamus as well. Of specific interest in our experiments was damage to the nigrostriatal dopaminergic tract (NST). To determine the amount of destruction of the NST, caudate dopamine (DA) concentrations were measured. MFB lesions produced an average decrease of 75% in caudate DA. During the first 2 months postlesion, MFB lesioned kittens (N=30) gained less weight, were more hyperactive and perseverated more often in making incorrect responses in a spatial discrimination than their intact littermates (N=37) or littermates with control (ventral thalamic) lesions (N=16). The present experiments were designed to ascertain the long-term effects of neonatal MFB lesions. Studies were made of learning ability, responses to amphetamine challenges and of striatal neuronal firing rates in these cats at juvenile and adult ages. When the animals were 3-4 months old their ability to learn a visual discrimination was assessed in a modified T-maze. MFB lesioned cats learned the discrimination in slightly fewer trials (210 + 20, mean + S.E.) than their intact littermates (265 + 20) or their littermates with control lesions (260 + 35). When the meaning of the cues in the discrimination was reversed the MFB lesioned cats responded more frequently to the previously reinforced cue than animals in the other groups. The behavioral effects of d-amphetamine (3 dosages, 1,2 and 4 mg/kg i.p.) were assessed when the cats were 9-16 months of age. Amphetamine was used because in adult animals depletion of striatal DA markedly attenuates some of its effects. In all animals amphetamine produced autonomic responses consisting of pupillary dilation, piloerection and salivation. In intact cats and in cats with control lesions amphetamine also induced vertical and horizontal head movements. The frequency and intensity of these movements were significantly reduced in the cats with neonatal MFB lesions. A final set of experiments was carried out when the animals were 12-24 months old to determine if long-term changes in spontaneous firing rates of caudate neurons were induced by the neonatal MFB lesions. MFB lesions produced minimal alteration in the spontaneous firing of caudate neurons. The average interspike interval of caudate neurons of intact cats was about 1700 ms compared to about 2200 ms in cats with MFB lesions. Taken together these results indicate that early postnatal damage to the MFB produced a complex set of behavioral deficits during maturation but little alteration in the spontaneous firing of caudate neurons per se. Supported by HD-05958 and NS-12324.

247 CHOLINOCEPTIVE NEURONS IN THE ISOLATED CAUDATE. Luis A. Marco, John C. Torri*, and Alberto B. Santos*. Dept. of Psychiatry, Med. Univ. of S.C. and VA Hospital, Charleston, S.C., 29403.

Many intrinsic short-axon neurons in the caudate nucleus are thought to possess cholinergic receptor sites on the basis of histochemical and lesion studies but neurophysiological evidence is still lacking. The caudate of cats and rats was surgically isolated in situ on one side from the rest of the neuraxis and left with its connections intact on the other side. Single unitary activity was investigated in intact and isolated caudates at least 2 wks. after isolation by means of 5-barrel micropipette assemblies. Three barrels were loaded with acetylcholine (ACh), dopamine (DA), and glutamate (Glut) for iontophoresis and the other two with saline for recording and current neutralization. In both species, best unitary recordings were obtained with overall multi-barrel tip size of 6-7 μ and individual pore resistances of 15-20 MΩ. Numerous neurons in the immediate vicinity of the recording pore were silent in both species on the isolated side, they could not be triggered to fire impulse discharges by closely apposed electrical stimulation (within 1.5 mm of the recording site), and could only be activated by iontophoresis of Glut (a general inducer of cell firing) or ACh. ACh-sensitive units were induced to fire at currents between 10 and 30 nA. Some of these otherwise silent units reached peak-to-peak amplitudes up to 1.6 mV and firing rates up to 100 Hz. These effects were not current-dependent however because a) the ACh-activating effect often had delays of 0.5 min. or longer, and b) identical amounts of current from the neutralization or the DA barrel failed to elicit them. Some other non-spontaneous units were induced to fire only after ACh iontophoresis had been turned off, again following a long delay of silence. We have not observed differential responsiveness to DA between neurons in intact and isolated sides. Detailed analysis of neuronal populations is underway. Since terminal degeneration is complete 6 days after surgical isolation, the ACh-sensitive cells in the isolated caudates must be intrinsic or local circuit neurons. If the nigroneostriatal (NS) DA input is inhibitory on intrinsic ACh-containing caudate neurons, one would expect in the isolated caudate disinhibition of such intrinsic neurons which would release sufficient amounts of ACh onto postsynaptic cholinoceptive receptor sites in the next neuron in the synaptic chain of transmission. The fact that additionally iontophorized ACh was required to trigger ACh-sensitive neurons would suggest rather a deficiency in ACh release or an excitatory role for the NS DA system on these ACh-containing neurons. Further neurobiological and clinical significance of these results will be discussed. (Supported by NINCDS Grant # NS14712-02).

248 QUANTIFICATION OF DENDRITIC MORPHOLOGY IN THE DEVELOPING CAUDATE NUCLEUS OF THE CAT. J.P. McAllister*, R.M. Bradford*, M.S. Levine C.D. Hull and A.M. Adinolfi. Mental Retardation Research Center, School of Medicine, UCLA, Los Angeles, CA. 90024.

As the continuation of a series of investigations designed to quantify neuronal development of the basal ganglia, the present study has examined the dendritic growth of spiny neurons in the kitten caudate nucleus. Tissue from 3, 10, 19 and 114 day old kittens was impregnated using the Rapid Golgi method. Neurons from each age group were drawn using a camera lucida attachment and subsequent three dimensional analysis performed with the aid of a PDP 11/40 computer system. In this way, accurate information was obtained on a variety of dendritic parameters. Results from the four age groups were compared to determine how the dendritic morphology of caudate spiny neurons changes with development. Preliminary analyses from 66 neurons (3 day = 15; 10 day = 15; 19 day = 13; 114 day = 23) indicate that neither soma diameter (mean = 23.7μm) nor the number of branches per dendrite (mean = 7.7-9.9) change appreciably between 3 and 114 days of age. The average maximum radius of the dendritic field, however, enlarges from about 150μm to 220μm, but this growth is not significant until after 3 weeks of age. Average branch length increases from 60μm in the 3, 10 and 19 day groups to 85μm in the 114 day group. Similarly, the average dendritic length measures 494, 592, 440 and 783μm at 3, 10, 19 and 114 days, respectively. The lower values for average dendritic length and number of branches per dendrite (7.7) at 19 days may reflect impregnation differences in that all cells at that age were measured from a single animal. Nevertheless, the maximum values, which should compensate for dendrites which may appear prematurely shortened because they pass out of the section, yield dendritic field radii of 195, 196, 214 and 303μm at 3, 10, 19 and 114 days, respectively. Such linear growth occurs distal to the primary dendrite, because the lengths of the first branch do not increase significantly. In contrast, the total branch lengths comprising an entire dendritic field are relatively uniform, ranging from 2650 to 2990μm for the early age groups to about 3300μm at 114 days. This may correlate with the most striking finding, that the total number of dendrites per neuron appears to decrease with age. At 3, 10 and 19 days there are 6.1, 5.3 and 6.2 dendrites per neuron, respectively. This compares to 4.4 dendrites per neuron at 114 days. Loss of dendrites with age may be due to fusion of basal membranes at the point of origin to provide a common primary stem for two or more main secondary branches.

249 LATERAL HABENULAR NUCLEUS: ORGANIZATION OF AFFERENT AND EFFERENT PATHWAYS. Russell L. McBride* (SPON: J. Sutin). Dept. Anat., Emory Univ., Sch. Med., Atlanta, GA 30322.

The lateral habenular nucleus (LHB) receives projections from the entopenduncular nucleus (feline homologue of the internal segment of globus pallidus) and lateral hypothalamus-preoptic region, and thus may be an integration site for limbic and subcortical motor systems. Evidence from anterograde and retrograde transport studies, however, suggests that there is at least some degree of segregation of afferent and efferent LHB pathways.

In anterograde experiments in cats, tritiated leucine (100 μCi/μl) was injected into regions projecting to LHB. Two days after injection cats were perfused and the brains processed with standard autoradiographic techniques. It was found that while the entopeduncular nucleus projects to the ventrolateral quadrant of LHB, anterior lateral hypothalamus projects to all of LHB except that region receiving input from the entopeduncular nucleus.

In retrograde transport experiments, a 50% solution of horseradish peroxidase (HRP) was injected into regions receiving projections from LHB. After two days survival, cats were perfused and brains processed with tetramethyl benzidine. Following injections into the central gray, near the dorsal tegmental nucleus and dorsal raphe nucleus, labeled LHB cells were located in the region receiving terminals from the anterior lateral hypothalamus; following HRP injection into the medial reticular formation lateral to centralis superior raphe nucleus, labeled LHB cells were located in the region receiving input from the entopeduncular nucleus and posterior lateral hypothalamus.

Preliminary electrophysiological evidence indicates that the output of the nucleus may be more homogeneous than suggested by the anatomical data. Extracellular recordings were made in barbiturate anesthetized cats from antidromically identified LHB projection neurons. Neurons, regardless of location in the nucleus, were inhibited for approximately 150 msec by either entopeduncular or lateral hypothalamic stimulation. The inhibition was frequently preceded by a 4 msec latency orthodromic action potential.

250 THE EFFECTS OF AGING ON NEURON "CELL ISLANDS" IN THE MOUSE NEOSTRIATUM. Patricia L. Mensah. Department of Anatomy, University of Southern California School of Medicine, Los Angeles, CA.

A number of studies have shown that neuronal aggregates or islands characterize the vertebrate neostriatum. To evaluate the possibility that these cellular territories change with age, the brains of C57Bl/6J mice 4, 10, or 27 months of age were fixed in Carnoy's solution and embedded in paraffin. Five micron coronal sections through the head of the caudate-putamen nucleus (the region of the nucleus rostral to the crossing of the anterior commissure), were stained with cresyl violet. Five sections from each animal were analyzed. The mediolateral extent of each section was divided into three zones--a lateral peripheral zone, a core or central region, and a medial peripheral zone. All large cells in each of the three zones were counted. To obtain data on the medium + small neuron population at each age, a 10 X 10 ocular grid calibrated at 400X magnification was placed over cellular islands in each region. All medium + small neurons in the field and all glial cell nuclei were counted. Two fields were selected and values added to give a single value each for medium + small neurons or glial cell nuclei per region. Only neurons with distinct nucleoli were included in the counts.

Possible sources of variance were ascertained using a three-level nested analysis of variance. Within cellular terriories, the number of medium + small neurons decreased with advancing age ($p < .05$). However, the total number of glial cell nuclei within these same territories showed no significant variation with age. Large neurons were also consistently present throughout the time period sampled in this study. In addition, it should be noted that, as indicated in an earlier report (Mensah, P. L., Brain Research, 137:53, 1977), large neuron variation was confined to regional variation within the head of the nucleus. At all ages, significantly more large neurons occurred in the core of central area than in either the lateral or medial peripheral zones ($p < .001$). These data suggest that physiological and biochemical peculiarities in aged mouse neostriatum may well be due to alterations in the medium + small cell population.

251 ELECTROPHYSIOLOGICAL ANALYSIS OF OLFACTORY TUBERCLE IN ISOLATED TURTLE BRAIN. Martha C. Nowycky* and Gordon M. Shepherd. (Spon: J.N. Crawley). Section of Neuroanatomy. Yale Univ. Sch. Med., New Haven Ct. 06510.

The functional organization of the olfactory tubercle has been studied in an isolated preparation of the turtle brain (see Nowycky, Waldow, and Shepherd, Neuroscience Absts. 4:583, 1978). The olfactory tubercle in the turtle may be considered as that cortical part of the striatum which receives direct projections from the olfactory bulb and also has a dense dopaminergic input from the midbrain (Parent, J. Anat., 114:379, 1973). The turtle olfactory tubercle shows rudimentary lamination of neuronal elements and in its depths is continuous with the underlying striatum.

Field potentials, extracellular spikes, and intracellular responses have been recorded in the olfactory tubercle following electrical stimulation of the following areas: olfactory nerve (ON), lateral olfactory tract (LOT), lateral forebrain bundle at the base of the striatum (LFB) and midbrain. Stimulation of ON, LOT, and LFB elicited a small negative field potential within 100 um of the surface, and, in deeper layers, a large positive field potential with a similar time course.

Extracellularly recorded single units which responded to ON stimulation were found to a depth of 600 um from the surface, i.e. well into the striatum. These cells frequently responded to LOT and LFB stimulation as well. The effects of various combinations of paired volleys were examined. A prominent effect was a long-latency facilitation of LOT and LFB test volleys following conditioning volleys in the same pathway. Another finding was a long-lasting suppression of ON test volleys following LFB conditioning.

Intracellular recordings have revealed impulse responses to all four stimulation sites. Several cells demonstrated brief EPSPs which gave rise to action potentials, followed by long-lasting IPSPs of several hundred msec duration. The effects of dopamine agonists and antagonists on the EPSP-IPSP sequences are currently under investigation.

252 EFFECTS OF CAUDATE OR FRONTAL CORTICAL ABLATIONS IN CATS AND KITTENS: PASSIVE AVOIDANCE. C.E. Olmstead and J.R. Villablanca. Depts. Psychiatry, Anatomy, and MRRC, UCLA Los Angeles, CA 90024.

A simple step-down passive avoidance task was used to evaluate the perceptual awareness of a fearful situation in 15 normal cats and in animals with extensive caudate lesions. The surgical groups were as follows: a) Adult lesions: 11 with bilateral caudate lesions (Md: 74%; range 36-90%). 8 with removal of the frontal cortices, 6 sham operated, and 5 unilateral acaudates. b) Kitten lesions (9-36 days of age): 8 bilateral acaudates (Md: 77%; range 44-93%), 8 bilateral afrontals, and 6 shams. All animals were tested as adults. On each of two days the animal was twice placed on a platform and the latency to step-down measured. Following trial 2 of day 2 the animal received a 10 sec. unescapable shock. Single step-down retention trials were carried out at 24 and 48 hrs. and 1 week following the one trial training. With the exception of two adult operated acaudates (28% and 61.2% removals), 1 unilateral acuadate and 1 adult operate which never stepped off the platform, all animals learned the avoidance task. A Friedman two-way ANOVA showed significant conditioning effect ($p < 0.001$). There were significant group differences only on trial 1 of day 1 ($p < 0.05$) where the adult acaudates stepped down significantly slower than both the intacts ($p < 0.05$) and the kitten acaudates ($p < 0.05$). For the adult acaudates there was a significant inverse correlation between lesion size and the step-down latency for both trials of the first pre-shock day and for the trial immediately preceding shock ($r_S = >-.64$, $p < .05$). Interestingly, partitioning the data for the adult operated acaudates according to the median caudate removal (73%.8%) showed significantly faster step-downs for the larger lesions on day 1-trials 1 and 2 ($p < 0.008$), but not on any of the test days. For the kitten acaudates no significant relationships were found between any of the parameters and lesion magnitude. These data show that 1) animals with total removal of the caudate nucleus or the frontal cortex learned one-trial passive avoidance as readily as sham operated and intact cats; 2) acaudate cats were distinguishable from the other groups only by slower step-downs on the first of the four habituation trials prior to shock; 3) cats made acaudate as adults a) extinguished more rapidly than either kitten acaudates or other control animals and b) showed an indirect relationship between lesion size and 1st trial habituation and extinction. We conclude that animals with extensive lesions of the caudate nuclei or frontal cortices are capable of avoiding an electric foot-shock. There are subtle changes in that avoidance behavior which may be attributed to the enhanced approach tendencies previously described in the acaudates (USPHS Grants HD-05958 and HD-04612).

253 DEMONSTRATION OF RECURRENT INHIBITION IN RAT NEOSTRIATUM. M.R. Park*, J.W. Lighthall*, & S.T. Kitai, Dept. Anat., Michigan State University, E. Lansing, MI 48824.

Recurrent inhibition has been demonstrated in rat caudato-putamen following direct stimulation, during intracellular recording, of a single neuron. Action potentials (AP) triggered by depolarizing square wave current pulses (2-5 msec; 0.5-5nA) conditioned a test EPSP evoked from stimulation of substantia nigra (SN). Reduction of the test EPSP amplitude, indicative of inhibition localized in the dendrites, occurred at interstimulus intervals of less than 20 msec. In nearly all cases where shunting of the test EPSP was observed, no corresponding hyperpolarizing potential was seen at the recording site. Time to peak of the test EPSP was not altered but its rate of decay was generally accelerated and the hyperpolarization following an SN EPSP often deepened. Reduction of the test EPSP by up to 35% was observed and was always less than that seen for inhibition resulting from solely extrinsic stimulation, as in double SN stimulation. To eliminate the possibility that the reduction of the test EPSP was due to an increase in conductance resulting from AP currents, two tests were performed. 1) When depolarizing pulses (250-350 msec) were injected triggering only a single AP, the depolarizing plateau following the AP remained flat, indicating no membrane conductance change. 2) If the conditioning AP was followed by a train of hyperpolarizing current pulses (1nA; 5.0 msec), there was no measurable conductance change. Neurons injected with HRP subsequent to testing for recurrent inhibition were recovered and identified as medium spiny neurons. (Supported by USPHS Grant NS 14886 and NIH BRSG RR 05772-04).

254 A GOLGI STUDY OF THE GLOBUS PALLIDUS IN MONKEYS. Pedro Pasik, Tauba Pasik and Marian DiFiglia. Dept. of Neurol., Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029.

Examination of 15 Golgi-Kopsch series of monkey brains (M. mulatta) revealed at least two neuronal types in the globus pallidus. A medium to large neuron (12 x 18 µm to 15 x 40 µm) is the most frequently impregnated. Generally, four thick dendrites (about 6 µm in diameter) arise from the soma, branch sparsely and course at least 800 µm before terminating. Some of the dendrites are of even thickness, and others, sometimes belonging to the same neuron, are varicose. A single dendrite may have both characteristics in different regions. Dendritic spines and protrusions of various sizes and shapes appear on all dendrites and are much more frequent on those of uniform diameter, particularly in the more distal branches. Frequently, dendrites terminate in a complex arborization composed of 5 to 6 irregularly shaped, often recurving branches, which give rise to numerous pleomorphic appendages of different sizes. Such endings may have abundant spines. The above features were observed in both young and fully mature animals. The axons of these neurons almost always originate from the soma and do not impregnate in our series beyond 30 µm. Small neurons, about 12 µm in diameter, are seen infrequently. They have 3 or 4 dendrites of smaller caliber which exhibit varicosities and an occasional spine, and end after sparse branching about 150 µm from the cell body. The axon emerges from the soma or a proximal dendrite, is thin, and arborizes locally into a few fine beaded processes.

Two categories of extrinsic fibers are observed: (1) the radial fibers are seen in sagittal sections as axons of intermediate diameter (0.5 µm) coursing in discrete bundles from the neostriatum into the globus pallidus. Immediately after entering the pallidum they give rise to numerous fine branching collaterals (0.2 µm) oriented orthogonally to the main axon and parallel to the dendrites of medium to large neurons. The dendritic fields of the latter may span 5 or 6 bundles of radial fibers. Occasionally, a radial fiber terminates in a few fine processes within the outer pallidum. (2) Large caliber axons (1-1.2 µm) are followed up to 1 mm before terminating. Thin processes with large varicosities (2-3 µm) arise from them and follow a straight or curving path. The curved ones end in clusters of 10-20 boutons. These axons are seen in both segments of the pallidum and some of them appear to enter the inner segment from its ventral aspect.

The above findings confirm the results of Fox et al. (1974; 1975) and provide additional information concerning the dendritic patterns of pallidal cells, and features of the intrinsic and extrinsic axons.

Aided by USPHS Grants #NS-11631 and EY-01926.

255 KAINATE-INDUCED NEURONAL DEGENERATION OF THE STRIATUM IMPAIRS SHORT-TERM MEMORY BUT NOT LONG-TERM MEMORY OF REWARDING EVENTS. Michele Pisa, Paul R. Sanberg and Hans C. Fibiger. Div. Neurol. Sci., Dept. Psychiatry, Univ. Brit. Col., Vancouver, Canada.

To assess the effects of neuronal degeneration in the striatum on short-term memory performance, rats with bilateral microinjections of kainic acid into the dorsal striatum (three nmoles in 0.5 ul of phosphate buffered saline, pH 7.4) were compared with vehicle injected controls in a reward-alternation runway task in which food was available in the odd but not in the even trials of daily sessions each consisting of a 12-trial sequence. Occurrence of speed alternation in this task, specifically running more slowly in the nonrewarded than in the rewarded trials of the sequence, is commonly interpreted to reflect memory of the recent consequences (reward or nonreward) of running. The rats were trained for 22 sessions with an intertrial interval (ITI) of 1 min, for 10 sessions with a 5-min ITI, and for 5 sessions in extinction. Separate measures were taken of the latencies in the start box, the alley and the goal box of the L-shaped runway. Throughout training with alternating reward the kainate-treated (KAT) rats ran significantly more slowly than the controls, irrespective of trial outcome. The rats of both groups ran significantly more slowly in the first, nonrewarded trial than in the second, rewarded trial of the sequence in all segments of the runway. This difference in speed was at least in part an effect of learning, because it strongly increased with practice. In the later trials of the sequence the control rats reliably alternated speed in all segments of the runway. In contrast, the KAT rats reliably alternated in the goal box only. On extinction, rate of suppression of the running response did not significantly differ among groups. Histology revealed severe neuronal degeneration of the dorsal striatum in all KAT rats. Some KAT rats also showed degeneration of the ventral striatum, and partial, unilateral or bilateral degeneration of the pyramidal neurones of the CA1 field of the hippocampus.

The present results indicate that striatal neuronal degeneration in rats does not affect long-term memory of invariant rewarding events, i.e. nonreward at the onset of the sessions. These lesions, however, possibly in combination with partial hippocampal damage, impair modulation of running performance reflecting short-term memory of variable rewarding events. In addition to these memory impairments, these lesions result in motoric alterations preventing running speeds comparable to those of control rats.

Supported by grant of the Medical Research Council of Canada and by MRC fellowship to M. Pisa.

256 STRIOSOMAL ORGANIZATION OF THE CAUDATE NUCLEUS: III. DISTRIBUTION OF AFFERENTS FROM THE FRONTAL CORTEX OF THE CAT. C.W. Ragsdale, Jr.*, and A.M. Graybiel (SPON: R.L.M. Faull). Dept. of Psychology, M.I.T., Cambridge, MA 02139.

Autoradiographic evidence suggests that the cortico-striate projection in cats and monkeys is organized in a complex pattern in which both grain-dense and grain-sparse figures can be recognized within the field of distribution of individual cortical areas. Since the grain-figures visible in autoradiograms have about the same dimensions as inhomogeneities in striatal acetylcholinesterase (ca. 500 um dia.), it seemed possible that the two patterns might be related. We have therefore compared them directly in the caudate nucleus of the cat.

Injections of ^{3}H-amino acids or ^{35}S-methionine were made into the pericruciate cortex of three cats. Up to 1m Ci of label was deposited in multiple closely spaced injections and the resulting injection sites involved parts of areas 4, 6 and surrounding cortical zones. Most sections were prepared for autoradiography, but at intervals sections were instead prepared by the acetylthiocholinesterase (AchE) method of Geneser-Jensen and Blackstad. Both processing techniques demonstrated marked inhomogeneities in the striatum. In the autoradiograms the caudate nucleus was massively labelled on both sides in a patterned manner confirming earlier accounts; in the AchE-sections irregularly shaped zones of low activity appeared against a matrix of dark stain. Autoradiograms were lined up with neighboring sections stained for cholinesterase. It was clear that while the inhomogeneities in grain-distribution in the autoradiograms were by no means always aligned with the zones of low AchE activity, there often was a match: sometimes the borders of the grain-dense patches corresponded to the borders of the pale AchE zones, sometimes grain-sparse and enzyme-poor zones were aligned. The grain-sparse areas corresponding to cholinesterase-poor zones appeared in the ventral half of the caudate nucleus both ipsilaterally (3 cases) and contralaterally (1 case). By contrast, instances of "filling in" of AchE-poor zones by grains in the corresponding autoradiograms were seen in the dorsal part of the caudate nucleus ipsilaterally (2 cases) and contralaterally (1 case). These last named alignments were especially prominent in one case (^{35}S) in which the cortical injection was centered in area 6.

We do not know how extensive such systematic correspondences may be for other cortical areas. Even for the fronto-striate projection quantitative analysis is difficult for technical reasons: in both the AchE staining and the autoradiography one must balance between prolonged processing that could mask some pale or grain-sparse zones, and brief processing that might fail to demonstrate the inhomogeneities adequately. Supported by NSF 78-10549BNS and NIH-1-R01-EY02886-01.

257 AN EXPERIMENTAL ANALYSIS OF THE AFFERENT PROJECTIONS TO THE CENTROMEDIAN AND PARAFASCICULAR NUCLEI IN THE CAT. G. James Royce, Michael F. Huerta, Joseph T. Weber and John K. Harting. Dept. of Anatomy, University of Wisconsin, Madison, WI 53706.

The method of horseradish peroxidase has been used to identify the various sources of afferent pathways to the centromedian and parafascicular nuclei in the cat. Following injections of HRP which involve only the centromedian-parafascicular region, an extremely wide distribution of labelled neurons is apparent within the cerebral cortex, brainstem and spinal cord.

Labelled neurons are present in approximately the rostral four fifths of the cerebral cortex. All labelled cells lie entirely within cortical layer V. Such cells occupy every neocortical gyrus, with the exception of the posterior lateral gyrus. The largest number of labelled neurons are present within the anterior sigmoidal gyrus and within the depths of the presylvian sulcus. A lesser, but considerable number of labelled neurons lie within the gyrus proreus, and the anterior sylvian, posterior sigmoidal and cingulate gyri. Scattered labelled cells can also be identified in the posterior sylvian gyrus, and in all of the ectosylvian and suprasylvian gyri.

This widespread distribution of afferent cortical cells is strikingly similiar to the pattern of efferent projectons from the CM-Pf complex, as revealed by autoradiographic methods (Royce '77). Further, it is interesting to note that the organization of afferent cells projecting to the CM-Pf nuclei is remarkably similiar to the pattern of afferent neurons which project to the head of the caudate nucleus (Royce, '77).

The superior colliculus contains many labelled cells. Such cells are restricted to layers IV-VII, with the following percentage distribution within each layer: layer IV, 62%; layer V, 19%; layer VI, 14%; and layer VII, 5%. All cell sizes are represented, however, most cells are small (less than 25 micra), while only a few cells are either medium-sized (25-39 micra) or large (greater than 40 micra).

The hypothalamus also contains HRP positive cells, especially the ventromedial nucleus and dorsal hypothalamic area. In addition, labelled neurons are present within the reticular thalamic nucleus, the entopeduncular nucleus, the periaqueductal gray, the principal sensory and spinal trigeminal nuclei, the vestibular complex, the fastigial nucleus of the cerebellum, all portions of the reticular formation, the locus ceruleus, the nucleus gracilis and the nucleus cuneatus, and lamina VII of the cervical spinal cord.

258 STRIATAL KAINIC ACID LESIONS, CATALEPSY, LOCOMOTOR ACTIVITY AND HUNTINGTON'S DISEASE. Paul R. Sanberg,[†] Michele Pisa, and Hans C. Fibiger. Div. Neurological Sci., Univ. of British Columbia, Vancouver, B.C., Canada, and [†]Dept. Behavioural Biology, Australian National Univ., Canberra, A.C.T., Australia.

Microinjections of the neurotoxin, kainic acid (KA), into the striatum of rats produce biochemical, anatomical and behavioral changes similar to those seen in patients with Huntington's disease (HD)(1,2). The present study examined the effects of drug-induced cholinergic and dopaminergic manipulation on cataleptic and locomotor behaviors of rats with KA lesions of the striatum.

Three nmoles of KA in 0.5µl of phosphate buffered saline were injected into the rostral striata of male Wistar rats. Control rats received injections of the vehicle only. During behavioral testing the drugs, haloperidol (0.5, 1 & 2 mg/kg), pilocarpine (25, 50 & 100 mg/kg), amphetamine (1 mg/kg) and scopolamine (1 mg/kg) were given i.p. Catalepsy was measured as the latency to remove the forepaws from an 8 cm high bar, and locomotor activity was measured by photoactometers over two hours.

In the first experiment (about 1 month post-op) the KA lesioned (KAL) rats showed substantial *decreases* in haloperidol and *increases* in pilocarpine-induced catalepsy, compared to controls. At higher, normally subseizure threshold, doses of pilocarpine all KAL rats showed clonic convulsions. Catalepsy measured after vehicle injections did not differ between groups. In the second experiment the KAL rats showed *increased* locomotor responses to both amphetamine and scopolamine, compared to controls. No differences were observed following saline in either experiment.

The results showing enhanced sensitivity of KAL rats to the behavioral effects of some anticholinergic, and dopaminergic agents are similar to the effects observed in HD patients. The attenuation of the behavioral response produced by the neuroleptic, haloperidol, in these rats, supports the view that the striatum is the site of action of this agent. Furthermore, it indicates why HD patients exhibit only a minimal "transqualizing" effect, compared to other non-striatal damaged neurological patients, following the common use of haloperidol. Finally, the increased sensitivity of KAL rats to pilocarpine warrants further study on the possible effectiveness of cholinergic drugs in HD.

259 SENSORY AND MOTOR CONCOMITANTS OF JAW MOVEMENTS IN CAT CAUDATE NEURONS. J. S. Schneider, F-C. T. Chang* and T. I. Lidsky. Dept. Psychol. SUNY, Stony Brook, N. Y. 11794.

Single neurons were recorded from the head of the caudate in partially restrained, behaving cats. Milk was presented to the animal via a tube resting against the upper lip at the midline. Milk delivery elicited rhythmic jaw movements and associated postural adjustments. Sampled cells were assessed first for involvement in ingestion-related movements and subsequently for sensory responsiveness.

Three populations of cells showed ingestion-related changes in activity. The most frequently encountered type (25% of sampled cells) showed firing rate changes that were time-locked to milk delivery. These cells possessed no obvious somatosensory or gustatory sensitivity. Response magnitude was unrelated to the topography of ingestion-related movements; indeed, unit responses persisted in the absence of any motoric response to the milk. Current work is investigating the possible involvement of these cells in attentional aspects of behavior.

The second type (15% of sampled cells) was characterized by a high degree of somatosensory responsiveness. Light tactile stimulation was optimal for effecting activity changes. Receptive field sizes were moderate (eg. front of lip) to large (eg. entire face) and always included the perioral tissue. Heterogeneity of response within receptive zones suggested encoding of stimulus location. Ingestion-related activity change in these cells was apparently secondary to facial stimulation caused by licking and jaw movements.

The third type (4% of sampled cells) showed neither somatosensory nor movement-related responsiveness in the usual sense. Jaw and postural movements alone or somatosensory stimuli alone evoked no activity changes. However, somatosensory stimulation, if presented during ongoing ingestional movement, caused increased firing in these cells. Receptive fields were contralateral, perioral, and located far posterior of the area contacted by the drinking tube. These response characteristics are compatible with the encoding of stimulus location during movement and suggest possible targeting functions.

These data underscore the involvement of the basal ganglia in oral-ingestive behavior. However, the nature of this involvement remains unclear, particularly in view of the absence of pure movement-related neuronal activity. The potent influence of trigeminal afferents upon caudate neurons emphasizes analysis of sensory processing as an advantageous approach to an understanding of basal ganglia function.

260 ENTOPEDUNCULAR NUCLEUS PROJECTIONS TO THE MESENCEPHALIC LOCOMOTOR REGION. R. Skinner, E. Garcia-Rill and S. Gilmore. Dept. Anat., Univ. Arkansas for Medical Sciences, Little Rock, AR 72201.

Recent electrophysiological studies have confirmed previous anatomical studies describing a projection from the entopeduncular nucleus (EN) to the nucleus tegmenti pedunculopontinus (NTPP). This nucleus lies embedded in the brachium conjunctivum, immediately ventral to the cuneiform nucleus (CF). From another line of evidence, stimulation in the region of the CF in the cat has been found to elicit rhythmic walking movements as long as, a) a precollicular-postmamillary brainstem transection is accomplished, and b) a moving treadmill is placed beneath the limbs while the animal's weight is supported. The present study first established that, following appropriate transection, walking could be elicited on a treadmill by stimulation of the medial edge of the CF. Best parameters were 0.05 mA, 1.5 ms pulses at 60 Hz. Secondly, it was established that single neurons recorded in EN could be antidromically driven (0.12 mA, 0.05 ms, > 300 Hz) from the medial edge of the CF. Histological verification of stimulating sites showed the sites to be indistinguishable from the walking-eliciting sites. Estimates of EN projections to NTPP range from 8% to 50% for other studies. Although we have a small sample, only 14% of EN cells appear to project to medial CF.

We have been able to elicit antidromic responses in EN cells from CF, transect and elicit rhythmic movements of the limbs from the same site in the same animal. We have been unable to generate smooth walking movements, after transection and recovery, in preparations which previously were lightly anesthetized or locally anesthetized-paralyzed during single unit recordings.

Parallel autoradiographic experiments are in progress to determine whether the motor cortex also projects to the CF region. Preliminary findings suggest that injections of H^3-leucine (total 3 μCi) into the gray matter of area 6 aβ (axial motor cortex) result in labeling in the CF region.

The present studies describe convergent projections from the EN and, at least, axial motor cortex to the mesencephalic locomotor region. Functionally, these projections may not be involved in the direct control of walking. The fact that spontaneous walking may occur in "thalamic" preparations precludes this notion. Basal ganglia and motor cortex projections to this area, rather, may be involved in the sequencing and ordering (syntax) of voluntary movements. This concept is an extension of the idea that the basal ganglia are involved in the preparation for movement.

Supported by a NIH grant to UAMS (RR0530) and MH-32878.

261 GLOBUS PALLIDUS COMPONENT IN OLFACTORY TUBERCLE: EVIDENCE BASED ON IRON DISTRIBUTION. Robert C. Switzer, III and Joanna M. Hill*. Laboratory of Brain Evolution and Behavior, National Institute of Mental Health, Bethesda, MD 20205

In Nissl-stained, parasagittal sections of rat brain the globus pallidus (GP) seems to extend rostro-ventrally in a cusp-like formation into the polymorph layer of the olfactory tubercle. Such an extension suggests a pallidal complement to the striatal cells of olfactory tubercle (OT) (see Heimer and Wilson, In: Golgi Cent. Symp. Proc., 1975; Heimer, In: Limbic Mechanisms, 1978). If sectors of the polymorph layer of OT are in fact components of GP then they should be characterized by the same endogenous molecular markers: gamma aminobutyric acid (GABA) and its synthesizing enzyme glutamate decarboxylase (GAD) (see Krieger and Heller, Soc. Neur. Sci. Abs., 1978, #1414), and ferric-iron. We treated rat brain sections with Perl's method for demonstrating ferric-iron. Macroscopically, the entire GP was highlighted by the Prussian Blue reaction product indicating the presence of ferric-iron. Proceeding rostrally from the level of the anterior commisure, a rostro-ventral cusp-shaped extension of GP is visible coinciding with the locus of neurons seen in the Nissl-stained sections. The blue zone extends above the horizontal limb of the diagonal band of Broca to include the rostral substantia innominata and joins the caudal OT in the polymorph layer. More rostrally, the iron-positive zone is divided by the cell bridges joining the ventral striatum above with the superficial layers of OT below. The elaborate relationship of the iron-positive zone with the islands of Calleja and striatal cell bridges is described elsewhere (Hill and Switzer, this volume). Microscopically, the large multipolar neurons of GP and of the rostro-ventral extension are embedded in a blue matrix of the neuropil populated by glia whose cytoplasm is stained intensely blue. Occasionally some of the fine processes of the glia are revealed by the Prussian Blue. Compared with the GP, the iron-positive glia in the caudate-putamen are sparse and the blue neuropil is absent. The boundary between the blue of pallidum and adjacent structures is distinct; even the narrow, striatal cell bridges of the OT are iron-negative in spite of the intense blue of the surrounding polymorph layer.

Taken together, the iron-positive glia and neuropil form a continuum which consolidates the telencephalic projection areas of the caudate-putamen, accumbens and the striatal cells of olfactory tubercle. Our findings complement those of Heimer and Wilson regarding the striatal character of components of OT and in light of the high GABA and GAD (Krieger & Heller) levels found in the polymorph layer, provide a strong argument for a pallidal component in OT--perhaps more correctly termed "paleo pallidum".

262 A LIGHT AND ELECTRON MICROSCOPIC STUDY OF THE DEVELOPING CAUDATE NUCLEUS IN THE PUPPY. Duke Tanaka, Jr. and Krystyna Dutkiewicz*. Dept. Anat., Coll. Med., Howard Univ., Washington, D.C. 20059 and Dept. Neurophysiol., Nencki Inst. Exp. Biol., Warsaw, Poland.

The caudate nuclei of puppies 6 hr to 30 days old were processed with the Golgi-Kopsch method or embedded in JB-4 plastic and stained with methylene blue and basic fuchsin. Sections were examined for maturational changes in somatic size, dendritic branching, and axonal arborization. Additional caudate nuclei of 3-5 and 19-20 day old puppies were processed for electron microscopic examination of the neuropil. All results were compared with data obtained from similarly prepared tissue from adult dogs. The Golgi and methylene blue-basic fuchsin stained sections revealed that significant somatic growth and dendritic maturation occurs during the first postnatal week. The somata increased in average diameter from 9μm at 4 days to 13μm at 7 days and dendritic length increased from 60-80μm at birth to 80-150μm at 7 days. In addition, fewer thick proximal dendrites, which are characteristic of immature neurons, were noted at the end of this week. Due to the immature features of these neurons, it was very difficult to classify neuronal types during the first week. However, during the second week the continued development of both axonal and dendritic processes allowed a differentiation between spiny and aspiny neurons to be made. Most spiny neurons were characterized by long thin dendrites (120-200μm long) possessing varicosities, long filopodia and protospines. A decrease in the number of filopodia and protospines occurred during the third week along with a gradual increase in the number of spines. By 22 days, the dendrites of spiny neurons ranged between 120-300μm in length and by 30 days, spine densities approached those seen in the adult. Although axons were rarely impregnated in newborn material, they could be followed for some distance in the more mature material (7 days and older) and formed part of the basis for classifying more mature neurons. Examination of the neuropil of the 3-5 day old caudate nuclei revealed the presence of immature synapses, axonal and dendritic growth cones, filopodia, and large areas of extracellular space. No myelinated axons were noted. By 19-20 days of age, the growth cones had disappeared as had most of the extracellular space while the number of mature synapses and small axonal processes had increased markedly. Thinly myelinated axons were occasionally seen in or adjacent to small fiber bundles. Synaptic density per $100\mu m^2$ in the 4 day old caudate was about 20% of that seen in the adult while the density in the 19-20 day old material had increased to about 60% of adult density.

263 MODIFICATION OF MOTOR ACTIVITY, PASSIVE AVOIDANCE CONDITIONING AND EVOKED POTENTIALS BY MICROINJECTIONS OF PICROTOXIN IN BOTH CAUDATE NUCLEI OF CATS. Carolina Téllez*, Francisca Vázquez*, Pablo de la Mora* and Héctor Brust-Carmona. Depto. de Fisiología, Div. de Investigación, Fac. de Medicina, C.U., México 20, D.F.

Different experiments have shown modifications of Passive Avoidance Conditioning by Striatum lesions or stimulation. The inhibitory influences upon motor activity by caudate nucleus (CN) which has been very well demonstrated, could be responsible for the behavioral modification which allows the cat to learn not to pass from one compartment to the other (PAC). This inhibitory action could be blocked by local application of picrotoxin (Pi).

In 18 cats stainless steel cannulae were implanted into the anterior rostral part of the head of CN. After 5-8 days, bilateral microinjection of 5μl of NaCl (N=9) or 6μg of Pi in 5μl of NaCl (N=7) were performed. Immediately after, gross spontaneous motor activity was observed and some reflex responses were clinically tested. After 10 min, the acquisition of one trial PAC was made. Next day the latency to cross from one compartment to the other (1st test trial) was again measured. Next day a second test was performed but 10 min after bilateral microinjection of Pi or NaCl. One-two days later in the same cats in acute experiments, the CN's evoked responses (ER) produced by stimulation of NCM were recorded on FM tape. The magnitude and latency of components were analyzed using a PDP11/40 computer. After 6 samples of 10 ER, taken every 2 min; 6 or 18μg of Pi were applied in both CN. Similar samplings were obtained in the following 40-80 min. After the Pi microinjections the cats stayed quiet cleaning themselves many times and then started walking and suddenly bursts of violent motor activity appeared. They ran with the extremeties flexed, very near to the floor "flying response on the floor". Sometimes the animal crashed against the wall and kept moving in an apparent effort to continue at all costs in one direction. In the acquisition session of PAC the cats injected with Pi crossed from one side to the other in $\bar{X}$=75 sec which was very similar to the NaCl injected cats ($\bar{X}$=61.7 sec). Both groups of cats in the first test did not move in 600 sec (learning criterion). In the second test under picrotoxin or NaCl effects, the cats of the first group crossed in $\bar{X}$=401 sec which compared with 600 sec of the second group revealed a significant difference ($U=4$, $n_1=4$, $n_2=6$, $P<0.05$). In general the ER consisted of three peaks with average latency of 9, 25 and 44 msec. After the Pi microinjections the first and second peak increased significantly at the level of $P<0.05$ ($N=95$, $x=21$, $Z=5.34$ for the first peak and $N=152$, $x=38.2$, $Z=6.08$ for the second; sign test). The described results further support the suggestion that the CN usually acts in a manner which produces inhibition both electrographically and behaviorally.

264 SINGLE DORSAL RAPHE NEURONS PROJECTING AXON COLLATERALS TO BOTH THE SUBSTANTIA NIGRA AND CAUDATE-PUTAMEN IN RAT. Derek van der Kooy and Toshi Hattori. Department of Anatomy University of Toronto, Toronto, Ontario, Canada.

The serotonin containing neurons of the dorsal raphe (DR) nucleus are known to have widespread forebrain connections. Single DR cells have been shown to innervate divergent forebrain areas through collateral axons. Recent autoradiographic anterograde transport reports have detailed the projections from the DR to the substantia nigra and to the caudate-putamen. The present retrograde fluorescent double labeling study investigated the organization of the raphe cells projecting to the substantia nigra in relation to those projecting to the caudate-putamen in rat. 0.2 - 0.4 ul of 10% Evans Blue, which fluoresces red, was injected into the caudate-putamen over two needle penetrations. 0.1 - 0.3 ul of 2.5% DAPI - 10% Primuline, which fluoresces blue, was injected into the substantia nigra lateral to the major bundle of serotonergic axons coursing in the ventral tegmental area. Neurons retrogradely labeled with Evans Blue were seen throughout the DR, whereas neurons labeled with DAPI-Primuline were restricted to the dorsal cluster portion of the DR. Even in this dorsal cluster, Evans Blue labeled cells outnumbered the DAPI-Primuline labeled cells. However, the most important finding was that 70% to 90% of the DAPI-Primuline labeled DR cells were double labeled with Evans Blue. The labeled DR cells were both fusiform and multipolar in shape. The average size of the labeled DR cells was approximately 18 u in diameter, similar in size to the DR neurons supposed to contain serotonin. Smaller size DR neurons (average of approx. 13 u) were less likely to be labeled. The ascending raphe axons can be separated into six separate bundles. Different bundles appear to innervate the substantia nigra and caudate-putamen. The present results suggest that single dorsal raphe cells send axon collaterals into more than one of the ascending axon bundles. In conclusion, two interrelated portions of the basal ganglia (caudate-putamen and substantia nigra) appear further related by virtue of their innervation from the same neurons in the dorsal portion of the DR.

265 EPSPs RECORDED IN RAT NEOSTRIATAL NEURONS FOLLOWING STIMULATION OF THE DORSAL RAPHE NUCLEUS. C.P. VanderMaelen, A.C. Bonduki, & S.T. Kitai, Dept. Anat., Michigan State University, E. Lansing, MI 48824

Investigators utilizing extracellular recording techniques have concluded that the projection from the dorsal raphe nucleus (DRN) to the neostriatum is inhibitory. In the present study intracellular recordings were obtained in neostriatal neurons of the rat in order to investigate the postsynaptic effects of DRN stimulation. Male hooded rats were anesthetized with urethane, and some of these were paralyzed with a mixture of Flaxedil and tubocurarine, and artificially respirated. Recording microelectrodes were filled with 2 M KCl or 2 M K-citrate, or with a mixture of 4% horseradish peroxidase (HRP), 0.4 M KCl, and tris buffer (pH = 7.3). Microelectrode resistances ranged from 30-70 megOhms. Electrical stimulation of the DRN was monopolar through stainless steel insect pins insulated except for about 1.0 mm at the tip. Single stimulus pulses of 0.15 msec duration and up to 18 V intensity were delivered once every 1.5 - 2.0 sec. Stimulating electrodes were also implanted in the ipsilateral cerebral cortex, and in some rats, in the contralateral brachium conjunctivum caudal to the DRN, as a control for stimulus spread from the DRN to this structure.

Stimulation of the DRN elicited monosynaptic EPSPs in neostriatal neurons. In no case was an initial hyperpolarizing response seen. Response latencies ranged from 2.4 to 7.2 msec (mean = 4.9; S.D. = 1.32; N = 33). In most neurons the EPSP was followed by an IPSP during which action potentials were suppressed. This, in turn was often followed by "rebound excitation" with spikes. The suppression of spikes during the IPSP, as well as the "rebound excitation" occurred even when the initial EPSP failed to generate an action potential. 90% of the neurons which responded to DRN stimulation also responded to stimulation of the cerebral cortex. Intracellular injection of some recorded neurons with HRP revealed them to be "spiny-I" neurons. These results are discussed in light of previous work which has shown 1) convergence of excitatory inputs from cortex, thalamus, and substantia nigra onto spiny-I neostriatal neurons; 2) the probable source of the IPSP as intrinsic to the neostriatum; and 3) the conflicting reports of excitation and inhibition in the neostriatum in response to microiontophoretically applied serotonin. 266 TESTOSTERONE AND 17-β ESTRADIOL LEVELS IN ACAUDATE, AFRONTAL AND INTACT CATS. J.R. Villablanca, C.E. Olmstead and G.H. Stabenfeldt* Depts. Psychiat., Anat., and MRRC, UCLA, Los Angeles CA, 90024 and Dept. Reproduction, Sch. Vet. Med., Univ. Cal. Davis, CA.

We have previously defined the behavioral changes which follow extensive caudate nuclei lesions in cats and kittens. A characteristic of caudatectomized male cats is the appearance, immediately after recovery from anesthesia, of a stereotyped estrous-like behavior to stimulation of the perigenital region which includes lordosis, tail deviation, hind paw treading and, occasionally, vocalization. The present experiments were designed to test if there is an endocrinological basis for this behavior. It has been postulated that the striatum may be involved in endocrine control (Barbeau, 1970, 1973). Plasma levels of testosterone and 17-β estradiol (Schille, et.al., in press) were measured by radioimmunoassay in intact (N=7), acaudate (N=7; median removal 84%, range 35-90%), afrontal (N=4; all tissue in front of A 22 removed) and operated control (N=4; 2 with a large septal lesion and 2 with hemispherectomy). Plasma samples (3-5ml) were taken at two day intervals from restrained cats over a two week period for a total of 10 samples per subject. The data analysis was on the daily medians for each group, subject medians across samples and grand medians for daily and subject medians. Intact cat values for both testosterone (md 6.7, range 2.6-9.3 ng/ml) and estradiol (md 15.4, range 10.0-19.6 pg/ml) agreed with values from other labs. A two-way ANOVA showed a significant group effect for both median testosterone ($p<.05$) and 17-β estradiol ($p<.001$). Comparisons of the group medians (Mann-Whitney U) showed that both acaudates ($p<.05$) and afrontals ($p<.05$) had significantly lower levels of testosterone than intact animals. Comparisons for 17-β estradiol showed afrontals to be significantly higher than either intacts ($p<.001$) or acaudates ($p<.01$), while the operated controls were significantly lower ($p<.001$) than the other groups. Spearman rank correlations between magnitude of the caudate lesion and plasma levels were not significant for either testosterone ($r_s=-0.34$, $p=.50$) or 17-β estradiol ($r_s=0.0$, $p=1.0$). However, a similar correlation of lesion and estrous-like behavior was significant ($r_s=.84$, $p<.02$) and the behavior was not suppressed by castration (performed in 2 acaudates). These data suggest that decreased plasma levels of testosterone are not specific to caudate ablation. In fact, this is a case of defined behavioral change without a hormonal specificity (acaudate) and of an increase in estrogens without detectable sexual changes (afrontals). We therefore hypothesize that the estrous-like behavior seen in acaudate males is probably due to the changes in somatosensory responsiveness and in "affect" that we have reported and not to shifts in their endocrinological status. (USPHS Grants HD-05958 and HD-04612).

267 A PHARMACOHISTOCHEMICAL PROCEDURE FOR GABA-TRANSAMINASE: IMPLICATIONS FOR BASAL GANGLIA ANATOMY. S.R. Vincent, H. Kimura*, and E.G. McGeer. Division of Neurological Sciences, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, Canada, V6T 1W5.

GABA is an important neurotransmitter in the basal ganglia, particularly in the descending striato-pallidal and striato-nigral pathways. However, striatal GABA neurons have not been successfully visualized histologically. GABA is catabolised by the enzyme GABA-Transaminase (GABA-T), and a histochemical method for this enzyme has been reported (Van Gelder, 1965). Results using this method indicate a neuronal localization for GABA-T in the cerebellum. Intense staining has also been observed in the striatum and substantia nigra, however, the precise location, whether in nerve cell bodies or in nerve terminals in juxtaposition was difficult to discern. This same problem has been reported for Acetylcholinesterase staining in the basal ganglia and was resolved by using the DFP pharmacohistochemical technique (Butcher, 1975). Recently, two specific and irreversable GABA-T inhibitors (EOS & Gabaculine) have become available, and we reasoned that they could be used to resolve the localization of GABA-T in the basal ganglia.

Adult Wistar rats received intraventricular injections of EOS (2mg/kg) and were sacrificed and processed with our modified GABA-T histochemical method at various survival times. Forty-five minutes after the injection of EOS, no striatal neurons staining for GABA-T could be observed. By four hours some neurons could be observed which stained for GABA-T, indicating that they had resynthesized the enzyme. Eight hours after the injection, the regeneration of GABA-T staining was almost complete. These results indicate that this pharmacohistochemical procedure for GABA-T may be a useful tool for the localization of GABA systems in the basal ganglia, and other areas of the central nervous system.

268 EFFECTS OF PICROTOXIN UPON SINGLE UNIT ACTIVITY OF SUBSTANTIA NIGRA NEURONS. B.L. Waszczak, N. Eng*, and J.R. Walters, NIH, NINCDS, Bethesda, MD 20205

The substantia nigra (SN) is the site of termination of at least one major GABAergic projection. GABA-containing afferents to the nigra from the striatum and globus pallidus have been thought to provide a tonic inhibition of SN pars compacta dopamine (DA) neurons. However, we have recently observed that while cells of the SN pars reticulata exhibited a marked sensitivity to the inhibitory actions of the GABA agonist, muscimol (administered i.v.), the pars compacta DA neurons were paradoxically stimulated (Waszczak et al., Neurosci. Abstr. 4:436, 1978). Similarly, pars reticulata neurons were found to be much more sensitive to inhibition by iontophoretically-applied GABA and muscimol than the DA neurons. These observations suggested that a population of neurons in the SN pars reticulata have the capacity to be more affected by a nigral GABAergic input than the DA cells. To investigate this possibility further, the effects of i.v. administration of the GABA antagonist, picrotoxin, upon the extracellular, single-unit activity of both types of nigral neurons were determined in chloral hydrate-anesthetized rats. Doses of picrotoxin, administered in 1 mg/kg increments to a total cumulative dose of 7.0 mg/kg, caused gradual increases in the firing of DA cells (n=12). The average increase in activity, which was maximal between 5.0 and 7.0 mg/kg, measured approximately 30% over the baseline firing rate. In contrast, these doses of picrotoxin induced dramatic dose-related increases in the firing of pars reticulata cells (n=9). The maximum stimulatory effect achieved was an increase to 154% over the baseline rate after 7.0 mg/kg picrotoxin. These results were consistent with the idea that the reticulata cells may be more likely recipients of a major GABAergic input to the SN than the DA neurons.

To assess whether previous destruction of the striatonigral GABA pathway might attenuate the stimulatory effects of picrotoxin upon nigral neurons, the effects of i.v. picrotoxin were also determined 2-3 weeks after unilateral kainic acid (KA) (1 µg/0.5 µl) lesions of the striatum and globus pallidus. There were no changes in the responses of DA neurons to i.v. picrotoxin in lesioned animals while there appeared to be a slight but insignificant attenuation of the stimulatory effect of picrotoxin upon reticulata cells. These findings suggest that 1) picrotoxin may stimulate nigral neurons by a non-specific excitatory mechanism unrelated to GABA receptor blockade, or 2) another GABA projection to the SN, other than that destroyed by striatal KA lesions, may either indirectly or directly inhibit these cells. This latter possibility is supported by biochemical evidence that approximately 30% of the control level of GAD activity consistently remains in the SN after striatal KA lesions.

269 Electrophysiological and Biochemical Examination of the Cholinergic System in Rat Neostriatal Slices. Molly H. Weiler*, Ulrich Misgeld*, Il-Jin Bak, Donald J. Jenden. Depts. Pharmacol. & Neurol., UCLA School of Medicine, Los Angeles, CA 90024 & Max-Planck Inst. Brain Res., Frankfurt, Federal Republic Germany

Local stimulation in superfused rat neostriatal slices evokes orthodromic (latency: 2.5-4 msec) and antidromic (latency: 0.5-1.5 msec) discharges (Misgeld et al., Exp. Brain Res. 34:575,1979). Pharmacological data indicate that acetylcholine (ACh) is the transmitter of this intrinsic excitation. Nicotinic agents such as d-tubocurarine (0.7×10^{-6} M), mecamylamine (10^{-5} M), or hexamethonium (10^{-4} M) selectively blocked the orthodromic discharges, and atropine (10^{-4} M) was without effect (Misgeld, Pfl. Arch. 379: R45, 1979). When the slices were exposed to an acetylcholinesterase inhibitor (physostigmine, 10^{-7} M; paraoxon 10^{-5} M; tetram 10^{-6} M) the amplitude of the orthodromic population spike increased. The synaptic activity of the neostriatal slices was unaffected by choline (10 µM) in the perfusion medium during electrophysiological recording. With higher frequency stimulations (10-30 Hz) the orthodromic population spike was facilitated in the presence of acetylcholinesterase inhibitors and this frequency facilitation was blocked by atropine (10^{-6} M). Intracellular recordings showed that a slow depolarizing potential caused the frequency facilitation. These results suggest that, as in cholinergic systems in the superior cervical ganglion and the spinal Renshaw cells, nicotinic receptors mediate a fast and muscarinic receptors a slow excitation in the rat neostriatum. Neurochemical studies of ACh synthesis in the neostriatal slices show that the concentration of ACh reaches an apparent steady state after 1 hr incubation (7.54 ± 0.32 nmol (mg protein)$^{-1}$). When hemicholium (5 µM) was present in the medium the ACh levels were 75% lower after 1 hr incubation (1.92 ± 0.13 nmol (mg protein)$^{-1}$). There was no clear cut effect of HC-3 on the evoked field potentials at lower concentrations (5 µM), and at higher concentrations (100 µM) there was no recovery of unitary spikes following high frequencies of stimulation. Thus, the in vitro slice preparation offers a unique electrophysiological and biochemical approach to studying the intrinsic cholinergic system of rat neostrial tissue.

270 EFFECT OF DOPAMINE AGONISTS ON ^{3}H-SPIROPERIDOL RECEPTOR BINDING. R.L. Weir*, R.E. Hruska, and F.K. Silbergeld (SPON: J.R. Walters). Howard University, Washington, DC 20060 and Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20205.

Dopamine agonists of the ergot alkaloid type (such as bromocriptine) have been shown to have beneficial clinical effects in Parkinson's disease and some endocrine disorders (amenorrhea or galactorrhea). Thus, it was of interest to study the effects of an ergot drug on dopamine receptors in the caudate nucleus, and to compare it to apomorphine.

Bromocriptine (15 mg/kg) was administered subcutaneously to rats for 4 days. The rats were sacrificed 24 hr after the last injection, the brains rapidly removed, and the caudate nuclei isolated. The tissue was homogenized and carefully washed before ^{3}H-spiroperidol binding was measured. The concentration of ^{3}H-spiroperidol was maintained at low concentrations (less than 200 pM) in our assays, to assure that only dopamine receptors were labeled. From Scatchard analyses, the number of binding sites decreased about 20% relative to controls, and there was no change in the affinity of the receptor sites for ^{3}H-spiroperidol. When bromocriptine was added in vitro to normal rat caudate tissue, the ^{3}H-spiroperidol binding was again decreased with an inhibition of 50% of the specific binding occurring at 2 nM. This indicates that bromocriptine interacts potently with the dopamine receptors labeled by ^{3}H-spiroperidol.

Apomorphine (1 mg/kg) was given intraperitoneally to rats and stereotypy was noted. The rats were sacrificed 30 min after injection, the brains removed rapidly, and the caudate nuclei dissected. After careful washing, Scatchard plot analyses did not show any change in ^{3}H-spiroperidol binding compared to controls.

The acute effects of dopamine agonists are apparently due to receptor stimulation without a detectable change in the receptor. The chronic administration of these drugs causes a decrease in the number of receptor sites available for stimulation by either endogenous dopamine or administered dopamine agonists. This may contribute to problems (e.g. on-off reactions) which occur with chronic clinical usage of dopamine agonists.

271 INTRACELLULAR STUDIES OF THE CONVERGENCE OF SENSORY INPUT ON CAUDATE NEURONS. J.S. Wilson*, C.D. Hull and N.A. Buchwald. Mental Retardation Research Center, School of Medicine, UCLA, Los Angeles CA. 90024.

Anatomical studies have revealed that the striatum receives afferents from all parts of the cerebral cortex including sensory areas. Neurophysiological studies have shown that the neostriatum receives sensory input from all modalities. The purpose of this research is to elucidate the post synaptic responses of caudate neurons evoked by auditory and somatosensory stimulation. Intracellular recordings, using potassium citrate-filled micropipettes, were made in the head of the caudate nucleus of cats. Auditory stimulation was provided by a "click" generated by a speaker placed inside a hollow ear bar ipsilateral to the recording electrode. Somatosensory stimulation was produced by a subdermal, electrical shock to the right or left forepaw. The effect of ipsilateral auditory stimulation was studied in 42 caudate neurons. Twenty-six cells showed an EPSP-IPSP (E-I) response; 11 cells appeared to receive only inhibitory input; and 5 cells showed no response. Following the initial E-I response, the cells often responded with an oscillating excitatory and inhibitory wave form which lasted for a second or more. The mean latencies 1) to the onset of the E-I were 30.8 ms ± 10.2, 2) to the peak amplitude of the EPSPs 50.4 ms ± 12.6, and 3) to the peak amplitude of the IPSPs 78.8 ms ± 23.7, as measured from the first stimulus pulse. The effect of ipsilateral somatosensory stimulation was studied in 34 cells. Twenty-two cells showed an E-I response, 8 showed an IPSP response and 4 showed no response. The mean latency of the EPSP, latency to peak amplitude of the EPSP and latency to peak amplitude of the IPSP were 27.9 ms ± 6.0, 65.2 ms ± 19.4 and 184.3 ms ± 41.0, respectively. In 32 cells, the effect of contralateral somatosensory stimulation was studied. Twenty-two cells showed an E-I response, 4 cells showed an IPSP response and 6 cells showed no response. The average latency of the EPSP, latency to peak amplitude of the EPSP and latency to peak amplitude of IPSP were 23.6 ms ± 4.8, 54.6 ms ± 10.6 and 184.9 ms ± 44.2, respectively. The convergence of auditory and somatosensory stimulation was studied in 24 cells. The majority of cells were bimodal (20 cells). Four cells appeared to receive only somatosensory input. In summary, sensory stimulation most frequently evoked an E-I response in caudate neurons which was often followed by an oscillating E-I wave form. The responses were not qualitatively different for the sensory modalities studied and most cells received a convergence of sensory inputs.

272 ACETYLCHOLINESTERASE NEURONS IN THE RAT CAUDATE-PUTAMEN COMPLEX: CHARACTERIZATION OF SOMATA TYPES AND STATISTICAL RELATIONSHIPS TO ONE ANOTHER AND TO THE TOTAL POPULATION OF STRIATAL CELL BODIES.

Nancy J. Woolf*[1] and Larry L. Butcher.[1,2] Dept. Psych.[1] and Brain Res. Inst.[2], UCLA, Los Angeles, CA 90024.

Using a pharmaco-histochemical regimen for acetylcholinesterase (AChE, EC 3.1.1.7) that demonstrates the enzyme in neuronal somata and their proximal processes to a degree not possible with other protocols (Butcher & Bilezikjian, Eur. J. Pharmacol., 1975, 34, 115-125), we examined the morphologies, organization, and staining patterns of AChE-containing neurons at 9 different rostral-caudal levels of the rat caudate-putamen nucleus. At each of these levels additional analyses were performed in the dorsolateral, dorsomedial, ventromedial, and ventrolateral quadrants. As described in previous publications from this laboratory, three broad categories of AChE-containing neurons could be discerned on the basis of somata dimensions. Of these, the Type I cells (maximum soma extent = 8-12μm) were most numerous, representing 50-65% of the total population of AChE striatal neurons. The Type I cells were more numerous at rostral and caudal levels than in medial portions of the nucleus. Over 70% of Type I neurons had oval cell bodies, and 75% stained lightly for AChE. Type II neurons (maximum soma extent = 13-23μm) could be further divided into two subcategories. Type IIa cells (maximum soma extent = 13-15 μm) represented 11% of the total number of AChE neurons in the striatum; Type IIb cells (maximum soma extent = 16-23μm) represented 27%. Most Type IIa and IIb neurons were oval. The Type IIa somata stained lightly or with medium intensity, the number of cell bodies in each intensity category being essentially equal. Over 80% of Type IIb somata stained with medium intensity. Type III cells (maximum soma extent = 24-30μm or greater), representing roughly 5% of the total number of striatal AChE neurons, were primarily fusiform and stained darkly or with medium intensity. The proportion of the three types of AChE somata to one another was approximately the same at all rostral-caudal levels of the caudate-putamen complex. Type I cells appeared slightly more concentrated in ventral portions of the nucleus, however.

In brain sections processed first for AChE (pharmaco-histochemical regimen) and then counterstained with thionin, it was found that AChE-containing neurons represented only approximately 3% of the total number of neurons in the caudate-putamen nucleus. Yet these neurons presumably account for all of the AChE in a structure possessing one of the highest concentrations of acetylcholine (Butcher et al., J. Microwave Power, 1976, 11, 61-65) and choline acetyltransferase in the mammalian brain [Support: USPHS NS 10928 to L.L.B.].

BRAIN METABOLISM AND NUTRITION

273 EFFECT OF ACUTE ADMINISTRATION OF NEUTRAL AND OTHER AMINO ACIDS ON CATECHOLAMINE (CA) METABOLISM

Agharanya, J.C. and Wurtman, R.J., M.I.T. Cambridge, Mass.

We have previously shown that tyrosine loading raises urinary CA and that this effect is blocked by pretreatment with a peripheral decarboxylase inhibitor, carbidopa. This finding suggests that TYR acts by increasing the saturation of the enzyme tyrosine hydroxylase, thereby enhancing CA synthesis in the sympathoadrenal system. However other mechanisms are possible, e.g.(i) a central hypotensive action via inhibition of sympathetic outflow, (ii) inhibition of CA degradation (iii) a nonspecific stress effect, causing CA release. The present study was designed to characterize the specificity of TYR effect and its biochemical consequences. Neutral amino acids (NAA) (TRP, VAL, ISOLEU, LEU, TYR) and non-neutral amino acids (GLU,ALA, LYS, ARG) were administered (at concentrations equimolar with 200 mg/kg of tyrosine) to overnight fasted rats. Urines (collected for a 3 hr. period), blood, brain, and adrenals were analyzed for CA, tyr, and MOPEG-SO4.

TYR caused 2 to 3-fold increases in tissue and blood TYR and urinary CA whereas NAA depressed these by 10-37%. GLU and ALA had no effect while LYS and ARG increased urinary CA by 10-30%. Serum TYR was highly correlated with urinary CA (r=.86). Except for TRP, coadministration of other NAA with TYR suppressed the increases in urinary CA. TRP potentiated TYR's effects on blood, brain, adrenal and urinary DA. TYR alone significantly raised brain MOPEG-SO4. In experiments with adrenalectomized rats TYR enhanced urinary DA and NE but had no effect on E. (Basal levels of DA and NE were similar in adrenalectomized and control rats.) These results show that (a) TYR is unique in causing major increases in urinary CA; its effect is not mimicked by related NAA; (b) changes in serum TYR are reflected by parallel changes in urinary CA; (c) as in the brain, TYR uptake into peripheral tissues seems to be subject to competition by NAA; however levels of NAA needed to compete are probably much higher. This study provides further evidence that availability of the amino acid precursor tyrosine affects peripheral CA synthesis and release.

(These studies were supported in part by a grant from the USPHS.)

274 CHANGES IN CORTICAL OXIDATIVE METABOLISM ELECTRIC ACTIVITY WITH ALTERED BRAIN PERFUSION PRESSURE.

George A. Austin, Ronald E. Jutzy,* Joe Willey, William Hill,* and Stephen Ritland.*
Section of Neurosurgery and Department of Physiology, Loma Linda University, School of Medicine, Loma Linda, CA 92350

Brain perfusion pressure is the difference between blood pressure and intracranial pressure. In the case of the open skull, intracranial pressure is normally close to zero and perfusion pressure equals local or diffuse arterial blood pressure. We have studied cortical oxidative metabolism in cats under N_2O/O_2 anesthetic in a 2/1 ratio, where the perfusion pressure was altered locally by - 1) bilateral common carotid occlusion; 2) unilateral common carotid occlusion; and, 3) pial artery compression. Perfusion pressure (PP) was altered diffusely by - a) intravenous Arfonad (lowered BP); b) intravenous Ephedrin (raised BP), or c) arterial bleeding (lowered BP). In general, these techniques caused a change in cortical PO_2 (bPO_2), which was proportional to the change in mean BP. The redox state of NADH and Cyt. a,a_3 were monitored by non-invasive optical techniques. Cortical electric activity was monitored with bipolar Ag-Agd$_2$ electrodes and analyzed in the frequency domain by a Fast Fourier Transform technique. Usually, decreased PP produced decreased bPO_2, and this was accompanied by reduction of NADH and Cyt. a,a_3; with the latter affected to a greater extent. Reducing the FiO_2 prior to lowering the perfusion pressure accentuated the reduction of NADH and Cyt. a,a_3, as well as prolonging the recovery period. Cortical electric activity, after 5-30 sec. of decreased PP, was initially increased in amplitude between 3 - 8 Hz. These studies correlate with the results of monitoring bPO_2 in patients undergoing microanastomosis for brain ischemia, where STA flow results in increased cortical PO_2 and oxidative metabolism. Increasing the perfusion pressure following microanastomosis of the STA to MCA in most patients showed increased STA flow and increased bPO_2.

275 THE EFFECT OF CHRONIC MIDDLE CEREBRAL ARTERY OCCLUSION ON LOCAL BLOOD VOLUME AND CYTOCHROME a,a_3 REDOX LEVELS IN RAT BRAIN.

B.J. Bergquist* and A.L. Sylvia. Department of Physiology, Duke University Medical Center, Durham, N.C. 27710 and Division of Neurosurgery, U.N.C., Chapel Hill, N.C. 27514.

The resting local blood volume and reduction/oxidation (redox) level of cytochrome a,a_3 were monitored in the brain region over a chronically occluded middle cerebral artery (MCA) on the ipsilateral side and compared with the opposite side (contralateral). The vascular and metabolic responses to alterations in the fraction of inspired oxygen (FiO_2) were also monitored in both the ipsilateral and contralateral hemispheres. The rats were anesthetized using sodium pentobarbital (50 mg/kg,I.P.) and immobilized with tubocurarine chloride (0.5 mg/kg, I.V.). The animals were placed on a positive pressure rodent respirator and the skin overlying the cranium was reflected. Dual wavelength reflectance spectrophotometry was used to monitor directly through the skull simultaneous changes in local blood volume and redox levels of cytochrome a,a_3 (605-590 nm). Monitoring was performed over the lateral, superior surface just posterior to the coronal suture. Arterial blood gases and blood pressure were also monitored throughout the experiment. At rest, the contralateral side maintained stable local blood volume and cytochrome a,a_3 redox levels. Responses to changes in the fraction of oxygen in the inspired gas (FiO_2) were predictable: a substantial decrease in FiO_2 resulted in an increase in the level of reduced cytochrome a,a_3 and a compensatory increase in local blood volume; an increase in the FiO_2 caused a marked oxidation of cytochrome a,a_3 and a decrease in local blood volume. In contrast, the ipsilateral hemisphere failed to maintain stable baseline levels; local blood volume randomly ebbed and flowed with simultaneous alterations in cytochrome a,a_3 redox levels reflecting these changes. Local blood volume increases occurred coincident with increases in the relative oxidation level of cytochrome a,a_3. Responses to alterations in the FiO_2 were attenuated and superimposed on the wandering "baseline": in the ipsilateral hemisphere. We interpret these data to represent a loss of autoregulation in the relatively ischemic cortex.

This work was supported by NIA Grant AG 00517 (A.L.S.).

276 THERMOREGULATION AND ADRENOMEDULLARY ACTIVITY: COORDINATED ADAPTIVE RESPONSES TO NUTRIENT DEPRIVATION.

Marvin Brown and David Fisher*. Peptide Biology Laboratory, The Salk Institute, La Jolla, CA 92037.

Activation of the adrenomedullary sympathetic nervous system (AMSNS) increases hepatic glucose production. Lowering of body temperature (T_B) reduces cellular utilization of substrates. Neural pathways capable of increasing nutrient mobilization (activation of AMSNS) and lowering T_B provide a mechanism to insure adequate metabolizable substrate for tissues such as the brain during periods of nutrient deprivation. The possibility that activation of the AMSNS and lowering of T_B might be controlled by similar mechanisms in a coordinated fashion has been investigated. These studies were carried out using rats with chronic lateral ventricular cannulae and intrajugular catheters. AMSNS activity was assessed by measuring plasma epinephrine and norepinephrine. Catecholamine determinations were made using a radioenzymic method. Bombesin (100ng) given to rats intracisternally (ic) or intracerebroventricularly (icv) reversibly lowers T_B and activates the AMSNS, thus showing that a single putative neurochemical messenger can produce these two effects. Lowering of T_B is not a result of increased AMSMS activity since adrenalectomy does not prevent T_B changes following bombesin. 2-deoxyglucose (2DG, 5mg) but not D-glucose (5mg) given ic or icv activates the AMSNS and lowers T_B. Insulin (50OmU) given subcutaneously increases AMSNS activity and reduces T_B. Fasting of animals transiently increases AMSNS activity and chronically lowers T_B. To determine if the decrease in T_B following the above treatments results because of irreversible inhibition of thermoregulation, we assessed the ability of animals made hypothermic by the methods cited above to respond to a neurochemical stimulus which increases T_B. Somatostatin and various central nervous system-specific analogs of SS increase T_B and decrease AMSNS activity. A central nervous system-specific analog of somatostatin, des-AA^{1,2,4,5,12,13}-[D-Trp^8]-somatostatin, acutely reverses the hypothermia and increased AMSNS activity induced by bombesin, 2DG, insulin-induced hypoglycemia and fasting. Thus, the animals receiving these treatments exhibit no impairment of their thermoregulatory response to the hyperthermia-producing stimulus of this somatostatin analog. These results show that several neural stimuli reversibly activate both the AMSNS and lower T_B. These data support the concept that changes in T_B may potentially subserve neurally induced mechanisms to reduce nutrient utilization in states which may pharmacologically or physiologically mimic nutrient deprivation.

277 CEREBRAL REGIONAL O_2 CONSUMPTION AND SUPPLY IN CATS.
Ellen Buchweitz, Harvey R. Weiss*, and Arabinda K. Sinha. Dept. Physiol. & Biophys., CMDNJ-Rutgers Med. Sch., Piscataway, NJ 08854.

The present study represents the first quantitative measurement of O_2 consumption and supply on a regional basis in the brain through the application of a new microspectrophotometric method. Twelve cats were tranquillized with ketamine and then anesthetized with α-chloralose. Artificial respiration was begun, and a left thoracotomy performed at the 5th intercostal space. Left atrial and femoral artery catheters were inserted. Heart rate, blood pressure, arterial and superior saggital sinus blood samples were obtained. 141-Ce microspheres (15 ± 3 μ) were injected into the left atrium and cereberal blood flow determined by the reference sample method. The cats' heads were quickly cut in 2 parts and frozen in liquid N_2. Ten different regions of the frozen brain were examined. Arterial and venous O_2 saturations were measured in each region by examination of vessels in 30 μ frozen sections with a Zeiss microspectrophotometer. O_2 consumption was determined as the product of flow and O_2 extraction. Blood pressure, heart rate, and blood gas values were within the normal range. Flow values ranged from 36 ± 9 ml/min/100g (Mean ± S.E.) in the medulla to 60 ± 20 ml/min/100g in the hippocampus. The highest O_2 extraction was noted in the thalamus (6.4 ± 1.0 ml O_2/100ml) and the lowest O_2 extraction in the anterior cortex (4.5 ± 0.5 ml O_2/100 ml). O_2 consumption ranged from 1.4 ± 0.4 ml O_2/min/100g in the medulla to 2.8 ± 0.8 in the thalamus. The lowest ratio of oxygen supply to demand was 2.76 ± .45 in the thalamus. Supply of O_2 to the brain regions studied was more than adequate to meet demand throughout the brain despite a two fold range in regional O_2 consumption. This new method for the determination of O_2 consumption and supply may be applied to many experimental conditions. Supported by grants from U.S. Public Health Service NS-13118 and HL-21172; a Grant-in-Aid from American Heart Association-NJ Affil., and by a grant from the Foundation-CMDNJ.

278 CHANGES IN DRUG INDUCED SLEEP PATTERNS DUE TO PROTEIN DEFICIENCIES.
E.M. Burns, MB.T. Buschmann, L.E. Comerford*, T.W. Kruckeberg*, P.K. Gaetano* and J.M. Meyer*. Dept. Gen. Nurs., College of Nursing, University of Illinois at the Medical Center, Chicago, IL 60612

A major health problem of today is that of chronic malnutrition. On admission to the hospital many surgical patients are moderately or severely malnourished. Depressed immunity, increased sepsis and a high mortality rate are associated with severe malnutrition. Protein deprivation specifically is often an unavoidable concomitant of the early postoperative period and this compounds the already poor nutritional status of these individuals. Sleep behavior is a sensitive index of neurological function. Thus, evaluation of the duration of drug induced sleep may reveal important information relevant to the neurological status of protein deprived individuals. Because pentobarbital is a frequently used central nervous system depressant in current medical practice, it was selected for use in this animal study.

The purpose of this study was to determine the effect of protein-calorie malnutrition during fetal and postnatal life in Sprague-Dawley rats on the duration of pentobarbital induced sleep. Dams of experimental animals were fed isocaloric diets containing either 25% casein (well nourished) or 8% casein (malnourished) for two weeks prior to mating, and throughout gestation and lactation. Dietary regimes were continued after weaning in the young and subsequently adult male and female offspring were administered varying doses of sodium pentobarbital. Each animal was given either 20, 40 or 60 mg/kg of the drug intraperitoneally. The time which elapsed from the injection of the drug to the loss of the righting reflex (onset of sleep) and from the loss to the regaining of the righting reflex (duration of sleep) was recorded.

The well nourished animals slept longer than the malnourished under the influence of the drug except for the females receiving only 20 mg/kg. Furthermore, at all doses the control and experimental females slept longer than the respective males. Finally, only 7 out of 11 females survived the 60 mg/kg dose. None of these animals died within 4.5 hours following drug injection.

The results demonstrate the well known dose dependency of the duration of sleep following intraperitoneal injection of pentobarbital in experimental animals. The wide variation in sleep time among females and their sensitivity to the 60 mg/kg drug dosage may well be related to their four-day ovarian cycle. However, in both sexes, attention should be given to other factors relating to drug dosage, such as the nutritional status of the individual.

This research was supported in part by HEW grant #HD 09792-01.

279 EFFECTS OF BOVINE SERUM ALBUMIN ON ARACHIDONIC ACID-INDUCED EDEMA IN ISOLATED RAT BRAIN CORTEX.
Pak H. Chan, Robert A. Fishman, Janie Lee*, Susan C. Quan*. Brain Edema Clinical Research Center, Dept. Neurol., Sch. Med., UCSF, San Francisco, CA 94143.

We have demonstrated previously that polyunsaturated fatty acids (PUFAs) induce rat brain cortical edema *in vitro* (Science 201:358, 1978). Edematous cortex is characterized by increased water content, lactate production and intracellular Na^+, and decreased extracellular space and intracellular K^+. The present study deals with brain edema induced by arachidonic acid (C20:4) and the effects thereon of bovine serum albumin (BSA). Cortical edema induced by arachidonate was dependent on the duration of incubation. Induction of brain edema approached a plateau after a 30 min incubation in 0.5 mM arachidonate which was followed by 60 min additional incubation in Krebs-Ringer control medium or in BSA (0.1 mM). Co-incubation of arachidonate (Ara) with BSA at a molar ratio of 5 (Ara/BSA) or less greatly inhibited the arachidonate-induced effects. Cortical edema increased as the molar ratio increased above 5. However, the swelling was not reversible by BSA, although the post-incubation of BSA released 46% of incorporated [^{3}H]arachidonic acid in cortical slices. [^{3}H]-arachidonic acid transport was completely abolished by 0.1 mM BSA and partially inhibited by exogenous arachidonate. We conclude that brain edema induction by arachidonate requires that free or unbound exogenous arachidonate be transported into cortical slices. It does not appear to be a surface effect. The molar ratio of Ara/BSA plays a critical role in the binding and the transport of arachidonate in isolated rat brain cortex. Supported by NIH Grant NS 14543.

280 INTRAVENTRICULAR INFUSIONS OF GLYCEROL PRODUCE BODY WEIGHT LOSS IN FEMALE RATS.
Barbara J. Collins* and John D. Davis (SPON. Ernest W. Kent). Dept. Psychol., Univ. of Illinois, Chicago, Ill. 60680.

It has been previously demonstrated by Wirtshafter and Davis (Science 198:1271, 1977) that subcutaenous injections of glycerol (40 mg/kg 4 times daily) produced body weight loss during the period of injections. Similar subcutaneous injections failed to produce an effect in female rats. However, in the present experiment injections of small amounts of glycerol into the third ventricle are shown to produce a decrease in food intake and body weight in females, as did similar injections in males previously reported by Davis and Wirtshafter (Neurosciences Abstracts, no. 525, 1978).

Body weight and food and water intake were measured twice daily in female rats before, during and after 11 days of continuous infusion of glycerol into the third ventricle of the brain. Vaginal smears were taken concurrently with above measurements to determine the stage of the estrus cycle. Unincumbered infusion of glycerol was accomplished by use of a subcutaneously implanted Alzet osmotic minipump connected to a stainless steel ventricular cannula by a section of polyethylene tubing. Glycerol was delivered at a rate of 27 μg/hr in a volume of 0.5 μl/hr.

During the period of infusion body weight decreased significantly, but increased after infusion was stopped. Food intake also showed an overall decrease during infusion. However, the normal rhythm of food intake in the female rat, which demonstrated a decrease in intake on proestrus and an increase during metestrus and diestrus, was not disrupted by glycerol infusions.

281 PROTEIN SYNTHESIS IN VARIOUS BRAIN REGIONS FOLLOWING ACUTE HEMISPHERIC ISCHEMIA. G.A. Dienel*, W.A. Pulsinelli*, and T.E. Duffy (SPON: J.P. Blass). Dept. of Neurology, Cornell University Medical College, New York, N.Y., 10021 and Dementia Research Program, Burke Rehabilitation Center, White Plains, N.Y., 10605.

Inhibition of protein synthesis during cerebral ischemia and delayed or incomplete recovery of synthesis in the post-ischemic recirculation phase could contribute to irreversible cell damage after stroke. We induced hemispheric ischemia in conscious rats by occlusion of the four major cerebral arteries (Pulsinelli & Brierley, Neurology 28:379, 1978). One day prior to the experiments, both vertebral arteries were cauterized and polyethylene cuffs were placed around both common carotid arteries of all animals. Ischemia was produced by constriction of the carotid cuffs; cuffs on control rats were only manipulated. After 10 or 30 min of ischemia, the carotid cuffs were removed and [1-^{14}C]valine (7.5 mmol/kg, 40 μCi/kg) was injected i.p. at different times during the recirculation period. The rats were killed 70 min after ^{14}C-valine injection, and the trichloroacetic acid-soluble and particulate fractions of 5 brain regions were analyzed. Measurements on control (n=6) and 6-hr post-ischemic (n=6) rats established that: (i) incorporation of ^{14}C-valine into protein was linear for at least 100 min after valine injection, and (ii) although brain valine content was 35-40% higher in the 6-hr post-ischemic animals, the specific activity of brain ^{14}C-valine was similar (within 12%) in both groups. The rates of incorporation of ^{14}C-valine into protein in cerebral cortex, caudate-putamen, hippocampus, midbrain-diencephalon, and brain stem of control animals (n=7) were similar, averaging 32.2±3.0 dpm/mg protein. In rats rendered ischemic for 30 min, protein synthesis in caudate, hippocampus, and cortex was inhibited by 80% during the first hour of recirculation (n=4). The rate of recovery of protein synthesis in these regions was slow: 50-60% of control rates were measured at 6 hr of recirculation (n=6), 75-85% at 12 hr (n=5) and 24 hr (n=7), and 100% at 48 hr (n=4). Midbrain-diencephalon, which is partially perfused during the ischemic interval, showed less inhibition of protein synthesis during the first hour of recirculation (65%), and recovery was complete by 12 hr. Protein synthesis in brain stem was unaffected, in keeping with the fact that this structure is continuously perfused during 4-vessel occlusion. Following a 10 min ischemic insult, protein synthesis in cortex was 35% of control during the first hour of recirculation (n=4); it recovered to 70-80% at 3 hr (n=6), remained at this level at 6 hr (n=6), and was normal at 24 hr (n=3). Thus, the degree of inhibition of brain protein synthesis and the time to re-establish normal rates of synthesis are dependent upon both the severity and duration of the ischemic insult.

283 ^{125}I-IODOBENZENE AS A RADIOCHEMICAL MYELIN MARKER. K. Frey*, C.A. Boast, D. Wieland*, L. Brown*, B. Dudzinski* and B.W. Agranoff. University of Michigan, Ann Arbor, MI 48109.

Successful radioautographic visualization of regional brain cerebral blood flow and glucose metabolism has been reported in a variety of species. Gray matter is visualized more readily than white matter in these studies due to its greater vascularity, rate of blood flow and metabolic rate. Recent technological developments in brain scanning have demonstrated that various radiochemical tools can be applied to non-invasive imaging for clinical purposes. We report here the direct radioautographic imaging of brain white matter. Although small, metabolically inert radiolabeled lipophilic substances injected intravenously initially distribute in the brain according to blood flow (that is, more in gray matter than in white matter), after an appropriate period of time, the high lipid content of myelin leads to preferential accumulation of the substance in white matter. We selected labeled iodobenzene as a candidate molecule for these studies because of its favorable size, melting point, chemical stability and apolarity. A preliminary experiment in the rat indicated that the white/gray matter distribution ratio of ^{125}I-iodobenzene was maximal 30-60 min after an intravenous pulse. Subsequent experiments using radioautography have provided direct visualization of myelin in both the rat and rabbit brain. Forty-five min after intravenous injection of ^{125}I-iodobenzene, the brains are removed and frozen. Cryostat sections are exposed to X-ray film at -70°C. The resulting radioautographs indicate that ^{125}I-iodobenzene provides an indication of the lipid content of major brain fiber bundles such as corpus callosum, internal capsule, fornix and optic tract. Potential clinical applications of labeled agents that accumulate in brain lipid include the evaluation of the integrity of myelinated CNS pathways.

282 LOCAL CEREBRAL GLUCOSE METABOLISM AFTER PORTACAVAL (PC) SHUNT. Thomas E. Duffy and Nancy F. Cruz* (SPON: P. Tsairis). Dept. of Neurology, Cornell Univ. Medical College, NY, NY 10021.

Portacaval shunting and the associated hyperammonemia increase global cerebral glucose consumption (James et al., 1972), but whether local utilization rises uniformly and to the same degree in animals shunted acutely and chronically is unknown. We used the ^{14}C-2-deoxyglucose (2-DG) method to assess regional cerebral glucose metabolism in rats at 1, 4, 8, and 12 weeks after the construction of a PC shunt and in weight-matched controls.

All animals were anesthetized with halothane for insertion of cannulae into one femoral artery and vein. At least 3 hr later with the rats awake, normotensive, normothermic, and restrained, 0.2 mCi/kg of [1-^{14}C]2-DG was injected i.v.; arterial blood was sampled at intervals for plasma glucose and ^{14}C-2-DG specific activity measurements. After 45 min, rats were decapitated; the brains were removed, frozen, and sectioned at 20 μm for autoradiography with calibrated ^{14}C-standards (Sokoloff et al., 1977).

Arterial blood ammonia concentrations were twice the control value of 85±7 μM in rats shunted for 1 week, and were 2.5 times control in the 4-, 8-, and 12-week PC groups. Plasma glucose, on the other hand, averaged 25-35% below the control value of 10.6±0.6 mM in all shunted groups. Local cerebral glucose use (μmol/100 g/min) among major neuroanatomical structures was

the same or decreased up to 4 weeks after shunting, whereas at 8 weeks, many, and at 12 weeks, most areas exhibited increased glucose use; cerebral cortex and white matter were notable exceptions to this trend. Changes in local glucose consumption after shunting thus appear to be unrelated to blood ammonia concentrations, per se; chronic hyperammonemia and other factors (e.g., the degree of astrocytic pathology, which develops only after 4 weeks) may be contributory.

284 PROGRESSIVE NEUROLOGICAL DEPRESSION DURING CONSTANT HYPOGLYCEMIA IN UNANESTHETIZED RATS. J.G. Ghajar*, F. Plum, and T.E. Duffy. Dept. of Neurology, Cornell Univ. Med. Col., NY, NY 10021.

A model of low-dose, insulin-induced hypoglycemia was developed in female rats that produced a constant level of plasma glucose for 1.5 hr. Female rats, weighing 200 g and fasted overnight were anesthetized with ether for cannulation of the tail artery and vein. Rats recovered for 2-3 hr before receiving i.v. insulin (U40 Iletin). Rectal temperature was kept near 38°C.

At 20 min after 4.5 U/kg insulin, plasma glucose fell below 1.6 mM, remained constant for 1.5 hr, and slowly recovered. At 20 min, rats had active EEGs, were lethargic, and nonsupportive. At 30-40 min, rats had high-amplitude, slow-wave EEGs and increasing lethargy. At 40-60 min, rats were stuporous, progressing to coma (at approx. 80 min) with isoelectric EEGs. After the comatose period, seizures occurred; rats then either died or slowly recovered. Rats that maintained a plasma glucose above 1.6 mM became lethargic and recovered after 2 hr, but never developed coma or seizures. Blood pressure, gases, pH and hematocrit remained normal during hypoglycemic stupor and coma.

For neurochemical studies, brains were "freeze-blown" at 20, 30, 40, 60, and 80 min after insulin (n=4 each group). Values in controls (mean±SEM, n=6) were 1.37±.13 mmol/kg brain (glucose), 0.143±.006 (glucose-6-P), 2.97±.12 (glycogen), 2.36±.05 (ATP), 3.73±.10 (P-creatine), 0.063±.007 (NH_4^+), and 5.87±.37 mM (plasma glucose). Within 20 min after insulin, plasma glucose fell to 1.35±.04 mM and remained constant through 80 min. Brain glucose and glucose-6-P decreased at 20 min to 7% and 59% of control, respectively, remained at these levels through 60 min, and then fell to 3% and 34% of control at 80 min (coma). Glycogen decreased progressively to 18% of control during coma; ATP and P-creatine remained normal prior to 60 min, but declined to 65% and 60% of control respectively, during coma. Ammonia levels rose 3-fold at 20 min, and were more than 1.0 mmol/kg during coma.

Rats at 40 min of hypoglycemia (1.29±.04 mM plasma glucose) were made normoglycemic (6.02±.14 mM) within 10 sec and maintained at this level for 10 min by a programmed i.v. infusion of 5% glucose-saline. All rats (n=5) became self-supportive and alert between 7 and 10 min. Brains were freeze-blown at 1 and 10 min (n=4 each group) after the start of glucose infusion. Brain glucose rose to 34% and 78% of normal, glucose-6-P to 74% and 98% of normal, and glycogen to 31% and 40% of normal at 1 and 10 min, respectively.

In summary, neurological depression, progressing to coma, occurs at a constant plasma glucose below 1.6 mM. Normalization of neurological function following hypoglycemic depression is not instantaneous with normalization of plasma glucose but requires at least recovery of brain glucose-6-P.

285 IMPAIRED SYNTHESIS OF ACETYLCHOLINE (ACh) BY MILD HYPOXIC HYPOXIA OR NITROUS OXIDE. G.E. Gibson, T.E. Duffy & D.J. Jenden. Dementia Program, Burke Rehab. Ctr., Dept. of Neurology, Cornell Univ. Med. Col., N.Y., N.Y. 10021, & UCLA School of Medicine, L.A., CA 90024.

Earlier studies have shown that even mild histotoxic hypoxia (KCN) or anemic hypoxia ($NaNO_2$) impair the synthesis of brain ACh without altering the concentrations of lactate, ATP or cAMP (Gibson et al., 1978). We now report that mild hypoxic hypoxia impairs ACh synthesis. Since previous studies of hypoxic hypoxia on brain metabolism have often involved, as controls, animals breathing N_2O-O_2 mixtures (c.f. Siesjö, 1978), we also examined the effect of N_2O on ACh metabolism.

Adult rats (200 g) were used for all experiments. Tail artery and jugular vein cannulae were inserted the day before the experiment. During the experiment, rats were restrained in a "brain-blower", modified with a nose cone to deliver defined gas mixtures. One min before sacrifice, the rats received an iv pulse injection of [U-^{14}C]glucose (1 mCi/kg) and [$^2H_4$]choline (20 µmol/kg).

ACh synthesis was decreased in animals breathing 70% N_2:30% O_2 for 40 min, compared to rats breathing 70% N_2:30% O_2. The specific activity of the ACh synthesized from [$^2H_4$]choline ([$^2H_4$]ACh/total ACh) declined 53.5% [0.016±0.003 (n=9) to 0.007±0.001 (n=6), $P<0.05$]. The specific activity of ACh synthesized from [U-^{14}C]glucose (^{14}C-DPM in ACh/nmol of ACh) declined 54% [55.7±6.6 (n=3) to 25.7±1.4 (n=3), $P<0.01$]. ACh levels did not change significantly. Decreases in ACh specific activity were not due to decreases in the specific activities of the precursors, glucose and choline, nor to changes in blood pressure, PaO_2, $PaCO_2$, pH, or body temperature.

Thus, hypoxic hypoxia was studied in rats breathing N_2:O_2, and not N_2O:O_2, mixtures. ACh synthesis from both precursors was reduced when the inspired O_2 concentration was reduced from 30% (Pa O_2=127±3 mm Hg) to 15% (PaO_2=65±3 mm Hg) or 10% (PaO_2=46±3 mm Hg) for 15 min. The specific activity of ACh from [$^2H_4$]choline was reduced ($P<0.05$) by 49±13% (n=4), and by 63±12% (n=2) by 15% O_2 and 10% O_2, respectively. The specific activity of ACh from [U-^{14}C]glucose was reduced ($P<0.05$) by 44±8% (n=3), & by 46±6% (n=3) with 15% & 10% O_2, respectively. Neither the level of ACh nor the precursor pool specific activities changed significantly. Brain lactate increased ($P<0.05$) by 84±13% (n=4) and 292±42% by 15% O_2 and 10% O_2, respectively. $PaCO_2$, pH, and body temperature were unaffected; blood pressure fell ($P<0.05$) in the 10% O_2 group (112±3 to 96±6 mm Hg).

In conclusion, nitrous oxide anesthesia & mild hypoxic hypoxia decrease ACh synthesis in brain. Since brain lactate also rose in the hypoxic animals, additional experiments with even milder degrees of hypoxia will be required to distinguish whether decreased ACh synthesis or increased lactate concentrations occur first.

286 ELEVATION OF PLASMA TYROSINE LEVELS IN NORMAL HUMANS AFTER ORAL ADMINISTRATION OF L-TYRSONE. Bruce S. Glaeser*, Eldad Melamed, John H. Growdon*, and Richard J. Wurtman. Laboratory of Neuroendocrine Regulation, M.I.T., Cambridge, MA 02139.

L-Tyrosine, 100 mg/kg or 150 mg/kg was administered to two groups of fasting human subjects. Plasma tyrosine levels were significantly elevated 2-8 hours after tyrosine ingestion. Mean plasma tyrosine levels were maximal at 2 hrs, rising from 69 ± 3 to 154 ± 10 nmol/ml after 100 mg/kg and to 203 ± 32 nmol/ml ($\bar{X}$ ± SEM) after the 150 mg/kg dose ($p < 0.001$ for both groups). The uptake of tyrosine into the brain is dependent on the tyrosine ratio, defined as the ratio of the plasma tyrosine level to the sum of the concentrations of the plasma neutral amino acids (i.e. valine, methionine, leucine, isoleucine, phenylalanine, and tyrptophan) that compete for the same blood-to-brain transport system. At 2 hours, the mean tyrosine ratio increased from 0.10 ± .02 to 0.28 ± .04 ($\bar{X}$ ± SEM) after the 100 mg/kg dose and to 0.35 ± .05 after the 150 mg/kg dose, indicating that oral tyrosine probably increases brain tyrosine levels in humans. In related studies, subjects took 100 mg/kg of tyrosine in 3 divided doses, along with 3 daily meals containing 115 grams of protein. The increase in plasma tyrosine was similar to that seen in the fasting subjects. The peak plasma tyrosine ratio was 0.21. In rats, administration of tyrosine elevates plasma and brain tyrosine concentrations and can accelerate the synthesis of brain dopamine and norepinephrine. If similar changes in catecholamine synthesis occur in humans, then tyrosine administration may be useful in treating certain CNS disorders characterized by inadequate catecholaminergic tone.

PLASMA TYROSINE CONCENTRATIONS AFTER TYROSINE ADM.

Tyrosine Dose	Plasma Tyrosine Concentration-nmol/ml ($\bar{X}$+SEM) 0HR	2HR	4HR	6HR	8HR
100 mg/kg	69±3	154±10	129±7	121±11	110±10
150 mg/kg	69±3	203±32	158±13	128±9	106±6

287 SCIATIC NERVE RESPONSES OF PROTEIN MALNOURISHED RATS INDICATE PERIPHERAL ORIGIN OF HYPERREACTIVITY TO FOOT SHOCK. Robert D. Hall. Worcester Foundation for Experimental Biology, Shrewsbury, Mass. 01545.

Rats subjected to protein or protein-calorie malnutrition early in life frequently have been found to be more responsive than well-nourished rats to electric foot shock. This hyperreactivity has been interpreted by some investigators to indicate a hyperemotionality resulting from early deprivation. It is difficult to interpret the foot-shock data, however, because it is uncertain that effective shock levels were equated for rats of different sizes. It has been reported that small rats are more responsive to foot shock than larger ones. The present study was undertaken to determine if the malnourished rat's greater responsiveness to foot shock might be related to peripheral factors such as body size or thickness of the foot pads. Compound action potentials (CAPs) of the sciatic nerve were compared for protein malnourished and well-nourished rats.

Chronically malnourished rats were born to dams maintained on an 8% casein diet from 5 weeks before mating until weaning. The pups were maintained on the same low protein diet until they were studied at approximately 75 or 160 days of age. Well-nourished rats were reared by dams fed a 25% casein diet.

To record sciatic nerve responses the rats were anesthetized with pentobarbital and immobilized with tubocurarine. Monophasic current pulses were presented through stainless steel rods, one supporting the hindpaw, another supporting the ipsilateral forepaw, in an attempt to approximate the stimulus conditions of behavioral foot-shock situations. Contact between feet and rods was achieved by a silver skin contact solution. Single stimuli of increasing intensity were presented until the maximum CAP amplitude was obtained. A descending intensity series followed. The DC resistance between foot electrodes was measured before and after each stimulus series.

Absolute amplitudes of sciatic CAPs were greater over the entire intensity range in malnourished than in well-nourished rats. Because it is not clear why the maximum responses were larger in the malnourished rats, CAP amplitudes were transformed to percentages of each rat's maximum response. These functions also show the malnourished rat to be more sensitive to shock stimuli. Resistances between stimulating electrodes were significantly lower in the malnourished animals.

These findings indicate that the hyperreactivity of malnourished rats may be principally related to peripheral factors and not to altered CNS functions.

288 THE EFFECT OF UNDERNUTRITION ON THE BRAINSTEM RETICULAR FORMATION OF THE RAT: A GOLGI STUDY. Ronald P. Hammer, Jr. Dept. Anatomy, Sch. Med., UCLA, Los Angeles, CA 90024.

Undernutrition has been shown to have a profound effect on the central nervous system of maturing experimental animals, not only on gross brain weight and content but also on cell structure and function. In this study, neonatal rats have been exposed to a moderate state of food deprivation to 20 days of age by increasing the litter size to 14 and removing the dam for 8 hours each day. Neurons of various Reticular Formation nuclei of the brainstem were then examined using modifications of Golgi stains.

Dendritic variation has been observed in experimental tissues in the form of nodularities and thickenings upon dendrites of lesser thickness and extent, and subtle increases in dendritic spine numbers. The resulting changes suggest that cell development is less advanced. The relative immaturity and abberant development of these neurons may be the morphologic substrate of behavioral variations observed in these animals.

289 AMINO ACID TRANSPORT INTO RAT BRAIN REGIONS IN VIVO.
Richard A. Hawkins, Anke M. Mans*, James J. Richter*, Barbara L. Helm* and Julien F. Biebuyck*. Depts. of Anes. and Phys., Hershey Med. Ctr., The Penn State Univ., Coll. of Med., Hershey, PA 17033

The carrier system transporting neutral amino acids from plasma into whole brain has been characterized in normal adult rats (Oldendorf (1971) Am.J.Physiol.22:1629-1639). The kinetics of this system, for which many neutral amino acids compete, changes considerably in rats with portacaval shunts or during hepatic failure, thus altering the rate of amino acid influx (Mans et al. (1979) J.Neurochem., in press). The localization of these changes to brain regions, however, has not been determined. In order to measure amino acid influx at the regional level, we developed a technique to measure the influx of amino acids into various regions of the rat brain under physiological conditions, (ie. without disturbing the normal equilibrium of plasma components or altering cerebral blood flow).

A tracer quantity of ^{14}C-labeled amino acid was infused intravenously at a rate which maintained a steady level of label in the blood for 1 to 3 mins (Bános et al., (1973) Proc.R.Soc. B 183: 59-70). Blood was collected throughout the experiment to obtain the plasma integral of the tracer concentration, and the complete amino acid profile by amino acid analysis. After decapitation, the brain was frozen, sections cut for quantitative autoradiography, and the regional dpm/g obtained by quantitative densitometry. The PS (permeability coefficient x capillary surface area) in different brain regions was calculated from the plasma integral and dpm/g brain after subtracting the background dpm in the area due to contaminating blood (Ohno et al., (1978) Am.J.Physiol. 235:H299-H307).

The PS values of tyrosine and phenylalanine in four brain regions in normal conscious rats are shown in the following Table.

	PS ($ml \cdot min^{-1}$)	
	tyrosine	phenylalanine
Cortex	0.066	0.11
Caudate	0.058	0.076
Hippocampus	0.057	0.070
Inferior colliculus	0.087	0.15

For tyrosine the corresponding influx rates were 6.5, 5.7, 5.5 and 8.8 $nmol \cdot min^{-1} \cdot g^{-1}$ in cortex, caudate, hippocampus and inferior colliculus, respectively. Other substrates with low uptake rates can be studied similarly.

290 EFFECTS OF ENDOGENOUS MAGNESIUM ON THE DIURNAL RELATIONSHIPS AMONG DOPAMINE, NOREPINEPHRINE, SEROTONIN AND ELECTROLYTES IN THE RAT BRAIN.
Mary D. Healy*, Audelio Rivera*, and Michael Borucki* (SPON: Arvind T. Modak). Incarnate Word College, 4301 Broadway, San Antonio, TX 78209.

Physiological deprivation of Magnesium manifests itself through various metabolic dysfunctions. Neurological disturbances constitute the most prominent clinical indications of magnesium deficiency (MGD). Rats placed on a magnesium deprived diet (Mg = 4.5ppm) exhibited audiogenic seizures and a high degree of irritability to touch which were more pronounced during the dark cycle and during the light period. A forty-day study has shown a correlation between the susceptibility to seizures and the concentrations of norepinephrine (NE) and serotonin (5-HT) in the rat brain. In the present study the concentrations of dopamine (DA), NE and 5-HT, as well as the ions, Mg, Ca, Na, K and Zn have been determined hourly throughout the 24-hour period of the fifteen day of dietary mg restriction. The data collected was compared statistically with that obtained from similar determinations on brains from rats maintained on a normal diet (mg = 650ppm). Experimental and control were plotted on polar coordinate paper and the experimental elipses shown as ratios of the control amplitude and phases. (Supported by NIH Grant 1-S06-RR-08170-01).

291 DETERMINATION OF BIOGENIC AMINES IN DISCRETE BRAIN AREAS OF FOOD DEPRIVED RATS USING HIGH PERFORMANCE LIQUID CHROMATOGRAPHY.
C.C. Loullis, D.L. Felten and P.A. Shea. Institute of Psychiatric Research, Depts. of Psychiatry, Biochemistry and Anatomy, Ind. Univ. School of Medicine, Indianapolis, IN 46223.

Levels of norepinephrine (NE), dopamine (DA), 5-hydroxytryptophan (5-HTP), 5-hydroxytryptamine (5-HT), and 5-hydroxyindole acetic acid (5-HIAA) in the lateral hypothalamus (LH), ventromedial hypothalamus (VMH), median raphe (MR) and dorsal raphe (DR) were determined in nondeprived and 48 hr. food deprived rats. Simultaneous determination of these compounds was accomplished by means of high performance liquid chromatography (HPLC) with electrochemical detection.

Tissue samples were homogenized in formic acid/acetone and the extracts washed with 0.5 ml of heptane/chloroform. The aqueous portion was then dried down and resuspended in 100 µl of the HPLC buffer. The HPLC system utilized a C-18 reverse phase column coupled with a glassy carbon detector set at a potential of 0.8 volts versus the reference electrode. The electronic controller was set at 5 na/v and the recorder at 0.1 volt full scale. The buffer was 0.1 M citrate-disodium phosphate, pH 3.5, containing 0.004% sodium octyl sulphate and 12.5% methanol by volume. The flow rate was maintained at 1.0 ml per min. Twenty microliters of each sample were injected on the HPLC. The compounds of interest (identified by retention times of standards) were quantified by determining the area under the peaks and their contents were determined from standard curves. Results of the HPLC assay procedure demonstrate that this is a simple, sensitive, and rapid method for the simultaneous determination of NE, DA, 5-HTP, 5-HT and 5-HIAA content in the same small brain sample.

When compared with controls, food deprived animals showed significant increases in 5-HT and 5-HIAA levels in the raphe nuclei, significant increases in 5-HIAA in the LH, but no changes in either 5-HT or 5-HIAA levels in the VMH. No changes in catecholamine levels were found in any of the brain areas studied. These results show that indoles in the raphe nuclei, as well as in the LH, are affected by food deprivation. The lack of change in indole levels in the VMH indicates that specific nuclei within the hypothalamus are differentially affected by food deprivation. (Supported by NIMH grant No. PHS-T01-MH10695-13, Indiana Dpt. of Mental Health Grant no. 178-679-005 and Indiana Attorney General's Fund.)

292 REGIONAL VULNERABILITY OF THE NON-HUMAN PRIMATE BRAIN TO REDUCED BLOOD SUPPLY.
Frank W. Marcoux, Richard B. Morawetz*, and James H. Halsey, Jr.* Neurosciences Program, Division of Neurosurgery, and Department of Neurology, University of Alabama in Birmingham, Birmingham, AL 35294.

Twenty-one unanesthetized macaque monkeys underwent temporary middle cerebral artery (MCA) occlusion by a snare ligature technique. Duration of MCA occlusion varied from 15 minutes in some animals to 3 hours in others. Local cerebral blood flow (LCBF) was measured before, during, and after MCA occlusion in cortical and subcortical gray and white matter within MCA distribution. Two to four weeks following temporary arterial occlusion, histologic examination documented cerebral tissue damage and its precise relation to LCBF recording sites. Histo-pathologic observations at sites having undergone a similar reduction in LCBF for the same duration were compared to define the more vulnerable site. The criteria for increased vulnerability to a decrease in blood flow was the degree of tissue damage. As an example, where 2 or more sites are subjected to a similar degree of ischemia during 1 hour of MCA occlusion, the more vulnerable site is that which suffers the greater histological consequences.

Gray matter sites (insular cortex, putamen, and caudate nucleus) revealed tissue damage of varying degree during 1 to 3 hours of MCA occlusion when LCBF fell to and remained at levels approximately equal to or less than 10 cc/100g/min. Incomplete tissue damage was associated with occlusion durations between 1 and 1.75 hours while total destruction occurred only between 2 and 3 hours of MCA occlusion.

White matter sites (subcortical and capsular areas) appear to be less vulnerable to decreased blood flow than gray matter during 15 minutes to 3 hours of MCA occlusion. No tissue damage was observed at white matter sites until 1.5 hours of MCA occlusion and then only at LCBF values of 6 cc/100g/min or less. Severe tissue damage at white matter sites occurred at LCBF's of 5 cc/100g/min or less after 2 hours of MCA occlusion and generally as a result of a fatal ischemic insult.

Sites in the caudate nucleus demonstrated the greatest vulnerability to reduced blood flow. Alterations in cellularity with apparent loss of neurons alone occurred in the caudate at LCBF levels as high as 10-15 cc/100g/min between 1 and 2 hours of MCA occlusion.

293 EFFECTS OF HYPERCAPNIA ON INTERMEDIARY METABOLISM OF DEVELOPING RAT BRAIN. Alexander L. Miller, David H. Corddry* and Colleen A. Kiney*. Labs. Psychiat. Res., McLean Hospital. Belmont, MA 02178.

Developing rats, 10 and 20 days post-natal, were placed in an atmosphere of 20% CO_2, 21% O_2 and 59% N_2 for periods up to 15 minutes. Brains were obtained with the freeze-blowing apparatus. Rates of brain glucose utilization were determined by measuring uptake of [2-^{14}C]glucose and [^{3}H]deoxyglucose. Metabolites were assayed by standard enzymatic methods.

In control rats glucose utilization by brain increased from 0.15-0.16 µmol/min per g at 10 days to 0.40-0.43 µmol/min per g at 20 days, about 60% of the adult rate. CO_2 treatment produced a 50% decline in brain glucose use which persisted throughout the period studied in animals in both age groups. In all conditions there was reasonable agreement between the rates calculated with each isotope.

Metabolite analysis indicated that early after the onset of hypercapnia (2 min) there was inhibition of phosphofructokinase out of proportion to other glycolytic enzymes. This inhibition became less evident over the time course, though glycolytic flux remained diminished. Concentrations of most intermediary metabolites and of glutamate progressively decreased during hypercapnia. It is hypothesized that these metabolites were oxidized in order to maintain energy production. In the case of the 20 day old animals, however, their rate of disappearance lessened with time, so that other non-glucose fuels would have been needed to maintain normal oxygen consumption at later times.

294 EFFECTS OF ADRENALECTOMY ON TRYPTOPHAN METABOLISM IN NORMAL AND PROTEIN MALNOURISHED RATS. Maravene Miller*, J. Patrick Leahy*, Oscar Resnick* and Peter J. Morgane. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Rats born to dams fed a low protein diet (8% casein) or a normal diet (25% casein) starting 5 weeks prior to conception were bilaterally adrenalectomized (ADX) at 30 days of age. At 60 days of age the 8% and 25% ADX rats were compared to sham (S) operated and control (C) litter mates of each diet. The results (Table below) indicate that ADX caused significant decreases of 28-40% for whole brain serotonin (5-HT) and 5-hydroxyindoleacetic acid (5-HIAA) levels, and significant increases of 38-47% for tryptophan (TP) levels in both the 8% and 25% ADX rats as compared to their respective controls. Plasma constituents showed no significant differences between the ADX and S+C rats of each diet group except for corticosterone (COR) levels. The latter findings indicate that the adrenal gland plays a minimal role in producing the changes in plasma albumin (ALB) and fatty acid (NEFA) levels and the resulting alteration in TP availability seen in the 8% casein rats (Miller et al., Exp. Neur. 57: 142, 1977). However, the effects of long-term ADX in young rats of both diet groups indicate that the adrenal cortex may regulate brain TP metabolism by: (1) maintaining normal activity of TP hydroxylase, the rate limiting enzyme in 5-HT synthesis, and (2) inhibiting the transport of TP to the brain.

Effects of Adrenalectomy on 8% and 25% Casein-fed Rats

295 CEREBRAL BLOOD FLOW IN NORMOXIA AND HYPOXIA FOLLOWING LESIONS OF MEDULLARY REGIONS MEDIATING PRESSOR RESPONSES TO BRAINSTEM ISCHEMIA. M. Nakai*, M. Kumada, G.R. DiResta* and D.J. Reis. Lab. of Neurobiol., Dept. of Neurol., Cornell Univ. Med. College, New York, NY 10021.

The elevation of systemic arterial pressure (AP) elicited by cerebral ischemia or brainstem distortion (Cushing reflex) is mediated by a restricted region of the dorsal medullary reticular formation (DMRF) comprising, largely, portions of the parvocellular and gigantocellular nuclei (Kumada et al., Circ. Res., 1979, in press). Electrical stimulation of this region simulates the vasomotor responses to brainstem ischemia or systemic hypoxia (Dampney et al., Circ. Res., 1979 in press). Electrical stimulation of this region in sympathectomized animals increases focal cortical cerebral blood flow (CBF) (MacKenzie et al., in press). Since systemic hypoxia also increases CBF, we sought to establish if lesions of the DMRF would also impair the CBF response to hypoxia. A total of 32 rabbits were anesthetized with urethane and paralyzed by gallamine. Their cervical sympathetic trunks were severed bilaterally. Blood gases and pH were controlled by artificial ventilation with O_2, CO_2 and N_2. Local CBF was measured in the gray matter of the parietal cortex by H_2 clearance. Bilateral electrolytic lesions, destroying most of the gigantocellular and parvocellular nuclei in DMRF, were placed 1-3mm (A1-3), or 5-7mm (A5-7) rostral to obex. AP was maintained in the autoregulated range at about 105mmHg. Continuous i.v. infusion of norepinephrine (NE) was required to maintain AP constant, especially after placement of lesions. Therefore cerebrovascular responsivity to hypoxia was always evaluated as a function of the dose of infused NE. CBF in normoxia in the intact rabbits was 43.7 ± 10.6 ml/min/100g tissue (n=41). Reduction in PaO_2 to 29.8 ± 1.5mmHg resulted in an increase in CBF to 147 ± 25% (n=19) of control. Cerebrovascular responsivity to hypoxia in the rabbits with intact DMRF, with lesions of A1-3 and A5-7, did not differ from each other ($P > 0.05$). Such lesions, however, resulted in approximately a 50% increase in CBF ($P < 0.01$). We conclude: (a) Integrity of regions in DMRF mediating vasomotor responses to cerebral ischemia and distortion are not required for the increase in CBF elicited by systemic hypoxia. (b) Neurons located within or passing through the lower medulla may tonically constrict cerebral blood vessels.

296 REGIONAL HISTOCHEMICAL ANALYSIS OF SORBITOL DEHYDROGENASE ACTIVITY IN THE NERVOUS SYSTEM OF THE RAT. Susan E. Orosz*, Samuel F. Townsend* and Patricia A. Tornheim* (SPON: G. Eckstein) Dept. Anat., Univ. Cincinnati College of Medicine, Cincinnati, Ohio 45267.

Sorbitol, a sugar alcohol, has been suggested to play a role in the development of diabetic neuropathy (Gabbay et al. Science 151:209, 1966) and cerebral edema associated with diabetic ketoacidosis (Clements et al. Lancet 2:384, 1968). Previous investigations concerning the presence of this polyol in the nervous system have consisted primarily of biochemical demonstration of sorbitol dehydrogenase activity in normal rat brain (Rehg and Torack J. Neurochem 28:655, 1977), normal and diabetic spinal cord, and normal and diabetic peripheral nerve (Gabbay and O'Sullivan, Diabetes 17:239, 1968). On the basis of their biochemical data, Gabbay and O'Sullivan suggested the activity of this enzyme is axonal in peripheral nerve and within neuronal cell bodies in the spinal cord. The present histochemical study was designed to provide fundamental information concerning regional localization of sorbitol dehydrogenase activity in the central and peripheral nervous systems of the normal rat.

For these histochemical studies, fresh, frozen samples were taken from brain (including cortex, corpus striatum, thalamus, and medulla), cervical spinal cord, and sciatic nerve in normal, adult male Sprague Dawley rats. Cryostat sections (15 u) were evaluated for the presence of sorbitol dehydrogenase activity according to the procedures described by Johnson (J. Histochem and Cytochem 13:583, 1965 and J. Histochem and Cytochem 15:207, 1967). These sections were incubated for 2 hrs in one of three media: (1) with sorbitol and phenozine methosulfate (PMS), (2) without PMS and (3) without sorbitol. Seminal vesicle was utilized as a tissue control.

Examination of sections through the central nervous system showed an absence of demonstrable enzyme activity in the parenchyma, but strong reactivity in the choroid plexus, ependyma and pia mater. Although enzyme activity was not visible in peripheral nerve processes, blood vessels associated with peripheral nerves were reactive. These data indicate that the greatest sorbitol dehydrogenase activity in the central and peripheral nervous systems of the rat is extraneuronal, not intraneuronal as suggested by Gabbay and O'Sullivan.

297 EFFECT OF PROSTACYCLIN ON LOCAL CEREBRAL GLUCOSE UTILIZATION AND CEREBRAL BLOOD FLOW. H. M. Pappius*, L. S. Wolfe, and U. Goehlert*. Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada H3A 2B4.

Vascular endothelium synthesizes prostacyclin, an unstable prostaglandin (t 1/2, 2-4 min. pH 7.4) which strongly inhibits platelet aggregation, increases cAMP synthesis and vasodilates most blood vessels. The capacity for synthesis of prostacyclin from endogenous precursor by rat cerebral arteries and arterioles is 2-4 μg/g tissue/10 min incubation periods at pH 7.4. Highly purified preparations of cerebral capillaries isolated from rat cerebral hemispheres also synthesize prostacyclin in amounts of 12-15 ng/mg protein. Topical application of prostacyclin (10-20 μg) for 3 minute periods to the exposed cerebral cortex of rats anesthetized with nembutal caused an immediate striking vasodilation of the surface blood vessels. Local cerebral glucose utilization measured by the ^{14}C-deoxyglucose technique was markedly increased (40-45%) in the parietal and auditory cortex and the effect was dose-dependent. Local cerebral blood flow measured by the ^{14}C-iodoantipyrine method was also significantly increased by 20-28% in the cerebral cortical region of application. Application of prostacyclin to the intact dura dilated the dural blood vessels but had no effect on the glucose utilization or blood flow in the underlying cerebral cortex. These studies suggest that prostacyclin released locally from cerebral vascular beds can not only affect blood flow but also increase cerebral glucose metabolism.

298 BLOOD-BRAIN BARRIER TRANSPORT AND BRAIN SEQUESTRATION OF THE STEROID HORMONES. William M. Pardridge, UCLA School of Medicine, Los Angeles, Ca. 90024

Gonadal steroids are concentrated severalfold in brain relative to plasma, but brain corticosterone levels are only 40% of plasma values; these observations suggest differences may exist between the kinetics of brain sequestration of the gonadal steroids vs corticosterone. The rate of brain sequestration of the sex steroid hormones (progesterone, 17-hydroxyprogesterone, dihydrotestosterone, testosterone, estradiol) vs corticosterone was investigated with a carotid injection technique in barbituate-anesthetized adult male rats. The rate of change with time of test steroid radioactivity (T) in brain after pulse labeling via the carotid artery was a function of the rate of efflux (k_2) of steroid back to blood minus the rate of sequestration (k_3) of the steroid hormone by brain. Therefore, by employing an internal ^{14}C reference (R), e.g., butanol or antipyrine, that left the brain at the same k_2 as the ^{3}H-test hormone, the rate of change with time in the T/R ratio lead to the estimation of k_3 for the steroid hormone. Based on a two-compartment model, the parameters (T/R), k_2, and k_3 were related as follows:

$$T/R = \frac{k_3}{(k_2 + k_3)} e^{k_2 t} + \frac{k_2}{(k_2 + k_3)} e^{-k_3 t}$$

Given the k_2 value for the reference, the T/R ratios at various times after carotid injection (0.25-4.0 min) were fitted to the above equation by a non-linear regression analysis. The $k_3 \pm$ SE:

Steroid	k_3 (min^{-1})	Octanol:Ringer's
Dihydrotestosterone	0.33 ± 0.03	1340
Progesterone	0.29 ± 0.03	1870
Testosterone	0.29 ± 0.04	530
Estradiol	0.27 ± 0.04	196
17-Hydroxyprogesterone	0.08 ± 0.01	1809
Corticosterone	<0.05	66

No correlation was found between k_3 and the octanol:Ringer's partition coefficient ($r=0.18$, $p<0.40$), suggesting the steroids were not being sequestered by brain lipid. No change in corticosterone k_3 was observed in the adrenalectomized rat, indicating the lack of brain retention of ^{3}H-corticosterone was not due to high levels of endogenous hormone. Thin layer chromatographic analysis of brain ^{3}H-progesterone radioactivity at 3 min after carotid injection showed progesterone was unmetabolized. Conclusions: The turnover rate of brain binding of blood-borne sex steroids, $t_{½}$ approximately 2 min, is much higher than for corticosteroids, a finding which correlates with the much higher volume of distribution of the gonadal steroids in brain relative to corticosterone.

299 ISOLATION OF γ-GLUTAMYL TRANSPEPTIDASE FROM GLIAL CELLS E. Reyes* and L.C. Saland (Spon. L.D. Partridge) Depts. Pharmacology and Anatomy, School of Medicine, University of New Mexico, Albuquerque, N.M. 87131

Membrane-bound γ-glutamyl transpeptidase (γ-GTP), believed to be the key enzyme required for the coupling of amino acid uptake to glutathione metabolism via the γ-glutamyl cycle, has been found in cellular elements of rat cerebral cortex. Neuronal and glial localization of the enzyme indicates that the operation of the γ-glutamyl cycle and thus amino acid transport via this cycle occurs in neuronal and glial cells. Although the physiological role of the enzyme has not been established, there is evidence to suggest that it may be involved in alcoholism, epilepsy and mental retardation. Multiple forms of the enzyme have been isolated and partially purified from brain. The intent of the present study was to determine if multiple forms of the enzyme were present in a glial enriched fraction of rat cerebral cortex. Rats were decapitated and the cortex dissected and chopped into 1-2mm sections while suspended in a solution of cold 7.5% polyvinyl pyrolidone (PVP), 1% BSA and 10mM $CaCl_2$. The tissue was passed through a series of sieves (333 to 73 μpore size) and layered onto a two-step discontinuous sucrose gradient (1.0 to 1.75M) and centrifuged. The impure glial cells at the 1.0-1.75M sucrose interface were resuspended in 7.5% PVP and 5% ficoll, sieved through 73μ sieve and layered on a discontinuous ficoll gradient. After centrifugation the band collecting at the 1.2-1.65M sucrose interface was washed in 0.32M sucrose and saved for enzyme isolation. A portion of the pellet was fixed in cacodylate-buffered 2.5% glutaraldehyde, postfixed in 1% osmium tetroxide, dehydrated in ethanol and embedded in Epon for microscopy. At the light microscopic level, the glial cell fraction consisted of some small cell fragments which had the appearance of glia, and a large amount of amorphous material. In contrast, the neuronal fraction contained larger cells and a few capillaries. Electron microscopy revealed that the amorphous material in the glial fraction was composed of membranes and ruptured organelles. The neuron fraction contained cells with obvious neuronal characteristics, including prominent nucleoli and abundant rough endoplasmic reticulum. Four different forms of the enzyme γ-GTP were isolated from the glial fraction by chromatography on concanavalin A. The isoenzymes were characterized with respect to molecular weight, Km for γ-glutamyl-p-nitroanilide, mobility on polyacrylamide gels and inhibitory effects of ethanol. Based upon the presence of γ-GTP in glia, we suggest that a possible role of glial cells is in the transport of amino acids to neurons via the γ-glutamyl cycle.

300 CONTROL BY CARBON DIOXIDE OF GLYCOLYTIC FLUX OF NICOTINAMIDE ADENINE DINUCLEOTIDE IN NEURONS OF DORSAL ROOT GANGLION.
Carlos Rodríguez-Estrada. Cátedra de Fisiología, I.M.E. Fac. Med. U.C.V., Caracas, Venezuela.

Previous works have shown that changes of carbon dioxide partial pressure increases oxidation of the steady state level of reduced nicotinamide adenine dinucleotide (NADH) in neurons of frog dorsal root ganglion. In this work it was expected that this change observed in aerobic and in anaerobic conditions would be blocked differentially with metabolic inhibitors. 2-Deoxy-D-glucose (2-DG) and Amytal were used as inhibitors. The 2-DG blocks NADH formation in the glycolytic pathway and Amytal blocks the respiratory chain. Fluorometric determinations of NADH were done on in vitro preparations of dorsal root ganglion as previously reported, pH and pO_2 were measured simultaneously. CO_2/O_2 (2.5%/97.5%), CO_2/N_2 (2.5%/97.5%) replaced temporarily the O_2 and N_2 of the chamber. All gases were moistened and records were taken at a temperature of 25°C. NADH showed and inmediate and fast decrease(oxidation) after O_2 was replaced with CO_2/O_2 and also after N_2 was replaced with CO_2/N_2 (about 3% and 15% respectively). After the incubation of the preparation in 2-DG (20 mM, 30-60 min), oxidation with CO_2 mixtures were not observed. After incubation of the preparation in Amytal (5 mM, 5 min), NADH oxidation was observed after CO_2 mixtures, but NADH did not change after O_2 was replaced with N_2, and after O_2 replaced N_2, Amytal blocked the respiratory chain and reduction of NAD and oxidation of NADH were not observed. The steady state level of NADH is higher than normal.

2-DG blocks the glycolytic pathway (phosphoglucoisomerase) and NADH is formed less. Under 2-DG inhibition the oxidation of NADH is not observed, neither in O_2, nor in N_2 with CO_2 mixtures, but oxidation of NADH is observed after O_2 replaced N_2(respiration). The Amytal blocks the respiratory chain (NADH-flavoprotein) and oxido-reduction was not observed during O_2-N_2-O_2 transitions. Under Amytal action oxidation of NADH with CO_2 mixtures can be attributed to lactate formation.

These results indicate that the oxidation observed with the CO_2 mixtures comes from the NADH of glycolytic pathway either in aerobic and in anaerobic conditions.

301 ^{14}C-2-DEOXYGLUCOSE UTILIZATION IN THE CEREBELLUM OF THE MONKEY DURING A CONDITIONED ARM MOVEMENT. Robert J. Schwartzman, Jen Yu, Guillermo M. Alexander*, Depts. of Medicine and PM&R, UTHSC, San Antonio, TX 78284, Joel Greenberg*, Martin Reivich, Dept. of Neurology, Univ. Pennsylvania School of Medicine, Philadelphia, PA 19104.

The metabolic rate for glucose was computed in the cortex and cerebellar nuclei using the quantitative ^{14}C-2-deoxyglucose (2DG) technique. The monkey was operantly conditioned to pull a one pound weight for 12 cm with its right arm while sitting in a primate chair. The animal was made to pull the weight for 10 minutes prior to injection of isotope, and throughout the 45 minute experiment. A bolus of 2DG (100 µci/kg) in 3 ml of saline was injected intravenously. Arterial blood samples (.5 cc) were drawn every 15 seconds for the first minute, at 1 minute intervals for the next nine minutes and at 5 minute intervals for the remainder of the study, in order to determine the arterial plasma ^{14}C and glucose concentrations. Forty-five minutes after 2DG injection the animal was sacrificed with an overdose of Nembutal followed by 10 cc of saturated KCl, the brain was removed and frozen in liquid freon. The brain was then cut into 20 micron sections and exposed on x-ray film, Kodak SB5. The tissue ^{14}C concentration was obtained by autoradiographic techniques with the aid of a microdensitometer (.25 mm aperture). The local metabolic rate for glucose was calculated quantitatively from the ^{14}C tissue concentration, the plasma 2DG and glucose curves and the rate and lumped constants as computed by Kennedy, et al (Ann Neurol 4:293-301, 1978). Cerebellar glucose utilization was analyzed from anterior to posterior in medial, intermediate and lateral cortex as well as fastigial, interpositus and dentate nuclei bilaterally. Glucose utilization was more active on the right side. The metabolic rate in µ moles/100g/min, ranged from 21.5 to 95.6 in the right cortical areas and 40.7 to 127.9 in the right nuclei. It ranged from 16.9 to 55.4 in the left cortical areas and 37.8 to 93.3 in the left nuclei. The bilateral difference varied from anterior to posterior according to present concepts of somatotopic localization. Our findings support present understanding of cerebellar physiology and anatomy. This study further demonstrates the value of the 2DG technique as an experimental tool in the study of functional neuroanatomical organization.

302 RELATIONSHIPS BETWEEN UNIT DISCHARGES, EXTRACELLULAR POTASSIUM ION ACTIVITY AND OXIDATIVE METABOLISM IN THE BULLFROG OPTIC TECTUM. Thomas J. Sick* and Norman R. Kreisman, Department of Physiology, Tulane University School of Medicine, New Orleans, La. 70112.

Unit activity, extracellular potassium ion activity (aK^+_o), and tissue oxygen tension (PtO_2) were monitored simultaneously in the optic tectum of the bullfrog (Rana Catesbeiana) in an effort to better understand the interactions between local electrical, ionic, and metabolic processes in brain. Local tissue oxygen tension and unit activity were measured from single polarographic microelectrodes and aK^+_o was monitored by means of liquid ion exchanger microelectrodes.

Physiological activation of units in the bullfrog optic tectum was achieved by moving a 10° black disc through the visual field. Such stimulation elicited a transient (2-4 sec) burst of multiunit activity, accompanied by a transient rise in aK^+_o of 0.5 - 1.0 mM. The potassium transients returned to baseline within 10-30 sec. with half-recovery times averaging 4.9 ± 0.29 sec (Mean ± SEM). These events were accompanied by a transient fall in local tissue oxygen tension lasting from 30 sec to as long as 3 min. Positive correlations were obtained between the intensity of the multiunit discharge and both ΔaK^+_o and ΔPtO_2.

Superfusion of the optic tectum with low concentrations of the Na-K ATPase inhibitor, ouabain ($5x10^{-6}$ to 10^{-5}M), resulted in a gradual rise in baseline aK^+_o. This rise was accompanied by a 50-100% increase in the half-recovery time of the potassium transient. Ouabain also reduced both baseline and ΔPtO_2 and diminished the intensity of the multiunit burst. Greater doses of ouabain induced episodes of spreading depression.

Ventilation of the bullfrog with 100% N_2 for 5-10 min produced a rise in baseline aK^+_o as well as a 50-100% prolongation of the half-recovery time of the potassium transient. The expected fall in baseline PtO_2 initially was accompanied by hyperexcitability followed by depression of multiunit activity in the optic tectum.

These results illustrate that a tight coupling exists between local electrical, ionic and metabolic events in the bullfrog central nervous system. They also demonstrate that active ion transport participates in the clearance of excess K^+_o. Energy for K^+ clearance is apparently derived, at least in part, from oxidative metabolism. The component of K^+ clearance which is mediated by oxidative metabolism is necessary for the maintenance of normal neuronal function.

(Supported by NIH grant NS-12419).

303 THE UTILIZATION OF L-3-HYDROXYBUTYRATE IN RAT BRAIN DURING DEVELOPMENT. Kenneth Swiatek*, George Dombrowski Jr.*, Kuen-Lan Chao* and Hsiang Chao* (SPON: R. Karrer). Inst. Study Dev. Disabilities, Chicago, IL 60608.

The in vivo and in vitro metabolism of L-(3-^{14}C)-hydroxybutyrate in rat brain was studied during development. Rat pups at birth, 6, 15, and 23 days of age were injected with either the D- or the L-isomer of (3-^{14}C)-hydroxybutyrate (10 µCi/100 g body wt). After 1 hr the animals were killed and the incorporation into cerebral proteins, lipids, and amino acids examined. The total incorporation as well as the incorporation into the protein, amino acid, and lipid fractions from either isomer increased from birth thru 15 days of age. Although the pups injected with the L-isomer contained significantly more label per gram brain than the controls at ages 6, 15, and 23 days, a greater proportion of the label was found in the non-metabolized (3-^{14}C)-hydroxybutyrate fraction. D-3-hydroxybutyrate labelled brain protein (1.6 X) and amino acids (1.9 X) more effectively than the L-isomer in newborn rats, and was a better precursor of brain protein at 6 and 15 days of age. Both isomers distributed similarly into four brain amino acids at 15 days of age, glutamate, glutamine, aspartate and GABA. Glutamate accounted for 51 % of the ^{14}C incorporated into brain amino acids for pups injected with either isomer. In newborn rats and at age 6 days greater incorporation into brain lipid was observed with the D-isomer. However at 15 and 23 days of age incorporation from the L-(3-^{14}C)-hydroxybutyrate into brain lipids was 2 X that found for the D-isomer. At 15 days of age 56 % of the labelled carbon of brain lipids from animals injected with the L-isomer was found in the sterol fraction, whereas only 41 % of the labelled carbon was found in the sterol fraction when the D-isomer was injected.

The production of CO_2 from both isomers was measured in vivo throughout the neonatal period as well as in a series of brain slice experiments from animals at 15 days of age. At 6 and 15 days of age the in vivo $^{14}CO_2$ production from the L-isomer was 50 % of that observed for D-3-hydroxybutyrate. In brain slices from animals 15 days of age the total CO_2 released by the oxidation of the D-isomer was 15-fold that produced by the L-isomer in 1 hr. ATP and Coenzyme A were found to stimulate the production of CO_2 from the L-isomer (2 X). Methylmalonate, a 3-hydroxybutyrate dehydrogenase inhibitor, decreased CO_2 production from the D-isomer, but was without effect on the oxidation of the L-isomer.

In conclusion it has been shown that L-3-hydroxybutyrate is incorporated throughout development into brain protein, amino acids and lipid and that its utilization is stimulated by ATP and Coenzyme A.

304 RELATION BETWEEN GLYCOGEN AND GLUCOSE LEVELS OF BRAIN STRUCTURES AND LACTIC ACID ACCUMULATION DURING CIRCULATORY ARREST. Kenneth R. Wagner and Ronald E. Myers. Lab. Perinatal Physiol., NIH, Bethesda, MD 20205

Certain nuclei in the brain stem accumulate lactic acid at high concentrations during circulatory arrest and this accounts for their special vulnerability to injury in food-deprived animals (Wagner & Myers, Neurol. 29: 546, 1979). Because circulatory arrest is associated with a metabolic locked-in state, extent of lactic acid accumulation, and, thus, vulnerability to injury is determined by glycogen and glucose levels. Vulnerable structures must contain one or both substrates at high concentrations. The present study examines this question by measuring glycogen and glucose in normal goat brain. Brain composition was preserved by in situ freezing (Welsh & Rieder, J. Neurochem. 31: 299, 1978). Tissue samples were assayed for glycogen, glucose, lactate, and ATP using enzymatic fluorometric procedures. The vulnerable brain stem nuclei contain glycogen at high concentrations (> 6.0 µmoles/g-glucosyl units). In contrast, cortex, hippocampus, caudate nucleus, thalamus, cerebellum, and hemispheral white matter all of low vulnerability exhibited lower glycogen contents (3-5 µmoles/g). Glucose varied and showed no definite pattern of distribution though it tended to be higher in cortex (range 3-5 µmoles/g) and lower in thalamus (2-3 µmoles/g) and brain stem (2.5-4 µmoles/g). Gray and white matter exhibited similar glucose levels. Lactic acid (1-3 µmoles/g) and ATP (1.75-2.5 µmoles/g) all fell within ranges described by others. These results show: (1) In situ freezing preserves normative values for metabolic intermediates throughout brain in large animals. (2) Vulnerable brain stem nuclei that accumulate lactic acid to a marked degree during circulatory arrest normally contain glycogen at the highest concentrations. (3) Glucose is distributed with no outstanding differences. Conclusion: In food-deprived animals exposed to circulatory arrest (anoxia), it is the glycogen concentration that most critically determines lactic acid accumulation and therefore the distribution of brain pathology.

305 REGIONAL VARIATIONS OF pH IN ISCHEMIC BRAIN: CORRELATION WITH TISSUE LEVELS OF ATP, LACTATE, AND NADH. Frank A. Welsh* (SPON: T.W. Langfitt). Division of Neurosurgery, University of Pennsylvania, Philadelphia, Pa. 19104.

Incomplete ischemia was produced in cat brain by occlusion of the common carotid arteries followed by rapid arterial hemorrhage to a mean arterial pressure of 30-50 torr. After 30 minutes of ischemia, the brain was recirculated for 2 hours, at which time the entire brain was frozen in situ with liquid nitrogen. This freezing technique traps metabolite levels in deep brain regions with neglible ischemic artifact (J Neurochem 31: 299-309, 1978). The frozen brain was sectioned at -15°C at a thickness of 40 μm, and the sections were layered onto an umbelliferone-containing acetate strip. The sections were melted, illuminated with ultraviolet light (366 nm), and the fluorescent images (450 nm) were recorded photographically. Since the fluorescence intensity of umbelliferone is pH-dependent, brain regions with a lower pH would be expected to fluoresce less intensely. Indeed, in the present investigation there were striking regional variations of umbelliferone fluorescence. In brain regions with decreased pH, lactate levels ranged from 20-40 mmol/kg in contrast to the 1-3 mmol/kg present in regions with a normal fluorescence intensity. In addition, these acidotic areas of brain showed markedly diminished levels of ATP and phosphocreatine (0.1-0.9 mmol/kg) compared to control levels of 2.4 mmol/kg (ATP) and 4.8 mmol/kg (phosphocreatine).

Thus the use of umbelliferone with frozen tissue sections is a rapid and simple qualitative indicator of tissue pH which may be generally valuable for a variety of applications.

(Supported by PHS grant NS 08803-09)

306 A LASTING EFFECT OF POSTNATAL UNDERNUTRITION ON THE RAT ELECTRORETINOGRAM. Wiggins, R.C., Fuller, G.N. and Dafny, N. (SPON: P. Gildenberg, M.D.). Univ. Texas Medical School at Houston, Dept. Neurobiology & Anatomy, Houston, TX 77025.

Paired photic stimuli, separated by varying time intervals, were used to elicit evoked responses as a physiological measurement to study the effect of postnatal undernutrition on the retina of adult rats. Experiments were performed on 12 rats (6 normals and 6 previously undernourished). Normal and undernourished pairs were littermates; the latter were separated from the mother for various intervals each day, leading to undernourishment (50-60% of normal body wt. at 20 days) as we have published previously. After weaning, all rats had free assess to lab chow. Electrophysiological experiments were carried out after about two months of nutritional rehabilitation, during which time growth "catch-up" brought the experimental rats up to 85% of control body weight. Animals were anesthetized with pentobarbital (50 mg/kg) and placed in a stereotaxic frame for the recording procedure. The recording electrodes were connected to conventional electrophysiological equipment and were fed into a NIC 1072 minicomputer and simultaneously monitored on a storage oscilloscope. Thirty two evoked responses (1 set) were averaged following photic (2.5 Hz) pair stimuli. Seven sets of pair stimuli (50,100,150,200,300,300 and 600 msec time intervals between the pair stimuli) were recorded at 10 min intervals, in both groups of animals. In general the amplitude of the electroretinogram (ERG) in adult, postnatally undernourished rats were reduced by more than 40% (40-60%). In both control and undernourished animals complete recovery of the second response from the pair were observed at 400 msec. In conclusion, postnatal undernutrition had a lasting effect on the ERG without changing the neuronal recovery function, even after prolonged nutritional rehabilitation. (This work was supported in part by Public Health Service Grant NS-13799.)

CEREBELLUM

307 DEVELOPMENT OF CEREBELLAR REGULATION OF FORELIMB TACTILE PLACING MOVEMENTS IN KITTENS. Vahe E. Amassian, Alan Rudell and Larry Eberle* Dept. of Physiology, SUNY Downstate Medical Center, Brooklyn, N.Y. 11203.

Contact placing (CP) movements were measured with a TV camera-PDP 11/45 computer system by recording as a function of time the XY coordinates of up to 4 paper spots, which were coated with fluorescent pigment, glued to the forelimb and illuminated with UV light. CP is hypermetric (and slow) in the neonate, the displacements increasing after the first postnatal week before markedly reducing in the 6th-7th week. The trajectory of the forepaw also changes from near 45° to a more vertical-then horizantal movement, with the final component directed vertically downwards. The steepening of the initial trajectory results from the forward horizantal vector of movement during elbow flexion being compensated by posterior flexion at the shoulder and ventroflexion of the paw. Thus, with maturation, angular rotations are not only reduced in amplitude but show improved coordination at several joints. (Flexion only at the elbow would result in an arc-like trajectory.)

Lesions of intermediate and varying amounts of lateral cerebellar cortex or hemicerebellectomy after the 5th-6th postnatal week result in marked hypermetria ipsilaterally, with an immature (near 45°) trajectory. The hypermetria, but not the immature trajectory was significantly improved within 2 weeks of the lesion. By contrast, similar or larger cerebellar lesions made during the 4th and 5th weeks did not increase or trivially increased the pre-existing hypermetria. Thus, the acquisition of economical CP with improved coordination of rotation at limb joints reflects the incorporation by the 7th week of cerebellar output into the higher sensorimotor control system.

Tested after the 6th week, cooling or carefully adjusted polarization or lesions of intermediate and lateral cerebellar cortex that result in hypermetria do not usually delay the initiation of CP. The average speed of the forepaw often increases during lifting (eg, from 16 to 28 cm/sec), but may remain unchanged. EMGs of biceps and anterior deltoid show an increased activation. The final, landing phase of CP is usually slowed. By contrast, cooling N interpositus reversibly delays, or abolishes CP and activation of a prime mover-biceps. Such findings suggest N interpositus facilitates the prime movers in mature CP, an inhibitory output from cerebellar cortex preventing hypermetria.

308 INTERACTION BETWEEN SIGNALS FROM THE VESTIBULAR AND FORELIMB RECEPTORS AS RECORDED FROM PURKINJE CELLS OF THE FROG VESTIBULOCEREBELLUM. J. Amat* and R. Llinás (SPON: H. Vanegas). Dept. of Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., New York 10016.

Extracellular microelectrode recordings were obtained from Purkinje cells in the dorsal rim of the cerebellum of paralyzed frogs during natural stimulation of vestibular and forelimb receptors. In the first (or control) experiments, recordings were made during natural stimulation of the canals and otolith organs. Stimulation was applied using a specially built turntable which rotated the animal sinusoidally about the longitudinal (roll) axis. Oscillations were in the order of 20° ipsilateral side down, or ipsilateral side up, with respect to the recording site. In the second (or test) set of experiments, the roll oscillations were combined with passive forelimb movement.

In most Purkinje cells, vestibular stimulation by roll (from the horizontal plane) evoked simple spike activation in the ipsilateral down direction and discharge of a few (1 to 4) climbing fiber evoked spikes upon stimulation in the opposite direction. Selective stimulation of otolith and canal receptors demonstrated that the above responses were due to activation of the two types of receptors. When the control experiments were combined with the passive limb movement (test paradigm), the control response showed reduction or absence of the climbing fiber response in Purkinje cells recorded in the mediolateral region of the dorsal rim, and little or no change of the simple spike response.

The present results suggest that the climbing fiber input to the vestibulo-cerebellum is involved in error signalling, given that its response only occurs in the absence of the appropriate compensatory limb movement. Thus, when the body-forelimb movement of the paradigm mimicked the compensatory movement of an unrestrained animal tilting sideways, no climbing fiber response was elicited. (Supported by USPHS grant NS-13742 from NINCDS and by the CONICIT Program of Graduate Fellowships)

309 SHORT LATENCY INHIBITORY ACTION OF A PARALLEL FIBER VOLLEY UPON ACTIVATION OF PURKINJE CELLS IN THE RAT CEREBELLUM: INDIRECT EVIDENCE FOR A FIELD EFFECT INHIBITION. Herbert Axelrad* and Henri Korn. INSERM U3. CHU Pitié-Salpêtrière. Paris 13°. France.

The influence of parallel fiber volleys set up by a surface (Loc) stimulation on antidromic spike potentials of Purkinje cells (PC) evoked by a juxta fastigial (JF) stimulation was studied on the cerebellum of lightly nembutalized albino rats. Data obtained at the level of the PC layer were computed with respect to the time of arrival of the superficially recorded presynaptic volley. The test/control curve obtained by progressively delaying the intervals between stimuli by steps of no more than 200 µsec revealed that the classical phase of PC chemical inhibition attributed to the action of cortical interneurons by ECCLES, LLINAS and SASAKI (Exp. Br. Res., 1 : 17, 1966) can be preceded by an earlier phase of inhibition. This first peak, not previously reported, starts about 0.5 msec after the presynaptic volley and lasts 0.5-1.2 msec, that is until PC activation; it brings about a slight reduction of the PC antidromic field potential of 5 to 20%. Its time course, brief duration and persistence after near complete chronic deafferentation (i.e. following section of the inferior and medial cerebellar peduncles) suggest that it is generated by a mechanism other than those already described in the cerebellum. Single unit analysis revealed that part of this peak is due to collision of the antidromic spikes with those evoked by direct activation of mossy fibers collaterals. However, in the absence of collision, a weak inhibition is still present during this period. It is indicated by a delay or a block of the PC antidromic spike under different experimental conditions: occasionally when the antidromic spike is evoked by single JF stimulations, or more consistently when it occurs during the relative refractory period of PC antidromic invasion, that is either after a spontaneous discharge of the cell, or after the second shock of adequately timed paired JF stimulations. Since this inhibition a) starts with a latency which is too short to be accounted for by two synaptic delays required for a chemical inhibition mediated through cortical interneurons b) indeed occurs well before intracellularly recorded IPSPs c) is resistant to picrotoxin unlike the chemical inhibition d) and since there is a peculiar mode of termination of basket cells upon PC (SOTELO and LLINAS, J. Cell Biol., 53 : 271, 1972) this early Loc evoked inhibitory effect is most likely the consequence of a field effect exerted by basket cells on the PC initial segment in a manner similar to that described for the Teleost Mauthner cell.

310 AUDITORY CORTICAL INPUT TO THE PARAFLOCCULUS: AN ELECTROPHYSIOLOGICAL AND ANATOMICAL STUDY. S. Ausim Azizi, Richard A. Burne and Donald J. Woodward. Dept. of Physiology, Univ. TX Health Sci. Ctr., Dallas, Tx., 75235.

This study was undertaken with the general aim of investigating areas in the rat cerebellum which receive auditory information.

In this report we describe anatomical and electrophysiological evidence that the parafloculus (Pf) receives information from the auditory cortex (AC) via relays in the pontine grey (PG). The techniques of 1) electrical stimulation of discrete regions within the AC and unit recording of parafloccular Purkinje cells and 2) orthograde and retrograde transport of labeled amino acids and horseradish peroxidase (HRP), respectively, were employed to demonstrate the existence of an AC input to the Pf.

From unit recordings of 52 identified parafloccular Purkinje cells in halothane anesthetized rats, post-stimulus time histogram (PSTH) analysis of 10 cells (19.2%) showed evidence of either mixed, excitatory-inhibitory (4 cells, 40%) or pure inhibitory (6, 60%) mossy fiber input following electrical stimulation of the AC (double pulses, 0.2 ms duration, -0.05 - -0.6 mA, 1-10 Hz). The mean latencies to the onset of excitation and inhibition were 9.5 ± 3 and 14 ± 2.4 ms, respectively. Climbing fiber input responses were not elicited with cortical stimulation.

Following hydraulic injections (0.1-0.2 ul) of tritiated leucine (77 uCi/ul) in the AC , autoradiographic labeling representing terminal fields were observed as a column of silver grains oriented dorsoventrally under the cerebral peduncle and extending through the lateral region of the middle pons. Placements of HRP in the Pf resulted in labeled cells in the lateral area of the PG, corresponding to the lateral region of AC afferents. This anatomical finding further supports the concept of a cerebro-ponto-cerebellar pathway as defined electrophysiologically.

Our previous studies have described a visual input to the Pf. The results of the present study also demonstrate an input from the AC, which indicates that the integration of auditory and visual information by the cerebellum is carried out at least by two areas- the well known classical posterior vermal region and the Pf. (Supported by NSF BNS 77-01174 and a grant from the Biological Humanics Foundation to DJW)

311 EXCITABILITY CHANGES OF NEURONS IN THE CEREBELLAR NUCLEI FOLLOWING CEREBELLAR SURFACE STIMULATION. Heinrich Bantli, Earl Wagor and Carl R. Hansen, Jr.* Dept. Neurosurg., Univ. Minnesota, Minneapolis, MN 55455

Electrical stimuli applied to the cerebellar surface have been proposed by some investigators to activate Purkinje cells resulting in the inhibition of neuronal activity in the cerebellar nuclei. The present experiments were undertaken to evaluate this hypothesis by recording the activity of neurons in the dentate and interposed nuclei in decerebrate cats before, during and after stimulation of the cerebellar surface. Several criteria were established to assess the level of excitability of neurons before starting the stimulation paradigm. If no decrease in excitability was observed in the PSTH when either the inferior olive, face or forelimb were stimulated, then no records were obtained from the particular cell. If several consecutive cells did not demonstrate any excitability decrease, then the experiment was terminated. The cerebellum was stimulated with capacitively coupled pulses applied with bipolar platinum plates (7.6 mm^2) placed on the surface of Crus I and II. The pulse width was 0.1-0.3 msec. and the amplitudes varied from 2-12 ma and the frequency from 10, 50, 100, 150 to 200/sec. The stimulus paradigm consisted of sequential 10 minute recording and stimulation periods for as long as the cell was isolated. Each 10 minute sequence was divided into 10 recording intervals of one minute duration. The neural spike train of each interval was stored as interval histograms on the PDP 11/34. The data was obtained from 63 neurons recorded from 56 cats representing a total of 256 stimulation and 320 recording periods. The analysis included a statistical evaluation of the interval histograms and changes in the mean firing rate between stimulation and control sequences. Based on the analysis the following conclusions were possible: 1) Many cells showed significant increases or decreases in excitability. 2) These excitability changes may be frequency or amplitude dependent for a particular cell but no correlation was observed when the entire cell population was considered. 3) All cells were modulated by the cerebellar surface stimuli as determined by inspection of PSTH although the statistical tests might not have shown significant changes between stimulation and control sequences. 4) Rebound phenomena were often observed. (Supported by NIH Contract NO1-NS-4-2332.)

312 RAPHE STIMULATION MODULATES EXCITATORY AND INHIBITORY PROCESSES IN THE CEREBELLUM. Charles D. Barnes, Jean C. Strahlendorf, and Howard K. Strahlendorf. Dept. Physiology, Texas Tech Univ. Sch. of Med., Lubbock, TX 79430.

It is becoming increasingly evident that norepinephrine may modulate excitatory and inhibitory processes in the cerebellum (Hoffer et al., 1978). Anatomical studies indicate similarities in the raphe (R) and locus coeruleus (LC) terminations within the various layers of the cerebellar cortex (Chan-Palay, 1978). Furthermore, stimulation of the R complex and LC predominately inhibit spontaneous firing of randomly encountered Purkinje cells. We have compared the effects of raphe stimulation upon spontaneous and evoked climbing and mossy fiber inputs, as well as GABA-mediated inhibition of Purkinje cells.

Glass micropipettes were used for extracellular recordings of Purkinje cells in α-chloralose anesthetized, flaxedilized, and artificially ventilated cats. Stimulation of the ipsilateral superficial radial nerve and contralateral sensorimotor cortex elicited mossy and climbing fiber discharges, respectively. "Off beam" inhibition was induced by stimulation of the superficial layers of the cerebellar cortex adjacent to the recording electrode. Evoked simple spike activity decreased after R conditioning from 3.8 to 0.6 spikes/stimulus representing an 81% change (average of 20 Purkinje cells) in comparison to a 62% decrease in spontaneous activity for a similar time period. With reference to evoked activity elicited via sensorimotor cortex stimulation, complex spike activity fell from 3.7 to 1.3 spikes/stimulus, representing a 77% change (average of 9 Purkinje cells) in comparison to a 67% decrease in spontaneous activity following R stimulation. Conditioning shocks to the R produced a marked augmentation of "off beam" inhibition at stimulus strengths (< 50μa) which failed to alter spontaneous firing patterns of Purkinje cells. Six cells sampled showed a 47% increase in the duration of "off beam" inhibition when central inferior raphe was stimulated; whereas, the maximal change in spontaneous firing failed to exceed 18%. These findings correlate with the potentiating effect of diazepam (0.1-1.0 mg/kg, i.v.) on R-induced inhibition of Purkinje cells. Diazepam enhanced the inhibition observed on Purkinje cells after R stimulation by 41% (N=4). Accordingly, bicuculline (0.01-0.1 mg/kg, i.v.) reversed the diazepam augmentation and given alone, diminished R elicited inhibition of Purkinje cells by 21% (N=6). The findings reveal a preferential inhibitory influence of the raphe nuclei on evoked simple and complex activity rather than spontaneous firing of Purkinje cells. Furthermore, the R appears to augment GABAergic "off beam" inhibition of Purkinje cells. (Supported in part by NIH Grant HL 7289).

313 DIFFERENT RECEPTORS FOR GABA AND MUSCIMOL IN THE RAT CEREBELLUM. G. Biggio*, M.G. Corda*, G. De Montis*, and G.L. Gessa* (SPON: G. Toffano). Institute of Pharmacology, University of Cagliari, Italy.

Kainic acid, handling and haloperidol were used in order to differentiate the specific receptors for GABA and muscimol in the rat cerebellum:

a) kainic acid (4 μg), microinjected into the cerebellar cortex, within 4 days decreased by 70% the number of specific binding sites for muscimol. On the other hand kainic acid markedly increased the receptor affinity for ^{3}H-GABA; this effect was associated with the almost complete disappearance of the endogenous inhibitor of GABA binding.

b) Differences in the number of specific binding sites for muscimol and GABA were present in the cerebellar cortical membranes obtained from naive rats and from rats habituated (for 15 days) to the handling maneuvers preceeding the sacrifice. Naive rats showed higher binding for ^{3}H-muscimol but lower binding for ^{3}H-GABA than habituated rats.

c) The acute administration of haloperidol (4mg kg^{-1}) decreased ^{3}H-GABA binding but increased that of ^{3}H-muscimol.

The results suggest that:

a) different receptors for GABA and muscimol are present in the rat cerebellum.

b) Receptors for muscimol are localized on neuronal structures sensitive to kainic acid while GABA receptors are localized on structures resistant to the toxic action of this drug.

c) Stress due to handling causes a sudden change in GABA binding, opposite to that of muscimol.

314 EMG AND COMPLEX SPIKE CHANGES DURING COOLING OF THE INFERIOR OLIVE[1]. V.B. Brooks, P.R. Kennedy[2], and H.-G. Ross[3], Dept. Physiol., Univ. of Western Ontario, London, Canada N6A 5C1.

Flexible cooling probe sheaths were chronically implanted just above the rostral end of the inferior olive (IO) with X-ray assisted stereotaxy (4) in 2 Fascicularis monkeys. Postoperative neurological signs receded in intensity after a few days, and were referable to tissue damage in the path of the implant. These were: ataxia of trunk and head (but never the limbs); neck deviation to the implanted side; ipsilateral facial palsy; vert. and horiz. nystagmus of both eyes; and ipsilateral ptosis and miosis. Cooling of IO for a few min, to a sheath tip temperature of 10°C or below, reduced firing frequency of spontaneous complex spikes (CS) of Purkinje cells in contralat. intermed. cerebellar cortex, as tested in one monkey (F2). Cooling IO occasionally reduced the number of repetitive CS discharges (wavelets) without diminution of amplitude of the initial spike, suggesting that wavelets are of olivary origin. The 20°C isotherm line delineated an area 5 mm in diameter and extended 2 mm forward from the tip at 10°C, and 3 mm forward at 5°C tip temp. Cooling accentuated nystagmus and ptosis, and caused fast tremor of the jaw and tongue. Accuracy of free reaching and grasping seemed unimpaired, as might be anticipated from results of partial rostral olivary lesions (5). The main finding, below, is more likely to be due to cooling IO rather than, e.g., the nearby n. reticularis gigantocellularis which would be expected to produce the opposite effect (6). During IO-cooling at tip temps tested (15°-5°C) biceps EMG responses to stretch increased while triceps EMG decreased or remained unchanged. This applied to tonic and phasic EMG in the anesthetized monkey (F2: Valium or Ketamine); but only to a lesser degree when awake and performing the Gilbert-Thach paradigm (7) at fixed load levels. The EMG increases seem to have been imposed by IO-cooling. In the awake monkey they coincided with disturbed task performance, consisting of fewer successes and less accurate return and holding of the handle with regard to the target.

315 THE PARAFLOCCULUS: A POSSIBLE ROLE IN HEAD-EYE ORIENTATION. Richard A. Burne and Donald J. Woodward. Dept. of Cell Bio., Univ. Tx. Health Sci. Ctr., Dallas, Tx., 75235.

Previously we presented anatomical and electrophysiological evidence demonstrating that the paraflocculus is a cerebellar target zone for visual cortical and tectal inputs. As part of the general aim of determining the functional significance of the parafloccular visual input, this study was undertaken to further clarify the diverse anatomical connections of the paraflocculus. In this report we describe anatomical evidence on 1) the sites of origin of additional afferent inputs to the paraflocculus and 2) the terminal field distributions of the efferent projection from the parafloccular lobule of the rat cerebellum.

Following electrophoretic injections (1 μA, 20 min) of a 4% HRP-Tris buffer solution (pH 8.6) into the parafloccular lobule and reaction with tetramethyl benzidine, HRP-labeled afferent neurons were observed 1) bilaterally in the lateral cuneate nucleus, prepositus hypoglossal nucleus, locus coeruleus (ipsilateral preponderance), pontine reticular tegmental nucleus and the basilar pontine grey (contralateral predominance), 2) in the contralateral medial accessory and principal olives, and 3) in the ipsilateral spinal nucleus of V and the cerebellar dentate nucleus. No HRP-positive cells were localized in the vestibular ganglion or nuclei. Of these sources, the largest afferent projection to the paraflocculus originates from the lateral pontine grey; the same pontine region that receives efferents from the visual and auditory cortices and superior colliculus.

Hydraulic injections (0.15-0.25 μl) of ^{3}H-leucine (77 μCi/μl) into the paraflocculus resulted in efferent terminal labeling over specific regions of the ipsilateral dentate and interpositus nuclei of the cerebellum. Autoradiographic silver grains were primarily localized over the ventral-caudal region of the large cell subdivision in the lateral nucleus, and over the small and large cell subdivisions of the ventral-caudal interpositus nucleus; regions previously implicated in head-eye movement control. No grain accumulations were seen in the vestibular or other brainstem nuclei.

These results support ongoing electrophysiological studies that demonstrate Purkinje cell responses in the paraflocculus to visual stimuli with specificity to orientation, position and velocity of movement.

The afferent-efferent connections of the paraflocculus, as described here, suggest a possible role in the mechanisms underlying head-eye orientation in visual space rather than involvement with vestibulo-motor integrations.

(Supported by NSF BNS 77-01174 and a grant from the Biological Humanics Found. to DJW.)

316 THE ACTIVITY OF DENTATE NUCLEUS AND Y-GROUP NEURONS IS RELATED TO HEAD AND EYE VELOCITY. M. Carroll Chubb* and Albert F.Fuchs Dept. Physiology and Biophysics, University of Washington,Seattle WA 98195.

The dentate nucleus of the cerebellum and the y-group of the vestibular nuclear complex have been shown to project to vertical eye movement nuclei in the midbrain, including parts of the oculomotor nuclei innervating vertical eye muscles. To investigate the role of the dentate and the y-group in vertical eye movements, neuron activity was recorded from these areas in alert rhesus monkeys trained to track a smoothly moving visual target while undergoing sinusoidal whole body rotation. The relation between unit activity and either head or eye position was determined by averaging 10 cycles of unit activity, fitting the average with the least square sine curve, and calculating its amplitude and phase relative to head and eye position. In the rostral dentate nucleus, the y-group and the adjacent areas just rostral to the dentate nucleus, the activity of some neurons was related to angular velocity of the head and eyes. When the stationary monkey tracked a target moving sinusoidally in the saggital plane these neurons fired approximately in phase with upward eye velocity. The activity of 15 units thus far analyzed during a peak to peak target excursion of 24 degrees at 0.5 Hz lagged upward target velocity by 6.7 $\pm$ 10.5 deg. When the monkey was rotated sinusoidally in the saggital plane while he tracked a spot moving with him so that his eyes did not move in his head, these units fired approximately in phase with upward head velocity. The activity of 16 units thus far analyzed during a peak to peak head movement of 20 degrees at 0.5 Hz lagged upward head velocity by 15.5 $\pm$ 4.3 deg. During smooth pursuit eye movement and during head rotation in the absence of eye movements, the sensitivity of these neurons to head and eye velocity (ie. the ratio of the amplitude of the modulation in unit firing rate to amplitude of the sinusoidal variation in head or eye velocity) remained constant over a range of frequencies from 0.3 to 1.0 Hz. Therefore, both the phase and sensitivity reflect a relationship of unit activity to head and eye velocity. For most units the sensitivities to head and eye velocity were nearly the same so that when the head and eyes moved the same amount in opposite directions, as when the rotating animal fixated a target stationary in space, the unit activity showed little or no modulation. During saccadic eye movements in all directions most of these cells fired a burst of action potentials. Therefore, the discharges of these units in the dentate nucleus and y-group are similar to those of flocculus Purkinje cells (Lisberger and Fuchs, 1979) and may have a role in modifying the vertical vestibulo-ocular reflex.

317 TOPOGRAPHY OF THE OLIVO-CEREBELLAR PROJECTION STUDIED BY A RADIOACTIVE TRACER METHOD. Jacques Courville and F. Faraco-Cantin. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal.

Injections of ^{3}H-L-leucine (vols: 0.2-0.5 μl; conc.: 75-100 μC/μl) in different regions of the inferior olive in the cat were used to demonstrate the topography of olivo-cerebellar climbing fibers. Taking advantage of the complete crossing of this projection, bilateral injections were utilized. It was thus demonstrated in the same animals that complementary injections of the olive correspond to projections to entirely distinct cerebellar regions. This organization observed throughout the material indicates that there is no convergence to any cerebellar cortical region from different olivary origins. On the other hand, small localized injections of the olive demonstrate extensive projection areas distributed at right angles to the longitudinal axes of the folia. This indicates a great deal of divergence in the olivo-cerebellar distribution. A general organization of the olivo-cerebellar projection was recognized. The caudal third of the olive corresponds to vermal regions and to the flocculus. The middle third of the olive only projects to the intermediate and lateral parts of the first four lobules and to the paramedian lobule. The intermediate and lateral portions of lobules V and VI and most of the crura are projected upon from the rostral two thirds of the olive. Lateralmost portions of the crura receive projections from the rostral third, only. More specifically, the caudal medial accessory olive (MAO) projects to a sagittal strip of cortex located next to the midline, in all ten lobules. In the anterior lobe, from medial to lateral, four additional sagittal projections are found: 1) the dorsal accessory olive (DAO); 2) the MAO; 3) the DAO again and 4) the principal olive (PO). In the posterior lobe lobules VIII and IX, additional sagittal projections from the DAO and rostral MAO were seen next to the midline MAO distribution. No clear data were obtained for lobule VII. In the paramedian lobule, there are three sagittally arranged strips of projection. From medial to lateral, they come from the DAO, MAO and PO. The crura receive projections from the MAO and DAO medially and from the PO, laterally. The paraflocculus receives its projections from the MAO and PO.

318 A COMPARISON OF THE RESPONSES OF MOSSY FIBERS AND PURKINJE CELLS TO TIME-VARIANT CUTANEOUS INPUTS. Timothy J. Ebner*, Teresa McMullen*,and James R. Bloedel (SPON: F. Torres). Dept. Neurosurg.,Univ. Minn., Minneapolis, MN 55455.

Experiments were performed in decerebrate unanesthetized cats to examine and compare the gain (sensitivity) and band-pass characteristics of the responses of mossy fiber afferents and Purkinje cells to natural cutaneous stimuli. The input signal consisted of a sinusoidal indentation of the skin in the animal's paw or forearm. The activity of Purkinje cells, identified by the presence of spontaneous climbing fiber activity, was recorded extracellularly from the ipsilateral anterior lobe of the cerebellar cortex. The responses of mossy fiber afferents were recorded in the same folia. Cycle histograms were constructed from the activity of both types of units to a wide range of input amplitudes and frequencies. The findings were twofold. First, the mossy fiber afferents were very sensitive to the cutaneous stimuli, being responsive to indentation from 75μ to 200μ peak to peak. In contrast, the activity of Purkinje cells proved to be very difficult to modulate by a continuously applied cutaneous input. In fact, the cycle histograms of most Purkinje cells did not exhibit any modulation. For units which did respond, their sensitivity to the stimulus was much less than that of mossy fibers. Second, the band-pass of the mossy fiber afferents to the modulated indentation of the skin was very wide, ranging from at least 1-100 Hz. In contrast, the responses of Purkinje cells which were modulated by the stimulus had a considerably narrower band-pass. Most cells were only modulated over a range of approximately 5 Hz. This range was usually centered around frequencies of 10-15 Hz. In conclusion, these studies demonstrate that the cerebellar cortex receives information through the mossy fiber afferents about the amplitude and frequency of time-variant, deterministic cutaneous input. However, the responses of Purkinje cells displayed considerable attenuation and filtering of the input signal. This filtering resulted in responses only over a very narrow range of frequencies. It is suggested that the processing of cutaneous information in the cerebellar cortex does not involve the modulation of Purkinje cell impulse activity over the same wide range of frequencies to which the input of this structure is modulated. 319 ALTERATIONS IN CORTICAL LAYERING SURROUNDING CEREBELLAR FISSURA PRIMA. M. A. E. Eriksson, W. S. T. Griffin, N. Stampfer*, M. del Cerro and D. J. Woodward. The University of Texas Health Science Center at Dallas, Dallas, Texas 75235 and The University of Rochester School of Medicine and Denistry, Rochester, New York 14623.

The three-layered appearance of the adult rat cerebellar cortex as it surrounds each lobule is well documented from pial surface to arbor vitae as pial cell layer, molecular layer, Purkinje cell layer and internal granular layer. However, we have regularly observed alterations in this three-layered arrangement of cortex surrounding fissura prima in adult rats, as well as in neonatal rats where the external granular layer is still present, adding a fourth layer. In 80 of 100 rat brains analyzed, the cortical layers surrounding fissura prima were found to be altered from the four (neonatal) or three-layered (adult) arrangement found in the majority of the remainder of cerebellar cortex. This common alteration extends long distances on either side of the midline causing fissura prima to become more and more shallow from its lateral to medial extent. In sagittal sections at the lateral edge of the alteration in neonatal cerebellum, the external granular layer and pial cells disappear leaving an expanse of molecular layer lying between internal granular layer cells of lobules V and VI. Proceeding medially toward the midsagittal section, the cells of the internal granular layer of lobules V and VI are situated closer together and often merge. In such sections Purkinje cells do not usually remain in a monolayer, but are displaced: sometimes clusters of these cells are found within the arbor vitae. Various complex configurations of internal granular layer, molecular layer, and Purkinje cell groups surrounding fissura prima were common place in regions of cerebellum as far lateral as 320 microns on either side of midsagittal. The greatest dorsoventral extent of such alterations measured was 400 microns. Although this work was an analysis of cerebella from unstressed control animals, we have regularly observed altered layering patterns in cerebella from animals with induced environmental stresses applied during cerebellar development. Therefore, analyses of structural changes in cerebellar cortical layers resulting from applied stresses should take into account the normally occurring alteration in layering patterns reported here.

320 GRANULE CELL DEGENERATION IN THE CEREBELLUM OF THE PURKINJE CELL DEGENERATION (pcd) MUTANT MOUSE. B. Ghetti, C. J. Alyea*, J. Muller*. Dept. Pathology, Div. Neuropath., Indiana University School of Medicine, Indianapolis, IN. 46223, USA.

The pcd mutation in mice is autosomal recessive. Homozygotes will at first show normal cerebellar development; only in adolescence do the Purkinje cells start to degenerate rather abruptly. Due to the severe neurological impairment, the mortality of mutants is high after the 1st year of age; only few animals survive beyond 16 months.

A longitudinal histological and ultrastructural investigation was conducted to analyze the degeneration of the Purkinje cells and the events following their disappearance. 36 affected and 25 normal littermates were used, 17 to 591 days old.

Before the onset of degeneration, the Purkinje cells show fewer cisterns of rough endoplasmic reticulum and a basal polysomal mass. By the 17th day of age many Purkinje cell dendrites contain a floccular material and osmiophilic bodies. Between 17 and 23 days numerous Purkinje cell axons have lost their organelles and the axon terminals contain dilated tubular cisterns and clusters of synaptic vesicles of uneven size. The Purkinje cells and their processes become dark, fragmented and are removed by glia over a period of several months.

In three month old mutants scattered degenerating granule cells are seen. At age six months, although the molecular layer is reduced to half the original thickness due to the loss of Purkinje cell dendrites, the parallel fibers do not seem to be reduced in number. The majority of the endings of both the parallel and the climbing fibers have lost their post-synaptic dendrites and are apposed to glial profiles. In mutants aged between 6 and 12 months numerous granule cells have an osmiophilic, pyknotic nucleus, dense homogeneous cytoplasm and have lost their cytoplasmic organelles. Between 12 and 19 months the granule cell layer becomes progressively more depleted of nerve cells and architecturally disorganized; the molecular layer is reduced to one third due to the sequential loss of Purkinje cells and parallel fibers. Whorls of glial processes replace the degenerated elements of the neuropil. In the disorganized granule cell layer, mossy endings remain, but many are deprived of their post-synaptic dendrites. Numerous mossy fibers have fewer synaptic vesicles and these are uneven in size.

321 QUANTITATIVE ANALYSIS OF STAGGERER ↔ WILD-TYPE CHIMERAS: FURTHER IMPLICATIONS FOR GENE ACTION AND NORMAL CEREBELLAR DEVELOPMENT. Karl Herrup and Richard J. Mullen*. Dept. Human Genetics, Yale Med. Sch., New Haven, CT and Dept. Neuroscience Children's Hosp. Med. Center, Boston, MA.

Staggerer (sg) is one of more than a dozen neurological mutants in mice which affects cerebellar structure and development. The cerebellum is smaller and less foliated than the wild-type. There is a virtually complete loss of granule cells, an absence of almost 75% of the medium-to-large cortical neurons (MLNs) and there are cytological aberrations in those MLNs which remain. Examination of staggerer ↔ wild-type chimeras revealed that all of the aberrations of the sg/sg MLNs visible in the light microscope were intrinsic to the MLN and not caused by external agents or factors (Herrup and Mullen, Brain Res., in press). These defects included small size, ectopic location and regional variation in cytology. While qualitatively it appeared as though the phenotype of reduced numbers was also expressed in the chimera, we undertook the current study to quantitate this impression. Counts were made on selected sections from 2 serially sectioned chimeric half cerebella stained for β-glucuronidase to allow distinction of sg/sg genotype cells independently of their phenotype (Ibid). The number of staggerer MLNs in the chimera (sgχ MLNs) was less than the number of MLNs in a staggerer homozygote (sg/sg MLNs) and the number of wild-type MLNs in the chimera (+χ MLNs) was less than the number of MLNs in the homozygous wild-type (+/+ MLNs). The relative numbers were such that if the number of sgχ MLNs was N% of the number of sg/sg MLNs, the number of +χ MLNs was (100-N)% of the number of +/+ MLNs. Expressed differently:

$$\frac{\text{sg}\chi \text{ MLNs}}{\text{sg/sg MLNs}} + \frac{+\chi \text{ MLNs}}{+/+ \text{ MLNs}} = 1.$$

For example, in one chimera, there were approximately 46,000 sgχ MLNs and 77,000 +χ MLNs. This compares with 66,000 MLNs in sg/sg and 243,000 MLNs in +/+ homozygotes. Thus, in terms of strict percentages, about 63% of the MLNs in the chimera were +/+. However, in terms of what we might call the original MLN pool, it appears that only 32% of the cells were +/+. This finding has two facets, both of which have important developmental implications. First, despite the presence of a relatively normal physiological and cytoarchitectonic environment sgχ MLNs were still reduced in number compared to wild-type. Second, despite the absence of many of their neighbors, the +χ MLNs were seemingly unable to compensate significantly by increasing their own numbers. The results will be discussed in terms of the timing of the action of the sg gene product. Supported by Nat. Fndn-March of Dimes, Basil O'Connor Grant and NIH Grant #HD 12213-01.

322 DETERMINATION OF POSTSYNAPTIC MEMBRANE STRUCTURE IS INTRINSIC TO THE PURKINJE CELL. Dean E. Hillman and Suzanne Chen*. Dept. of Physiol. & Biophys., New York Univ. Med. Ctr., New York 10016.

A fundamental question in understanding the developmental organization of the nervous system is whether the extent of postsynaptic specialization is determined by afferent connections or intrinsically determined by the postsynaptic cell. A reduction in granule cell number follows administration of malnourished diets during postnatal development (Winick & Noble, J. Nutrition 89: 300, 1966). Here we show that in the malnourished female the number of synaptic contacts on each Purkinje cell is also reduced; however, the total synaptic contact area remained constant for each cell. An 8% protein diet with calories equal to a 25% control diet was fed to rat dams. Sixty-day-old female offspring had an average total reduction in number of granule cells in excess of 26% while granule cells of males were decreased by only 13% as compared to their respective controls. At the same time, total Purkinje cell numbers remained unchanged in both sexes. Quantitation of molecular layer volume and synaptic density indicated that total number of spine synapses in cerebellum of males was unchanged while in the female it was reduced as much as 18%. Thus, the male Purkinje cell-parallel fiber synapses were completely compensated by an increase in synaptic sites on parallel fibers of granule cells. The females also compensated but had a residual deficit of about 18% fewer spine synaptic contacts than controls or malnourished males. Severely affected females displayed giant spines and attained a synaptic deficit greater than 30%. Electron microscopical quantitation of the spine-synaptic contact length for controls, experimental males, and experimental females with and without giant spines showed that the area of postsynaptic thickening on spine processes increased inversely with the number of Purkinje cell-parallel fiber synapses. The average synaptic contact area in males was unchanged while the females had an area increase of 17%. In severely affected females which displayed giant spines, this average area was over 30%. We conclude that (1) the total postsynaptic specialization area on each Purkinje cell remains constant following various degrees of afferent deficit, (2) postsynaptic specialization-macromolecules distribute to available parallel fiber synaptic sites, and (3) Purkinje cell spines can synaptically compensate in number up to 13% when afferents are reduced. The constancy of total spine postsynaptic area on each Purkinje cell indicates that postsynaptic junctional macromolecules must be predetermined by the Purkinje cell (presumably through the genome) and thus serve as one of the parameters that establish fundamental neuronal organization in the cerebellum. (Supported by USPHS grant HD-10934 from NICHD.)

323 TOPOGRAPHY OF PROJECTIONS FROM SENSORIMOTOR CORTEX, RED NUCLEUS, CEREBELLUM AND SPINAL CORD TO THE LATERAL RETICULAR NUCLEUS IN THE CAT. Alan W. Hrycyshyn* and Brian A. Flumerfelt. Department of Anatomy, University of Western Ontario, London, Canada.

Using autoradiographic, silver impregnation and horseradish peroxidase (HRP) tracing methods, the topographic organization of the projections to the lateral reticular nucleus (LRN) was investigated in the cat. Initially, the origins of the afferent projections were studied following injection of 20% HRP into the LRN and subsequently reacting the tissue with the chromagen benzidine dihydrochloride. Serial sections throughout the brain and spinal cord were examined for the presence of HRP-labelled neurons. The results were then mapped using an X - Y plotter. Labelled cells were found mainly within Rexed's laminae IV through VIII of the spinal cord, the anterior sigmoid and coronal gyri of the sensorimotor cortex, the caudal three quarters of the red nucleus and the ventral aspect of the fastigial nucleus. The topography of these projections within the LRN was next investigated using anterograde methods. Injections of a mixture of [^{3}H] - leucine and [^{3}H] - proline, or [^{3}H] - leucine alone were placed within pericruciate cortex, red nucleus and fastigial nucleus. After survival times of 3 - 7 days, the animals were perfused, and then frozen sections through the LRN and the injection site were processed for autoradiography. In a corresponding series of animals, electrolytic lesions were placed selectively into the above sources of reticular afferents, and degeneration within the LRN was demonstrated with the method of Fink and Heimer. An extensive input from the spinal cord was found to terminate predominantly on the ipsilateral side throughout the entire rostro-caudal extent of the LRN, except for a small rostromedial area in the magnocellular portion. The cortical projection terminated diffusely within the rostral aspect of the contralateral magnocellular part of the nucleus. The projection from the red nucleus terminated extensively within the contralateral subtrigeminal portion and the dorsolateral region of the rostral magnocellular portion of the LRN. The fastigial nucleus was found to give rise to a sparse contralateral projection, mainly to the medial aspect of the rostral extent of the magnocellular portion, with less to the parvocellular and subtrigeminal portions.

The LRN therefore receives spinal and supraspinal projections that terminate within specific areas of the nucleus in a partially overlapping fashion. This pattern of input allows for an extensive integration of converging impulses from two or more afferent centres within each of the subdivisions of LRN.

324 SUPERIOR COLLICULUS PROJECTIONS TO TACTILE AREAS OF RAT CEREBELLAR HEMISPHERES. Jeffrey J. Kassel. Dept. of Neurophysiology, Univ. Wisconsin, Madison, WI 53706.

The spatial organization of the projections of the superior colliculus to the contralateral cerebellar hemisphere and posterior vermis was examined using micromapping techniques in barbiturate-anesthetized rats. Using two independent, ball-tip, tungsten microelectrodes, multiple unit clusters were recorded from tactile areas in the stratum griseum intermediale of the superior colliculus (SC) and the granule cell (GC) layer of cerebellar cortex. The receptive fields of both areas were defined by threshold mechanical stimulation of cutaneous tissues. Electrical stimulation (monopolar, biphasic pulses; 10-40 μa; 2/sec) through the SC electrode evoked responses in limited regions of the contralateral GC layer of cerebellar cortex. In most experiments, the SC stimulating electrode remained stationary while the cerebellar electrode was used to map the region of the GC layer activated by SC stimulation. In a few experiments, the cerebellar recording electrode remained fixed while the SC electrode mapped the area of effective stimulation. Puncture densities up to 75/mm^2 were necessary to fully determine the spatial pattern of these projections.

Major results are: (1) Cerebellar responses to SC stimulation are found in the GC layer of contralateral Crus I and the paramedian lobule; no responses have been seen in the uvula. (2) Peripheral receptive fields of the interconnected SC and GC loci include primarily facial structures (especially vibrissae, crown and eyelid). (3) SC sources project only within the confines of GC patches (defined by Shambes et al., BBE 15: 94-140, 1978) with homologous receptive fields. (4) Latencies of GC layer activation following SC stimulation are typically 3.0 - 3.5 msec.

326 *THE ONTOGENY OF THE INFERIOR OLIVARY COMPLEX IN THE OPOSSUM.* *J.S. King, B.E. Maley and G.F. Martin: Dept. of Anatomy, Ohio State University, Columbus, Ohio 43210*

The inferior olivary complex of the opossum is first recognizable in Nissl preparations on pouch day three (15-16 days after conception). However, the nuclear subdivisions are not distinct until pouch day twenty-one (33-34 days after conception). By this latter time olivary axons from the spinal cord, midbrain and deep cerebellar nuclei have reached their respective nuclear targets. These olivopetal systems have been identified by the Fink-Schneider method subsequent to either midthoracic transections or metencephalic hemisections. The latter lesion interrupts both the midbrain-olivary and cerebello-olivary afferents on the side of the lesion and the cerebello-olivary axons on the contralateral side. Examination of the olivary complex in unoperated animals with the electron microscope at the same age reveals that many fine structural features characteristic of the adult are not present. For example the spiny appendages localized within synaptic clusters, (glomeruli) which are the primary targets of midbrain and cerebellar axons, are not evident. Golgi impregnations confirm the lack of spiny appendages at this age. The developing neuropil is characterized by small diameter neurites which contain microtubules, beaded dendrites and immature axodendritic synaptic profiles. Synaptic junctions are present, but the presynaptic profiles are only sparsely populated with synaptic vesicles.

It is not until pouch day 60 (72-73 days after conception) that electron micrographs show synaptic clusters with features comparable to those seen in the adult. Gap junctions also are evident in animals of this age. These results suggest that immature axons reach their nuclear targets prior to the development of their postsynaptic excresences which are characterestic of the adult animal. When compared to the rat (Altman and Bayer '78, J.C.N. 179:49), the time frame (pouch day 3 to day 60) for olivary differentiation in the opossum appears to be much longer.

327 SYNAPTIC ALTERATIONS IN THE CEREBELLAR NUCLEI OF QUAKING MICE. Donna L. Koniecki* and Victor L. Friedrich, Jr. (SPON: J. S. Cowen). Dept. of Biobehavioral Sciences, University of Connecticut, Storrs, Ct. 06268.

In addition to the widespread deficit of myelin in quaking mice, axons in the cerebellar white matter exhibit focal swellings up to 10 µm in diameter (Suzuki & Zagoren). Here we report abnormalities in the ultrastructure of synaptic terminals in the cerebellar nuclei of 40 to 330d old quaking mice.

Synaptic terminals in control mice resemble those in the rat (Chan-Palay). Synapses in quaking mice share essential features with those of the control mice; however, many boutons show dystrophic alterations --- including enlargement of the terminals; increased content of mitochondria, also often enlarged; membrane whorls; and excessive numbers of synaptic vesicles.

In addition to the apparently normal synaptic vesicles, many endings contain dense clumps of very small (150-250 Å) vesicles which may be abnormal synaptic vesicles. These are seen both in profiles which are otherwise unremarkable and in profiles with the dystrophic changes described above. The affected boutons maintain their synaptic adhesions with the normal range of postsynaptic sites --- i.e., somata and dendrites.

To assess the possible loss of synapses, we measured the fraction of surface of neuronal somata in the medial cerebellar nucleus apposed to synaptic boutons; this was not reduced in quaking mice. Thus, net loss of synapses does not occur and degeneration of terminals (if it occurs at all) is followed by replacement.

We believe that the majority and perhaps all of the dystrophic terminals and those with vesicle clumps belong to Purkinje cells. Many altered profiles closely resemble Purkinje cell boutons of normal mice (moderately dense ground substance, characteristic cisternae of ER, and characteristic vesicle shapes). In addition we find the vesicle clumps and other changes in the superior and lateral vestibular nuclei and in the infra-ganglionic plexus of cerebellar cortex, where Purkinje cell axons are known to terminate. Finally, mossy and climbing fibers in the cerebellar cortex were not seen to be affected.

The relationship between the deficit of myelin and the axonal and synaptic abnormalities is moot; however, the behavioral symptoms of quaking mice might derive, at least in part, from abnormalities within neurons rather than from defective myelination.

The clumps of small vesicles found in the mutant are to our knowledge unique and may signal an altered life cycle of synaptic vesicles.

328 SUBSTANCE P-LIKE IMMUNOREACTIVITY IN CEREBELLAR MOSSY FIBERS AND TERMINALS IN THE TURTLE. Gary E. Korte*, Antonj Reiner , and Harvey Karten. Dept. of Psychiatry and Behavioral Sciences ,Health Sciences Center , SUNY,Stony Brook,N.Y. 11794

Using immunohistochemical methods , we have identified a population of mossy fibers and terminals which contain substance P-like immunoreactive material (SP in the cerebellar cortex of the red-eared turtle , Chrysemys scripta elegans. The identification of the SP+ profiles is based on their exclusive location in the granule cell layer and their similarity to golgi impregnated mossy fibers and terminals. The SP+ profiles are not found in control sections treated with antisera blocked by addition of synthetic substance or in sections stained for enkephalin-like immunoreactivity.

The greatest number of SP+ mossy fibers and terminals are found in the rostral cerebellum , at levels where the cerebellum is attached to the brainstem. In this region , the lateral parts of the cerebellar cortex contain the greatest number of SP+ mossy fibers and terminals. Their numbers taper off sharply in more caudal sections. Although the cells of origin were not readily apparent , the axons of the SP+ mossy fibers could be traced into the cerebellum from a distinct fascicle of fibers located on the dorso-lateral surface of the medulla. Some fibers also enter from the periventricular region of the fourth ventricle. In the cerebellum , they course sagittally through the granule cell layer as parallel arrays.

This observation provides further evidence that cerebellar mossy fibers are histochemically heterogenous (eg. Hunt and Schmidt,1978) . More broadly , it supports suggestions that there are histochemical differences among the members of the several morphologically similar classes of neurons and afferents which make up the cerebellar cortex(Sar et-al,1978).

329 AN AUTORADIOGRAPHIC ULTRASTRUCTURAL IDENTIFICATION OF TERMINALS OF CEREBELLAR NUCLEOCORTICAL FIBERS IN THE CAT. K. Kultas-Ilinsky, D.L. Tolbert, and I.A. Ilinsky. Coates EM and Murphy Neuroanat. Res. Labs., Depts. Anat. and Surg., Sch. Med., St. Louis U., St. Louis, MO 63104.

The cerebellar nucleocortical projection has been identified in a number of different laboratory animals. From ^{3}H-leucine injections in the cat and monkey cerebellar nuclei, orthogradely labeled nucleocortical axons could be followed into the granular layer of the cortex where they appeared at the light microscopic level to terminate within cerebellar glomeruli (Tolbert et al., Neurosci. 1:205, 1976; Exp. Brain Res. 30:425, 1977). To confirm these light microscopic observations EM autoradiographic experiments were undertaken following injections of 3'4'5-tritiated leucine into the cat dentate, interposed, and fastigial nuclei. Following survival periods of 2 to 7 days these animals were sacrificed and samples of the cerebellar cortex were processed for EM autoradiography. Only the structures with 2 or more developed silver grains overlying them were considered to be orthogradely labeled. Numerous labeled large myelinated axons were observed entering the cortex at the base of the granular layer, but only labeled unmyelinated axons were found in the granular layer itself. The most common type of labeled terminal occurred at an expansion of a large unmyelinated fiber and was characterized by numerous mitochondria, very dense packing of synaptic vesicles, and a central core of neurofilaments. The majority of the synaptic vesicles within these terminals were of a round and clear type, with some dense core vesicles also being present. In most cases developed silver grains were localized over mitochondria and the synaptic contact. Labeled axonal expansions formed the central core of a glomerulus and established asymmetrical-type synaptic contacts with surrounding granule cell dendrites. Occasionally en passant synapses were observed between labeled fibers and granule cell dendrites. In several instances labeled fibers synapsed on a granule cell dendrite which was also postsynaptic to terminals forming symmetrical type contacts which were presumably Golgi cell axons. Silver grains were never observed to be above background levels in the Purkinje cell or molecular layers. This ultrastructural study confirms previous light microscopic data that the cerebellar nulceocortical projection has a mossy fiber-type termination within the granular layer.

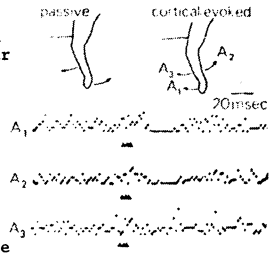
330 GLIAL CELL ANTIGENS DETECTED BY MONOCLONAL ANTIBODIES Carl Lagenaur*, Ilse Sommer* and Melitta Schachner. Institute of Neurobiology, University of Heidelberg, Im Neuenheimer Feld 347, 6900 Heidelberg, G.F.R.

Monoclonal antibodies that distinguish glial subpopulations in mouse cerebellum were detected in froze thin sections by indirect immunohistology. Mice immunized with crude mouse cerebellar membrane preparatio or with bovine corpus callosum provided spleenocytes that were fused with NS 1 mouse myeloma by the technique of Lemke, et al. (Nature 271:249, 1973) to yiel antibody producing hybridomas. Antibody M-1, arising from crude cerebellar membrane immunizations, stained fibrous astrocytes in the white matter, but did not stain other cerebellar glial cell types. Although Bergmann glial cells in wild type cerebella were M-1 negative, this cell type was M-1 positive in homozygous weaver mutant cerebella.

Antibody C-1, arising from bovine corpus callosum immunizations stained only Bergmann glial cells in adult mouse cerebellum. C-1 was detectable in Bergmann glia at least as early as postnatal day 2 when glial fibrillary acidic protein is not yet detectable by immunofluorescence. Astrocytes in presumptive white matter were C-1 positive in young mice but became C-1 negative in adults. These antibodies provide sensitiv probes for glial development and cell separation.

331 MOTOR CORTICAL MODULATION OF CEREBELLAR AND RUBRAL OUTPUT. Kenneth D. Larsen and Haruhide Yumiya*. The Rockefeller University, N.Y., N.Y., 10021.



The purpose of these experiments was to determine the manner in which the motor cortex modulates cerebellar and rubral output. An array of microelectrodes was implanted in the motor cortex, 12-pulse stimulus trains were delivered through each electrode to evoke movements, and then neurons in the intermediate and lateral cerebellar nuclei of cats and the red nucleus of cats and monkeys were isolated with recording electrodes. The neurons were identified by their somatosensory receptive field, determined with natural stimulation, and the averaged response to three-pulse cortical stimulation was seen in peri-stimulus time histograms. A receptive field was identified in 143 of 196 cerebellar neurons, 83 of which were driven by passive movement of one (59) or two (24) joints in one direction. When 46 of these 83 were tested, 33 had response pattern A in which they were driven by passive movement of a joint in one direction and were suppressed by stimulation of the cortical site from which movement was evoked in the opposite direction (figure). Increasing the duration of the cortical train increased the duration of the suppression. Ten other cells had response pattern B in which their discharge was suppressed by stimulation of a cortical site which evoked movement at an adjacent joint or at the same joint in a different plane. Red nucleus neurons had the same response patterns as cerebellar neurons although a short latency facilitation, presumably mediated by the direct corticorubral projection, occurred either preceding or without the response presumably mediated by the cerebellum. Not all components of the response (i.e. the corticorubral facilitation and the cerebellar-mediated suppression) were present in every cell, but in cats pattern A was present in 23 of 40 neurons which were tested, and 7 of 20 responded with pattern B. The same response patterns which were found in cat rubral neurons were also found in monkeys in rubral neurons with an input from proximal joints as well as those with an input from digits. Of 41 neurons, 17 responded with pattern A, while 12 of 25 had pattern B. In summary, the predominant pattern found in the cerebellar nuclei and mediated to the red nucleus was that neurons driven by passive movement of a joint in one direction were suppressed by stimulation of the cortical site from which movement was evoked in the opposite direction.

332 GRANULE CELL MIGRATION IN DEVELOPING CEREBELLAR CORTEX STUDIED WITH ALTERED THYROID STATES. Jean M. Lauder. Dept. Anatomy, Univ. North Carolina School of Med., Chapel Hill, N.C. 27514.

^{3}H-thymidine autoradiography with multiple survivals was used to determine the transit time and rate of movement of labelled cells from the proliferative zone (PZ) of the external granular layer (EGL) to the subproliferative zone (SPZ); from the EGL(SPZ) into the molecular layer (ML); and from the EGL(SPZ) to the internal granular layer (IGL) in 10-day-old control rats and in 10-day old rats made hypo- or hyperthyroid from birth.

Hyperthyroidism accelerated movement of labelled cells from the EGL to the IGL (granule cell migration), and increased the rate of entry of these cells into the ML from the EGL. The magnitude of the effect on granule cell migration rate was directly proportional to the previously reported effect on rate of parallel fiber (PF) growth (Lauder 1978, Br. Res. 142:25-39). Hypothyroidism, on the contrary, decelerated both granule cell migration and PF development. The effects of hyperthyroidism lend support to the hypothesis that the granule cell body is translocated within the descending portion of the elongating PF whose growth provides the motive force for granule cell migration. The alternative hypothesis that the amoeboid-like movement of the cell body provides the main impetus for migration seems less likely since accelerated PF growth would probably not result in faster migration in this model, even though PF growth would still be a requisite condition for perikaryal movement towards the IGL.

Granule cell acquisition in the IGL was decelerated in both thyroid states apparently as a consequence of combined effects on cell production in the EGL and movement of cells to the IGL. In hyperthyroidism, a reduced proportion of proliferating precursor cells in the EGL and slower movement of postmitotic cells from the PZ to SPZ resulted in slower granule cell acquisition in the IGL which could not be compensated for by the accelerated rate of migration. In hypothyroidism, the slower rate of granule cell migration was also coupled with a reduced proportion of proliferating cells in the EGL causing an even slower rate of cell acquisition in the IGL. The net result of hyperthyroidism was to produce a deficit in the number of labelled cells reaching the IGL, whereas hypothyroidism led to a transient deficit which was eventually compensated for by a prolonged migration period.

These results demonstrate the usefulness of such hormonal manipulations for the study of normal neurogenic events and provide evidence for an intimate link between parallel fiber growth and granule cell migration in the developing cerebellar cortex of the rat. (Supported by NIH grant NS-13481).

333 SOMATOTOPIC ORGANIZATION OF CLIMBING FIBER PROJECTIONS FROM CUTANEOUS AFFERENTS TO LOBULE V VERMAL CORTEX OF THE CAT CEREBELLUM. Kenneth D. Laxer*, Lee T. Robertson, and Ann Mason*. Neuro. Sci. Inst., Good Sam. Hosp. & Med. Ctr., Portland, OR 97209.

Previously we have demonstrated the fine detail of climbing fiber projections to the pars intermedia of lobule V in the cat cerebellum in response to low threshold natural cutaneous stimulation. These projections form a complex mediolateral organization of patches that were elongated in the anteroposterior direction. The cortex received input from the entire ipsilateral, anterior quadrant of the body; the face was represented laterally and the distal forelimb medially. The present study investigates the cutaneous climbing fiber projections to the vermis of the lobule V in the cat cerebellum. Extracellular single unit Purkinje cell responses to natural stimulation were recorded in 20 cats anesthetized with pentobarbital. A computer-controlled punctate stimulus was used to delineate those areas which could activate climbing fiber responses (CFR). Peri-stimulus histograms were computed for CFR's; the latency and thresholds were determined.

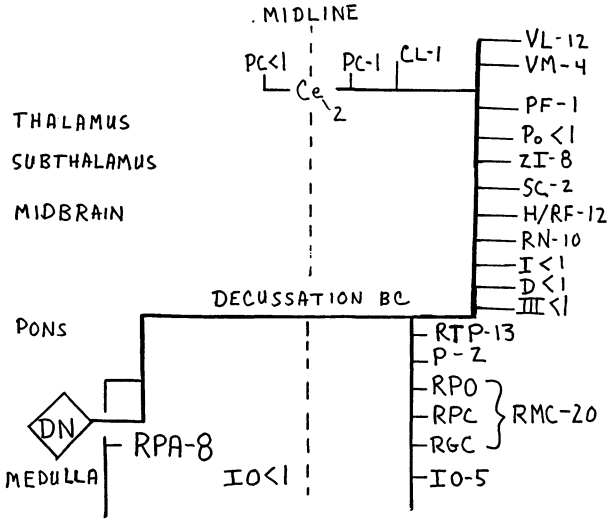
In contrast to the organization of the pars intermedia, the CFR in the vermal cortex showed no distinct topographic distribution of cutaneous input. Although small clusters of cells with similar receptive fields were occasionally identified, the vermal cortex typically consisted of a mosaic of cells that responded to low to high threshold stimulation of the forelimb, hindlimbs, and back. In the most medial area (midline to 1.0 mm), the majority of cells (82%) could not be activated by any cutaneous stimulation, although interspersed throughout this zone were a few CFR's that responded to stimulation of the upper dorsal trunk. The more lateral vermal cortex (1.0-2.5 mm) consisted of a heterogeneous mixture of responsive (80%) and unresponsive (20%) Purkinje cells. The responsive cells were predominately activated by stimulation of the ipsilateral forelimb, which included the paw and wrist (59%), wrist (13%), or forearm (4%); whereas 22% of the units were sensitive to stimulation of the hindlimb. Unlike the findings in the pars intermedia, no cells were identified that were responsive to stimulation of the face or to the contralateral limbs. The distribution of CFR's in the lobule V vermal cortex activated by natural stimulation was similar to that described by Eccles but was contradictory to that produced by electrical stimulation of the peripheral nerves as reported by Oscarsson.

334 LONG TERM EXCITABILITY CHANGES IN MAMMALIAN INFERIOR OLIVE NEURONS IN VITRO. R. Llinás and Y. Yarom* (SPON: E.Simon). Dept. Physiol. Biophys., New York Univ. Med. Ctr., New York 10016.

Electrical activity of inferior olive neurons was analyzed intracellularly in guinea pig brain stem slices and in vitro whole brain stem. As reported in the accompanying communication (Yarom & Llinás, 1979), inferior olive neurons demonstrated two calcium conductance changes to both depolarization (dendritic) and hyperpolarization (somatic) membrane changes, the latter as an unmasking of a calcium conductance inactivated at resting potential. Following D.C. depolarization or hyperpolarization from resting level, both calcium currents required a certain minimum time for their appearance and once uncovered, the membrane retained this new conductance for a certain period of time (tens of seconds). More specifically, starting from a resting potential of -70 mV, an abrupt D.C. depolarization caused a large conductance change (demonstrable by test current pulses). During this time, dendritic calcium spikes were difficult to generate, probably due to the short λ. If depolarization was continued, the membrane conductance decreased and there was a small shift of the membrane level. This was accompanied by the generation of local responses and finally full calcium action potentials by the test current pulse. If the membrane potential was returned quickly to resting level for a few seconds and then returned to previous value, dendritic calcium spikes were obtained without delay and the input resistance remained high. A similar finding could be seen when the membrane was hyperpolarized from resting; i.e. there was initially a large conductance change which subsided and allowed somatic inactivating calcium spikes to occur during test pulses. While the long term excitability change generated by membrane depolarization can be ascribed to the inactivation of the voltage-dependent potassium conductance change which had a time course of tens of seconds, the mechanism for the membrane conductance change to hyperpolarization is as yet unclear. Preliminary data suggest that it may involve the activation of a potassium current generated by inward calcium current due to the increased E_{Ca} during hyperpolarization. The above results taken together with the electrotonic coupling suggest that the inferior olive is capable of complex and long term excitability changes. In addition, bath application of harmaline (known to produce oscillatory behavior in inferior olive) hyperpolarized the neuron and thus unmasked the calcium-dependent somatic spike. The actual mechanism for harmaline action is unclear; since it was not accompanied by large conductance change, one must assume either activation of an electrogenic pump or its acting as a transmitter on a probable catecholaminergic receptor. (Supported by USPHS grant NS-13742 from NINCDS)

335 CEREBELLAR DENTATE NUCLEAR OUTPUT - A QUANTIFICATION OF TERMINAL FIELDS. Eric Lothman*, Terry Der* and Robert C. Collins. (Spon. Sven G. Eliasson) Dept. of Neurol., Wash. Univ. Med. Sch.; St. Louis, MO 63110

Although descriptions of cerebellar efferents exist, quantitative data of the relative density of the terminal fields is lacking. A quantitative autoradiographic method (Collins and Der - these abstracts) was applied to the rat dentate nucleus (DN). 14C-proline (0.03 to 0.18µl, 1µCi/µl) was stereotactically injected into DN. After 24 hours brains were perfused/fixed and triplicate 20µm sections were cut every 300µm to obtain autoradiographs of the entire brain. These sections were thionin stained later. Rostrally, DN projects almost entirely to contralateral fields. Caudally there are ipsi- and contralateral projections. Terminal fields were calculated from optical densities x volume, measured planimetrically, and expressed below as percent of total (terminology of Faull, JCN 178: 495, '78).



336 KAINIC ACID NEUROTOXICITY IN THE MOUSE CEREBELLUM. Kathryn L. Lovell and Margaret Z. Jones. Dept. Path., Michigan State Univ., East Lansing, MI 48824.

Kainic acid (KA), a structural analogue of glutamic acid, has been proposed as a specific lesioning agent which destroys cell bodies possessing glutamate receptors while sparing fibers of passage and neurons without glutamergic input. However, a few studies have suggested widespread and/or non-specific effects of intracerebral KA injections. In the cerebellum; glutamate is the putative neurotransmitter of granule cells while the other identifiable cell populations (Purkinje, basket, stellate and Golgi II cells), which receive afferent input from granule cells, are not glutamergic. This cytoarchitecture provides a model system which can be used to assess the mechanism of KA neurotoxicity. A previous report concerning injection of this agent into the rat cerebellum indicated a selectivity of KA action consistent with a neurotoxic effect mediated via glutamate receptors. The present study was undertaken to further delineate the mechanism of KA toxicity in the mouse cerebellum and to evaluate the resulting reaction to injury in this species.

Several doses of KA (between 0.4 µg and 1.0 µg) in 0.4 µl saline were injected into the cerebella of weanling mice. Two or 7 days after injection the mice were perfused with 1% glutaraldehyde and 0.5% paraformaldehyde in 0.12 M phosphate buffer. Sagittal sections of the cerebellum were postfixed in osmium tetroxide, dehydrated, and embedded in Epon-araldite for light and electron microscopy. In contrast to previous studies, substantial numbers of granule cells throughout most of the affected cortex were damaged by KA. This result suggests mechanisms of toxicity other than those proposed for cells with glutamate receptor sites. Of those cells receiving glutamergic input, basket and stellate cells were severely affected while Purkinje cells were often spared. The deep cerebellar nuclei, which receive no identified glutamergic innervation, also showed some neuronal destruction. Additional pathological changes included macrophage infiltration in all cortical layers and hemorrhages at sites remote from the needle track. Thus, in the mouse cerebellum unexplained factors other than glutamergic innervation apparently are responsible for the major neurotoxic effects of KA.

337 PURKINJE CELL ACTIVITY IN THE VERMAL CEREBELLUM OF THE CAT DURING TRAINED SACCADIC EYE MOVEMENTS AND FIXATIONS. James G. McElligott Depart. of Pharm., Temple Univ. Medical School, Phila.,Pa.19140.

Purkinje cell activity from the posterior vermis (lobes VI and VII) of the cerebellum was recorded in awake,head restrained cats. These animals were trained to maintain fixations or to make precise saccadic eye movements to visual target lights (green light emitting diodes). These were mounted in a square matrix array (10 x 10) placed at 5 degree intervals in horizontal and vertical orientations on a tangent stimulus board. Chronic unit recording was carried out, while the horizontal and vertical components of the eye movements were recorded via an ocular electromagnetic search coil technique. The position of the fixation points as well as the position, amplitude and direction of the saccades were dictated by training the animal to look at sequences of illuminated target lights. The experiment was controlled by a digital computer which randomized light presentations and determined if the animals made proper fixations and saccadic eye movements. Successful completion of a sequence of fixations and saccades was followed by a milk reward. Previous results from our lab indicated that feline Purkinje cells were directionally sensitive and modulated their firing rates (increases, decreases or biphasic combinations), before as well as after the initiation of a saccade. Fifty percent of the Purkinje cells manifested short phasic responses related to saccadic onset. Twenty-five percent of these phasic cells also produced different tonic firing rates related to eye position. Typically, for these cells a tonic response would be recorded for movements along one primary axis (e.g. vertical) and phasic responses recorded along the other axis (e.g. horizontal). For most of the multi-directional cells (80%), there was a change in the temporal relationship between the neural response and saccade initiation that depended on the direction of the movement. The majority (60%) of the eye movement related cells also produced neural responses that were dependent on the absolute position of the saccade. Comparisons between saccade amplitude and the neural response, showed that 50% of the cases tested produced equal neural responses to saccades of different amplitudes. The other 50% of the cases were divided evenly into 2 groups that produced either direct or an inverse relationship between the amplitude and the magnitude of the neural response. Thus, it appears that direction and absolute eye position before and during saccades are 2 of the important parameters for determining the response characteristics of the Purkinje neural response.

338 EFFECTS OF BULBOSPINAL SYSTEMS ACTIVATED FROM THE DENTATE NUCLEUS ON THE STRETCH REFLEX. Teresa McMullen* James R. Bloedel .Dept. Neurosurg., Univ. of Mn., Minneapolis, MN 55455.

Experiments were performed on decerebrate cats which were either unanesthetized or anesthetized with halothane. The tendon of the gastrocnemius muscle was mounted on a muscle puller, and a fine wire was inserted into the belly of the muscle to record multiple unit EMG activity. Responses to muscle stretch were recorded in the presence and absence of dentate stimulation at frequencies ranging from 5-100 Hz. To ensure that the activation of rubrospinal and reticulospinal pathways was not accompanied by the activation of spinocerebellar fibers, the responses evoked in the cervical spinal cord by the dentate stimulus were monitored. The electrode was positioned so that only descending projections were activated. When these conditions were satisfied, dentate stimulation produced one or both of the following changes in reflex activity: (a) reduction or total elimination of the response of one or more motor units; (b) an decrease in the phase lead of the response of individual motor units. These effects were more pronounced and occurred more frequently among motor units producing large spikes than those producing small spikes. In addition, when several motor units were affected, those with the largest spikes were always affected first after the onset of dentate stimulation. This observation was made at several recording sites within the same muscle. These data indicate that descending projections from the brain stem which are activated by the dentate nucleus produce characteristic changes in the excitability of stretch reflexes and suggest the possibility that motor units are differentially affected by these descending systems according to their size. (Supported by NIH Grant # RO501-NS-09447 and NIH contract NS 42332).

339 AN ELECTRON MICROSCOPIC AND HRP STUDY PROVIDING EVIDENCE THAT BOTH THE CORTICOPONTINE AND CEREBELLOPONTINE SYSTEMS ARE EACH COMPOSED OF TWO SEPARATE NEURONAL POPULATIONS. Gregory A. Mihailoff and Carl B. Watt* , Dept. Cell Biology, Univ. Texas Health Science Center at Dallas, Dallas, Tx.

As part of ongoing studies concerning the synaptic organization of the rat basilar pontine nuclei (BPN), an attempt has been made to 1)identify axonal boutons of the corticopontine and cerebellopontine systems using routine electron microscopic degeneration techniques and 2)to demonstrate the cells of origin of these two systems by injecting horseradish peroxidase (HRP) into the BPN. Our results indicate that following unilateral decortication, two separate populations of boutons in the BPN appeared to undergo degeneration. Most numerous were small boutons (less than 1 um) exhibiting the typical dark type of degeneration and observed to contact small dendrites and spines. Also apparent (but in smaller numbers) were larger boutons (1-3 um) terminating on proximal portions of pontine neurons and exhibiting a filamentous reaction prior to becoming electron dense. When lesions were restricted to sensorimotor cortex, the same mixture of dark and filamentous boutons were noted, however, when lesions involved visual cortex, essentially only filamentous boutons were observed. Similar results were obtained when the brachium conjunctivum was unilaterally transected thereby interrupting cerebellar nuclear axons projecting to the BPN. Numerous large boutons contacting a characteristic cluster of dendritic protrusions underwent filamentous degeneration while at the same time a population of small boutons having a different postsynaptic locus exhibited electron dense degeneration. Taken together, these results suggest that both the corticopontine and cerebellopontine systems might each be composed of two neuronal populations, one type providing filamentous degenerating boutons, the other dark degenerating boutons. To test this notion, HRP was injected into the BPN using a ventral approach. Labelled neurons in sensorimotor cortex were distributed throughout layer Vb while in the cerebellar nuclei, numerous large spherical neurons were labelled along with a lesser number of smaller spindle-shaped somata. These findings, when correlated with the degeneration studies suggest that the sensorimotor cortical input to the BPN consists of 1)corticospinal axon collaterals (dark boutons, soma in deep layer Vb) and 2)corticobulbar or direct corticopontine axonal terminals (filamentous boutons, soma in superficial layer Vb). Similarly the cerebellopontine system consists of two components, large neurons which provide collaterals (filamentous boutons) to the BPN as they project rostrally to the red nucleus or thalamus and collaterals (dark boutons) of smaller neurons which project caudally to the inferior olive.

340 CELLULAR LOCALIZATION OF β-1 AND β-2 ADRENERGIC RECEPTORS IN RAT CEREBELLUM. K.P. Minneman*, R.N. Pittman*, P.B. Molinoff and D. J. Woodward (SPON: R. Lasher). Dept. of Pharmacol., Univ. of Colo. Med. Ctr., Denver, CO and Dept. of Cell Biol., Univ. of Texas Health Sci. Ctr., Dallas, TX.

The rat cerebellum contains both β-1 and β-2 adrenergic receptors. Although β-1 adrenergic receptors comprise 18% of the total number of receptors in the cerebellum in 2 week old rats, by 3 months of age β-1 receptors comprise only 2% of total β-adrenergic receptors in the cerebellum. Since we have previously shown that in the rat cerebral cortex the β-1 adrenergic receptors are involved in neural transmission, it was of interest to examine the cellular localization of the β-1 and β-2 adrenergic receptors in the cerebellum.

Rats were subjected to X-irradiation on days 1, 4, 6, 8, 10, 12 and 14 of life. Conventional histological techniques were used to confirm the nearly total absence of the late-maturing granule, basket and stellate cells. The early-maturing Purkinje cells were spared, however, and both histological and electrophysiological studies suggest that these cells are relatively "normal" after X-irradiation.

Rats were killed after 2 or 6 weeks of life and β-1 and β-2 adrenergic receptors were measured in homogenates of the cerebellum and cerebral cortex. The density and total number of each receptor subtype was compared to that in control animals subjected to sham X-irradiation. No differences were observed in the concentration of β-receptor subtypes in the cerebral cortex of X-irradiated animals as compared to controls. Large changes were seen, however, in the cerebella of X-irradiated animals. At both ages a large (60-75%) decrease in the weight of the cerebellum was observed. There was, however, a 62-70% increase in the density of β-1 adrenergic receptors in the X-irradiated cerebella, indicating that remaining cellular components were enriched with respect to β-1 receptors. Conversely, the specific activity of β-2 adrenergic receptors was unchanged at 2 weeks of age but decreased by 53% at 6 weeks of age in the X-irradiated cerebella. This indicates that the cellular components destroyed by X-irradiation are relatively enriched with respect to β-2 adrenergic receptors. Calculation of the total number of receptors in the cerebellum at six weeks of age showed that the number of β-2 adrenergic receptors per cerebellum had decreased by 83% in the X-irradiated animals, but that the number of β-1 adrenergic receptors per cerebellum had decreased by only 33%. These data are consistent with the hypothesis that there are β-1 adrenergic receptors on Purkinje cells of rat cerebellum. (USPHS NS 13289 and 09199).

341 EYE VELOCITY AND POSITION SIGNALS IN FLOCCULAR PURKINJE CELL ACTIVITY DURING SMOOTH PURSUIT EYE MOVEMENTS. Hiroharu Noda, Tateo Warabi* and Naohiro Ishii*. Brain Research Institute, Depts. Physiol. and Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

When a monkey moved its eyes, pursuing a sinusoidally oscillating visual target, simple spike discharges of Purkinje cells of the flocculus showed a cyclic modulation. The modulation frequently occurred in phase with the eye velocity curve, exhibiting a ½ π radians phase shift from the horizontal EOG. However, in the majority of Purkinje cells, the peak activity did not occur in phase with the maximum eye velocity. A wide range of phase shifts was observed between the activity and the EOG. The activity in these cells included a non-velocity component in addition to the eye velocity component. The velocity component could be demonstrated by changing the frequency of sinusoidal excursions of a constant magnitude. The peak firing rates were found to increase linearly with higher frequencies which were associated with higher peak velocities. In Purkinje cells showing a phase shift from the eye velocity curve, a source of the non-velocity component was the activity representing eye position. The eye position component was demonstrated in the following ways: (1) These cells exhibited tonic activity which was proportional to eye position during steady fixation of a stationary target. (2) During a zig-zag eye movement, tracking ramp target movements of a constant velocity, the firing rate of these cells increased or decreased depending on the direction of the eye movement. (3) When sinusoidal eye movements were executed, pursuing a target oscillating in the central, right, or left visual fields, the level of the cyclic modulation in activity varied markedly depending on the field of eye movement. (4) Eye velocity and position components of unit activity were dissociated during eye movements involved with pursuing a complex target motion driven by a composite of sinusoids of different frequencies. In such complex tracking eye movements, the peak eye velocity as well as the peak eye position were different in every cycle and the potential predictability of a pure sine wave was eliminated. Instantaneous discharge rates during such eye movements were continuously correlated with the eye position curve (EOG) or eye velocity curve (the derivative of the EOG). The activity during smooth pursuit eye movements included both eye velocity and eye position signals, although their proportions differed from unit to unit. (Supported by NIH Grant EY 01051).

342 CEREBELLAR COORDINATION : COVARIANT ANALYSIS AND CONTRAVARIANT SYNTHESIS VIA METRIC TENSOR. A TENSORIAL APPROACH TO THE GEOMETRY OF BRAIN FUNCTION. A. Pellionisz and R. Llinás. Dept. Physiol. & Biophys., New York Univ. Med. Ctr. 550 First Ave, New York 10016

A wealth of experimental data indicates brain function (e.g. motor coordination by cerebellar networks) to be a distributed and parallel property. It is imperative, however, to develop formal treatments capable of allowing precise conceptual descriptions and quantitative formulations of such global properties. Thus, a tensorial approach was introduced (Pellionisz & Llinás: *Neurosci. Abst.* 4,1978; *Neuroscience* 4:323,1979) which considered brains in terms of abstract geometry. Here, tensor network theory is utilized in the analysis of the coordination of limb movements and vestibulo-ocular responses.

Movements emerge from collective vectorial actions of the many segments of a limb, or of the extraocular muscles. The present treatment is based on the view that movements are reference frame invariant vectors (i.e. tensorial entities). Since movement vectors occur both in the 3-dimensional space and in the multi-dimensional space of the CNS, the fundamental problem of motor coordination is: how can an intended movement (which refers to the 3-space) be executed by a high dimensional motor system? This leads directly to the inherent properties of the spaces that contain the vectors : *a) Is the CNS hyperspace metric?* Then, if the coordination problem is regarded as an embedding of the 3-dimensional space into the CNS hyperspace, the question is: *b) How can the decomposition be unique despite the overcompleteness of the hyperspace?*

We assume that the CNS space *is* endowed with an inherent geometry: which in the case of motor system is given by the prewired matrix of the cerebellar metric tensor: Θ. Assuming a local homomorphism of the two overlapping spaces (3-dimensional and CNS hyperspace) leads to a two-step scheme of coordination. *(1) A decomposition of the intended vector into an overcomplete number of covariant components, using the geometry of the three-space, (2) A transformation of the covariant components into contravariant components by a CNS metric tensor.*

As shown by computer modeling, the covariant vector components can be established, even for an overcomplete number of coordinates. However, when used directly to generate the intended movement, the covariant components yield an ataxic, dysmetric movement, but when transformed to contravariant components, the intended movement is generated in a coordinated unique style.

Beyond providing a formal scheme of coordinated motor action by the known cerebellar neuronal network, some general conclusions are reached regarding the properties of CNS space and generalizing the covariant analysis and contravariant synthesis to sensory systems.(Supported by USPHS grant NS13742 from NINCDS)

343 VESTIBULO-CEREBELLAR AFFERENTS FROM THE INFERIOR OLIVE AND THE VESTIBULAR NUCLEAR COMPLEX. Kevin D. Phelan* and William R. Mehler. (SPON: J. deGroot) Ames Res. Ctr., Moffett Field, CA 94035 and Dept. Anat. Univ. Cal. San Francisco, CA 94143.

Single horseradish peroxidase (HRP) injections (.5-2.0 ul, 50%, Sigma VI) were placed into the nodulus, uvula or lingula by a horizontal stereotaxic approach via the posterior vermis of the cerebellum of 10 adult cats (42-72 hr survival, 0.5% para - 1.5% glut, DAB or BDHC substrate). These experiments showed cell labelling chiefly in the contralateral olive while cells in other brainstem nuclei, such as the vestibular nuclei, labelled bilaterally.

Afferents to the nodulus were shown to arise mainly from the dorsal cap of Kooy (dc), the ventrolateral outgrowth of the dc (vlo) and some cells in the rostral part of the medial accessory olive (MAO). Labelled cells consistently appeared in dc and vlo only when the spread of HRP involved the nodulus. These findings are similar to those cell patterns reported in the rabbit (Alley, et al., Brain Res. 98:582-589; Hoddevik and Brodal, J. Comp. Neur. 176:269-280, 1977). In injections involving mainly the uvula without apparent nodular spread, heavy cell labelling was found throughout nucleus B and the dorsal medial cell column (dmcc) and in the rostral parts of the MAO, as has been previously reported in cats (Brodal, J. Comp. Neur. 166:417-426, 1976). In some nodular injection cases varying amounts of leakage occured in passage through the folia of the uvula and in all available cases the HRP spreads into the overlying ventral uvula, part of which belongs to the vestibulo-cerebellum. Thus, in all nodular cases, labelling of B and dmcc cells occured in varying degrees, increasing in number of HRP positive cells as the spread into the uvula increases. These experiments suggest that there are possible B and dmcc projections onto the nodulus, but further small injection experiments utilizing various angular approaches to the nodulus are needed to settle this question. The HRP spread in the presently available experiments are too large to confirm the topographical projections of B and rostral MAO onto the nodulus as suggested by recent autoradiographic studies in the cat (Groenwegen, Voogd and Freedman, J. Comp. Neur. 183:551-602, 1979).

Anterior lobe injections using this horizontal approach into the lingula and some parts of centralis strongly label cells only in the caudal ventrolateral MAO, the caudal ventrolateral DAO and B, results similar to those reported by Brodal and Walberg (J. Comp. Neur. 172:85-108, 1977) using a more dorsal approach.

Patterns of labelled cells projecting from the vestibular nuclei and other brainstem nuclei to the folia composing the vestibulocerebellum will be discussed.

344 TOPOGRAPHY OF CLIMBING FIBER PROJECTIONS TO THE INTERMEDIATE CEREBELLAR CORTEX OF THE MONKEY. Lee T. Robertson and Kenneth D. Laxer*. Neuro. Sci. Inst., Good Samaritan Hosp. & Med. Ctr., Portland, OR 97209.

The organization of climbing fibers to the cerebellum has been extensively studied in the cat, but almost no similar data are available for the monkey, which has a larger cortical area and a different repertoire of movements. The present work describes the somatotopic organization of climbing fibers in the intermediate zone of lobule V of the Macaca fascicularis that were responsive to natural stimulation. In monkeys anesthetized with pentobarbital, extracellular recordings of single Purkinje cells with climbing fiber responses (CFR's) were evaluated by gentle taps to the body and by computer controlled punctate stimuli. Peristimulus histograms were computed for the CFR's; latency and force thresholds were measured. The stereotaxic position of each unit was determined; electrode location was confirmed histologically.

The climbing fiber projections consisted of a mediolateral (3-9 mm) organization of patches that were elongated parasagittally. (1) Hindlimb--a 1.0 mm wide cell population that responded to low threshold stimulation of the ipsilateral dorsal foot and leg; a few cells responded to stimulation of the hip or tail. (2) Nonresponsive--a 0.5-1.0 mm strip of cells that did not respond to any of our cutaneous stimuli. (3) Forelimb--a 1.0-1.5 mm wide area where the majority of cells were activated by low threshold stimulation of the dorsal hand or to 2-3 fingers; a few cells received input from just the thumb or a finger or from the proximal areas of the limb. (4) Face--a 2 mm wide region that could be subdivided into a medial portion that primarily received input from the ophthalmic and maxillary divisions of the trigeminal nerve and a lateral portion where cells were activated by stimulation of areas supplied by the mandibular division. (5) Nonresponsive--a 1 mm zone where no cells responded to cutaneous stimulation.

The general somatotopic organization of intermediate cortex of lobule V in monkey is similar to the pattern described for the cat, but the proportion of cells responding to a particular receptive field is very different between the species. In the monkey only a few cells were activated by stimulating the ventral hand; a large proportion of cells were associated with the fingers, lower jaw, teeth, and tongue. It is proposed that the different somatotopic arrangement reflects diverse spatially organized skilled movements.

345 SURFACE PROTEINS OF CULTURED MOUSE CEREBELLAR CELLS. H.Rohrer+ and M.Schachner, Institute of Neurobiology, Heidelberg University, Heidelberg, GFR (Sponsor: V.Braitenberg)

Surface proteins of cultured monolayer cells from embryonic and early postnatal C57BL/6J mouse cerebella were identified by a lactoperoxidase catalysed ^{131}iodine labeling technique. Iodinated proteins have molecular weights of approximately 200, 145, 120, 85, 65, 50 and $30x10^3$ daltons (P200, P145 ...) as estimated by SDS-polyacrylamide gel electrophoresis in gradients of 4-15%. Membrane glycoproteins of apparent molecular weights of 200, 145, 100, 85 and $50x10^3$ daltons are detectable by biosynthetic labeling with ^{3}H-fucose. The two major iodinated proteins are the glycoproteins P200 and P145. P145 is released from the surface into the medium.

No changes in the patterns of labeled cerebellar cell surface proteins are detectable between embryonic day 12 and postnatal day 10. A pattern similar to the one seen with cerebellum is obtained with embryonic cerebral cortex, whereas early postnatal retina displays a distinctly different pattern, with P145 not being a major iodinated component.

An antiserum to 4-day-old cerebellar membrane fraction (anti-NS-4) reacts with P200 and P145 from solubilized plasma membranes of embryonic cerebral, and postnatal cerebellar and retinal cells. No structural similarities between these polypeptides is detectable by one-dimensional finger print mapping of peptides from Staphylococcus aureus V8 protease digests.

P200 and P145 are found most prominently in granule cell enriched fractions obtained by a bovine serum albumine step gradient separation method. The glial cell enriched fraction shows increased P100, P85 and P50. These three proteins are also increased in cultures of staggerer mutant mice.

346 SPONTANEOUS AND EVOKED RHYTHMIC, SYNCHRONOUS NEURAL ACTIVITY IN INFERIOR OLIVE UNDERLIES HARMALINE-INDUCED TREMOR. Jesse Schulman* and Floyd Bloom. (SPON: E.F. Battenberg) A.V. Davis Ctr. for Behav. Neurobiology, Salk Inst., La Jolla, CA 92037.

Much indirect evidence suggests that cells of IOC tend to fire rhythmically and that neighboring IOC cells tend to fire synchronously. This evidence comes primarily from studies demonstrating synchronous occurrence of climbing fiber-mediated excitation in neighboring Purkinje cells (Bell and Kawasaki, J. Neurophysiol. 35, p.155, 1972), and from studies of the drug harmaline, which elicits a 8-12 Hz tremor by causing rhythmic and synchronous activity in IOC (deMontigny and Lamarre, Br. Res. 53, p. 81, 1973; Headley et al., Br. Res. 101, p. 461, 1976). However, there is no report directly demonstrating the normal occurrence of such activity in IOC itself and the suggestion that harmaline accentuates rather than generates such an occurrence is unproven. Using extracellular metal microelectrodes, which are particularly useful for recording aggregate activity of groups of neurons, we find episodes of spontaneously occurring rhythmic and synchronous activity in IOC, and find that cutaneous stimulation can evoke episodes of such activity lasting .5 seconds or more. Responses were recorded throughout IOC, but were most consistently found in caudal dorsal accessory nucleus or in medial accessory nucleus near the center of its rostro-caudal extent. Moreover, recording from IOC before and after administration of harmaline shows directly that spontaneous episodes are increased in amplitude and duration by the drug. By filtering the signal from the metal microelectrode in different ways, we found it possible to study simultaneously single-unit, multi-unit, and aggregate neuronal activity. We find that the waves of both evoked and spontaneous aggregate activity, and repetitive evoked single-unit responses, all express the same underlying rhythm, whose period is identical to the most common interspike interval of the spontaneously firing unit. These findings constitute the first direct demonstration that a tendency to rhythmic and synchronous activity underlies spontaneous, evoked, and harmaline-induced activity of IOC. Implications of these findings regarding transmission in the olivo-cerebellar pathway will be discussed. Further, there exists a normal physiological 8-12 Hz tremor (see Joyce and Rack, J. Physiol. 240, p. 375, 1974). Since harmaline produces a similar but more severe tremor by exaggerating normal IOC activity, this physiological tremor may be a consequence of spontaneous IOC activity.

347 ERRONEOUS ZONES OF THE CEREBELLAR FLOCCULUS. John I. Simpson. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., New York, N.Y. 10016

The climbing fiber (CF) projection from the inferior olive to the cerebellar cortex is organized into a number of zones oriented normal to the long axis of the folia. By taking an eclectic approach focused on the flocculus, a proposal on the nature of CF zones may be offered in specific behavioral terms. Groenewegen and Voogd (1977) have shown anatomically in the cat that the CF projection from the dorsal cap of the inferior olive to the rostral flocculus delineates three zones — a central zone which receives from the caudal dorsal cap and two bordering zones which receive from the rostral dorsal cap. In this laboratory we have shown that dorsal cap CFs in rabbit are visually responsive in a direction and speed selective manner. The CF signals constitute error signals (retinal image slip) indicating deviation from optimal motor performance. In addition, we have also shown that three preferred directions in visual space are defined by the visual CFs. Two of the preferred directions (horizontal, up with a posterior component) are signaled in the flocculus from the ipsilateral eye. The third direction (down with a posterior component) is signaled from the contralateral eye. Recordings from the dorsal cap have shown that the horizontal direction is represented in the caudal part of the dorsal cap while the off-vertical directions are represented more rostrally. Taken together, the anatomy and physiology indicate that the central zone of the rostral flocculus is related to horizontal eye movements while the two bordering zones are related to off-vertical eye movements. These predictions are borne out by the finding (Ito, et al, 1978) that with electrical stimulation of the rabbit flocculus three zones can be distinguished on the basis of the directions of the evoked eye movements. Horizontal movements are evoked from a central zone and off-vertical movements are evoked from the bordering zones. The three directions of the evoked eye movements have an internally consistent relation to the three directions of visual space established by the visual CFs. Thus, each of the three visual CF zones in the flocculus is associated with one of three specific directions, which may be viewed as coordinates of sensory-motor space for compensatory eye movements. For the flocculus, the coordinates represented by the CF zones can be readily referred to the external world geometry, but for most other cerebellar regions interpretation of CF zones in terms of coordinates of sensory-motor space will not likely be so directly referable to the external space. 348 ACTIVITY OF NEURONS IN THE CEREBELLAR CORTEX RELATED TO PARAMETERS OF A CONTROLLED ISOMETRIC PREHENSION TASK PERFORMED BY MONKEYS. Allan M. Smith and Daniel Bourbonnais*(SPON: H.H. Jasper). Centre de Recherche en Sciences Neurologiques, Université de Montréal, Montréal, Québec.

Recent studies of the cerebellum have emphasized the role of this structure in the initiation of quick movements. In contrast the present study was designed to examine the discharge of cerebellar cortical neurons during highly controlled finger pressures Monkeys were trained to exert and maintain precise forces on a hand held strain gauge for fruit juice reward. An exhaustive analysis of 26 forearm and intrinsic muscles of the hand indicated that the task is accomplished by co-contraction of antagonist muscles. To date recordings have been made from 136 neurons in the paramedian border area between the anterior and posterior lobe (lobules V and VI). Sixty-six units had receptive fields on the forearm, wrist and fingers and discharged in relation to the task. In general, neurons which did not demonstrate a climbing fiber discharge increased activity during prehension. In contrast, most, but not all, Purkinje cells identified by the presence of complex spikes were inhibited during some phase of the task. Complex spike activity did not appear related in any way to the task performance. Several of the unidentified neurons demonstrated significant correlations between discharge frequency and either rate of force change or force or both these parameters. These preliminary findings suggest that the cerebellum plays at least as important a role in slow controlled motor function as it does in fast movements. Furthermore, the discharge pattern of Purkinje cells indicates that the majority of these neurons are inhibited during the co-contraction of antagonist muscles.

349 A NON-INACTIVATING VOLTAGE-DEPENDENT SODIUM CONDUCTANCE IN MAMMALIAN PURKINJE CELL SOMATA, STUDIED IN VITRO. M. Sugimori* and R. Llinás (SPON: M. E. Hatten). Dept. of Physiol. Biophys., New York Univ. Med. Ctr., New York 10016.

An in vitro slice preparation of guinea pig cerebellum has allowed investigation of the voltage-dependent electroresponsiveness of Purkinje cells at somatic and at different dendritic levels. While it was previously reported that, in these neurons the somatic action currents are mainly carried by sodium, and the slower dendritic action potentials by calcium current (Llinás & Sugimori, Soc. Neurosci. Abst. 4, 1978), a new type of voltage-dependent spike was recently observed. Thus, following blockage of the slow calcium current (by adding either manganese, cobalt or cadmium salts to the superfusion fluid, or by simply exchanging calcium with magnesium), direct stimulation of the soma generated, besides simple spikes, a slowly rising and prolonged all-or-none response. This response had a lower threshold and thus served to trigger simple action potentials during its rising phase. At its plateau level approximately 40 mV from the resting potential (generally 65 mV), there was a complete inactivation of the fast spikes. This plateau was maintained as long as the depolarizing current was applied and its duration outlasted the stimulus. The duration of the plateau after termination of the stimulus may range from a few milliseconds to several hundred milliseconds, depending on the stimulus amplitude. A test pulse applied during the plateau indicated a fourfold increase in membrane conductance during this period.

Application of 10^{-5} tetrodotoxin to the bath reversibly blocked both the action potentials as well as the plateau response. Similar findings could be obtained if sodium was replaced in the superfusion fluid by tris or by choline chloride.

Results similar to those obtained at soma may also be seen at dendritic level. However, in these cases the amplitude of the response was much smaller and its threshold higher, indicating that this non-inactivating sodium current is most prominent at somatic level.

It is thus concluded that at the soma Purkinje cells are capable of demonstrating a non-inactivating (or very slowly inactivating) sodium current which is distinct from that generating the fast action potentials. The plateau level of this all-or-none response seems to be produced by an equilibrium state between voltage-dependent sodium (g_{Na}) and potassium (g_K) ionic conductances since if tetraethylammonium was injected intracellularly, the plateau level of this sodium response was shifted towards E_{Na}. The possible role of this slow sodium current in Purkinje cell integration will be discussed in light of the repetitive firing properties of this cell. (Supported by USPHS grant NS-13742 from NINCDS)

350 VISUAL AND PURSUIT EYE MOVEMENT SIGNALS IN THE MONKEY VERMIS. David A. Suzuki*, Manabu Kase* and Hiroharu Noda (SPON: S. Hagiwara) Brain Research Institute, Depts. Physiol. Anat., Sch. Med., UCLA, Los Angeles, CA 90024

The cerebellar vermis has been known to be involved with the processing of various sensory information and recently with the control of smooth pursuit eye movements. To further elucidate the relationship between motor and sensory signals in the vermis, three paradigms were employed whereby a monkey was trained to 1) track a moving small red spot, 2) fixate a stationary red spot during movement of a random dot background or 3) during movement of a small, white test spot not associated with a reward.

Modulations in Purkinje cell and mossy fiber activities recorded from lobules VI and VII were observed in association with the various paradigms employed. All units in our population exhibited discharge modulations which reflected the velocity of smooth pursuit eye movements. In addition to having this eye velocity component, some units were also found to be responsive to retinal image motion. When eye movements were minimal or absent, the movement of the background pattern was associated with activity changes reflecting background movement velocity or with a direction dependent increase in firing whereby movement per se, rather than velocity, was the determining factor behind peak firing rate.

Modulation in unit activity was observed in some units in conjunction with the movements of the test spot occurring while the monkey fixated the stationary red spot. As the velocity of test spot movement increased, the peak firing rate exhibited by these units also increased, within limits, in a fairly linear manner. For sinusoidal test spot movements, unit activity was modulated in phase with the changes in the retinal slip velocity associated with the test spot movement. The encoding within the same unit of retinal slip and eye velocity signals implicates the presence of neural correlates of target velocity signals.

Among the units whose activities reflected both eye and retinal slip velocities, some were also responsive to slippage of the entire visual field across the retina. In these units, it was again the velocity or the direction of movement which were the parameters reflected in unit discharges. Visual signals within the vermis, therefore, appear to convey 1) velocity information with respect to moving visual stimuli in general or 2) velocity information concerning discrete targets (spots) and directional information concerning movement of non-discrete images (background) across the retina. The target velocity signals would be of specific import with respect to the role that lobules VI and VII of the vermis play in the control of oculomotor function. (Supported by NIH Grant EY01051).

351 VISION STABILIZES FASTIGIAL NYSTAGMUS. T. Vilis and J. Hore, Dept. of Ophthalmology and Dept. of Physiology, University of Western Ontario, London, Canada.

The role of the fastigial n. in the maintenance of a stationary eye position was examined in 7 Cebus monkeys. Eye position was measured by EOG's or by the magnetic search coil technique. Reversible lesions of the fastigial were produced by means of a stereotaxically implanted cryoprobe.

In complete darkness, cooling the fastigial produced, in all monkeys, a pronounced nystagmus with horizontal drift (vel. approx. 100 deg/sec) of the eye towards the side of the lesion. The rate of drift was independent of eye position. Vision stabilized this drift in two phases; a fast phase in which the velocity dropped by 20% in less than 1 sec and a slow phase in which the velocity dropped exponentially by 63% of the remaining velocity in approximately 6 sec. A return to darkness usually reestablished the drift with a linear time course (63% increase in 8 to 25 s) and with the drift reaching a smaller maximum velocity. After multiple periods of light and dark, the drift tended to stabilize or occasionally reversed in direction. In this latter case a subsequent period of light and dark frequently reestablished a high velocity drift in the original ipsilateral direction.

The degree of cooling and thus the size of the reversible lesion did not affect the drift velocity in a graded fashion. In 3 monkeys in which this was studied, temperatures above a critical value produced no drift or drift that quickly stabilized, while temperatures below this value produced maximum drift.

If during cooling in the dark the monkey was rotated in the horizontal plane, the drift velocity was modulated above and below the mean value obtained without rotation. For sinusoidal rotations of .5 to 1 Hz, the gain of the VOR in the dark increased from .8, prior to cooling, to 1.0 during cooling.

These results suggest that lesions of the fastigial n. produce a destabilizing effect on the tonic balance between the vestibular n. which normally provide an internal estimate of head velocity. Vision corrects this velocity error by providing 1) a short term contribution (probably through a combination of the pursuit and optokinetic systems) which masks the velocity error as long as vision is present and 2) a long term homeostatic contribution which attempts to rebalance velocity in subsequent darkness.

352 EFFECT OF RETINAL IMAGE MOTION UPON FLOCCULAR PURKINJE CELL ACTIVITY DURING SMOOTH PURSUIT EYE MOVEMENTS. Tateo Warabi*, Hiroharu Noda and Naohiro Ishii* (SPON: H. W. Magoun). Brain Research Institute, Depts. Physiol. and Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

During smooth pursuit eye movements, simple spike activity of floccular Purkinje cells of monkeys exhibited cyclic modulations. The modulation occurred in darkness where only a red spot was visible. As retinal image movement was negligible, the modulation reflected signals arising in the oculomotor system. In some Purkinje cells, the discharge pattern was markedly modified when eye movements occurred in light, implicating an interaction between oculomotor and visual signals.

Five paradigms were employed in order to dissociate these signals: (1) tracking of a red spot in darkness, (2) tracking of the target in the presence of a stationary random-dot background, (3) fixation of the stationary target while the background was moved sinusoidally, (4) tracking, with target and background moving together in the same direction, and (5) tracking, with target and background moving in opposite directions.

In the first group of Purkinje cells, the modulation of activity appeared only in association with eye movements, and merely moving the background (paradigm 3) failed to produce any consistent modulation. The firing patterns observed during smooth pursuit in the presence (paradigm 2) or absence of the background (paradigm 1) were almost identical in these cells and primarily reflected eye velocity. In the second group of Purkinje cells, the presence of visual background (paradigm 2) markedly modified the activity changes associated with pursuit eye movements in the dark. The movement of the image of the background was the primary cause of the modification, since the background and target movement in opposite directions (paradigm 5) produced the most dramatic effect. The activity pattern associated with movement of the target and background in the same direction (paradigm 4) was the same as seen in darkness (paradigm 1). In some Purkinje cells, the secondary modification was due to an inhibitory effect of the visual inputs. In these cells, when the background was moved sinusoidally, during fixation of the stationary target (paradigm 3), discharges decreased in relation to the peaks of the velocity curve of the background movement. Purkinje cells of the flocculus appear to encode both eye and retinal image motion information. To different degrees, therefore, both oculomotor and visual information aid the flocculus in the control of smooth pursuit eye movements.(Supported by NIH Grant EY 01051).

353 THE CEREBELLOPONTINE SYSTEM IN THE RAT; AN AUTORADIOGRAPHIC AND HRP STUDY. Carl B. Watt* and Gregory A. Mihailoff. (SPON: E.D. Ross). Cell Biology, Univ. Texas Hlth. Sci. Ctr., Dallas, Texas.

In Long-Evans rats the autoradiographic technique was utilized to investigate the pattern of organization in the cerebellopontine projection system. Tritiated leucine was deposited in the deep cerebellar nuclei utilizing either a pressure or an electrophoretic injection system. After a 24 hour survival period, frozen sections were processed routinely for light microscopic autoradiography and exposed for four weeks. The results of the investigation were threefold. First, pontine afferents appeared to originate from each each of the major nuclear subdivisions of the deep cerebellar nuclei. Projections arising from the lateral cerebellar nucleus terminated extensively throughout the rostrocaudal extent of the contralateral pontine nuclei. Furthermore, terminal zones of the lateral nucleus were found within each major subdivision of the pontine nuclei including the dorsal peduncular nucleus. The interpositus nucleus was observed to project less extensively to the contralateral pontine gray with most of its terminal zones lying within the same pontine regions receiving input from the lateral cerebellar nucleus. The medial nucleus appeared to give rise to the least extensive number of cerebellopontine axons which terminated contralaterally within a small restricted portion of the dorsomedial pontine region throughout the caudal 3/5 of the pontine nuclei. Unlike the projection zones of the lateral and interpositus nuclei, the projection zones of the medial cerebellar nucleus did not consist of continuous, longitudinally oriented columns but rather formed an interrupted series of relatively small bursts of terminal labelling in the dorsomedial pontine region. Second, comparison of the various cerebellopontine terminal zones with the projection zones of other pontine afferents revealed that, although certain pontine regions were reserved for cerebellar nuclear input, there was significant overlap with projections from sensorimotor cerebral cortex as well as the superior colliculus. In addition, it was noted in several cases that the pontine projection from the lateral and interpositus nuclei gave rise to a small, but readily distinguishable ipsilateral component. Third, injections of horseradish peroxidase within the deep cerebellar nuclei demonstrated the existence of a ponto-deep nuclear projection system arising in part from each of the major subdivisions of the pontine nuclei. Furthermore, it appeared that many of the HRP-labelled somata were located within the same pontine regions which received an input from the cerebellar nuclei as determined in the previous autoradiographic studies. Such observations support the notion of reciprocal connectivity that has been reported to exist between the cerebellar nuclei and the pontine gray.

354 BRANCHING OF TRIGEMINAL MOSSY FIBER AXONS AND THE PRECISION OF BODY SURFACE REPRESENTATION IN THE CEREBELLUM. D.C. Woolston*, J.J. Kassel, J.M. Gibson, and W.I. Welker. Dept. Neurophysiology U. Wisconsin, Madison WI 53706.

Micromapping studies of tactile inputs to the rat cerebellar granule cell layer have revealed a precise mode of body surface representation termed "fractured somatotopy" (Shambes et al., BBE 15: 94,1978). It is characterized by the existence of "patches": precisely organized somatotopic representations of body parts, arranged into a non-somatotopic mosaic. Regions of the head and mouth are typically represented on several folia, and more than once on a single folium. Anatomical studies reveal extensive inter- and intra-folial branching of mossy fiber inputs, and have been interpreted as precluding precise spatial patterning of cerebellar afferents. A hypothesis compatible with both findings is that trigeminal mossy fiber branching occurs, but within the framework of precise, fractured somatotopy. Experiments with barbiturate anesthetized rats involving alternate stimulation and recording with tungsten microelectrodes in homologous patches on separate folia supported the hypothesis. Monopolar stimulation in crus IIA, crusIIB, and the paramedian lobule yielded short latency (0.75-1.0ms) responses which were confined to homologous patches in the uvula, lobulus simplex B, and crus IIB, respectively. To determine that these responses were mediated by trigeminal mossy fiber collaterals, experiments were conducted with two cerebellar stimulating electrodes (monopolar stimulation, 20-100μs biphasic pulses, 3-100μA) and a third electrode for recording antidromically evoked responses in the homolateral spinal nucleus of V, pars interpolaris. The three electrodes were positioned until similar receptive fields were obtained; in such cases antidromic spikes were frequently evoked from both stimulating loci. Collision of the responses at short intervals between stimulation at the separate loci was sought as evidence for axon branching. Such collisions were obtained with granule cell layer stimulating loci in the following pairs of folia: crus IIA & crus IIB; simplex B & crus IIB; crus IA & crus IC; crus IIA & the uvula; crus IIA & crus IIA contralateral; and simplex B & crus IIA; branching was also demonstrated between two like patches on the same folium. The probability of collision increased with the degree of receptive field overlap between the stimulating loci.

We conclude that the characteristic collateralization of mossy fibers is compatible with the finding of precise, fractured somatotopy, since the branching of trigeminal mossy fibers appears to occur in a highly organized manner within and among homologous body part patches. (Supported by NIH grants NS14748 and NS07026, and NSF grant BNS 77-16230.)

355 ELECTROPHYSIOLOGICAL PROPERTIES OF MAMMALIAN INFERIOR OLIVE NEURON IN IN VITRO BRAIN STEM SLICES AND IN VITRO WHOLE BRAIN STEM. Y. Yarom* and R. Llinas. Dept. of Physiol. & Biophys., New York Univ. Med. Ctr., New York 10016.

Two in vitro brain stem preparations have been developed. First, using our cerebellar slice technique (Llinás & Sugimori, Soc. Neurosci. Abst. 4, 1978), sagittal slices were prepared from guinea pig brain stem, which allowed direct recording from identified neurons in the inferior olive and in several reticular and motor nuclei. The second preparation consisted of whole brain stem comprising the levels from the C_1-bulbar junction to the inferior colliculus. Brain stems were perfused with modified Ringer's solution through the basilar artery following ligature of both vertebral arteries. While the slice preparation could survive for >48 hrs after isolation, the brain stem survived for close to 7 hrs. Both preparations permitted the study of electrical properties of inferior olive cells. These neurons were seen to generate, through antidromic or direct stimulation, a fast action potential followed by a prolonged calcium-dependent spike. This spike, most probably of dendritic origin, triggered a potassium conductance change which generated a large (10-15 mV) after-hyperpolarization lasting for 200-250 msec. The initial fast spike could be blocked by 10^{-5} tetrodotoxin or by removal of external sodium from the perfusion medium. The calcium dendritic spikes were not blocked by those procedures but could be prevented either by application of cadmium, cobalt, or manganese salts, or by removal of calcium from the superfusion fluid. In addition to the above, hyperpolarization of 5-10 mV beyond resting level (70 mV) revealed a second calcium current of probable somatic origin. This voltage-dependent calcium conductance, which was inactivated at the normal resting potential, was capable of generating a calcium spike at a lower threshold than that required for generating sodium-dependent action potentials. However, it was not blocked by tetrodotoxin or removal of sodium, but was blocked by cadmium, cobalt or manganese. In addition, and as opposed to the dendritic calcium spikes, it showed a marked refractoriness indicating that these two g_{Ca} differ in their properties and location. Thus, during the normal firing, sodium-dependent action potentials activated dendritic calcium action potentials. In turn, the large calcium-dependent potassium conductance generated the prolonged after-hyperpolarization, and as a rebound from this hyperpolarization a calcium-dependent somatic spike, which restarts the whole cycle. The inferior olive cell is therefore capable of behaving as a single cell oscillator if modulated to the proper membrane potential levels. Finally, simultaneous penetration of a pair of inferior olive cells allowed direct demonstration of electrotonic coupling between these neurons. (Supported by USPHS grant NS-13742)

CEREBRAL CORTEX

356 BOTH OBJECT AND LOCATION REVERSAL ARE IMPAIRED AFTER FRONTAL OR HIPPOCAMPAL SYSTEM DAMAGE IN RATS. J.T. Becker*, D.S. Olton, C.A. Anderson, & R.S. Margolies, Dept. of Psych., The Johns Hopkins University, Baltimore, MD, 21218, U.S.A.

This experiment investigated the effects of lesions of the Medial Frontal Cortex (MF) and the Fornix (FX) on the retention and reversal of a non-spatial Object Discrimination and a spatial Location Discrimination.

Acquisition training, prior to surgery, resulted in each rat learning one of the two discriminations. The Object discrimination was designed so that the rats learned to discriminate between two objects based on characteristics of the objects themselves. Neither the location of the objects in the test arena nor the turns required to approach them predicted the correct choice. The Location Discrimination was designed so that rats learned to discriminate between two objects based on their location within the test arena. Neither the objects themselves nor the turns required to approach them predicted the correct choice. All rats learned a discrimination and performed well on various transfer tests designed to be sure they had used the appropriate choice strategy.

Retention testing began three weeks after the rats had received either 1) a lesion of the MF, 2) a lesion of the FX, or 3) a control procedure. Rats with lesions of the MF were unimpaired in the retention of both the Object and Location Discriminations. Rats with lesions of the FX, however, were impaired in the retention of the Location but not the Object Discrimination.

Reversal training was begun after the rats had completed retention testing. Each rat was given three successive discrimination reversal problems. Rats with lesions of the MF were impaired in both reversal tasks, as were rats with lesions of the FX. Rats with FX lesions, however, were significantly more impaired in reversal than rats with MF lesions.

In summary, reversal of the discriminations was impaired regardless of the modality tested after both frontal and hippocampal system damage. This provides no support for the theories which suggest that these brain areas are differentially involved in spatial (as compared to non-spatial) tasks.

Retention was unimpaired following MF lesions while only the retention of the Location Discrimination was impaired following FX lesions. This suggests that the retention in the spatial modalities may be particularly sensitive to damage in the hippocampal system.

357 ASSOCIATION AND COMMISSURAL PROJECTIONS FROM AREA 18 AND THE MEDIAL BORDER OF AREA 17 IN THE ALBINO RAT. Helen Benzinger, Leo C. Massopust and Paul A. Young. Francis and Doris Murphy Neuroanat. Res. Lab., Dept. Anat., Sch. Med., St. Louis University, St. Louis, MO 63104.

The purpose of this investigation was to examine by a modern hodological method the connections of area 18 and the medial border of area 17 as defined by Krieg in the albino rat. Injections of tritiated leucine were made in these cortical areas and the locations of the injections were determined by means of coronal sections made in the same plane as those in the atlas of Konig and Klippel (1963). Brain sections were processed using the autoradiographic technique of Cowan et al. (1972). Fibers from the injected areas crossed in the splenium of the corpus callosum and terminated in a columnar configuration in the contralateral homologous cortical area, with slightly heavier labelling in layers I, IV and inner V. Immediately adjacent to the injection site a spray-like projection reached Krieg's areas 29b and 29c of the cingulate cortex with the heaviest concentration of terminal silver grains in layers I and IV. In sagittal sections two columnar configurations were seen in ipsilateral area 18a. Since the axis of these configurations was in the sagittal plane, they could not be discerned in coronal sections. A light projection to cortical layer I in the superior lip of the rhinal sulcus was also observed. In area 17 contiguous to the injection site a density of silver grains was found with the heaviest concentration in layers I, II, III, and V. Thus, area 18 and the medial border of 17 have commissural connections to the contralateral cortical homologue, whereas ipsilaterally these areas connect with the contiguous area 17 and area 18a. There also appear to be ipsilateral connections with the limbic system, specifically through the cingulate cortex and the cortex in the superior bank of the rhinal sulcus.

358 CORTICAL LOCATION OF PYRAMIDAL TRACT NEURONS ESTABLISHED WITH HRP. M.A. Biedenbach and J.L. De Vito. Dept. Physiol., U.T. Health Science Ctr., San Antonio, TX 78284 and Reg. Prim. Res. Ctr., U. of Wash., Seattle, WA 98195.

Past evoked potential and lesion studies attempted to determine the location of neurons whose axons project in the pyramidal tract (PT). Results indicated that all PT-neurons reside in the rostral third of the cerebral cortex, with maximum concentration in motor and somatosensory cortex. However, both methods yield only very approximate surface maps of underlying "PT-cortex" and do not identify the exact location of PT-cells.

We used the horseradish peroxidase (HRP) technique to determine quantitatively the distribution in cortex of the total population of PT-cells and to study cell morphology. In anesthetized cats, one pyramidal tract was microdissected off the ventral surface of the medulla. A complete cross-sectional cut was made and HRP applied to the proximal PT-stump. Thirty hours later, the cats were perfused and the brains removed. Whole-brain frozen sections were cut (frontal and sagittal planes), reacted with DAB and stained with cresyl-violet. Using dark-field microscopy and an x-y plotter (controlled by the microscope stage), the brain sections were outlined on paper and each labelled neuron in the section plotted as a dot. The total cortical region containing PT-cells was divided into eight subregions and the percent of PT-cells determined in each. Subregions 1, 3 and 8 are surface cortex: #1 (containing 6-12% of PT-cells) extends rostral to the cruciate sulcus, #3 (15-20%) extends caudal to cruciate sulcus up to the lateral sulcus, #8 (7-8%) covers cortex laterally adjacent to #3. Subregions 2, 4, 5, 6, and 7 represent sulcal cortex: #2 (containing 8-10% of PT-cells) is the lateral bank of presylvian sulcus, #4 (16-22%) the ventral bank of the cruciate sulcus (Brodmann's area 6), #5 (30-35%) the dorsal bank of the cruciate sulcus (Brodmann's area 4), #6 (2-5%) the dorsal bank and #7 (1-4%) the ventral bank of the coronal sulcus. Thus, the HRP-technique revealed that only 30-40% of PT-cells reside in surface cortex, but the majority in sulcal cortex. However, projection of all labelled PT-cells to overlying surface cortex yields an area of "PT-cortex" in rough agreement with that of the older studies. PT-cells were also found in a new cortical area, the lateral bank of the presylvian sulcus, thus far not considered part of "PT-cortex". The cruciate sulcus extends for a considerable distance (10 mm) caudally, below surface cortex. The hidden banks of this sulcus contained greatest concentration of PT-cells.

Supported in part by NSF grant BNS 78-06953 and NIH grant RR-00166.

359 ARCHITECTURE OF MURINE THALAMOCORTICAL CONNECTIONS. V.S. Caviness and D.O. Frost. Eunice Kennedy Shriver Ctr. for Mental Retardation, Waltham, Mass. and Inst. of Anat., U. of Lausanne, Lausanne, Switzerland.

The pattern of thalamocortical projections was studied in 49 adult mice. In each animal a lesion was made in either the anterior, lateral, metathalamic, or posterior (but not in the medial or intralaminar) nuclear groups; after 4 days the animals were sacrificed and their brains stained with the Fink-Heimer method. Sections from unoperated brains stained with cresyl violet or the Fink-Schneider silver stain for normal fibers were used to establish cytoarchitectonic parcellations of the thalamus and neocortex.

Thalamocortical projections terminate in three distinct tiers superficial, intermediate, and deep in the neocortex. There are two types of thalamocortical axons: Class I - intermediate and large diameter axons whose telodendria are concentrated in the middle tier (layer IV and/or layer III) although they may send collaterals to the inner or outer tiers; Class II - small axons whose telodendria are not concentrated in the middle tier and which may terminate in one or more tiers. All thalamic nuclei projecting to the neocortex have class II projections; many also have class I connections. With one possible exception, a single cytoarchitectonic area of the neocortex appears to receive class I projections from only one thalamic nucleus, although it may receive the class II projections of multiple nuclei.

Small thalamic lesions produce intracortical terminal degeneration with a restricted tangential distribution. Class I projections produce in the tangential cortical plane a topologically continuous representation of two dimensions of their nucleus of origin. This representation appears to be topologically continuous with that of at least one adjacent nucleus (lesions straddling part of the internuclear border produce degeneration straddling the border of the corresponding cortical projection areas) such that the ensemble of class I connections produces a topologically continuous cortical representation of the ensemble of their nuclei of origin.

Variations of lesion position parallel to the third nuclear axis (not represented in the cortical tangential plane) produce systematic changes in the overall density of intracortical degeneration without altering the relative densities in the three tiers or the tangential distribution of degeneration. From this it is inferred that i) thalamic relay neurons are organized along "lines of projection", neurons in the same line projecting to the same tangentially restricted cortical region and ii) the neurons of origin of class I and class II axons are intermixed along the lines of projection.

360 AUDITORY "ASSOCIATION" CORTEX AND DELAYED VISUAL MATCHING. John A. Costalupes, James H. Dewson, III, and Richard C. Placone, Jr*. Auditory Neurobiology Laboratories, Hearing and Speech Sci., Stanford Univ School of Medicine, Stanford, CA 94305.

Five monkeys (M. fascicularis), previously evaluated on a delayed cross-modal symbolic matching task, have been trained to perform a delayed visual identity-matching task (red and green) in which intratrial delays are varied from trial to trial by titration. The group includes three animals with lesions of the left superior temporal gyrus (so-called auditory association cortex), one with a unilateral lesion of the primary auditory cortex, and one unoperated control. In a previous report (Dewson, et al., J ACOUST SOC AMER., 58:S66, 1975), the operated animals were required to pair, after unfilled delays, an acoustic sample (a tone or a noise) with a visual match (red or green). Animals in which the left superior temporal gyrus had been removed could not achieve the delay durations they had achieved preoperatively on this task. In the present experiment, as would be expected, delays achieved for strictly visual matching are longer than those attained on the cross-modal task. Ablation of the auditory "association" cortex does not, therefore, appear to affect performance on a delayed visual identity-matching task.

In addition, the monkeys are being tested on a delayed visual symbolic matching task in which a cross and a triangle are matched with the colors red and green, respectively. This experiment will demonstrate whether ablation of the left superior temporal gyrus affects symbolic matching in the visual modality. Deficits in performance on the symbolic visual task attributable to prior removal of the auditory "association" cortex would show that the observed effect cannot be limited specifically to the auditory modality and would further suggest that the deficit is due to a disruption of a second-order association of the match with the sample.

361 DEVELOPMENTAL DIFFERENCES IN AFFERENTS OF MEDIAL PREFRONTAL CORTEX IN THE GOLDEN HAMSTER. James E. Crandall and Christiana M. Leonard. Dept. Neuroscience, Col. Med., Univ. of Fla., Gainesville, FL 32610.

Hoarding, a complex sequenced motor behavior, appears during the fourth week of life in the golden hamster. Since hoarding is dependent on the integrity of medial prefrontal cortex (MPFC or mediodorsal projection cortex) (Shipley and Kolb, 1977), we have initiated studies to determine whether developmental changes in the connections of this region might be associated with the emergence of this behavior.

Small volumes (.01-.1 µl) of 30% HRP were injected unilaterally through glass micropipettes (tips=30-60 µm) into the MPFC of hamster pups. The animals were sacrificed after 24 hours and their brains processed with the TMB procedure of Mesulam (1976). We describe here preliminary results from 8 brains (2 each at 10, 20, 25 and 33 days of age) with relatively large injections involving areas 8 and 24 from the frontal pole to the level of the genu.

Heavily labeled neurons were located at all ages in subcortical structures including substantia innominata, lateral preoptic area, globus pallidus, lateral nucleus of amygdala, claustrum, numerous thalamic nuclei (mediodorsal, anteromedial, ventromedial, midline and intralaminar groups), ventral tegmental area, raphe nuclei, and mesencephalic reticular formation. After injections at Day 10, glia were heavily labeled bilaterally in the corpus callosum, anterior commissure and internal capsule. Few labeled cortical neurons could be found outside of the injection site. Although callosal projections were heavily labeled by Day 20, ipsilateral cortical projections were sparse with only a few labeled neurons present in caudal suprarhinal cortex. Widespread labeling of ipsilateral cortical neurons was first seen after MPFC injections in Day 25 and 33 animals in layers V and VI of area 35 just dorsal to the rhinal fissure and extending dorsal into areas 40 and 41 (parietal and temporal association cortex). Whether the difference in cortical labeling seen after injections at different ages reflects a difference in uptake or transport mechanisms or a true difference in neuronal connectivity is currently being investigated.

This research supported by NIH grant JS 13516 to C.M.L. and a NSF predoctoral fellowship to J.E.C.

362 EFFECT OF VISUAL CORTEX LESIONS ON RADIAL MAZE PERFORMANCE IN RATS. Robert H. I. Dale* and Melvin A. Goodale* (SPON: M. L. Wolbarsht). Dept. Psych., Univ. West. Ont., London, Ont., Canada N6A 5C2.

Rats, like many animals, are able to distinguish places they have visited from places they have not. A number of investigators, using the radial maze (Olton and Samuelson, JEP: ABP 2: 97, 1976), have shown vision is an important component of this ability. In our previous experiments it was found that naive rats blinded by enucleation made significantly more errors than naive sighted rats before reaching criterion performance on an eight-arm radial maze. However, experienced rats exhibited only slight and temporary decrements in performance after blinding.

The present experiment was designed to investigate the role of the visual cortex (areas 17, 18 and 18a) in the maintenance (retention) of performance on the radial maze. Following training to criterion on the eight-arm radial maze, rats received either sham operations (group C), bilateral eye enucleations (group E), lesions of the visual cortex (group VC), or eye enucleations plus lesions of the visual cortex (group EVC). While group E showed a slight but significant performance decrement relative to group C, the other two groups, with lesions of areas 17, 18 and 18a, each showed a massive deficit. This large deficit was observed even in group EVC in which both the eyes and the visual cortex had been removed.

These results suggest that the visual cortex not only plays an important role in the maintenance of accurate radial-maze performance in sighted animals, but that its integrity is necessary for the maintenance of criterion performance in blind animals.

363 CORRELATION OF METABOLISM, BLOOD FLOW AND BLOOD VOLUME WITHIN SUPERFICIAL MICROAREAS OF THE CAT BRAIN CORTEX BY MICROFLUORO-REFLECTOMETRY. András Eke* and Arisztid G. B. Kovách* (SPON: Vernon Pegram). Exp. Res. Dept., Semmelweis Med. Univ., Budapest

Simultaneous, optical assessment of tissue NADH-level, blood flow and blood volume in superficial microareas of the brain cortex with dimension of the order of 1 mm^3 is presented. Focusing on the exposed brain cortex through a glass window implanted into the parietal bone of anesthetized cats, the intensity of the diffusely scattered light and that emitted by the NADH molecules was continuously measured at 366 nm and 450 nm respectively. The tissue NADH-level was monitored by measuring the NADH-fluorescence at 450 nm (according to Chance et al.(Science 137:499-508,1962)) and it was corrected for the hemodynamic artifact following the method of Harbig et al.(J. Appl. Physiol. 41:480-488,1976). The absolute values of blood flow and blood volume were determined at the same microarea by the microreflectometric indicator dilution method of Eke et al.(Am. J. Physiol. 236(5):H759-768,1979), which analyzes the optical density of the tissue at 366 nm during induced tissue hemodilution. A computer controlled microfluororeflectometric system measures all of these parameters automatically, providing a value for the corrected NADH-level, blood flow and blood volume every 30 second. In this way an accurate correlation of these parameters with respect to time can be made, even during extremely rapid transients of tissue metabolism and blood supply (see shaded area in the figure). As the neuronal tissue and its supplying microvessels are in contact only at the microcirculatory level, and since we are monitoring events at this level, our method can provide needed data on the interdependence and interrelated control of tissue metabolism and blood supply in the brain cortex. The non-invasive feature of the methodology seemes essential in such a study.

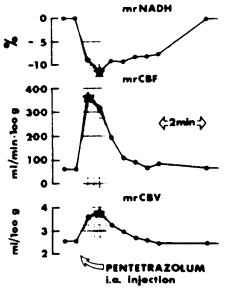

Figure: Cerebrocortical microregional corrected NADH-level (mrNADH), blood flow (mrCBF) and blood volume (mrCBV) before, during and after an induced epileptic seizure indicated by burst activity in the fronto-parietal ECoG (shaded area). After this time the ECoG activity returned to normal. Pentetrazolum was injected to induce the seizure in a dose of 27 mg/kg body weight into the cerebral circulation via the ipsilateral lingual artery.

364 CATECHOLAMINES LIBERATION IN THE BRAIN CORTEX DETECTED BY A VOLTAMMETRIC TECHNIQUE. Juan García Ramos. Dept. Physiol. Escuela Médico Militar, Mexico.

At the peak of a triangular pulse applied to two similar circuits consisting each of a graphite anode and a large silver plate as cathode, the extra-currents due to the electro-oxidizable substances near the graphite electrode tip were recorded on a Grass Model 79 Polygraph, as potential differences with opposite polarities, through resistances of equal values. The voltage reached its peak of 0.28-0.32 volts in 200 milliseconds. The pulses were applied every five seconds.

In one of these twin circuits the graphite anode was placed over the cortical surface of a curarized cat. In the other the graphite anode was over the skull bone, on a piece of cotton wet with the cerebrospinal fluid of the same animal. In this type of circuits the extra-current is due to the electro-oxidizable substances at the anode. At the voltage employed these substances can be the catecholamines or their metabolites. The difference in the extra-current occurring in both sircuits can reasonable be attributed to changes in the concentration of an oxidizable substance in the brain cortex. Unfortunately, with this technique it is not possible to differentiate electrochemically catecholamines from ascorbate, for example. Previous studies*, however, indicate that the experimental results may be attributed mainly to changes in concentration of noradrenaline.

The measured currents increased when the animal cortex changed from the sleeping to the waking condition. There were also increases after stimulation of several afferent nerves, as well as after an intravenous administration of adrenaline, or after a short period of asphyxia. Conditions all that were already reported to be associated with noradrenaline liberation into the cortical brain layers.

365 BICUCULLINE AND MOTOR CORTEX. J.D. Glass, G.H. Fromm, and A.S. Chattha*, U. of Pittsburgh School of Medicine, Pgh. PA 15261

We previously described in detail the visually evoked response from the motor cortex of cat. These studies reported the postnatal development of the response in normal[1] and visually deprived cats[2,3] and the responses interaction with arousal levels[3,4]. We now report the effects of bicuculline applied topically to the motor cortex upon the slow-wave and unit response.

Full-field patterned stimuli were presented to chloralose anesthetized cats. Slow-wave and unit activity were recorded from the forearm region of motor cortex. A microliter syringe was used to apply to the recording area microliter quantities of bicuculline (10^{-3}, 10^{-4} M) dissolved in saline.

The bicuculline, in a dose dependent fashion, decreased the positive component and increased the negative component of the slow-wave response. Prior to the application of the bicuculline, single units were not spontaneously active and discharged only in association with the positive component of the evoked potential. Following the application of the bicuculline, a record with an isolated unit was changed to a multi-unit record with intense spontaneous activity and an increased response to the stimulus. The larger amplitude spikes continued to occur only during the positive wave while the smaller amplitude spikes occurred during both positive and negative waves. There was an intense suppression of unit activity following the bicuculline enhanced negative wave.

Our results show, as reported by others, that bicuculline has a convulsant effect upon unit activity. In addition, we found bicuculline to enhance a slow-wave component associated with a suppression of unit activity. This suggests that bicuculline induces heightened activity levels in cortical neurons whose collateral axons synapse upon inhibitory interneurons. The increased interneuron activity then generates an enhancement of inhibition.

366 THALAMIC CONNECTIONS OF PARALIMBIC CORTEX IN THE TEMPORAL POLE OF THE MACAQUE. E. C. Gower* and M.-M. Mesulam. Neurological Unit, Beth Israel Hospital, Boston, MA 02215

Temporo-polar cortex is generally known as TG, but it is cytoarchitectonically heterogeneous and contains at least two distinct subareas. The anterior, lateral and inferior faces of the pole are isocortical in type,but with a poorly developed ivth layer. On the other hand,the medial face is similar to the perirhinal regions with which it is caudally continuous,and is characterized by clustered large, chromophilic neurons in lamina ii. We will refer to both of these subdivisions as examples of paralimbic cortex.

Each subdivision of TG has an individual pattern of thalamic connectivity,and these can be demonstrated both by autoradiography and by HRP neurohistochemistry. When a ^{3}H AA(amino acid)injection is restricted to lateral TG,silver grains were observed only over nuclei of the posterior thalamus: the medial pulvinar, the densocellular division of the medial dorsal nucleus(MD) and the nucleus limitans. When lateral TG injections of ^{3}H AA extended more caudally,additional grain appeared over other posterior nuclei: the medial geniculate complex,the suprageniculate nucleus and the parafascicular nucleus. In three cases with HRP injections in lateral TG,retrogradely and anterogradely transported label was seen in the same set of thalamic nuclei. In a fourth case,the injection was predominantly in medial TG, and the medial pulvinar, the medial dorsal and the limitans nuclei were labeled as before. However, a significant proportion of HRP-containing perikarya were found in midline structures: namely, the paratenial,the paraventricular, the reuniens and the subfascicular nuclei, and the central superior, intermediate and densocellular nuclei. In two cases, all HRP-containing perikarya in the thalamus were counted in a series of coronal sections separated by 400 μ. With a lateral TG injection, the thalamus contained 2585 labeled neurons; 52% of these occupied the medial pulvinar and adjoining caudal MD, and 36% appeared in the medial geniculate complex. Midline structures contained less than 1% of the total. When both lateral and medial TG were injected,the medial pulvinar nucleus together with MD still contained 53% of the labeled perikarya. However, in contrast to the previous case,24% were located in midline thalamus and only 7% in the medial geniculate complex. Intralaminar neurons accounted for the residual in both cases.

These results support two hypotheses concerning the thalamic connectivity of the temporal pole. (1) The paralimbic regions of TG are reciprocally associated with a sector of the posterior thalamus that includes the medial pulvinar and adjacent subdivisions of the medial dorsal nucleus. (2) Lateral TG is clearly innervated by the posterior thalamus. While medial TG may share these connections, it is also prominently associated with midline nuclei of the thalamus. (Supported by NIH grant NS-09211).

367 AN EXAMINATION OF COMMISSURALLY PROJECTING NEURONS IN THE PRIMATE SOMATIC SENSORY CORTEX. S.H.C. Hendry* (SPON: E.G. Jones. Washington University School of Medicine, Department of Anatomy and Neurobiology, St. Louis, MO 63110.

Commissurally projecting neurons in the first somatic sensory area (SI) of the cynomolgus monkey have been examined by light and electron microscopic methods. Neurons have been identified as commissurally projecting in one of two ways: 1) in histochemically processed material, by the presence of a reaction product in cells which had retrogradely transported horseradish peroxidase (HRP) from the contralateral SI; 2) in Golgi processed material, by the characteristic size, shape and location of these cells. The fine structure of cells identified in either way has been examined in material in which thalamocortical terminals have been "labeled" by retrograde degeneration.

The commissurally projecting neurons in SI are pyramidal in shape and are located predominantly in layer IIIB. Their basal dendrites, however, are present within layer IV, where they ramify extensively. Axon collaterals of commissurally projecting neurons can be seen to arise in layers IIIB and IV. On the somata and proximal dendrites of these neurons a small number of symmetric synapses are present. Axosomatic synapses arise, in part, from axons which form two or more en passant contacts with a single cell. By contrast with the somata and dendrites, the axon hillock-initial segment region receives a large number of symmetric synapses. Apparently several types of terminals end upon this region, each at a characteristic point along the length of the initial segment.

Evidence suggesting that some commissurally projecting neurons receive monosynaptic thalamocortical inputs will be presented.

368 THALAMIC PROJECTIONS TO LAYER I OF RAT NEOCORTEX. Miles Herkenham. Lab. Neurophysiol., NIMH, Bethesda, MD 20205.

In previous autoradiographic studies of thalamocortical connections, I have shown that the ventromedial nucleus (VM) projects to layer I of widespread neocortical regions (JCN, 1979, 183, 487), whereas intralaminar nuclei project to deep cortical layers of a similarly wide cortical extent (Anat. Rec., 1978, 190, 420). Analysis of over 100 cases of small iontophoretic injections of tritiated amino acids placed into most of the thalamic nuclei has revealed a region of thalamus, located for the most part laterally adjacent to the intralaminar nuclei, that projects primarily to layer I. The region comprises the ventral anterolateral (VAL), posterior (PO), and magnocellular medial geniculate (MGm) nuclei. The projections from this region differ in two respects from those of VM: they are directed to more restricted cortical areas, and they have secondary layers of termination. The dorsal and medial parts of VAL project far beyond the limits of the traditionally accepted terminal zones in the motor areas, into layers I and VI of parietal and occipital areas. Termination in the superficial half of layer I of visual cortex is remarkably dense. PO projects to layers I and V of parietal areas; the heavy layer I band occupies a deeper location, in Ib, whereas the secondary band is situated in the cell poor zone, Va. MGm projects to the outer two-thirds of layer I, and to a lesser extent to deep layers in the regions of auditory cortex and more rostral levels. Depth profiles indicate that there are no sharp boundaries of terminal layering, even in layer I, after the MGm injections.

Still other thalamic nuclei project to layer I, but not as heavily as to deeper layers. These include the mediodorsal, lateral dorsal and lateral posterior (LP) nuclei, whose primary layer of termination is found in layers III and IV. Interestingly, several thalamic nuclei have terminations whose laminar patterns are area-dependent. The VAL nucleus has a tri-laminar distribution in motor cortex, but the aforementioned I/VI distribution in most other areas. The PO nuclear group projects to Ib and Va of SmI cortex but to I and IV of the region of SmII cortex and to I and III of motor cortex. Another striking instance of area-dependent lamination is seen after posterior LP injections; both cortical areas 17 and 18 are labeled, but whereas the laver I band is continuous across the cortical boundary, the intermediate band shifts from layer IV to Va in passing from 18 to 17. Taken together, the results show a large area of thalamus laterally adjacent to the intralaminar nuclei that sends widespread projections to layer I and, in addition, to deeper layers whose precise locations are area-dependent.

369 THE DISTRIBUTION OF THALAMOCORTICAL SYNAPSES ON THE APICAL DENDRITES OF LAYER IV,V, AND VI PYRAMIDS. Steven M. Hersch* and Edward L. White. Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA. 02118

Every cortical neuron which has dendrites within layer IV and lower layer III has been found to receive thalamic afferents (White,'78; Peters et al, in press). Quantitative data on the thalamocortical afferents in mouse primary somatosensory cortex has suggested that, for a given length of dendrite, nonspiny stellate and bipolar cells receive more input from the thalamus than spiny neurons, and that spiny stellate cells receive thalamic afferents with the next greatest frequency, followed by the basal dendrites of layer III pyramids and, finally, by apical dendrites of superficial layer V pyramids which receive only few thalamic synapses. Other types of deep pyramids, in layers IV-VI, were not examined and there is evidence that, in rat visual cortex, pyramids with cell bodies deep in layer V receive greater numbers of thalamocortical synapses than those superficial in layer V (Ryugo et al., '75). In the present study, layer IV, V, and VI pyramids, located in the postero-medial barrel subfield of the mouse (CD/1), are being examined in order to characterize the distribution of thalamic synapses on the layer IV and lower layer III portions of their apical dendrites. Electrolytic lesions have been placed in the ventro-posterior thalamus, pars lateralis, and in the posterior thalamic nucleus to induce degenerative changes in thalamic terminals. Pyramidal cells postsynaptic to the degenerating terminals have been identified with the Golgi/EM technique of Fairen et al. ('77). A single deep layer V pyramid, whose apical dendrite bifurcates at the lower border of layer IV into two main branches which later terminate in layer III, has so far been examined in serial thin sections. The density of thalamo-cortical synapses per unit length of its dendrite is comparable to that of layer IV spiny stellate cell dendrites. Most of these synapses are axospinous and the remaining few are with small dendritic protrusions which might be considered sessile spines. Quantitative data on the thalamocortical relations of layer IV, V, and VI pyramids will be presented and their functional implications discussed.

370 HOPPING LOCOMOTION IN RATS IRRADIATED IN UTERO. Samuel P. Hicks and Constance J. D'Amato. Department of Pathology, University of Michigan, Ann Arbor, Michigan 48109.

A spectrum of highly reproducible malformations can be induced in rats with pre- or early postnatal x-irradiation, and much is known about their morphogenesis (Hicks and D'Amato, 1978). 150 R on the 13, 14, or 15th day yielded a large subcortical ectopia, a thin cortex, a malformed spinal cord, and a hopping gait. The malformed cord and deficiencies of forebrain commissures have been suggested as causes of the hopping. Our studies point to abnormalities of the "spinal locomotor generator" as a major part of the problem, but they also indicate that the cortex and other supraspinal mechanisms adapted their controls to the abnormal cord. The cord abnormality was a deficiency of neurons and distortion of the architecture of the gray matter, especially the posterior horns, with midline fusion of the central gray. H_3 thymidine labeling showed that most large ventrolateral motor neurons were proliferated early in the 12-16 day period followed by neurons of ventromedial, central and posterior horn, and contributions to Rexed laminas I, II last. Posterior horns were the most affected after 13-15th day irradiation, because of the balance between cell destruction and regulative capacity for repair peculiar to that period. Retrograde HRP labeling showed a diminished complement of corticospinal neurons, some appearing in the ectopia; corticospinal tracts were formed. From birth, fore- and hindlimb pairs moved synchronously rather than in the normal alternating mode. Some animals gradually switched to a partially or nearly normal gait of forelimbs at about three to five weeks, but only rarely did hindlimbs switch. Most animals jumped accurately from one level platform to another; they swam as they walked. They righted when dropped from a supine position, but limb movements were not recorded. Tactual placing by one forelimb could be elicited, even in rats that hopped with forelimbs, but scratching by one hindlimb was accompanied by mirror movement of the other. Hours after transection of the mid-thoracic cord, firm pinching of one hind foot elicited an exaggerated, repeated crossed extension reflex (mass reflex), and simultaneous pinprick of the dorsa of hindfeet resulted in withdrawal of both feet, in both normal and irradiated rats. As the animals became stabilized, normal rats usually responded to bilateral pinprick with crossed extension, and irradiated rats showed withdrawal of both feet.

(USPHS NS 10531).

371 LAMINAR DISTRIBUTION OF CHOLINERGIC INNERVATION IN RAT NEOCORTEX: LESIONS OF EXTRINSIC AND INTRINSIC COMPONENTS. Michael V. Johnston and Joseph T. Coyle. Dept. Pharmacology, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

Cholinergic neurotransmission plays an important role in cortical function. Lack of a highly specific neuroanatomical method for visualizing cholinergic neurons has prevented a precise description of the organization of this innervation. Our previous experiments indicated that half of the cholinergic innervation to rat fronto-lateral neocortex projects from neuronal perikarya in the basal nucleus (BN) (Trans. ASN 10:73, 1979); and up to 40% may reside in intrinsic cholinergic neurons (Brain Res., in press).

In the present experiments, the laminar distribution of cholinergic innervation was examined quantitatively by measuring the activities of choline acetyltransferase (CAT) and acetylcholinesterase (ACHE) in microdissected rat sensorimotor cortex. Fresh slabs of rat lateral neocortex were frozen onto a microtome stage and five reproducible laminar samples of 350μ thickness were obtained by shaving with the blade at progressively deeper layers. Small portions of each layer were left attached to the remaining specimen which was then examined histologically to correlate biochemical and cytoarchitectonic composition. In the unlesioned rats (N=8), CAT activity was higher in cortical laminae I (116 $\pm$ 2% of mean cortical specific activity) and laminae IV and V (105 $\pm$ 3%) than in laminae II-III (90 $\pm$ 2%) and lamina VI (85 $\pm$ 4%). The distribution of ACHE activity was similar to that of CAT. One week following injection of 3.5 nmol of kainic acid into BN, CAT activity in ipsilateral cortex was lowered 43 $\pm$ 3% (N=5, $p < .01$) and ACHE was reduced 52 $\pm$ 3% ($p<.01$). These reductions were reflected equally in all cortical laminae.

The laminar distribution of these cholinergic markers was also examined in the neocortex from adult rats that had been treated at 15 days gestation with methylazoxymethanol acetate (MAM) which deletes neurons in laminae II-IV. CAT activity in cortex following this lesion is almost entirely related to subcortical afferents since electrolytic NB lesions in MAM treated rats reduced total CAT by 90%. In MAM treated rats, CAT activity was highest in the outer layers and decreased progressively in lower layers so that the deepest zone was 58% lower than the subpial zone.

Data from these experiments are consistent with the view that rat neocortex contains subcortical cholinergic afferents projecting to all layers and a population of cholinergic intrinsic neurons localized to the superficial layers which may project to deeper cortical layers. Supported by USPHS grants MH-26654, NS-13584, RSDA II MH-00125 and Fellowship NS-06054.

372 A (^{14}C)DEOXYGLUCOSE STUDY OF SOMATOSENSORY AND ASSOCIATED CORTICAL AREAS IN THE MONKEY. S. Juliano*, P. Hand, B. Whitsel, C. Goochee*, P. Karp*, and R. Bajcsy*. Department of Animal Biology School of Veterinary Medicine, School of Allied Medical Professions; and Moore School of Electrical Engineering, University of Pennsylvania, Philadelphia, PA 19104; Department of Physiology, School of Medicine, University of North Carolina, Chapel Hill, NC 27514; and Laboratory of Cerebral Metabolism, NIMH, Bethesda, MD 20014.

In a previous report, we described cortical columnar (modular) organization, using the (^{14}C)-2-deoxyglucose (2DG) technique, in primary and secondary somatosensory cortices (SI,SII) of an unanesthetized, paralyzed Cynomolgous monkey. This animal was stimulated on volar thumb, thenar eminence and index finger with servomotor controlled brush strokes. (Anat. Rec., 193; 260-1, 1979). Our current work has evaluated an unstimulated animal and 2 additional monkeys, varying the proximodistal location of the stimulus. These animals were brush stroked either from the proximal interphalangeal joint to the tip of the left index finger or on the anterior midline of the left forearm (1.5x6cm). 2DG methodological details were after Sokoloff (J. Neurochem., 28; 1977). We found the size of modules and basic organizational pattern of metabolic activity to compare with that of our initial results in SI and SII. Contralateral modules in 3a and 3b averaged 360u, and in area 1, 320u. The modules for these two recently stimulated monkeys were: (a) confined to a more restricted cortical topological area (b) decreased in number and (c) primarily in areas 1 and 3b. This labeling corresponded to somatotopic representations in SI as previously described. In the control animal there was a paucity of modules in areas 3a, 3b, 1 and 2. In all four monkeys examined there was additional labeling in other cortical areas. These included areas 5 and 7, area 4 adjacent to 3a, the inferior bank of the lateral fissure, the insula, and both banks of the superior and inferior aspects of the superior temporal sulcus (STS). Activity in these areas was columnar in nature, but the modules were less regular in tangential extent and shape than those of SI. Also, many of these modules were present in the control animal. Thus, they may reflect cortical activation other than somatosensory. Some possibilities for the nature of this labeling include: (a) attempts by the paralyzed animal to tactually or visually manipulate its environment or (b) multiple somatosensory or polysensory areas (e.g. auditory input). The sizes of these modules were in the following ranges: areas 5 and 7 (360-600u), STS (600-890u); inferior bank, lateral fissure (540-720u); insula (600-720u); area 4 (540-660u).

373 PREFRONTAL NEURON ACTIVITIES RELATED TO DIRECTION AND SIZE OF THE MOVEMENT DURING DELAYED-RESPONSE. K. Kubota and S. Funahashi*. Dept. Neurophysiol., Primate Res. Inst., Kyoto Univ., Inuyama, Aichi, 484, Japan.

Recent findings that the motor cortex PTN activity is modified by instructions given prior to movement onset prompted us to re-examine prefrontal (PF) neuron activities in a delayed-response in which motor responses are strictly controlled and PTN activities are well defined. It was aimed at extracting a specific PF neuron activity related to the choiced movement.

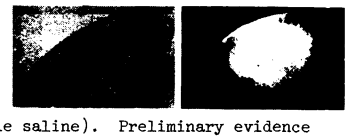
Monkeys performed wrist extension or flexion movement from a predetermined start zone to a predetermined target zone (displacement, 8°-40°), according to the visual cue presented prior to movement. The first task was a two-choiced visual tracking of single step. Rotating the handle to a central 8° zone, green lamp was on. Three sec later (preparatory period), its color was changed to red (GO signal). Simultaneously one of target lamps was on, indicating the direction of the movement (flexion or extension) of the same size. Then the monkey rotated the handle to an appropriate target zone (8°). The second task was a two-choiced delayed-response; one of target lamps (0.5 s) was on as soon as the green lamp was on, and succeeding 2.5 s was the delay period. In the third task only one of choiced movements was repeated, being the sequence the same as above tasks. In two macaque monkeys, 67 PTNs were rocorded from the hand motor area and 175 PF neurons were from the dorsolateral prefrontal cortex.

During a preparatory period of the first task both PF neurons and PTNs showed a steady activity and after GO signal they were activated in association with movement either unidirectionally or bidirectionally, though occurrence of unidirectional pattern was less frequent in PF neurons than in PTNs. With 0.3-0.7 s before GO signal of the third task there developed a preparatory activity (gradual increase on one direction of movement and decrease on the other). After GO signal these changes were further enhanced. During early phase of delay of the second task there appeared an activity, higher or lower than that in the first and third tasks. This activity superimposed upon preparatory or movement-coupled activities. Neuron activities were further tested in a task in which two different sizes of the movement of the same direction were presented. Size-dependent activity appeared in delay period in PF neurons but not in PTNs. Higher rates correlated to larger movement was observed in 26 and those to smaller one were in 8 PF neurons.

It is concluded during delay priod of the delayed-response task that in PF neurons both direction and size of the movement are differentially coded and that in both PF neurons and PTNs there are activities capable of facilitating movement-coupled activations of PTNs.

374 THE PREFRONTAL PROJECTION TO THE SUPERIOR COLLICULUS IN THE MONKEY. G.R. Leichnetz, R.F. Spencer and J. Astruc. Dept. of Anatomy, Medical College of Virginia, Richmond, Va. 23298.

A projection from the cortex within the concavity of the arcuate sulcus, the "frontal eye field," of the monkey, has been previously described by Kuypers and Lawrence (1967) and Astruc (1971) using silver methods, and more recently by Kunzle, Akert and Wurtz (1976) using the autoradiographic method. We have found that the use of our horseradish peroxidase gel (Griffin et al Br. Res. in press) in combination with the TMB procedure produces superb delineation of both anterogradely and retrogradely transported enzyme, such that one can virtually study the afferent and efferent projections of a given cortical area in the same experimental case. In this study, HRP gel placements were made within the arcuate cortex of both rhesus and cebus monkeys. The animals were allowed to survive for 24 hrs. and were processed according to the Mesulam TMB protocol (1978). The results illustrated below in both bright and dark field demonstrate the heavy projection of the frontal eye field to the stratum intermedium of the ipsilateral superior colliculus. While some anterogradely transported HRP was present in the stratum opticum above, and stratum profundum below, clearly the heaviest projection is to the intermediate stratum. The HRP technique did not appear to confirm the projection to the stratum zonale suggested in autoradiographic studies.



In an effort to determine the source of prefrontal projections to the tectum we injected HRP into the superior colliculus in a series of cebus monkeys (0.05 µl 25% HRP in sterile saline). Preliminary evidence confirms the projection from the frontal eye field to the colliculus. Large numbers of small pyramidal and stellate elements of Area 8 were labelled ipsilateral to the injection. Remarkably, the labelled cells were heavier in the inferior portion of Area 8, and large numbers of labelled small and medium-sized pyramids were present in layers III and V of the inferior bank of the principal sulcus and inferior convexity rostral to the arcuate cortex. While some labelled pyramids were often present in the dorsal convexity, it appears to us that the prefronto-tectal projection is primarily from inferior Area 8 and the prefrontal convexity inferior to the principal sulcus. The possible significance of these findings will be discussed. Supported by NSF Grant 78-22971.

375 Brightness Encoding in Cells of Area 17 in the Awake Behaving Rhesus Monkey. Maguire, W. M.*, Baizer, J. S. & Weiss, C*. Division of Neurobiology, Department of Physiology, School of Medicine, SUNY, Buffalo, NY 14226.

The manner in which such stimulus dimensions as orientation, direction and wavelength affect the responses of the cells of striate cortex has been described in detail in recent years. Less is known about the manner in which stimulus intensity is encoded. We have found that different functional cell classes show different sensitivities as a function of luminance. In particular, we have found that orientation specific cells are differentially sensitive over a narrower range of luminances than non-orientation cells.

Single unit responses were recorded extracellularly in the awake rhesus monkey trained in a visual fixation task. Receptive field organization was determined using stimuli of high contrast which varied in size, shape, color, orientation and velocity.

Following classification, the responses of these cells to moving bars and large spots of light (exceeding receptive field boundaries) were tested. Responses to these stimuli were recorded at 9 different luminances which covered a range exceeding 3 log units. Background luminance was maintained at .15 ft lamberts and the maximum stimulus luminance was 10.8 ft lamberts. We analyzed both peak response frequency and total number of spikes.

Orientation specific non-color cells discriminate only a small range of stimulus intensities. When tested with an optimal stimulus they are sensitive only over a range from .5-1.5 log units, from threshold to saturation. In general these cells were unresponsive to or weakly inhibited by large spots.

The majority of cells lacking orientation specificity responded both to white moving bars and large white spots. Cells which were excited by large spots continued to discriminate luminance differences throughout the range tested. Some of these cells would likely discriminate even higher intensities. The range of luminances of a moving bar discriminated by non-oriented cells is somewhat narrower, but most cells show differential responses over a range in excess of 2 log units. These results suggest that orientation specific cells contribute no differential information about luminance at higher stimulus luminances. The wide sensitivity ranges of most non-oriented cells suggest that these cells may encode luminance information for both patterned and diffuse stimuli. Supported by NIH Grants 1 RO1 EY02230-02 and 5 T32 EY07019-04.

376 CORTICAL CELL RECORDING AFTER 3 YEARS WITH CHRONICALLY IMPLANTED MICROELECTRODES. J.S. McIntosh, E.M. Schmidt and M.J. Bak. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Chronic microelectrodes have been implanted in the precentral cortex of a number of monkeys for long term monitoring of single unit activity. The longest implant was 3 years and 49 days. On the day of sacrifice two of the eleven implanted electrodes were still recording neuronal activity. Examples of this activity are shown in Fig. 1.

During the course of the implant a number of different cells were recorded from a single electrode, indicating that the electrodes were moving in the brain. The movement was usually very slow, allowing the same cell to be recorded for many days or months. The criteria for classifying the neuronal activity as originating from the same cell were: (a) the wave shape was similar from day to day, (b) sensory field was the same, (c) the cell maintained the same firing pattern during trained movements, and (d) when the cell was operantly conditioned to fire at specific rates the monkey made the same movements on succeeding days. The longest recording from the same cell was 108 days.

Vapor deposited Parylene-C was used to insulate the iridium microelectrodes and gold lead wires. With three of the of the eleven electrodes the insulation remained intact over the entire period of implantation. Pin holes through the insulation along the electrode shafts developed in the other electrodes. When the electrode impedance dropped due to insulation breakdown, neuronal activity was usually lost due to the shunt paths. Scanning electron micrographs of some electrodes show surface defects in the insulation that may have been due to procedures in initial electrode preparation.

Histological examination of the brain tissue revealed little or no reaction to Parylene coated electrodes. From these results it appears that very long term recordings from the nervous system are possible.

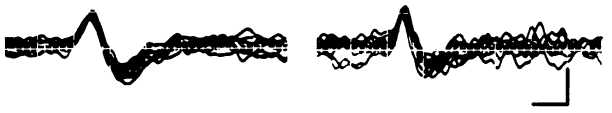


Fig. 1. Neuronal activity recorded from two of the electrodes 3 years and 49 days after implantation. Calibration .2 ms, 50μv.

377 VISUAL RECEPTIVE FIELD OF DORSOLATERAL PREFRONTAL NEURONS IN CHRONIC MONKEYS. A. Mikami*, S. Ito* and K. Kubota. Dept. of Neurophysiol., Primate Res. Inst., Kyoto Univ., Inuyama City, Aichi, 484, Japan.

Recent neurophysiological studies in behaving monkeys indicate that the dorsolateral prefrontal (PF) neurons are activated by visual cue stimuli, but relations between physical parameters of the stimulus and neuronal responses have not yet been examined systematically. Present study attempts to determine visual response properties of PF neurons, more specifically, their visual receptive field (RF) size.

Four rhesus monkeys were trained to perform a visual fixation task; fixating their eyes for 0.5-5 s on a small circular spot (0.3°, 1.0 cd/m^2) at the center of a tangent screen (1.5 X 1.2 m). The trial was started by depressing the lever. After a fixed waiting period, a spot appeared and then 0.5-3 s later, a slit stimulus (2.5 cd/m^2), unrelated to reinforcement, was presented for 0.5 s. Within 0.5-3 s after the slit, spot brightness was changed. Releasing his hand from the lever, he was rewarded.

A total of 197 neurons was sampled from the dorsolateral PF cortex while the monkey was performing a task in which moving slit stimulus of relatively large size (6°-40°/s, 3° X 30°) was routinely presented in the contralateral visual field. Seventy neurons showed clear changes of their discharge rates in response to the fixation spot with latency of 100-300 ms. Of these, 48 neurons responded also to extrafoveal slit stimuli with similar latency. Presence of neurons responding exclusively to the fixation spot suggested a mechanism related to the foveation. Further, 127 neurons responded only to the slit.

The RF was determined in 35 neurons, using 1° X 5° or 1° X 1° slit stimuli. Its size varied from about 10° X 10° to 60° X 60° and in 28 neurons it was larger than 30° X 30°. Often it was difficult to draw a boundary line between responsive and unresponsive areas because responses became gradually weaker when the slit was moved away from the RF center. Only 5 neurons showed a clear surround inhibition. In 16 neurons the RF was contralateral to the recorded side and in 2 it was ipsilateral. In 17 neurons it expanded from contralateral to ipsilateral side. As for topography of recorded neurons, rostrally located neurons tended to have larger RF. Responses to stationary and moving slits were compared in 26 neurons, and 7 showed stronger responses to the moving slit (6°-12°/s) than stationary one. Differential selectivities of rate changes depending on the direction of movement were found in 8 neurons.

Thus, dorsolateral prefrontal neurons have relatively large visual receptive fields. It is projected mainly from the contralateral hemifield.

378 AFFERENT VISUAL SIGNALS FOR DIRECTED VISUAL ATTENTION. Brad C. Motter*and Vernon B. Mountcastle, The Johns Hopkins University School of Medicine, Baltimore, Md.

Single neuron studies were made in the cortex of the inferior parietal lobule (area 7) in 8 hemispheres of macaque monkeys trained in tasks requiring maintained, directed visual attention. Area 7 contains a number of sets of cortical neurons, including those active during projection and manipulation with arm and hand; those active during visual fixation, tracking, or saccading; and those responsive to visual stimuli, per se; and those displaying various combinations of these properties. A large set of the visual neuron group is responsive to stationary and/or moving lights within response areas that commonly extend towards the contra lateral perimeter of the binocular visual field, and centrally towards but rarely to include the fixation point, where lights may evoke suppression. These response areas may be maximally sensitive close to the binocular perimeter, and may be bilateral. A smaller group is responsive to stimuli within the monocular portion of the field. Another is activated, not suppressed, by foveal and immediately peri-foveal stimuli, but not by small visual targets adequate for fixation and detection. Cells of all these sets show a remarkable directionality when tested with moving lights, and the response areas determined by moving and stationary lights are frequently not coincident. The responses of light sensitive cells frequently are changed in amplitude or even reversed in direction from excitation to suppression, or vice versa, by changes in background illumination. A small number of light sensitive cells appears to be related to response areas located in head-body, not retinal coordinates. No instance of orientation selectivity has been observed.

379 HUMAN LANGUAGE CORTEX: IDENTIFICATION OF COMMON SITES FOR SEQUENTIAL MOTOR MOVEMENTS AND PHONEMIC PERCEPTION, SEPARATE SITES FOR MEMORY, SYNTAX. George A. Ojemann, Catherine Mateer*. Dept. Neurological Surg. RI-20, UW, Seattle, WA, 98195.

Electrical stimulation mapping of human periSylvian cortex during standard tests of naming, reading, short-term verbal memory, single and sequential oral facial movements, and phonemic perception was undertaken during craniotomy under local anesthesia for resection of epileptic foci. The evoked changes in each of these tests were measured at 8-15 preselected sites in left brain of 5 patients and right brain of 1 patient, all of whom were shown to be left brain dominant for language by preoperative intracarotid amytal testing. The procedures used for obtaining informed consent for the research portions of this study in these patients had been reviewed in advance by the institutional biomedical sciences review committee in accordance with the applicable Public Health Service guidelines for human experimentation. Stimulation currents were at the highest level that did not alter discharges (mean 4.8mA).

The ability to mimic sequential oral facial movements and to perceive phonemes was altered by stimulation of the same left brain sites, at least 2 in each patient. This identifies a cortical sequential motor-phonemic perception language system that provides a link between speech production and understanding. This is an anatomic basis for the motor theory of speech perception (Liberman, et al., Psychological Reviews 47:431, 1967). These sites are in periSylvian cortex of frontal, temporal and parietal lobes, an area that would be included in almost every cortical lesion that gives rise to persisting language disorder. Phonemic perception was not disturbed at sites where motor movements were intact. Surrounding these cortical sites is a separate series of at least 2 left brain sites in each patient, where only short-term verbal memory was altered by stimulation, with stimulation during storage altering memory at parietal and temporal lobe sites and retrieval stimulation at frontal sites. Between the sequential motor-phonemic perception and memory sites are left brain sites in each patient where only naming or reading are altered by stimulation, including sites with changes only in the syntactic organization of language. In motor and immediately premotor cortex, are sites where all types of oral movements are altered and arrest of all aspects of language evoked, identifying a final motor pathway for speech. Stimulation mapping of the periSylvian cortex in nondominant right hemisphere showed no changes in any of these tests outside of motor cortex.

This research was supported by NIH Research Grant NS 04053, awarded by NINCDS, PHS/DHEW.

380 CONNECTIONS OF THE FRONTAL EYE FIELDS IN THE CAT. G.J. Pascuzzo* and L.C. Skeen. Inst. Neuroscience and Behavior, Univ. Del., Newark, DE 19711.

In several mammalian species electrical stimulation of discrete areas within the frontal cortex, the frontal eye fields (FEF's), elicits specific eye movements. Although the FEF's have been studied with a number of techniques, the involvements of these cortical areas in ocular movements remain uncertain. In order to further elucidate their role in specific eye movements we are tracing the connections of the FEF's with horseradish peroxidase (HRP) in conjunction with electrical stimulation studies.

In cats lightly anesthetized with chloral hydrate, the FEF's are stimulated with 25-50 uA negative current via bipolar electrodes to produce a specific eye movement, whereafter 0.2-0.05 ul of 10-40% Sigma VI HRP is injected at the site of lowest threshold. The brains are processed for HRP after 48 hr. survival time utilizing a tetramethyl benzidine procedure similar to that described by Mesulam (1978).

Retrograde and anterograde transport of HRP can be traced to cortical and subcortical structures. In the frontal cortex retrogradely labeled cells appear primarily in laminae II and III of the contralateral FEF. Labeled cells are present ipsilaterally in restricted areas of the cingulate, suprasilvian and ectosilvian gyri.

Heavy retrograde and anterograde labeling is apparent in the ipsilateral claustrum. Significant numbers of cells are found throughout structures in the rostral basal forebrain, including the vertical limb of the diagonal band of Broca, the substantia innominata, the anterior hypothalamic area and the basal magnocellular amygdaloid nucleus.

In the ipsilateral diencephalon HRP is found in the dorsal thalamus and hypothalamus. The ventrolateral portion of the medial dorsal nucleus, the medial portions of the ventral anterior and ventral lateral nuclei, and the ventral medial nucleus all exhibit retrograde and anterograde transport. Retrogradely labeled cells are also seen in the lateral and medial areas of the hypothalamus.

Several large labeled cells are found in the suprageniculate nucleus and pretectal area, ipsilaterally. In the brain stem labeled cells are seen in the dorsal tegmental nucleus, locus coeruleus and raphe nuclei.

381 A COMBINED GOLGI-EM STUDY OF THE SYNAPTIC RELATIONSHIP BETWEEN A SMOOTH STELLATE CELL AND A PYRAMIDAL NEURON IN RAT VISUAL CORTEX. Alan Peters and Charmian C. Proskauer*. Dept. Anat., Boston Univ. Sch. Med., Boston, MA 02118.

In a previous study of smooth and sparsely-spined stellate cells in the rat visual cortex using a combined Golgi-electron microscope technique (Peters and Fairen, J. Comp. Neur., 181: 129, 1978), it was shown that the axons of these neurons form symmetric and inhibitory synapses. The postsynaptic elements are various and include the cell bodies and dendrites of pyramidal neurons. However, this study provided no information about how many synapses one stellate cell can make with an individual pyramidal neuron, or how these synapses are disposed. The opportunity to investigate this arose when a light microscopic examination of a Golgi impregnated preparation, which had been goldtoned for electron microscopy, revealed a stellate cell axon giving rise to some boutons which were apparently associated with an impregnated pyramidal neuron in layer III. On the basis of light microscopy we predicted that some of the axonal boutons of the stellate cell apparently apposed to the pyramid were forming synapses with it. Upon ultrastructural examination of the apposing boutons in serial thin sections, in which the profiles of both neurons were identified by their content of gold particles, the prediction was shown to be correct. Some of the boutons observed in the light microscope resolved into two separate axon terminals when the thin sections were examined and nine axon terminals were found to synapse with the pyramidal neuron. Five terminals formed axosomatic synapses, one synapsed with the shaft of the apical dendrite, and three synapsed with basal dendrites.

In addition we encountered a synapse between an axon terminal of the stellate cell and one of that cell's own dendrites. Although synapses of this kind have been supposed to exist in the cerebral cortex, so far as we are aware this is the first electron microscopic demonstration of one of them. Supported by NINCDS Research Grant NS 07016.

382 SUBCORTICAL PROJECTIONS OF THE PERICRUCIATE GYRUS IN CAT. E. Ramon-Moliner. Dept. Anat., School of Medicine, Univ. of Sherbrooke, Sherbrooke, Quebec, Canada, J1H 5N4.

Following injections of radioactive aminoacids in various points of the precentral, postcentral and coronal gyri, the brains were studied for the autoradiographic demonstration of efferent connections in sagittal and coronal sections. A massive efferent system terminates in the ipsilateral thalamus within which a somatotopic distribution can be envisaged. The reticular nucleus of the thalamus appears well outlined on the basis of what appears to be a specific plexus. There is a bilateral projection to the head of the caudate nucleus, the contralateral one being reached through fibers present in the rostral corpus callosum. Within the subthalamus one can see the origin of a sizeable vertical system of collateral fibers (the prerubral bundle of Cajal) in the form of ascending fibers which are labeled by the slow component of axonal transport. It could terminate in certain isolated islands within the pretectal tegmentum. It does not send fibers to the red nucleus. The latter center was devoid of evident afferent fibers, except in one case where the injection had been placed in the most lateral portion of the gyrus pericruciatus (coronalis). The contribution to the nucleus subthalamicus was uncertain but the region dorsal to this center (zona incerta) received a sparse by unquestionable projection. Within the lower brain stem the motor nuclei were devoid of afferents. Only the contralateral "lateral reticular nucleus" was labeled. The pyramidal tract was labeled by the slow axonal transport throughout its length. It could be followed until its decussation in the lower medulla oblongata. This indicates that a sizeable projection must reach the spinal cord. This structure, however, has not yet being processed for autoradiography and only further research will clarify the precise distribution of these cortico-spinal fibers. The contrast between the lack of projections to brain stem motor nuclei and this postulated projection to the spinal cord appears to indicate that if the cranial motor nuclei receive direct afferents from the cerebral cortex in cat, it must be from regions other than the pericruciate gyrus. However, the possibility cannot be excluded that they may receive indirect afferents via some relay station for the fibers of Cajal's prerubral bundle.

383 DIRECT AND INDIRECT PROJECTIONS FROM THE MOTOR CORTEX TO THE INFERIOR OLIVE IN THE CAT. J.A. Saint-Cyr and J. Courville. Centre de Recherche en Sciences Neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec.

Injections of horseradish peroxidase (HRP, 20-30% Type VI, .1-1.6 µl) in the inferior olivary complex of 10 cats resulted in the retrograde labeling of cells in the motor cortex. The labeled cells were found in layer V ε were more numerous ipsilaterally. They were mainly in the presylvian gyrus and the banks of the cruciate sulcus and were sparsely distributed. A few were also present in the orbital, coronal and proreal gyri.

Injections of tritiated amino acids (^{3}H-ℓ-leucine [150-330 µCi/µl] or ^{3}H-ℓ-proline, leucine, lysine and ℓ-amino acid mixture [200 µCi/µl] NEN, vols. .2-2.0 µl) were made in the pericruciate region of 8 cats. Five injections involving the anterior sigmoid gyrus resulted in the labeling of the inferior olive. In the inferior olive, the caudal medial portions of the medial accessory olive (MAO) excluding subnucleus β were bilaterally labeled in two cases. The grain density was greater ipsilaterally than contralaterally. In three other cases, similar but very weak deposits were present. Previous studies had indicated terminations from the cortex in the rostral principal (PO) and dorsal accessory (DAO) olive (Sousa-Pinto and Brodal, Exp. Brain Res. 1969, 8: 364). Numerous fibers of passage were observed to pass through the rostral PO and DAO in our material and the presence of terminations was equivocal. Further experiments using shorter survival times are planned in order to resolve this question.

In the mesencephalon, deposits of silver grains over the nucleus of Darkschewitsch, the interstitial nucleus of Cajal and the rostro-medial pole of the red nucleus were present ipsilaterally in four cases. These cellular groups were previously identified as major sources of input to wide areas of the homolateral MAO and PO (Saint-Cyr and Courville, Neurosci. Abst. 1978, 4: 168). It is suggested that the motor cortex may influence widespread areas of the cerebellar cortex via the climbing fiber system principally through these mesencephalic relays.

Supported by a grant from the Canadian MRC to the group in Neurological Sciences, University of Montreal.

384 THE INTRAHEMISPHERIC CONNECTIVITY BETWEEN MOTOR CORTICES (MI AND MII) AND SOMATOSENSORY CORTICES (SI AND SII) IN THE RACCOON. Sharleen T. Sakai* and Paul Herron* (SPON: L. O'Kelly) Neuroscience Program and Depts. of Psychology and Biophysics, Michigan State University, East Lansing, MI 48824.

The purpose of this study was to investigate the interconnections of MI and MII with SI and SII in terms of the topography of body representations, specifically, with regard to the connections of the same body representation (homofunctional) or different body representation (heterofunctional). The cortico-cortical connections were investigated using the horseradish peroxidase (HRP) retrograde transport technique in the raccoon. Electrophoretic/pressure injections of 30-50% HRP were made into electrophysiologically defined regions in MI, MII, SI or SII in chloralose anesthetized raccoons. Following a survival period of 12-72 hours, the animals were intracardially perfused with a buffered aldehyde mixture. The brains were processed for HRP histochemistry using tetramethyl benzidine and dihydrochlorobenzidine as the chromogens on adjacent sections. Following an injection into MI forepaw/arm area, labelled cell bodies were observed in SI forepaw/arm area, MII and SII while following an injection into SI forepaw area, labelled cells were found in MI forepaw area. Injections into MI trunk area resulted in reactive neurons in a homofunctional area of SI and caudal SII. Following an injection into the SI hindlimb region, HRP positive cells were found in MI hindlimb area. After an injection in SII hindlimb region, labelled afferents were observed in a homofunctional area of MI. SII hindlimb area also received projections from an area caudolateral to MI forepaw and rostral to SI, a region which may correspond to area 3a. Following an injection into the distal limb area of MII labelled cells were observed in MI hindlimb area; HRP positive cell bodies were also found in the inferior and superior banks of the suprasylvian sulcus, a region which corresponds to the boundary region between SI and SII. The intrahemispheric cells of origin appear to be laminae specific. The SI and SII cells of origin primarily arise from layers III and V. The intrahemispheric projections of MII originate predominately from layers II and III, while the MI cells of origin largely arise from layer III. The cells of origin are distributed into clumps or clusters. Typically, a waxing and waning of labelled cells is observed interspersed by a rather continuous band of labelled layer III pyramidal cells. The results indicate that while there are reciprocal cortico-cortical connections between homofunctional areas of motor and somatosensory cortices, there are other interconnections as well. (Supported by Grant No. BNS 78-00879 from the National Science Foundation).

385 DIFFERENTIAL CONNECTIONS OF SOMATOSENSORY AND MOTOR CORTEX IN THE RAT. Jean Schoenen*, J. Neal Naranjo*, and Valerie B. Domesick. Department of Anatomy, Harvard Medical School, Boston, Massachusetts 02115 and Mailman Research Center, McLean Hospital, Belmont, Massachusetts 02178.

In a previous study, HRP injected into the spinal cord was found to label pyramidal cells in a cortical region much larger than previously described. This region includes at least three cytoarchitectonically distinct strip-like zones arranged sagittally alongside each other. According to neurophysiological studies, the medial of these strips corresponds to motor cortex (R.D. Hall and E.P. Lindholm, Brain Research 66 (1974) 23-38), while the more lateral correspond to the somatosensory cortex (C. Welker, Brain Research 26 (1971) 259-275). In order to define the thalamic dependencies of each of these strips, HRP was injected into each separately, whereas their efferent connections were demonstrated autoradiographically following injection of tritiated leucine-and-proline. Results indicate that the medial strip has reciprocal connections with the thalamic nuclei VL, VM, and PO, and the more lateral strips with VB and PO. Corticospinal fibers to the ventral horn originate only from the medial strip, whereas the spinal projection from the more lateral strips does not extend ventrally beyond the dorsal horn. The corticostriate projection from each of the three strips distributes bilaterally to a long sagittal zone of caudatoputamen; the three zones are somewhat different but overlap widely. Cortico-cortical fibers from the medial strip project to the two, more lateral strips, and in each are distributed in a discrete vertical column. In addition, the medial strip projects to a narrow perirhinal region of cortex which, as revealed by our previous HRP study, projects to the spinal cord. The two more lateral strips project to the medial strip in a more diffuse pattern. Contralateral (callosal) associations mirror the ipsilateral connections, indicating a greater heterotypy than previously suggested. The present findings tend to identify the medial cortical strip as motor and the two lateral strips as somatosensory cortex. Electrophysiological evidence of sensory-motor overlap may require a re-evaluation on the basis of overlap of projections from the medial and the two lateral strips in PO and striatum, as well as cortico-cortical interconnections. (Supported by USPHS grant 1-PO1-MH31154.)

386 EARLY EXPERIENCE, BRAIN ASYMMETRY, AND MURICIDE IN THE ALBINO RAT. Gordon F. Sherman*, James A. Garbanati*, Michael J. Hofmann*, Glenn D. Rosen*, David A. Yutzey*, and Victor H. Denenberg. Dept. Biobehav. Sci., Univ. Conn., Storrs, CT. 06268

Previous research (Denenberg et al. Science, 1978, 201, 1150-1152) has found that stimulation in infancy can produce an asymmetrical brain organization in the rat. This asymmetry was apparent in open-field activity and indicated the preferential involvement of the right hemisphere. The open field measures both exploratory behavior and emotional reactivity. Therefore, mouse-killing, a species-specific spontaneous behavior, was used in the present study as a more direct test of emotional reactivity.

Animals were handled or left undisturbed for the first 20 days of life. In adulthood 4 male littermates were given a right neocortical ablation, a left ablation, sham surgery, or no surgery. Approximately 8 months after this the rats were tested for mouse killing. The rats were individually housed and, 24 hours later, a mouse was put into each rat's cage. Latency to kill, in hours, was recorded. The means are given below (Exp. 1) with number of animals in parentheses. An asymmetrical effect was found in the Handling condition (t for Right vs Left lesion = 2.90, $p<.01$). However, the Handled sham group differed from the no-surgery group (t = 2.60, $p<.05$). There was no evidence of laterality in the Nonhandled groups.

We carried out a partial replication to further substantiate our findings and to explore the sham-control difference in our Handled groups. As shown in the table below (Exp. 2), the right-left difference is still present in the Handled animals (t = 2.69, $p<.02$). Therefore, we have replicated our finding that Handled rats with only an intact left hemisphere are significantly slower to kill than their littermates with an intact right brain. The sham difference found in Exp. 1 appears to be due to sampling error. Again no differences were found among the Nonhandled rats.

Handling induces brain laterality with respect to mouse killing by rats, with the right hemisphere preferentially involved. This is the same pattern as reported by Denenberg et al., and thus replicates and extends their prior findings.

Latency to Kill (in hours)

		R	L	Sham	Control
Exp. 1	H	66.74 (19)	31.87 (22)	54.80 (15)	21.74 (23)
	NH	61.47 (19)	63.11 (18)	29.65 (20)	26.40 (20)
Exp. 2	H	54.00 (8)	26.88 (8)	11.25 (4)	9.75 (4)
	NH	34.38 (8)	43.63 (8)	13.25 (4)	35.25 (4)

387 CORTICOTECTAL CONNECTIONS IN THE GERBIL. H.B. Sherman*, V.S. Caviness, Jr., and D.J. Ingle (SPON: J.B. Martin). Brandeis Univ. and E.K. Shriver Ctr., Waltham, MA 02154

The connections between the neocortex (NC) and the superior colliculus (SC) have been studied in the gerbil by a combination of two methods: horseradish peroxidase injected into the SC and tritiated amino acids injected into a majority of the cytoarchitectonic fields of the NC.

The corticotectal projection arises widely from layer V of the occipital, parietal, temporal, and frontal fields. This extensive projection includes at least eight, and probably more, individual projections; by individual projections is meant a projection which arises in one, in some instances two or three adjacent complete cytoarchitectonic fields and has its terminals distributed in a single plane throughout the tangential dimensions of the SC. To some extent these planes are complementary, to some extent overlapping, in the radial dimension of the SC. Individual projections arising in occipital fields 17, 18a, and 19 project in overlapping succession to the deeper levels of the stratum griseum superficiale, stratum opticum and the superficial levels of the stratum griseum intermediale. Parietal fields 3 and 1, temporal fields 22, 36 and 41, medial cortical fields 8 and 24 and parietal fields 40 and 14 project in overlapping succession to the stratum griseum intermediale and stratum album intermediale. Finally, frontal fields 6 and 4 project to the stratum griseum profundum and stratum album profundum. Projections which arise in the occipital fields and those arising in the frontal fields terminate in a continuous plane in the superficial and deep strata of the SC, respectively. The remaining projections, by contrast, terminate in a "puffs and holes" pattern, i.e., a discontinuous pattern within the intermediate collicular strata.

Each projection appears to be topologically organized; the cytoarchitectonic boundaries of the fields of origin of each projection are directed to the margins of the SC. In some instances, adjacent points in the cortex on opposite sides of a common cytoarchitectonic border are in radial register with each other at the margins of the SC, e.g., at the 17/18a, 18a/19 borders. As a consequence of this principle of alignment, homologous points in the separate visual cortical representations are probably in register with each other within the SC. In other instances, adjacent points on opposite sides of a common border appear not to be in register with each other in the SC. This occurs where cytoarchitectonic borders probably separate projections affiliated with different functional systems, e.g., at the 22/40a and 8/6 borders. These borders probably lie between fields associated with the AI and SII and the Eye field and MI cortical representations, respectively.

388 A MODEL OF CORTICAL CIRCUITRY IN THE TURTLE BASED ON MORPHOMETRIC ANALYSIS OF THALAMIC FIBER INPUTS AND THEIR CORTICAL CELL TARGETS. Leslie M. Smith* and Ford F. Ebner, Neuroscience Sect., Div. Biol. Med. Sci., Brown University, Providence, RI 02912.

Evoked responses in turtle cortex to optic nerve or thalamic stimulation habituate rapidly when the stimuli are repeated more frequently than 0.5 Hz (Belekhova and Kosareva, '71). Our experiments provide a model that explains why habituation is the dominant cellular response in this neural system. The model requires knowing whether the visual pathways to cortex synapse on more than one cell type, and, if so, what the ratio of thalamic synapses are onto each cell type. We studied the ultrastructure and distribution of thalamic synapses, plus the density of thalamic terminals and cortical cells in equivalent volumes of cortex. Fourteen days after unilateral removal of the thalamus, we prepared the ipsilateral cortex for routine EM in 15 Pseudemys turtles. All thalamic fibers end within 100 um of the cortical surface, contain round agranular vesicles and form asymmetrical (type I) contacts. 86% of thalamic contacts are on dendritic spines and 14% are on dendritic shafts. Unequivocal evidence was found for thalamic contacts on the scattered cells located in the molecular layer. We calculate that there are 6.15 million thalamic synapses in a 1 mm cube of turtle cortex. Morphometric analysis of the cells in an equivalent volume of cortex leads to an estimate of 15,000 cells in the main cell lamina and 400 cells in the overlying molecular layer. Golgi preparations show that neurons in the main cell lamina have numerous spines on their apical dendrites. These dendrites ascend through the molecular layer into the thalamic input zone. In contrast, the vast majority of the cells in the molecular layer have smooth (aspinous) dendrites. For this calculation, we assume that the 86% of thalamic contacts on dendritic spines are onto main lamina cells (pyramidal cells) while those 14% onto dendritic shafts contact molecular layer cells (stellate cells). Given these assumptions, there are 5.29 million thalamic contacts onto the 15,000 pyramidal cells and 0.86 million thalamic contacts onto 400 stellate cells. The final step in this calculation produces a surprising and counterintuitive result, namely, that there are 6X as many thalamic synapses on each stellate cell as on each pyramidal cell (5.29 million ÷ 15,000 = 353 contacts/pyramid and 0.86 million ÷ 400 = 2150 contacts/stellate). We hypothesize that stellate cells in the molecular layer are inhibitory interneurons that receive 6X more excitatory thalamic input per cell than pyramidal cells. A single afferent volley activates both cell types, but the secondary effect of stellate cell activation is to leave the pyramidal cells hyperpolarized and refractory to further stimuli for periods in excess of a second. (Supported by NSF grant BNS 78-15933.)

389 PERFORMANCE OF NEMESTRINA MONKEYS WITH BILATERAL INFEROTEMPORAL CORTEX LESIONS IN A SIMULTANEOUS VISUAL PATTERN DISCRIMINATION TASK DEMANDING OF ATTENTION. Henry V. Soper, Susan Zweizig*, Thomas Gilman* and Donald B. Lindsley. Depts. of Psychol., Physiol. and Brain Res. Inst., UCLA, Los Angeles, CA. 90024.

Typically, monkeys with inferotemporal cortex lesions exhibit deficits in ability to learn visual pattern discriminations that are difficult. Recently, Gross (J.comp.physiol.Psychol., 1978, 92, 1095-1109) has reported that Rhesus monkeys with inferior temporal lesions are relatively unimpaired in learning difficult, rotated-pattern discriminations, involving pattern orientation differences rather than pattern differences.

Using 90° rotated patterns (N vs Z) presented tachistoscopically (10 ms) on two adjacent lucite panels by rear projection, we have studied the pre- and post-operative performances of three Nemestrina monkeys with emphasis upon retention, relearning and distractive stimulus additions (N and Z with annular surrounds). The task demands attention and fixation of the panel displays. The monkey with gaze directed to the panels, presses a lever to the right and after a 300 ms "alerting" delay receives the N and Z patterns. A press on the correct panel brings a banana pellet reward followed by a 15 sec inter-trial interval. Incorrect presses are penalized only by the inter-trial delay without reward. Each daily session consists of 20 practice trials followed by 100 training or test trials. Criterion performance is three successive days at 90% or better.

Monkeys A and B exhibited nearly identical pre-operative learning performances (28 and 25 sessions to criterion), typical of other monkeys we have trained on the same task. Both monkeys reacted similarly on pre-operative distraction and retentions tests and, following posterior inferotemporal lesions, showed a retention loss which only gradually recovered with retraining, requiring 80 to 100 daily sessions. Postoperatively, neither monkey could perform the task at criterion level with the distracting annular surrounds even after the prolonged retraining to criterion. Retention after a two-week interval, following criterion performance on retraining, was quickly re-attained in both. Monkey F was atypical on original learning pre-operatively, requiring twice as many sessions to reach criterion performance, but showed stabilized retention on pre- and post-operative tests.

In this attention-demanding task the postoperative performances of monkeys A and B indicate that posterior inferotemporal lesions cause partial loss of retention and require prolonged retraining to attain criterion. We believe this is not because of memory loss or pattern discrimination inability per se, but may rather be due to an attentional loss which penalizes those functions. Supported by USPHS grant MH-25938 and by grant from Grant Foundation. H.V.S. held NIMH fellowship 1-F32-MH05051.

390 EFFERENT ORGANIZATION OF VISUAL AREA I IN THE RABBIT. Harvey A. Swadlow* and Theodore G. Weyand* (SPON: A.L. Brickman). Dept. Psychol., Univ. Conn., Storrs, Conn. 06268.

Cortico-fugal and cortico-cortical efferent neurons of visual area I (V-I) in Dutch Belted rabbits were studied using anatomical (HRP) and physiological (antidromic) methods. Anatomical studies showed: (a) nearly all efferents to the lateral geniculate nucleus (LGN) are found in layer VI; (b) layer V is the origin of most neurons which project to the superior colliculus (S.C.) though significant numbers are found in layer IV; (c) layer II-III is the origin of most callosal efferent neurons, but some of these cells are also found in layers IV and V. Preliminary analysis of neurons projecting to visual area II (V-II) indicate that most of these cells are found in layer II-III.

In physiological studies efferent neurons were identified by antidromic activation following electrical stimulation via electrodes located within target structures of the efferent systems. The conduction velocities of most V-I→V-II and many V-I→LGN axons were very low (i.e., < 1.0 m/sec), suggesting that most axons of these systems were non-myelinated. In contrast, the conduction velocities of >90% of V-I→SC axons were >3.0 m/sec, suggesting that these axons were predominently myelinated. The number of cells studied (n) and the range (r) and median (M) conduction velocities of efferent axons were as follows: V-I→LGN (n=100, r=0.39-10.0 m/sec, M=1.2 m/sec; V-I→SC (n=121, r=1.1-23.6 m/sec, M=8.4 m/sec; V-I→callosum (n=69, r=0.55-8.0 m/sec, M=2.44 m/sec; V-I→V-II (n=69, r=0.23-5.7 m/sec, M=0.64 m/sec).

Antidromic tests for branching axons (utilizing collision techniques) provided no evidence for multiple destinations of the V-I→V-II, V-I→callosal or V-I→LGN efferent systems. Thus, although the laminar origins of the V-I→V-II and V-I→callosal systems overlap significantly, these systems are apparently independent. However, approximately 1/3 of V-I→SC cells were shown to project a collateral branch into the thalamus. The thalamic destination of these collaterals has not yet been determined.

391 PHYSIOLOGICAL PROPERTIES OF PROJECTION FROM AREA 3a TO 4γ OF THE CEREBRAL CORTEX IN THE CAT. R. Waters*, H. Yumiya*, K.D. Larsen and H. Asanuma. The Rockefeller University, New York, N.Y. 10021.

It has been shown, anatomically and physiologically, that neurons in the area 3a of the sensory cortex project topographically to area 4γ of the motor cortex. The present experiments were undertaken to further characterize the properties of this projection. Under Halothane anesthesia, the pericruciate and colonal sulci were exposed and a double-barreled closed chamber was installed over the sulci. All the wound tissue was infiltrated with a long lasting local anesthetic and experiments were carried out with a sedative dose of Nembutal (10mg/kg). Two independent manipulators were attached to the chamber and one electrode was inserted into area 3a and the other into area 4γ. Intracortical microstimulation (ICMS) was delivered to area 3a and the effects were examined by averaging the discharge of neurons in area 4γ. In one group of experiments, ICMS was delivered to a fixed site in area 3a. In these cases the facilitatory effects appeared in a small region of 4γ which extended along the direction of radial fibers constituting a columnar shape. The diameter of these columns ranged from 0.5 to 0.8 mm. In the other group of experiments the 4γ electrode was fixed to a position where the electrode picked up unitary activity of a given neuron or a given pair of neurons. ICMS was then systematically delivered to various sites in 3a. The sites which facilitated a target neuron were always restricted to a small region which extended along the direction of radial fibers with the diameter being less than 1.0 mm. In no one case did we find a 3a site which projected to more than one region in the motor cortex nor a 4γ neuron which was facilitated from more than one locus in 3a. Since both electrodes could be used for either stimulation or recording, receptive fields of neurons in both areas could also be examined. In the majority of cases, neurons in limited regions in 3a and 4γ which were connected received peripheral inputs from the same part of the body or adjacent areas. The results indicated that the projection from 3a to 4γ is highly localized, suggesting some particular built-in function for this system. However, the role played by 3a neurons in specifying the receptive fields of neurons in 4γ seems to be minor because the modalities of adequate stimuli were often different and ICMS did not elicit obligatory discharges in 4γ neurons but simply facilitated their activity. (Supported by the Grant NS 10705).

392 **SYNAPTIC PROFILES OF SPINY AND NON-SPINY STELLATE CELLS.**
Edward L. White and Michael P. Rock*. Dept. Anat., Boston Univ. Sch. Med., Boston, MA. 02118.

Thalamocortical (TC) afferents to the posteromedial barrel subfield (PMBSF) of mouse SmI cortex synapse with several different types of neurons (White, '79). The most frequent recipients of TC input are the stellate cells whose somata occur in layer IV and whose dendrites are mostly restricted to barrel hollows. The purpose of this study is to assess the locations of TC and all other synapses onto the cell bodies and dendrites of a spiny and a non-spiny stellate cell of mouse PMBSF cortex. The method used to identify TC axon terminals was lesion induced degeneration; a lesion was used to destroy the cortical projections from the nucleus ventralis posterior pars lateralis and the nucleus posterior thalami in a 2 month old CD/1 mouse. Lesion induced degeneration is generally considered unreliable for the identification of TC axon terminals because in most systems TC terminals degenerate over a varied time course such that some terminals have been phagocytosed before others have begun to degenerate. This is not true of terminals degeneration in mouse PMBSF cortex where all affected terminals - ~20% of the terminals in layer IV neuropil - degenerate simultaneously. A Golgi impregnated spiny stellate cell from layer IV of PMBSF cortex ipsilateral to the lesion was gold-toned and deimpregnated (Fairen et al., '77) so that its synaptic connections could be examined with the electron microscope. A series of thin sections containing the deimpregnated cell was cut and electron micrographs were taken of each part of the spiny stellate cell and of a neighboring non-spiny stellate cell which was not impregnated, but which could be identified on the basis of its cytology and synaptic connections. These cells were then reconstructed from wooden sheets of appropriate thickness at a final magnification of 20,000 X. TC and synapses of unidentified origin are depicted on the reconstructions. About 10% of the asymmetrical synapses onto the spiny stellate cell are from the thalamus; all of these synapses are with spines. By contrast, the non-spiny stellate cell receives a much larger share of its input from the thalamus and these synapses contact both its cell body and dendrites. An intriguing finding is that TC inputs are distributed in a non-random fashion over extensive regions of the spiny stellate cell. For example, the necks of 5 spines which receive TC input attach to one primary dendrite at intervals of 5± 0.5 μm. Our interpretation of this periodicity is that it reflects the spacing of TC axodendritic "junctions" prior to the time of spine formation.

393 SUBLIMINAL SYNAPTIC INPUT TO CORTICAL NEURONS AND ITS DETECTION BY THE MODIFICATION OF ANTIDROMIC RESPONSES. D. Wiggin* and P. Zarzecki (SPON: C. Romero-Sierra). Department of Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

Collision-extinction testing can be used to investigate synaptic inputs to neurons whose axonal projections have been identified by antidromic activation. A serious limitation of this method is its inability to detect subthreshold synaptic events and it seems, therefore, to underestimate the extent of synaptic input (Zarzecki et al., Exp. Brain Res. 33: 269, 1978). An alternative method of assessing synaptic input is suggested by the observation that subthreshold excitatory inputs to spinal motoneurons facilitate somatic invasion of an antidromic action potential (Brock et al., J. Physiol. 122: 429, 1953). In the two systems which we have examined, an apparent facilitation has been observed as a change in the shape of extracellularly recorded antidromic spikes.

Extracellular recordings were made from cortico-cortical and pyramidal tract neurons in cats lightly anesthetized with Nembutal. Stimulation of forelimb nerves was frequently followed by a change in the shape of the antidromic action potential, even in the case of neurons which did not fire in response to the peripheral stimulus. The change in the antidromic spike most often consisted of a clear decrease in the time from onset to peak. The decrease was especially evident for neurons whose antidromic spike was fractionated, in which cases the inflection of the rising phase was reduced or eliminated. This modification of the antidromic spike could be easily distinguished from those resulting from changes in presynaptic excitability (Dubner and Sessle, Exp. Neurol. 30: 223, 1971) or axonal excitability (Swadlow et al., Exp. Brain Res. 32: 439, 1978).

We conclude that the decrease in time from onset to peak is a result of an increase in the excitability of the soma. Therefore, monitoring changes in the time from onset to peak of extracellularly recorded antidromic spike potentials is a more sensitive method of detecting synaptic inputs than is collision-extinction testing. We have now used this method to investigate the patterns of sensory convergence upon identified populations of cortico-cortical and pyramidal tract neurons, as will be described in the following abstract.

394 CONVERGENCE OF SOMATOSENSORY AND PROPRIOCEPTIVE INPUTS UPON CORTICO-CORTICAL AND PYRAMIDAL TRACT NEURONS. P. Zarzecki and D. Wiggin*. Department of Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

This study asked whether the same group of cortico-cortical neurons which relay group I muscle afferent input from area 3a to the motor cortex (Zarzecki et al., Exp. Brain Res. 33: 269, 1978) also receives input from cutaneous afferents. Excitation of pyramidal tract (PT) neurons of area 3a was also examined.

In cats under light Nembutal anesthesia, extracellular recordings were made in area 3a from neurons antidromically activated by microstimulation of the motor cortex (area 4γ) or from the medullary pyramid. PT neurons were tested for a projection to the spinal cord (C2-3). Identified cortico-cortical and PT neurons were tested for excitation from up to five contralateral forelimb nerves; deep radial (muscle), superficial radial (cutaneous), median (mixed) and ulnar, the latter divided into its dorsal cutaneous and palmar (muscle) branches. Volleys recorded from proximal nerve trunks were used to grade stimulus intensities (usually less than 2 x T) and to control for stimulus spread between nerves. Excitatory input to a cortico-cortical or PT neuron was concluded when nerve stimulation either elicited spikes which collided with the antidromic response or was followed by a decrease in the time from onset to peak of the antidromic spike (for justification see Wiggin and Zarzecki, this volume).

Among cortico-cortical neurons, 22 of 28 (79%) showed alterations of antidromic spike shape from each of two or more nerves. Sixteen (57%) showed this evidence of subliminal excitation from both muscle and cutaneous afferents. On the other hand, spike responses were evoked in only 11 of 59 cortico-cortical neurons (19%) by stimulation of two or more nerves and in only 4 (7%) from both muscle and cutaneous nerves.

Among PT neurons of area 3a, 11 of 18 projected to the spinal cord, 15 (83%) showed alterations of spike shape by two or more peripheral nerves, and 14 (78%) by both muscle and cutaneous afferents.

In conclusion, the majority of cortico-cortical and PT neurons of area 3a showed evidence of convergence from muscle and cutaneous forelimb afferents, although at the nerve stimulus intensities used these inputs were very often subthreshold. Neurons of these two types could be involved in cortical processing of information of several sensory modalities. This possible role might not be suspected from studies which require neurons to fire for the detection of an input.

CHEMICAL SENSES: SMELL AND TASTE

395 TASTE INTERACTIONS IN MIXTURES OF SUCROSE WITH NACL AND SUCROSE WITH QHCL. Linda M. Bartoshuk. John B. Pierce Foundation Laboratory and Yale University, New Haven, CT 06519.

When taste substances are mixed, their tastes change in intensity even when there are no chemical interactions among the substances. These mixture interactions are complex and no attempt to formulate a set of taste mixture laws has yet been completely successful. One variable not considered in earlier mixture studies is the shape of the psychophysical function that describes perceived intensity versus concentration. When substances with similar tastes are mixed, the interactions are highly dependent on the shapes of these functions. For example, mixtures of substances with psychophysical functions that are compressed (i.e., successive increments in concentration produce smaller and smaller increments in perceived intensity) show suppression (i.e., the perceived intensity of the mixture is less than the sum of the perceived intensities of the component). This is not particularly surprising since mixtures of substances with the same taste quality would be essentially the same as higher concentrations of a single component if the substances act through a common receptor mechanism. There is less reason to expect interactions in mixtures of substances with different taste qualities to be dependent on the shapes of psychophysical functions, yet some show such dependence. The results of a series of studies show that mixtures of quinine hydrochloride (QHCl) and sucrose (of equal perceived intensity when unmixed) show interactions that can be related to the shapes of the unmixed psychophysical functions. That is, the more compression shown by the psychophysical function of a component, the more suppression shown by the substance in the mixture. On the other hand, in similar mixtures of QHCl and sodium chloride (NaCl), the bitterness of QHCl is always suppressed more than the saltiness of NaCl no matter what the shapes of the psychophysical functions. These two mixtures can also be distinguished by a cross-adaptation experiment. In general, if the tongue is adapted to one component of a two component mixture, then the mixture will taste like the other component does when it is unmixed (i.e., this is as if the mixture suppression exerted by a component is released when that component is "removed" by adaptation). This release of mixture suppression fails to occur for QHCl in mixtures of QHCl and NaCl tasted after adaptation to NaCl. All of these experiments taken together suggest that the mechanisms underlying mixture interactions for these two classes of mixtures are not the same and that bitterness may be at least partially suppressed in mixtures of QHCl and NaCl at the tongue surface.

396 **OROPHARYNGEAL AND HYPOTHALAMIC INPUT TO THE SAME NTS NEURONS.** **D.A. Bereiter, H.-R. Berthoud* and B. Jeanrenaud*. Lab. Res. Med., Univ. Geneva, SWITZERLAND.**

Oropharyngeal sensory input is capable of evoking an early, so-called cephalic phase secretion of immunoreactive insulin (IRI). Hypothalamic electrical stimulation is also reported to alter serum IRI levels. The neural mechanisms within the CNS underlying such modulation of IRI levels have not been fully investigated. We now report that these two seemingly different mechanisms may share a common neural substrate at the brainstem level. Single neurons located in the nucleus tractus solitarius (NTS) responsive to lingual nerve (L) or chorda tympani (CT) electrical stimulation (ES) were often responsive to lateral hypothalamic (LHA) ES. Caudal brainstem units were recorded using glass micropipettes filled with 2 M NaCl and Fast Green dye in male rats anesthetized with pentobarbital sodium. NTS cells responding to L- or CT-ES were subsequently tested for hypothalamic sensitivity. Among the diencephalic structures stimulated (50 - 350 μA, 0.2 msec, coaxial bipolar) the LHA was most effective in evoking short latency (< 15 msec) orthodromic unit activity in NTS cells responsive to L- or CT-ES. Diencephalic stimulation sites located in the dorsomedial hypothalamus, ventromedial hypothalamus, optic tract or medial amygdaloid nuclei generally had no influence on NTS cells responding to L- or CT-ES. Within the LHA, sites effective in evoking NTS unit activity extended anteriorly from the retrochiasmatic level and posteriorly to the ventral premammillary nucleus. These results demonstrate a significant degree of excitatory convergence between LHA and both trigeminal and CT afferents onto single NTS neurons. This convergence may provide a basis for a common neural substrate underlying LHA-induced and cephalic phase IRI secretion.

397 CHEMORESPONSIVE NEURONS OF THE GOAT GENICULATE GANGLION. James C. Boudreau, Joseph Oravec* and Nga Kieu Hoang*. Sensory Sciences Center, University of Texas at Houston, TX 77025.

Single unit recordings were taken from taste neurons of the geniculate ganglion of the anesthetized goat. Neurons typically innervated more than one fungiform papilla (10 or more not uncommon). Almost all neurons exhibited spontaneous activity. ISI's of this activity were usually multipeaked with peaks in the short interval range corresponding to fixed interval bursting (although intervals shortened as a function of order in burst). Neurons were stimulated with a test series developed on the carnovore and a food and herb series. Many nonresponsive units were encountered. Amino acids in general were poor stimuli but monovalent salts and carrots were often potent stimuli. At least three different neural groups could be delineated on the basis of responses to chemicals. These groups also differed, in part, in latency to electrical stimulation, area of tongue innervated, and spontaneous and evoked discharge patterns. The two large fiber groups innervated all parts of the tongue, while the small fiber group innervated only the back. Only one of the large fiber groups (the Brønsted acid responsive group) could be compared with the neural groups described in the carnivore. This research was financed in part by NSF Research Grants.

398 CHANGES IN TASTE RESPONSES FROM SHEEP CHORDA TYMPANI NERVE DURING DEVELOPMENT. Robert M. Bradley and Charlotte M. Mistretta. Dept. Oral Biol., Sch. Dent., U. Mich., Ann Arbor, MI 48109.

We previously reported that response characteristics of taste neurons in the sheep solitary tract and nucleus change during fetal development (Science 202, 535-537, 1978). When the tongue was stimulated with 0.5 M NH_4Cl, KCl, NaCl and LiCl, solitary neurons in fetuses <114 days of age only responded to NH_4Cl and KCl, whereas neurons in older fetuses, lambs and adults responded to all four salts.

To determine if these results relate to peripheral or central taste system maturation, recordings were made from the chorda tympani nerve in 8 fetal sheep aged 108-110 days of gestation (term=147 days), and 4 lambs aged 44-50 days after birth. Both whole nerve and few or single fiber (n=13) responses were recorded while stimulating the tongue with 0.5 M NH_4Cl, KCl, NaCl and LiCl. The whole nerve responses were passed through an AC to DC converter, and the frequency of single and few fiber responses was counted using a rate meter. Effectiveness of chemical stimulation was then evaluated on the basis of height of the whole nerve response, or frequency of unit responses.

Analysis of both whole nerve and unit data demonstrated that in 108-110 day fetuses the most effective stimuli are NH_4Cl and KCl, in that order. Although responses were recorded to lingual stimulation with NaCl and LiCl, they were minimal. In the lamb, NH_4Cl remains the most effective stimulus; however, compared to the fetus, KCl becomes less effective and NaCl and LiCl become much more effective. Thus, the preliminary data indicate that the order of effectiveness of the four salts is:

Fetus: $NH_4 > K > Na = Li$.
Lamb: $NH_4 > K = Na = Li$.

The mean response frequency for all four chemicals increases with age. The average frequency for NH_4Cl in the fetus is 47 impulses/sec while the frequency in the lamb is 82 impulses/sec, an increase of 74%. The change in frequency for KCl is much less, 48%. However, the increases for NaCl and LiCl are very striking, at 248% and 284%, respectively.

These changes in peripheral taste nerve function during development confirm the reported central nervous system changes. At both levels, NaCl and LiCl become more effective stimuli as development progresses. The results support our hypothesis that the developmental change in salt taste responses is related to receptor maturation rather than maturation of taste synapses and fiber tracts. (Supported by NSF Grant BNS 77-09920 and National Institute of Dental Research, N.I.H., Research Career Dev. Award DE00066 to C.M.M.)

399 Depressed chorda tympani responsiveness in zinc deficient rats. Frank A. Catalanotto and Marion Frank, Dept. of Ped. Dent., Univ. Conn. Sch. Dent. Med., Farmington CT. 06032 and Rockefeller Univ. New York, NY

Previous behavioral studies in zinc deficient rats(Zn-) demonstrated abnormal preferences for sodium chloride (N), sucrose (S), quinine (Q), and hydrochloric acid (H) solutions when tested in a 2-bottle preference procedure(J.Nutr. 109:436-442, 1977).We hypothosized that the altered preferences were the result of a decrease in taste sensitivity and therefore measured the integrated whole nerve chorda tympani responsiveness to tastant solutions in control (Zn+) and Zn- rats. The experimental animals were male rats initially weighing 125-150 grams; they were fed either a Zn- diet (1.3 ppm Zn) ad libitum or pair fed a Zn+ diet (100 ppm Zn) for 4-6 weeks before being studied. This time period allowed for moderate sysmptoms to develop including anorexia, failure to grow, alopecia, and mild inflammation and scaling of the paws; control rats appeared normal.

The right chorda tympani was dissected free using a mandibular approach, sectioned centrally, and the proximal end placed on a nichrome wire electrode. Response of the whole nerve was differentially amplified and fed into a Beidler summator and ink writer; time constants were 0.6 seconds (s) rise and 2.6 s fall. The rats anterior tongue was enclosed in a flow chamber fitted with a rubber dam to exclude saliva. Solutions were delivered by gravity flow for 15 s and always immediately preceded and followed by 15 s of water flow. A series of 10 N(0.00003 to 1.0 M), 5 S (0.01 to 1.0 M), 7 Q and 7 H (0.00001 to 0.01 M) solutions were utilized. Peak amplitude of the charted record was used as an indicator of total neural activity.

The initial statistical analysis compared the frequency of responses above and below the median response magnitude of both groups of rats for each concentration in the series; chi-square analysis of the results indicated that the Zn- rats manifested significantly ($p<0.001$) fewer responses above the median and more responses below the median, as compared to the Zn+ rats. In addition, the data were plotted utilizing a number of different coordinate systems frequently used in electrophysiological research such as Response(R) vs. log concentration(C), log R vs. log C, 1/R vs. 1/C , and R vs. C/R . Results also demonstrated significant differences between the responsiveness of the groups.

This study suggests that the integrated whole nerve chorda tympani response to tastant solutions flowed over the tongue of zinc deficient rats is significantly decreased compared to control animals. These findings support and extend the results of previous behavioral studies; however, the etiology or locus of the defect is unclear. Further research is indicated.

400 SEXUAL AND HORMONAL INFLUENCES ON ODOR PREFERENCE MODIFIABILITY IN RATS AND HAMSTERS. Catherine Cornwell-Jones, Gina Dunston*, Cheryl Holder* and Kathryn Kovanic*. Dept. Psych., Princeton Univ., Princeton, NJ 08544.

Olfactory preference modifiability declines with age in male rats and hamsters (Cornwell-Jones, J. Comp. Physiol. Psych., 93, #4, 1979). The present experiments determined whether a similar decline in modifiability occurs in females of the two species, and if either neonatal or postpubertal testosterone manipulation influences the decline. In each of three experiments, odor preferences of rats and hamsters were examined in a two-choice situation immediately following three days of differential olfactory exposure. The testing apparatus allowed animals to smell but not touch or taste differently scented wood shavings placed in two compartments beneath a screen floor.

Animals reared in pine shavings generally avoided the odor of cedar shavings in favor of pine shaving odor, regardless of age at testing, sex, species, or hormone treatment. Housing normal animals in cedar shavings for three days before testing increased preference for cedar odor in male infants but not male juveniles of both species, and in females of both species at both developmental stages. The results indicate that olfactory preference modifiability declines less with age in females than males of both species.

Some olfactory-innervated brain regions are sexually dimorphic. The dimorphism depends on the presence or absence of neonatal androgens (Raisman & Field, Brain Res. 54: 1-29, 1973). In the second experiment, rat pups 2 days old and hamster pups 4 days old were injected with 300 µg testosterone propionate in .05 cc oil or with oil alone. Animals were differentially exposed and tested as juveniles. Neonatal treatment did not significantly influence exposure-induced differences in juvenile preferences for cedar vs. pine in females of either species. The results suggest that sexual differences in the anatomy of olfactory-innervated brain regions cannot, alone, account for sexual differences in juvenile odor preference modifiability.

In the third experiment, postpubertal male rats and hamsters were either castrated or sham-operated, allowed to recover from surgery in pine shavings in the isolated olfactory environment, and then were exposed differentially and tested. Housing in cedar shavings increased preference for cedar odor in rat castrates and sham operates, and in hamster castrates but not sham operates. The results suggest that in normal hamsters, age-dependent increases in endogenous testosterone levels may contribute to declining odor preference modifiability during development.

401 TEMPORAL CODING OF SENSORY QUALITY: EVIDENCE FROM SINGLE UNIT TASTE RESPONSES IN THE RAT NTS. Ellen Covey and R.P. Erickson. Dept. Psychology, Duke Univ. Durham, NC 27706.

The temporal charachteristics of responses by single neurons of the rat NTS to 50 widely different stimuli were compared, and their similarities computed by comparing the direction and amount of change in firing rate from one 0.1 sec interval to the next for 2 sec. The overall similarity value was the algebraic sum of the individual 0.1 sec comparisons.

Individual neurons did not respond with their own charachteristic temporal patterns; rather the temporal pattern seemed to be largely determined by the identity of the stimulus. Similarity values for repititions of the same stimulus across many different neurons were significantly higher than those for different stimuli, even within the same neuron.

To determine whether it is possible to identify a stimulus solely on the basis of its temporal response pattern, multiple responses to 4 different stimuli (NaCl, HCl, Quinine HCl, and sucrose) were averaged, giving "standard responses" for each stimulus. Individual "test responses" to the 4 stimuli were compared to the standards, and the standard giving the highest similarity value was taken to be the predicted stimulus identity for the test response. Identification was correct at least 70% of the time, and this was true over a fairly wide range of test response concentrations. When the number of stimuli was increased to 25, test stimuli were still most often identified with the correct standard, and errors in identification usually involved confusion with stimuli known to be similar in taste(e.g.NaCl might be identified first as another Na or Li salt, but showed very low similarity to HNO_3).

These results strongly suggest that temporal aspects of the neural response make an important contribution to the coding of stimulus quality in taste, and electrical stimulation studies to demonstrate whether these temporal patterns are actually used by the animal to discriminate stimulus quality are presently underway.

402 TASTE AND TACTILE RECORDINGS FROM THE RAMUS RECURRENS IN THE CATFISH. Cynthia J. Davenport* and John Caprio. Dept. of Zoology and Physiology, Louisiana State University, Baton Rouge, LA 70803.

The ramus lateralis accessorius (ramus recurrens of VII) innervating the flank of the channel catfish, Ictalurus punctatus, responded to both amino acid and mechanical stimulation of the flank skin. Results were obtained employing conventional extracellular electrophysiological technique. Tactile stimuli consisted of fine streams of water directed to the flank by glass pipettes as well as slight mechanical deformation and stroking of the skin surface with glass probes. Most nerve twigs responded only to the mechanical stimulation, but taste recordings when obtained were correlated with the region of highest mechanical sensitivity. The time-averaged phasic gustatory responses increased exponentially with logarithmic increase in stimulus concentration. L-alanine and L-arginine were the most effective compounds tested, with thresholds estimated below 10^{-6}M. Individually identified taste units responed best to L-alanine or L-arginine. These data are similar to the results obtained from maxillary barbel taste recordings in the same species (Caprio, J. J. Comp. Physiol. 123:357, 1978), suggesting an analogous chemical response profile of facially innervated taste buds irrespective of their anatomical location in the catfish.

The ramus recurrens is believed to be the sole innervator of flank taste buds, with tactile stimulation being supplied by adjacent cutaneous free nerve endings, thought to originate in the dorsal root ganglion (Herrick, J. J. Comp. Neurol. 15:375. 1905). In the present experiments both intra- and extra-cranial neural recordings from the ramus recurrens indicated that mechanical responsiveness was not attributable to spinal innervation. It would thus appear that the ramus recurrens is a gustatory nerve with high mechanical responsiveness. Recent studies in other vertebrate species have also revealed mechanical sensitivity of taste units (Marui, T. Brain Res. 130:287, 1977; Yamane, S. Comp. Biochem. Physiol. 61A:451, 1978). These data raise the question whether taste cells share both mechano- and chemoreceptive properties, or whether taste cells are innervated by branches of the same sensory nerve fiber that forms mechanically sensitive free nerve endings in the surface epithelium.

403 OLFACTORY BULB NEURONS TERMINATE IN THE RECEPTOR EPITHELIUM. Roger E. Davis, Neurosciences Laboratory, The University of Michigan, Ann Arbor, MI 48109.

A radioautographic investigation of the fiber projections of the olfactory bulb of the teleost Macropodus opercularis revealed that bulbar neurons enter the olfactory nerve and terminate selectively in the olfactory receptor epithelium. Four adult Macropodus were administered 0.2 to 0.5 μCi of L[^{3}H-2,3] proline on a dry 60 to 80 μm diameter bead of Dowex resin which was implanted unilaterally in the olfactory bulb (Davis, R.E. and Agranoff, B.W., 1977, Brain Res. 124:341-346. Following a 10 day survival period, the head was removed, fixed in formalin, decalcified and embedded in paraffin. Ten micron horizontal or transverse sections were dipped in Kodak NBT-2 emulsion and stored for 3 weeks. Following development of the emulsion the tissue was lightly stained with cresyl violet acetate. The implanted bulb was heavily labeled by grains of reduced silver. Labeled protein was distributed in the ipsilateral olfactory nerve and olfactory receptor epithelium in the nasal sac. The segments of indifferent epithelium were lightly labeled. The contralateral olfactory bulb and nerve were also only lightly labeled. The pattern of labeling in the nerve suggested that axons of efferent neurons intermingle with the afferent primary receptor neurons. Similar results have been obtained in the goldfish, Carassius auratus.

The cells of origin of efferent fibers in the olfactory nerve were investigated using the peroxidase method (Coleman, D.R., Scalia, F. and Cabrales, E. 1976. Brain Res. 102:156). A 1 x 2 mm piece of filter paper was soaked in saline containing 0.4 μg horseradish peroxidase per 10μl and placed in the nasal sac for 40 hours. Carassius was used in this experiment. The brain, olfactory nerves and epithelium were embedded in gelatin to obtain 40 micron thick horizontal sections. The diaminobenzidine tetrahydrochloride procedure was used to localize the peroxidase reaction product in unstained sections. Control sections were stained with cresyl violet acetate.

The olfactory bulb on the side which received the HRP and the contralateral bulb showed similar distributions of endogenous peroxidase in capillary walls and erythrocytes. Fibers in the superficial layer of the anterior zone of the ipsilateral bulb contained reaction product. The primary receptor neurons terminate in this layer. The ipsilateral bulb also contained many labeled cells embedded in the superficial layer and in the periglomerular region. The peroxidase-labeled cells in Carassius closely resemble the amphibian efferent neurons described by Rubaschkin (1903, Arch. mikr. Anat. 62, 207). The data indicate that the olfactory efferent neurons in fish terminate selectively in the receptor epithelium, which suggest a receptor modulation function. However, whether the efferents synapse with receptors or some other cells remains to be investigated.

404 DEVELOPMENTAL CHANGES IN NEURAL TASTE RESPONSES IN POSTNATAL RATS. Fay Ferrell*, Robert M. Bradley, Charlotte M. Mistretta and Kathy Miklossy*. Dept. Oral Biol., Sch. Dent., U. Mich., Ann Arbor, MI 48109.

Response characteristics of taste neurons in fetal sheep have been shown to change during development (Mistretta and Bradley, Science, 1978, 202, 535). Older fetuses respond to a greater number of salts and acids than do younger fetuses, and responses to specific salts and acids develop in a particular sequence. To learn whether functional changes also occur in a species in which the taste system develops postnatally, we examined taste responses in 11 preweaning (8-21 day), 20 weaning (22-60 day) and 10 adult (>60-day) rats.

Rats aged 8-30 days were anesthetized with Chloropent and older rats with Nembutal. Responses were recorded from the whole chorda tympani nerve while stimulating the tongue with 0.1M NaCl, LiCl, KCl and NH_4Cl, 0.01N HCl, 0.0025M citric acid, 0.5M sucrose, and 1.0M urea. Neural responses were passed through an AC to DC converter, and the height of the steady-state component of the response was measured. Ratios of the responses to each stimulus compared to the NaCl response were calculated.

As age increases, the order of effectiveness of the monochloride salts changes. Our preliminary data indicate that whereas the order in preweaning rats is NH_4 > Li > Na > K, in adults the order is Li > Na > NH_4 > K. Thus, NaCl and LiCl become more effective stimuli; NH_4Cl, less effective. HCl, citric acid and sucrose usually elicit larger responses than NaCl in preweaning rats, but equal to, or smaller responses in adults. Responses to LiCl and urea seem to remain stable with respect to NaCl.

The transition from preweaning to adult response characteristics seems to occur between about 20 and 30 days. By 40-50 days, responses relative to NaCl are essentially the same as for adults. These changes in taste function in rats after birth confirm the developmental changes observed in fetal sheep. Such changes in stimulus effectiveness may reflect maturation of taste receptor membranes. (Supported by NIH Postdoctoral Fellowship DE-05154 to F.F., and by NSF Grant BNS 77-09920 to R.M.B. and C.M.M.).

405 DIFFUSION OF TASTE STIMULI TO FUNGIFORM TASTE BUDS IN ZINC DEFICIENCY. John E. Ewen* and Lloyd M. Beidler. Department of Biological Science, Florida State University, Tallahassee, FL 32306

Zinc deficiency (zn-) produces altered taste sensations in humans (elevated detection and recognition thresholds) and altered taste preference behavior in rats. The exact mechanisms responsible for these effects are not known. Several laboratories have shown that zn- produces a hyperkeratosis of the tongue's dorsal surface in a variety of species. In our laboratory this hyperkeartosis accompanying zn- has been seen to completely cover fungiform taste buds or to gradually build up and surround fungiform papillae which resulted in "pit-like" structures with taste buds submerged 100-200μ below the epithelial surface. These results suggested that the hyperkeratosis of zn- may affect the diffusion of taste stimuli applied on the dorsal surface of the tongue. The purpose of the present study was to compare quantitatively the diffusion of taste stimuli to taste cells in control (zn+) and zn- rats. The rates of diffusion of various stimuli (representing the 4 taste qualities) were computed as a function of time of application and distance from the taste pore to the tongue's dorsal surface. These calculations show that the increased distance to the taste cells in zn- rats dramatically reduces the rate of stimulus concentration increase at the taste cells. These results suggest that altered taste sensation in zn- humans and taste preference behavior in zn- animals may be partially explained in terms of the decreased rate of taste stimulus onset and concentration at the taste pore as calculated by diffusion processes.

406 IONIC BASIS FOR REGULATION OF OLFACTORY RECEPTOR CILIARY MOVEMENT. R. C. Gesteland, D. L. Blank and K. M. Hanlon*. Northwestern Univ. Dept. of Biological Sciences, Evanston, IL 60201 and Naval Research Laboratory, Washington, DC 20375.

Movements of the cilia which grow out of the apical dendrites of olfactory receptor neurons in the frog are dependent upon odorous stimulation. Control of the motion appears to be by way of ciliary membrane conductance changes analagous to those which occur in some ciliated protozoans. Ciliary activity was observed at the edge of a fold of isolated epithelial tissue immersed in amphibian Ringer viewed with differential interference contrast optics. When the membrane was depolarized by reducing external (Cl^-) motion slowed and stopped. Changes in external (Na^{++}) had no effect. Reduction of external (Ca^{++}) increased the rate of ciliary motion. Addition of EDTA or EGTA in the absence of Ca^{++} blocked motion after a brief increase in activity. 0.01% Triton X (which probably reduces membrane ionic diffusion barriers) also first increased then blocked activity. Chelators plux Triton do the same only more rapidly. A wide variety of odorous substances presented at low concentrations modulates ciliary motion. These may increase activity, reduce activity or induce successive periods of increase and decrease. In the unstimulated state each cilium beat consists of a power stroke followed by a recovery stroke. There is no metachronal synchrony between neighboring cilia on the same cell or on adjacent cells and no resulting directed mucus transport. Stimulated increase in rate of activity does not affect either the stroke direction or asynchrony. Slowing of rate of movement is accompanied by metachronal synchrony and directed fluid transport. The direction of the power stroke also appears to change. These observations are consistent with a model of the ciliary membrane which is quite permeable to K^+ and/or Cl^- and slightly permeable to Ca^{++} in the unstimulated state. Factors which cause hyperpolarization are associated with increased beat frequency and asynchrony. Increase in membrane Ca^{++} conductance and depolarization result in slowing of rate and metachronal synchrony. All motion is blocked by removal of an essential ion (Mg^{++}?) from the cilium interior. The control processes postulated here for olfactory receptor cilia motion are the ones that have been shown to be responsible for motion reversal upon mechanical contact in *Paramecium caudatum*. The mechanical stimulus initiates a Ca^{++} action potential. We suggest that olfactory receptors are excited by odor-evoked increases in cilium membrane Ca^{++} conductance and inhibited by evoked increases in K^+ and/or Cl^- conductance and that a single receptor process both initiates a useful transport process and generates the neural signal. Supported in part by NIH Grant No. NS 14663 and NSF Grant No. BNS 78-17479.

407 UPTAKE PATTERNS OF 2-DEOXYGLUCOSE ASSOCIATED WITH ELECTRICAL STIMULATION OF THE OLFACTORY NERVE IN RAT AND IN VITRO TURTLE OLFACTORY BULB. C.A. Greer, W.B. Stewart, J.S. Kauer, K. Mori* and G.M. Shepherd. Sections of Neuroanatomy, Neurosurgery and Gross Anatomy, Yale Univ. Sch. Med., New Haven, CT, 06510.

Odor stimulation elicits distinct patterns of 2-deoxyglucose (2DG) uptake in the glomerular layer of the rat olfactory bulb, as detected by the Sokoloff autoradiographic method. The results suggest that increasing odor concentration is correlated with increased activity in the axons of specific groups of receptor cells and that the axons project to groups of glomeruli in the olfactory bulb (Stewart, Kauer and Shepherd, J. Comp. Neurol., In Press). We have sought further information about the contribution of receptor axons to the patterns by examining 2DG uptake associated with selective electrical stimulation of the olfactory nerve. The nerves were exposed in rats and stimulated through a bipolar electrode while recording evoked potentials in the bulb. Stimulation of the nerve bundles in the dorsal recess of the nasal cavity produced evoked potentials limited to the lateral anterior aspect of the ipsilateral bulb. Autoradiography revealed an intense focus of 2DG uptake in that region. Low frequencies (1/4 sec.) and low intensities of stimulation yielded uptake patterns centered in the glomerular layer. Increasing frequency (up to 10/sec.) and higher intensities resulted in progressive extension of the 2DG focus into neighboring laminae of the bulb. Stimulation of other olfactory nerve bundles, or antidromic stimulation of the lateral olfactory tract, produced readily distinguishable patterns. The general characteristics of 2DG uptake found here are similar to those observed following odor stimulation, which supports the interpretation that odor induced 2DG uptake is primarily due to increased activity in olfactory axons.

Similar experiments have been carried out in the isolated turtle olfactory bulb. The Sokoloff method was adapted to the in vitro preparation by continuously infusing the bath with ^{14}C-2DG (50μC/100ml) during the 45 min. period of stimulation. This was followed by a 15 min. washout with turtle Ringer prior to freezing and standard preparation for autoradiography. Stimuli were submaximal in intensity and delivered at a rate of 1/2-5 sec. while recording evoked responses in the bulb. Stimulation of an entire nerve bundle, to either the dorsal or ventral aspect of the bulb, produced extensive 2DG uptake in the corresponding part of the bulb. Following these relatively intense volleys, the induced 2DG uptake could be seen throughout most of the bulbar layers. The results demonstrate that the Sokoloff method can be applied successfully to in vitro preparations of the CNS, and moreover that the results are qualitatively similar to those observed in vivo.

408 NEURAL ONTOGENY OF CHORDA TYMPANI TASTE RESPONSES IN THE RAT. David L. Hill* and C. Robert Almli. Dept. Psychol., Ohio Univ., Athens, Ohio 45701.

We are in the process of examining the neural taste responses of the chorda tympani (CT) in the developing rat. In order to examine the developmental changes in the CT responses that may be associated with important developmental stages of consummatory behaviors, we have obtained summated multi-unit CT responses from male and female adult rats (90-120 days), postweaning-prepubertal rats (34-35 days), weanling rats (19-20 days), and preweaning rats (12-13 and 9-10 days). We have recorded responses from a few 6-day-old rats and are presently investigating the CT responses of rats at this age, as well as in younger rats.

To examine the developmental changes of CT responses to qualitatively different stimuli, 10 ml each of 0.5M NH_4Cl, 0.5M NaCl, 0.5M LiCl, and 0.1M citric acid were applied to the anterior two-thirds of the tongue. In addition, a concentration series of 0.1M NH_4Cl, 0.25M NH_4Cl, 0.5M NH_4Cl, and 1.0M NH_4Cl were applied similarly to assess the ontogeny of quantitative characteristics of the CT responses. Following each stimulus presentation, the tongue was washed with 20 ml of distilled water. A standard stimulus of 0.5M NH_4Cl was periodically applied to establish the stability of the preparation.

Preliminary results indicate that the CT is responsive to all of the above stimuli in rats as young as 6 days of age. We have found that as the rat progresses from the preweaning ages, through the weanling and postweaning-prepubertal ages, and finally to adulthood, the CT responses to 0.5M NaCl and 0.5M LiCl become progressively larger in magnitude relative to the CT responses to 0.5M NH_4Cl. In contrast to the equimolar salt response comparisons, the CT response to 0.1M citric acid appears to decrease in magnitude relative to that of 0.5M NH_4Cl as the rat matures, although the decrease in the response to citric acid does not seem to be associated with consummatory stages of development. In response to the concentration series of NH_4Cl, CT responses at all ages examined thus far increase in response magnitude as the concentration increases.

Developmental changes of CT responses to equimolar salts suggest that important changes are occurring in the development of taste buds. In addition, these data suggest that after the buds are mature, changes in their sensitivities to salts may occur concomitantly with important periods in development of consummatory behaviors. Supported by: OURC Grant No. 520.

409 AIR/OLFACTORY MUCOSA PARTITIONING OF ODORANTS. D. E. Hornung*, M. M. Mozell and J. A. Serio*. Dept. Physiology, Upstate Medical Center, Syracuse, NY 13210.

To better define the mucosal sorptive events, we have developed a technique, using tritium labeled odorants, to measure partition coefficients. Partition values for odorants can now be obtained, not only between air and water (often accepted as representative of the air/mucosa partition) but also between air and the mucosa itself. For various periods of time samples of frog mucosa or water were exposed in a closed environment to humidified air saturated with either tritiated butanol or tritiated octane. The radioactivity recovered from each of these samples, as determined by liquid scintillation counting, was used as a measure of odorant uptake. For butanol, the air/water partition coefficient was in good agreement with that reported by Amoore and Buttery (Chem. Sens. Flavor, 3:57, 1978) who used a gas flow technique. This agreement supports the validity of the present technique. We determined that, after equal exposure times, the water and mucosa samples sorbed equivalent amounts of butanol. This suggests that for butanol, uptake by olfactory mucosa is not significantly different from uptake by water. Therefore, the air/water partition coefficient can be taken to represent the air/mucosa partition coefficient. However, for tritiated octane, the mucosal uptake was about 1.5 times that of water, indicating that olfactory mucosa may have an increased ability over water itself to sorb octane molecules. Perhaps, then, for slightly water soluble odorants like octane the air/water partition coefficient may not be a very good indicator of mucosal uptake.

This technique allowed us to generate curves showing the uptake of odorant by the mucosa as a function of exposure time. Therefore, we were able, by extrapolation, to estimate the mucosal uptake during exposure times short enough to represent sniffs like those artificially produced in our earlier in vivo studies (Hornung and Mozell, J. Gen. Physiol. 69:343, 1977). This work suggests that the air/mucosal partition coefficient may be basic to the establishment of the different odorant distribution patterns earlier observed across the mucosa.

In experiments designed to study odorant desorption, mucosal or water samples were again exposed to a humid environment saturated with tritiated odorant. The samples were then quickly transferred to a humidified environment containing no odorant where desorption was allowed to occur for ten minutes. The remaining radioactivity in the samples was counted. For octane, the amount of desorption from the mucosa was significantly less than from water. This again suggests that the mucosa has an increased ability, over that of water itself, to sorb and retain certain types of odorant molecules. (NIH Grant NS 03904)

410 OLFACTORY FUNCTION IN BIRDS: NEUROPHYSIOLOGY AND BEHAVIOR Larry V. Hutchison and Bernice M. Wenzel. Dept. Physiol., Brain Res. Institute, Sch. Med., UCLA, Los Angeles, CA 90024.

Previous neurophysiological study has revealed major ipsilateral and contralateral forebrain centers which receive mono- and polysynaptic input from the olfactory bulb (OB) in the pigeon Extensive connections exist to sensory processing and relay areas and also to areas homologous with limbic structures and basal ganglia in mammalian forms. Characteristic evoked potentials and distinctive temporal patterns of unit responses to olfactory nerve (ON) stimulation are recorded in anatomically localized cell populations. In addition to topographical specificity, many possibilities exist for information coding in the olfactory pathway in terms of systematic changes in temporal parameters in unit activity. To examine some of these possibilities, detailed time series analyses are being conducted by computer on spontaneous activity and modifications of the firing rates of single cells. Recently, we extended anatomical and physiological study of the avian olfactory system to the Northern Fulmar (Fulmarus glacialis). This species, like other procellariiform birds, has relatively extensive olfactory conchae, mucosal area, and a larger olfactory bulb/cerebral hemisphere ratio than most other birds. Compared to the pigeon, the forebrain structures receiving fibers from the OB in the fulmar also appear proportionately more extensive. Further, the prepiriform cortex and olfactory tubercle are denser and more readily distinguished in Nissl stained sections. Bipolar stimulation of one bundle of ON twigs with 8-12 V pulses (single or train), 0.5-1.0 ms duration, at 0.1-1.0 Hz resulted in evoked responses in both OB's and in significant modifications of spontaneous unit activity (± 20% change in rate). Characteristic evoked potentials and modifications of unit activity were recorded from forebrain sites in areas comparable to those receiving first- and higher-order projections in the pigeon, viz., hyperstriatum, prepiriform cortex, parolfactory lobe, and the paleostriatal complex. Odor stimuli combined with ambient air blown directly into the nares produced significant changes from pre-odor baseline firing rates in several bulbar cells. The result was either enhancement or inhibition depending upon qualitative differences among stimuli. Unit activity was consistently inhibited by natural food odors (cod liver oil and krill homogenate) but not significantly modified by ambient air and control solvent. In our systematic program of experiments at sea we have found that procellariiforms including this species, detect and are attracted from downwind to sources of food-related odors with visual cues controlled. (Supported by USPHS grant NS 10353 to B.M. Wenzel and NINCDS Postdoctoral Fellowship NS 05896 to L.V. Hutchison).

411 PROCESSING OF CHEMOSENSORY AND MECHANOSENSORY INFORMATION BY APLYSIA NEURONS. Behrus Jahan-Parwar and Steven M. Fredman. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Chemo- and mechanosensory input from the anterior tentacles of Aplysia project into the cerebral ganglion. In our previous work we have examined the responses of cerebral neurons to these modalities (1,2). We now present evidence that the identifiable cerebral B cluster neurons are second-order neurons in both pathways and that the tentacular mechano- and chemoreceptors are physiologically distinct. The responses of the B neurons to tactile and food chemosensory (seaweed extract, SWE) stimulation of the anterior tentacles, persisted after synaptic transmission in the tentacles had been blocked. Similarly, following blocking of polysynaptic pathways in the CNS, both tactile and food chemosensory stimulation still evoked EPSPs (many of which appeared to be unitary) in the B neurons. These data indicate that the tentacular mechano- and chemoreceptor cells synapse directly on the B neurons. B neuron tactile responses were phasic. Increased stimulus durations failed to produce proportionately longer responses. This appears to be due to decrement at the mechanoreceptor-B neuron synapses. B neuron responses to SWE were essentially tonic and lasted until the stimulus solution was washed out. The difference in the responses cannot be accounted for simply by the number of receptors activated. Seawater flowing over the tentacles which stimulated mechanoreceptors over the entire tentacle surface, still produced only phasic responses in the B neurons. This suggests that the mechano- and chemoreceptors are physiologically distinct and that the modalities are distinguished by the properties of the first-order synapses.

This work was supported by grants NS 12483, NS 14388 and BNS 77-24174 to B.J-P.

412 STIMULATION AND INHIBITION OF TASTE RECEPTOR CELLS BY GYMNEMIC ACIDS AND ZIZIPHIN. Linda M. Kennedy and Bruce P. Halpern*. Depts. Psych., Harvard Univ. and Cornell Univ.; Dept. Psych. and Sect. Neurobiol. and Behav., Cornell Univ., Ithaca, NY 14853.

Gymnemic acids and ziziphin (from Gymnema sylvestre and Ziziphus jujuba) suppress fly behavioral and neural responses to sucrose in a manner similar to that in which they suppress sweetness perception in humans (Kennedy et al., 1975; Kennedy and Halpern, 1978, 1979). Aqueous solutions of purified components from G. sylvestre (KGE) (Bartoshuk et al., 1969) and Z. jujuba (ZjE-A)(Kennedy, 1977) stimulated two cells in single taste sensilla of the blowfly Phormia regina. Responses to KGE and ZjE-A presented either as single solute stimuli, in mixtures with sucrose, NaCl, or 50mM LiCl, or during mechanical stimulation, suggested that the two cells were not the "sugar," "salt," or mechanoreceptor cells. Responses to KGE, ZjE-A, 50mM LiCl, NaCl, or sugars after adaptation to sucrose, KF, or distilled water, confirmed that aqueous solutions of KGE and ZjE-A stimulate the "water" and "fifth" cells.

Responses of the "fifth" cell to 2 sec stimulations with KGE and ZjE-A were concentration dependent, but slow and not always phasic-tonic. Prolonged stimulation (≥ 2 min) often led to volleying and cessation of firing. A 3 min pretreatment with KGE or ZjE-A resulted in an initial depression, subsequent recovery, and eventual increase and volleying of action potential responses to sucrose.

Dose-response curves for stimulation of the "fifth" cell and inhibition of the response to sucrose were bell-shaped and suggested that mechanisms of stimulation and inhibition are related. Consequently, it is unlikely that KGE and ZjE-A suppress sucrose perception by "occupying," and thus "blocking," sweet receptor sites. The stimulation/inhibition effects suggest disruption of the plasma membrane. Similarities of stimulation/inhibition by the amphipathic molecules, KGE and ZjE-A, with stimulation/inhibition by amphipathic fatty acid salts (Dethier and Hanson, 1968) support the notion (Dateo and Long, 1973; Kennedy et al., 1975; Kennedy, 1977) of a role for surface active properties in the action of gymnemic acids and ziziphin.

(Supported by NSF dissertation grant BNS-7822149. L.M.K. is a Danforth GFW Fellow).

413 INVOLVEMENT OF GUSTATORY NEOCORTEX IN THE RAT'S NEOPHOBIC AND ASSOCIATIVE RESPONSES TO TASTE AND ODOR STIMULI. Stephen W. Kiefer and Kenneth W. Rusiniak*. Dept. Psych., and Ment. Retard. Res. Ctr., UCLA, Los Angeles, CA 90024

In normal rats, odor alone is a weak conditioned stimulus (CS) for LiCl-induced illness (US); taste alone is an effective CS. However, if odor and taste are presented as a compound CS and followed by lithium illness, both odor and taste become effective CSs when tested alone. Odor and taste in compound also evoke a strong neophobic response before conditioning. The gustatory neocortex (GNC) has been implicated in both neophobia and taste aversion conditioning. In this experiment we tested the role of the GNC in compound conditioning that involved taste and odor.

One month prior to behavioral training, rats were given either bilateral suction ablation of the GNC or sham surgery. For aversion training rats were first accustomed to a restricted drinking schedule. On the two conditioning trials, intubations of LiCl (.15M, 2% B.W.) immediately followed the drinking period; two groups of rats, (GNC, n=7; sham, n=5), drank distilled water in the presence of an almond odor, and the other two groups (GNC, n=8; sham, n=6), drank .1% saccharin in compound with the almond odor on the conditioning days. After conditioning, extinction tests were given to all rats with the almond odor and the saccharin taste presented separately on alternate days.

Results showed 1) that GNC rats did not show a strong neophobia to the odor/taste compound that was found in the sham controls; consumption of the compound odor-taste fluid by the GNC rats was the same as that of the GNC rats given odor alone, 2) GNC rats did acquire significant odor aversions, but not as efficiently as sham controls, 3) both GNC and intact groups trained with the odor alone tended to extinguish faster on the odor component than the groups trained on the odor/taste compound, 4) only the control group trained on the compound displayed significant aversions to the taste. GNC rats trained on the compound acquired virtually no aversion to the taste, consuming saccharin at control levels.

Thus rats lacking GNC did not exhibit normal neophobia to odor-taste stimuli. In addition, following compound conditioning, GNC rats acquired aversions for the odor but not to taste in contrast to the sham controls, which acquired aversions to both components. These results have implications for the neural basis of odor-taste interaction during illness aversion conditioning.

414 REGIONAL PATTERNING OF RESPONSE TO ODORS IN THE SALAMANDER OLFACTORY MUCOSA. John L. Kubie and David G. Moulton. Dept. of Physiol., Univ. of Penn. and V.A. Med. Ctr., Phila. PA 19104

Electro-olfactograms (EOGs) were recorded from various mucosal positions to determine whether different odorants elicit different spatial patterns of response. To eliminate "chromatographic" effects, (i.e., uneven odorant distribution imposed by sniffing) odorants were delivered through a modified "punctate" device that was positioned immediately above the electrode tip.

Experiment 1. Two stationary electrodes, one anterior and one posterior, were positioned on either the dorsal or the ventral epithelium. Each odorant was presented to each position in an ascending series of ½ log concentration steps. Eight ventral and 3 dorsal surfaces were tested with butanol, limonene and occasionally other odorants. For each mucosal surface and at all concentrations the anterior electrode position was more sensitive to butanol while the posterior position was more sensitive to limonene. The average composite difference in sensitivity exceeded one order of magnitude.

Experiment 2. We mapped EOG responses to odorants on 17 ventral and 6 dorsal surfaces. Eighteen to 25 positions were selected on each surface and a fixed stimulation sequence was constructed. Each odorant was presented at one concentration (usually one that produced 1.5 mv EOGs in previous experiments) sequentially to each point on the epithelium. Each receptor sheet was mapped for limonene, butanol and several other odorants. On all mucosal surfaces (both dorsal and ventral) we recorded strongest responses to butanol anteriorly and strongest responses to limonene posteriorly. Point-by-point correlations between butanol and limonene response maps were always negative. Fifteen odorants exhibited anterior patterns (trimethyl amine, cinnamic acid, cyclopentanone, acetone, isoeugenol, butanol, methyl butyrate, cantharidin, napthaline, methly sulfide, vanillin, B-ionone, acetophenone, valeric acid, and terpineol); 4 odorants exhibited posterior patterns (limonene, camphor, pinene, and hexachloroethane); and 3 appeared to stimulate the epithelium evenly (amyl acetate, decyl acetate and cyclohexanone).

This is the first demonstration made by direct recording from both dorsal and ventral surfaces of the olfactory mucosa that there is a clear dissociation of regional sensitivity to odorants. Since these results are totally independent of chromatographic effects, they may account for previous findings attributed to chromatographic effects or they may complement the normal sniff patterns of odorant distribution. There is also some indication that patterns other than those described here may exist for some odorants.

415 STIMULUS ACCESS TO AND ACTIVATION OF THE GUINEA PIG VOMERONASAL SYSTEM. Judith W. Lerman*, Gary K. Beauchamp*, Charles J. Wysocki and John L. Kubie. (SPON: John H. Teeter). Monell Chemical Senses Center, 3500 Market St. and Dept. Physiol., Univ. Pennsylvania, Philadelphia, PA 19104.

When presented with conspecific female urine, male guinea pigs spend considerable time investigating, sniffing, licking and head bobbing to the stimulus. Females, when presented with conspecific urine, also investigate, sniff, and lick the urine, but not with the intensity exhibited by males. Our hypothesis, generated from these observations, was that urine per se may be transported to the vomeronasal epithelium where subsequent sensory processing is initiated. If correct, then urine or some constituents thereof, should be localized in the vomeronasal organ after exposure of a guinea pig to urine. Additionally, if the vomeronasal system is utilized in the detection of urinary constituents then activation of the vomeronasal epithelium should be reflected as an increase in activity of central nervous system structures associated with the vomeronasal system, e.g., the accessory olfactory bulb.

The hypothesis that low volatile compounds can enter the vomeronasal organ during urine investigation was pursued through the use of fluorescent dye-adulterated urines. Guinea pigs were offered urine with or without a fluorescent dye, rhodamine (B or 6G) hydrochloride. After a short exposure to the urine (less than 10 min), the guinea pig was sacrificed and the vomeronasal organ was removed, frozen, sectioned, and examined with a fluorescence microscope. In animals exposed to adulterated urine, dye fluorescence was observed in the vomeronasal organ but not on the olfactory epithelium. In addition, fluorescence was consistently observed in the mouth and nasopalatine ducts. Dye fluorescence was not observed in tissues from animals exposed to unadulterated urine.

The hypothesis that urine investigation activated central structures in the olfactory and accessory olfactory pathways was investigated by using the [14C] 2-deoxy-D-glucose (2DG) technique. Male guinea pigs were injected with 2DG and exposed to a series of female urine samples during the 2DG incorporation period. Autoradiographs revealed activation of the vomeronasal organ and the accessory olfactory bulb after exposures to female urine. To our knowledge, this is the first demonstration of activation of the vomeronasal system through the use of radiolabeled 2DG.

These results suggest activation of the vomeronasal system by liquid borne, possibly high molecular weight, compounds.

416 LAMINAR DISTRIBUTION OF ASSOCIATION FIBER SYSTEMS IN THE OLFACTORY CORTEX IN THE RAT. M.B. Luskin* and J.L. Price. Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Recent studies using the autoradiographic method have elucidated the laminar and topographic organization of the association fiber projections from subdivisions of the olfactory cortex. Two major laminar patterns of termination have been found. Previous studies have demonstrated that projections arising in the anterior olfactory nucleus (AON), piriform cortex (PC) and lateral entorhinal area (LEA) terminate in layers Ib and III (Price, '73) (curve B below); the projection to layer Ib is complementary to the projection to layer Ia from the olfactory bulb (curve A). These association projections are organized such that projections arising in more anterior structures project principally to areas deep to or near the lateral olfactory tract (LOT), while projections arising in more posterior structures terminate primarily in areas medial, lateral and caudal to the LOT (Haberly and Price, '78).

Another set of intracortical fibers has been found which terminates in layer II, the deeper portions of layer Ib, and in layer III (curve C). These projections arise from the ventral tenia tecta (VTT), dorsal peduncular cortex (DPC) and periamygdaloid cortex (PAC). Although the projection from the individual subdivisions terminate in different areas, collectively they innervate most of the olfactory cortex. The VTT projects principally to the AON; the DPC projects principally to the PC; and the PAC projects principally to the olfactory tubercle (OT), PC, anterior cortical amygdaloid nucleus (Co_a) and LEA.

Two further association projections have also been found: a projection from the Co_a to the PC, medial part of the AON, VTT and PAC which terminates throughout layer I, including both layers Ia and Ib, and a bilateral projection from the nucleus of the lateral olfactory tract to the medial PC and lateral OT, which is heavily concentrated over and around the cells of the edge of the PC and the superficial islands of Calleja.

A - Olfactory Bulb
B - Anterior Piriform Cortex
C - Dorsal Peduncular Cortex

417 RESPONSE PROPERTIES OF RAT OLFACTORY BULB NEURONS. Robert G. Mair* (SPON: W.J. McEntee). Psychology Dept., Brown University, Providence, R.I. 02912.

Neural activity was recorded from 65 units located near the mitral cell body layer in the rat olfactory bulb. These neurons were stimulated with 2 second odorant pulses delivered by an air dilution olfactometer and their responses were quantified as averaged peristimulus time histograms (PSTH's). Analysis of the PSTH data obtained from units driven by varying concentrations of single odorants suggests the existence of three discrete populations of neurons. Each of these are distinguished by characteristic temporal patterns of activity, evoked during the stimulus event, which change in a consistent manner as a function of stimulus concentration. Neurons driven by more than one of the test odorants exhibited similar patterns of activity in response to all effective stimuli. Type I responses are marked by an increase in activity within one second of stimulus onset. At low stimulus concentrations type I responses are characterized by a single burst of action potentials. At higher concentrations they consist of two shorter bursts of action potentials separated by a relatively quiet period. The activity of type II neurons is suppressed during the stimulus event when these units are driven by weak stimuli. Type II neurons driven by stronger stimuli exhibit a post-inhibitory burst of action potentials the latency of which decreases as a monotonic function of increasing concentration. The activity of type III neurons is decreased by all concentrations of effective stimuli. The extent and duration of this inhibition increases with stimulus concentration. Intensity related changes in type I and II responses were quantified in terms of three measures: number of action potentials fired during the stimulus event, latency of action potential bursts, and peak rate of activity during action potential bursts. The amount of evoked activity was not as consistently correlated with stimulus concentration as was the pattern of evoked activity. Increases in activity following stimulus offset (off responses) were apparent for some units and appeared to be of two types: phasic and tonic. Off responses occurred in some cells that did not respond during the stimulus event and in some of the cells exhibiting type I, II, and III responses during the stimulus event. It thus appears that the occurrence of off responses is not dependent on a unit's response during the stimulus event.

418 DEVELOPMENT OF TONGUE EPITHELIUM GRAFTS IN FETAL SHEEP. Charlotte M. Mistretta, Robert M. Bradley, and Hazel M. Stedman.* Dept. Oral Biol., Sch. Dent., U. Mich., Ann Arbor, MI 48109.

To study nerve-tissue interactions during development of lingual taste buds and papillae, grafts of tongue epithelium were made during sterile surgery in fetal sheep. In 16 fetuses, aged 52-107 days of gestation, anterior tongue epithelium containing fungiform papillae was transplanted to an external cheek site. In 4 fetuses, aged 62-73 days of gestation, posterior tongue epithelium containing circumvallate papillae was transplanted to the external cheek. Fetuses with grafts were replaced in utero to remain for the rest of gestation (term= 147 days). Near term or after birth, fetuses were perfused and graft tissues were prepared for light microscopic examination.

In anterior tongue grafts, filiform papillae acquired the structural characteristics of normal tongue. However, neither taste buds nor typical fungiform papillae developed. A few structures that resembled fungiform papillae were found in about one-half of the grafts; these structures were of smaller diameter than control papillae and usually had more keratin on the dorsum. Posterior tongue grafts contained the glandular structures found in control tongue; but only one or two papillae resembling circumvallates were found in each graft, and no taste buds were present. The papillae that resembled circumvallates were atypically small and were usually keratinized.

In the 4 fetuses with posterior tongue grafted to external cheek, the posterior site from which circumvallate papillae had been removed was examined. No circumvallate papillae developed in the smooth epithelium that covered areas from which lingual tissue had been dissected. However, several taste buds not associated with gustatory papillae were found in this epithelium.

We conclude that: 1. Gustatory papillae and taste buds will not develop under the influence of the trigeminal innervation to the external cheek. However, with trigeminal innervation, anterior and posterior tongue do retain some characteristics of the respective lingual tissue (for example, filiform papillae and glands). 2. Gustatory papillae will not regenerate if removed during development. 3. Taste buds will develop in tongue epithelium that does not contain gustatory papillae.

419 NEURONAL RESPONSES TO l-CARVONE IN THE RAT PIRIFORM CORTEX: AN EXTRACELLULAR AND INTRACELLULAR STUDY. James W. Nemitz* and Stephen J. Goldberg. Dept. of Anat., Med. Col. of Va., VCU, Richmond, VA. 23298.

Bipolar electrical stimulation of either the lateral olfactory tract (LOT) or olfactory bulb (OB) in urethane anesthetized (1.5g/kg) male rats (≃300 grams) elicited characteristic field potential and single unit responses in the ipsilateral piriform cortex. An air-dilution olfactometer was used to deliver ≃250 msec. pulses of l-carvone to cells identified with electrical stimulation. A tracheal tube and a tube ascending to the choana were inserted. Controlled suction (≃8ml/sec.) applied to the ascending tube produced an artificial sniff during odor presentations. Recordings were made with beveled, potassium citrate (1.6M) filled micropipettes (20 MΩ). Electrodes were inserted from dorsal to ventral through the rats' cortices. The neuronal recordings were made in both anterior (3-4 mm anterior bregma) and posterior (at bregma) piriform cortex.

A total of 38 cells were studied in response to electrical stimulation. LOT stimulation was used to elicit responses in 9 cells which showed latencies to spike initiation ranging from 3 to 16 msec. with an average of 9.1 msec. OB stimulation was used to elicit responses in 29 cells with latencies to spike initiation ranging from 4 to 28 msec. with an average of 13.3 msec. 10 of these 38 cells were studied intracellularly and exhibited latencies of 1-6 msec. to initiation of the EPSP. 28 of the total 38 cells were subjected to odor stimulation with l-carvone (1 part/100). In 22 extracellularly recorded cells, 11 were excited and 11 showed no response to odor stimulation. In 6 intracellularly recorded cells, all showed excitatory responses although 2 neurons did not produce action potentials in response to odor stimulation, but EPSPs were present. Latencies to spike initiation ranged from 1.1 to 5.0 sec. in response to odor stimulation.

These results indicate that piriform cortex neurons respond to l-carvone stimulation with excitation. Neuronal inhibition was never observed either extracellularly or intracellularly using our stimulation parameters. At this time we can see no difference between the response patterns in anterior and posterior piriform cortex. We are presently continuing our studies using a variety of odors and odor concentrations.

420 TRANSECTION-INDUCED DECLINE IN IXth NERVE TASTE RESPONSES DEPENDS UPON SEASON BUT NOT AGE. Bruce Oakley and Lee B. Jones*. Div. Biol. Sci., Neuroscience Lab. Bldg., Univ. of Mich., Ann Arbor, MI 48109.

Following transection of the gerbil's (Meriones unguiculatus) IXth nerve, summated impulse discharges to taste solutions declined by 50% in 119 ± 44 min ($\bar{x}$ ± S.D., N = 15). Compound action potentials were still normal, indicating that the nerve trunk remained viable. We noted, however, that the taste responses of a number of the animals remained stable after nerve transection. We defined a stable response as one which was maintained longer than 3.5 hours (the mean decline time plus two S.D.); in fact, most stable responses showed no sign of declining in a 5 hour recording session. Over a four year period we have analyzed the influence of season of the year, age and sex on the likelihood that transection would produce a rapid decline in the nerve's taste response. 119 IXth nerves were transected in the months September through April. Taste responses declined in 98% (39 of 40) of the cut nerves recorded from September through December, yet declined in only 73% (58 of 79) of cut nerves recorded from January through April ($p < .01$, chi square). Gerbils were caged with littermates of the same sex and maintained on a 12/12 light/dark cycle. The occurrence of a significant population of nerves which failed to decline in January through April seems not to be related to the age or sex of the animal. Gerbils with stable and declining taste responses had identical age ranges (12 to 36 weeks) and no significant difference in mean age ($p > .15$, chi square). 57% of those nerves giving stable responses were from male gerbils while only 40% of the nerves with declining responses were from males. This difference is not significant ($p > .2$, chi square). We conclude that the physiological taste responses of the gerbil display seasonal variation which may be related to neurotrophic maintenance in the gustatory system.

421 ACROSS FIBER SPECTRUM FOR SUGAR IN TASTE. Elizabeth Omand and Jacob Zabara, Temple University Health Sciences Center, Depts. of Physiology & Biophysics, Philadelphia, PA 19140.

Dipteran chemoreceptors respond to more than one chemical class. Amino acids as a group stimulate two cells and initiate distinct behaviors. We report here that certain sugars may likewise stimulate the same two distinct receptor types.

Using standard tip recording through third molar LiCl six sugars were tested over a wide range of concentrations on "largest" labellar hairs (#1-12) of intact male Phormia regina, Meigen, 1-3 days old, unfed and reared in a 12:12 light cycle at 24°C, and 60% R.H. Sucrose and Maltose evoked receptor responses characteristic of a single unit. Monosaccharides at high concentrations commonly yielded irregular interspike intervals denoting two active units with similar impulse amplitudes. Spike "pairs" and single impulses alternated, the latter with amplitudes denoting degrees of coincidence. The pattern was consistent with the presence of two independent impulse trains. That appearing at lower concentrations had good correspondence with (tarsal) behavioral thresholds, and is assumed to be from the sugar receptor. Slope consistency with chemical class supported this interpretation. The train appearing at the higher concentration generated a response curve with a slope much greater than that by the other train to any sugar. Barring a facilitative electrolyte effect, "fifth" cell response to monosaccharides is indicated, with this order of effectiveness: Sorbose>D-arabinose>Glucose>Fructose. Apparently some carbohydrates can stimulate two receptor types, which therefore, exhibit spectral overlap. The overlap enhances the possibilities for across fiber patterning. Common action between carbohydrates and amino acids also occurs in mammals, and maybe be reflected in receptor responses which display mutuality for these chemical classes in the blowfly. The results are consistent with the concept of a continuum among taste stimuli. Discrimination among sugars appears possible in the blowfly based on across fiber patterns of discharge which differ between disaccharides and monosaccharides, especially those which are uncommon in nature.

422 PONTINE UNIT RESPONSES TO TASTE MIXTURES IN THE HAMSTER. Susan E. Plock* and David V. Smith. Dept. Psychol., Univ. Wyoming, Laramie, WY 82071.

Taste-responsive neurons in the hamster brainstem have been shown to be more broadly responsive to the four classical taste stimuli (sucrose, NaCl, HCl, and quinine) than peripheral taste fibers (Smith, Travers & Van Buskirk, 1979; Travers & Smith, 1978). This increase in breadth of tuning is accompanied by greater response complexity (e.g., inhibition) at more rostral levels. The responses of pontine neurons to mixtures of the four basic stimuli may provide an indication of the way in which these neurons process information about more complex stimuli. Responses of neurons in the parabrachial region of the pons were recorded extracellularly from urethane-anesthetized hamsters. Stimuli were 0.1 M sucrose, 0.03 M NaCl, 0.003 M HCl, 0.001 M quinine hydrochloride (QHCl) and the six undiluted two-component mixtures of these compounds, delivered to the anterior portion of the tongue.

Predicted responses to the six mixtures were calculated for each neuron from the algebraic sum of the responses to each individual component. Approximately half of the responses to these mixtures were a linear summation of the responses to the two components, whether or not the components produced excitation or inhibition. Nonlinear interactions were complex. For example, in several cells, when sucrose elicited an excitatory response and QHCl suppressed the ongoing spontaneous rate, the response to the mixture was considerably less than the algebraic sum of the component responses, i.e., there was enhancement of the inhibitory effect. Thus, inhibition appears to be a more powerful phenomenon in these taste mixtures than is evident from the inhibition of the spontaneous discharge. When the responses to both stimuli were excitatory, the response to the mixture could be either suppressed or enhanced. For example, a mixture of sucrose and NaCl often produced no greater response than that elicited by the more effective component. This complete suppression occurred more frequently than partial suppression, in which the response to the mixture was less than the sum of the responses to the individual stimuli but greater than that produced by the more effective component. Less frequently, the response to a mixture was synergistic, being greater than the sum of the responses to the individual stimuli. Cases of nonlinear summation occurred with all possible mixtures of the four basic stimuli and sometimes varied for different mixtures within an individual neuron. Thus, the response to complex taste stimuli cannot be predicted readily from the responses to these four compounds.

This research was supported by NINCDS Grant NS10211 and Research Career Development Award NS00168.

423 TASTE RESPONSES TO L-AMINO ACIDS IN RAT: A SINGLE NEURON ANALYSIS. Thomas C. Pritchard* and Thomas R. Scott (SPON: Jeffrey B. Malick) Dep't. Psychol. and Inst. for Neurosci. and Behav., U. Delaware, Newark, DE. 19711.

The physiological importance of l-amino acids (aa's) to animals implies that the gustatory system should be sensitive to their presence in the environment. Studies of bacterial chemotaxis and teleost taste responses confirm that chemical sensitivity to aa's in these species is indeed great. Humans report a wide range of taste experience from aa's, with a flat-bitter component predominating for many. The amplitude of whole-nerve chorda tympani responses from rats correlates well with human magnitude estimates of aa concentration, suggesting that human and rat sensitivities to these stimuli are similar. We sought to further analyze the rat's neural responses by recording the activity of single axons from the chorda tympani. Stimuli were 12 l-amino acids which were washed over the anterior half of the tongue at concentrations which evoked one-half the maximum whole nerve response for that chemical. The mean activity of 40 axons indicated that stimuli had the following order of effectiveness: .006 M CYS > .3 M ARG > .03 M LYS > 1.0 M GLY > 1.15 M PRO > .15 M ALA > .001 M HIS > .01 M LEU > .1 M THR > .003 M TRY > .03 M ISO > .06 M MET. This ranking correlates +0.78 with that established by whole nerve recordings. Most axons appeared to respond to this range of stimuli with a similar profile, with the overall responsiveness of the cell being the critical variable in determining breadth of sensitivity. For example, if a neuron's response to a standard solution (.1 M NaCl) was robust (> 20 spikes/sec), that cell was likely to respond to some degree to all 12 stimuli. Moderate responses (10 - 20 spikes/sec) to the standard indicated sensitivity restricted to the more effective aa's, and weak salt responses accurately predicted activity only to CYS, ARG and LYS. Thus for these stimuli there was basically one neuron "type" with varying degrees of sensitivity to stimuli in general. The relative similarity of any two aa's, as indicated by correlations among across-fiber patterns, was in general accord with that seen in human and rat psychophysical studies. (Supported by NIH grant NS 10405)

424 MORPHINE INHIBITION OF PARABRACHIAL TASTE UNITS REVERSED BY NALOXONE. G.H.Rogers, R.C.Rogers and D.Novin
Brain Res. Inst., UCLA, Los Angeles, Calif. 90024

Immunohistochemical studies have localized endogenous opioid peptide activity within central nuclei (eg. nucleus tractus solitarius, parabrachial nucleus, ventromedial hypothalamus, amygdaloid complex) implicated in modulation of consummatory behavior as well as peripheral sites (eg. myenteric plexus and sympathetic ganglia). Behaviorally, systemic administration of morphine or its antagonist, naloxone, markedly reduced water intake in water-deprived animals (Rogers, et al 1978, W.Pharmac.Soc.).

Our most recent studies indicate that responsiveness of para brachial (PBN) gustatory units to stimulation (salt) can be modified by intravenous administration of morphine. These effects on unit activity are readily reversed following naloxone infusions, thus suggesting a specific effect of morphine on these cells.

Rats were anesthetized with urethane (1.5gm/kg) and provided with vena cava cannulae. The animals were then mounted into the stereotaxic frame; the skull trephenated and glass microelectrodes (filled with Pontamine dye) lowered into the PBN. Single unit neural responses were monitored with an oscilloscope coupled to an audio-amplifier and a pulse integrator-polygraphic chart recorder. Gustatory units were identified by increased activity in response to washing the tongue with 1.8%NaCl solution followed by a return to baseline activity in response to washing the tongue with water. Upon localization of such a taste activated unit, morphine was infused via the vena cava. Within 15sec, both baseline activity and responses to stimulation were greatly diminished. Although no further decline in baseline activity was seen, all responses to stimulation were lost 20min post-infusion. At this time, naloxone was infused via the vena cava and both baseline activity and responses to stimulation were readily returned to pre-morphine levels. The location of such identified cells was then marked by iontophoretic application of Pontamine dye. The responsive cells were thus identified following preparation for standard Nissl histology.

Perhaps the suppressant effects on feeding or drinking that are observed with systemic administration of morphine or naloxone are attributable to the altered activity of these gustatory units ie."blunting" of taste reception, which has previously been demonstrated to modulate consummatory behavior (Ernits & Corbit, 1973, JCPP).

425 EFFECT OF LESIONS ON AMINO ACID DISTRIBUTION IN RAT OLFACTORY BULB. C.D. Ross, D.A. Godfrey and J.A. Carter. Dept. Anat. and Neurobiol. and Dept. Pharmacol., Washington Univ. Sch. Med., St. Louis, MO. 63110.

Distributions of GABA, glutamate and aspartate were determined in the olfactory bulb of control and lesioned rats using quantitative histochemical mapping procedures. Data from these same rats concerning the cholinergic system in the bulb and amino acids in the piriform cortex have been reported previously (NS Abst. 4:86,91, 1978). In rats A and B, knife cuts were placed caudal to the anterior olfactory nucleus through the LOT, extending more deeply in B than A. In rats C and D, lesions were placed immediately caudal to the bulb in an attempt to separate it from the rest of the brain. Survival time was 1 week. Amino acid levels are given in mmoles/kg dry wt. in a control rat and in rats A-D (control, lesion side). (EPL, IPL: ext., int. plexiform layer; decreases significant: + at p= .05, * at p= .006).

LAYER	Control	Rat A	Rat B	Rat C	Rat D

granular	10	8, 9	8, 8	11,16	11, 8+
periventricular	7	6, 7	7,11	8, 8	8, 5

The significant decrease in glutamate in all layers deep to the glomerular layer in rats C and D is consistent with a centrifugal glutamatergic pathway entering the bulb in its deepest layers. (Amer. Cancer Soc. BS4S; USPHS NS-08862 and NS-08000).

426 THALAMO-CORTICAL MECHANISMS IN ODOR GUIDED BEHAVIOR: II. EFFECTS OF LESIONS OF THE MEDIODORSAL NUCLEUS AND FRONTAL CORTEX ON ODOR PREFERENCES AND SEXUAL BEHAVIOR IN HAMSTERS. R. M. Sapolsky* and H. B. Eichenbaum. Dept. Anth., Harvard Univ., Cambridge, MA. 02138, Dept. Bio. Sci. Wellesley Coll., Wellesley, MA. 02181, and Dept. Psych., MIT, Cambridge, MA. 02139.

Hamsters crucially depend on the patency of the main and accessory olfactory sensoria for successful reproductive behavior. Only recently have modern techniques clarified the secondary olfactory projections and little is known about their functions. This study is an attempt to discover the role of one of the secondary olfactory pathways, the mediodorsal thalamic nucleus (MD) and associated prefrontal cortex, in natural odor preferences and sexual behavior in hamsters.

Preoperatively, male hamsters demonstrated normal preferences to odors produced in the home cage and normal sexual performance In two separate experiments, subjects received either sham surgery or lesions limited to MD or to the frontal neocortex either of the medial wall (MW) or of the dorsal bank of the rhinal sulcus (RS). Post operative odor thresholds of all animals were normal. However, both attraction to pure odors and odors of mal and female conspecifics and discrimination among these odors was significantly reduced in hamsters who had received damage to MD and RS but not MW or controls.

In post-operative tests of sexual competence all subjects continued to mate successfully. However, male hamsters who receive lesions of MD or RS (relative to those who received lesions of MW or control surgery) spent more time sniffing the female's body rather than its genitals and often mounted an inappropriate body position of the female.

Only the medial subdivision of MD receives direct olfactory input and only this subdivision projects primarily to RS. It appears that disruption of this thalamocortical olfactory pathway disrupts discriminitive aspects of odor preference and sexual performance, but does not eliminate detection of odors or their potential for "priming" sexual behavior.

427 WAR GASES AS OLFACTORY PROBES. R. Schafer, D. W. Criswell*, and F. L. McClure*. Dept. Biol., N. Texas State University, Denton, TX 76203.

In most theories of olfaction, it is assumed that receptor sites exist on the excitable portions of olfactory receptor membranes where odorous molecules bind momentarily to initiate olfactory transduction. However, little is known of this chemical interaction and the nature of the odorant-binding receptor sites.

Any biochemical or physiological investigation is greatly enhanced when specific and irreversible inhibitors are available to use as chemical probes (e.g., alpha-bungarotoxin in studies of acetylcholine receptors). Although sulfhydryl reagents (in combination with protection techniques) have been used as olfactory inhibitors, there has been no report of marker agents or inhibitors which preferentially bind to specific classes of olfactory receptor sites. We are attempting to develop such agents from a novel source.

Chemical agents once used as war gases (mainly of pre-World War II vintage) are being tested as possible probes using the frog nose as a model system. For example, ethyl bromoacetate (a "fruity-smelling" tear gas) blocks electroolfactogram (EOG) responses to amyl acetate and other "fruity-smelling" esters, but does not block responses to isoamyl amine and other "fishy-smelling" amines. The blockage is irreversible inhibition, not simply sensory adaptation. The presumption is that ethyl bromoacetate preferentially deactivates ester-binding sites in the olfactory mucosa, but leaves amine-binding sites intact. Ethyl bromoacetate's effect is not totally specific, however, because it inactivates responses to sulfides such as isoamyl sulfide as well as responses to amines. Many other war gases are available, including mustard gas (sulfur-containing Bis(2-chloroethyl) sulfide, with a garlic-like sulfide odor) and nitrogen mustard (the amine mechloroethamine, with a "fishy" odor). These alkylating agents also inactivate olfactory responses in the frog nose with varying degrees of specificity. The advantages of these agents are (1) some specificity which can be experimentally augmented using protection techniques, (2) irreversible action over a period of at least several hours, and (3) application in the vapor phase. Since the agent is applied as a vapor, the experimenter can monitor the progressive effect of inhibitor application, unlike the application of inhibitors in liquid solutions which block testing.

428 COLLATERAL BRANCHING OF OLFACTORY TRACT AXONS. John W. Scott. Dept. of Anat., Sch. Med., Emory Univ., Atlanta, GA 30322.

Single neurons of the mitral cell and external plexiform layers of the olfactory bulb of the rat were activated antidromically by stimulation of the lateral olfactory tract, the olfactory tubercle and several points on the olfactory cortex. Antidromic activation was confirmed by collision tests. To date, 76 cells have been observed which responded antidromically to stimulation of one or more of the projection areas. Fifty-two (68%) cells were activated antidromically from both the olfactory tubercle and the olfactory cortex. Seventeen of these cells were shown by collateral collision tests to have separate collateral branches to the olfactory tubercle and to the cortex. These tests involved showing that stimulation at one point blocked antidromic responses to stimulation at the second point for a time period which could only be accounted for by invasion of a collateral by the action potential. Miscalculation of collision times due to spike suppression by reciprocal synapse inhibition was ruled out in each of these cases. Sixteen cells (21% of the total sample) could be antidromically activated only from the olfactory tubercle. These spikes were recorded almost exclusively from the ventral, posterior portion of the olfactory bulb (both mitral cell and external plexiform layers). These results indicate that many of the projection cells of the olfactory bulb have axon collaterals to two or more widely placed terminal areas. The results also indicate differential origin of axons projecting exclusively to the olfactory tubercle.

429 TASTE RESPONSES TO L-AMINO ACIDS IN RAT: A BEHAVIORAL ANALYSIS. Thomas R. Scott, Thomas C. Pritchard*, Kathleen Keene* and Margaret F. Parsons*. Dep't. Psychol. and Inst. for Neurosci. and Behav., U. Delaware, Newark, DE. 19711.

The relative similarities of 12 l-amino acids (aa's) to one another has been determined from single neuron data from the rat chorda tympani nerve. In this study we took a behavioral measure of stimulus similarity based upon generalization gradients around the conditioned stimulus (CS) in a conditioned taste aversion (CTA) paradigm. Stimuli were 12 aa's all at concentrations which evoked one-half the maximum whole chorda tympani nerve response for that chemical (see Pritchard and Scott, this volume). In addition, stimuli representing the four basic tastes (.1 M NaCl, 1.0 M sucrose, .03 M HCl, .001 M QHCl) were included to determine whether the tastes of the aa's could be encompassed within the dimensions of salt, sweet, sour and bitter. One hundred forty-four male rats under 18-hour water deprivation were trained to lick rapidly for water presented during a 15-minute period each day. When this was accomplished, each was offered a CS followed by an intraperitoneal injection of LiCl (426 mg/kg). Suppression ratios were calculated from the volume consumed by experimental rats divided by the volume consumed by matched controls (distilled water CS). The similarity between two stimuli was determined from the mutual suppression which each caused in the other. These behavioral similarity measures were in general agreement with similarity judgments based on across-fiber patterns from chorda tympani axons and with those from human psychophysical experiments. For example, ALA, GLY, PRO and sucrose are all reported to be predominantly sweet by humans, show highly correlated patterns of activity in the rat CT, and generalize well to one another in the CTA paradigm. Some aa's generalized strongly to a single basic taste stimulus. Others related less strongly to two or three basic stimuli, indicating a more complex taste, but one still manageable within the concept of four primaries. However four aa's (ISO, LEU, MET, TRY) showed no generalization to any of the four basic stimuli, suggesting that in the label-free language of licking, salt, sweet, sour and bitter are insufficient dimensions to describe all tastes. (Supported by NIH grant NS 10405)

430 THALAMO-CORTICAL MECHANISMS IN ODOR GUIDED BEHAVIOR: I. EFFECTS OF LESIONS OF THE MEDIODORSAL NUCLEUS AND FRONTAL CORTEX ON ODOR DISCRIMINATION IN RATS. K. J. Shedlack*, H. B. Eichenbaum and K. W. Eckmann*. Dept. Biol. Sci., Wellesley Coll., Wellesley, MA. 02181 and Dept. Psych., MIT, Cambridge, MA. 02139.

Olfactory information travels directly from primary olfactory cortex to the mediodorsal nucleus of the thalamus (MD) and then to prefrontal cortex. These, in turn, are intimately connected with limbic structures crucial to cognitive and affective behavior. Thus MD and prefrontal cortex appear to form an interface between sensory and limbic systems. As such, these structures may be involved in both sensory and cognitive functions.

In a number of experiments, rats were tested for their abilities of olfactory detection and discrimination. Individual experiments involved lesions either of MD or of its two cortical projection targets. Animals with lesions in MD were significantly impaired relative to sham operated controls in post-operative discrimination of three different odor pairs. Only the lateral part of frontal cortex, the frontal pole and dorsal bank of the rhinal sulcus, receives input from the part of MD which is the target of olfactory cortex efferents. Lesions of the frontal pole and rhinal sulcus (RS) produced a similar significant deficit in olfactory discrimination of these three odor pairs. No deficits were associated with lesions of the frontal cortex target at the medial wall (MW).

Detection and threshold tests revealed that the discrimination deficit observed with lesions in MD and RS is not secondary to a general anosmia or an elevated sensory threshold. Futhermore, the degree of discrimination deficit observed in MD-lesioned animals is sensitive to factors of problem novelty and difficulty. The impairment is diminished by pre-operative odor pair training and is enhanced in discriminations involving highly similar odors. Thus, the thalamocortical olfactory pathway is not crucial to odor detection but seems to play a role in higher order cognitive functions such as stimulus assimilation or value assignment.

431 NEUROGENESIS IN THE OLFACTORY EPITHELIUM. Peter A. Simmons and Thomas V. Getchell. Dept. Physiol., Yale Univ., Sch. Med., 333 Cedar St., New Haven, CT 06510 and Dept. Anatomy, Wayne State Univ., Sch. Med., Morin Memorial Lab., 550 E. Canfield, Detroit, MI 48201.

Unilateral olfactory nerve section was performed on the salamander, Ambystoma tigrinum. Physiological recordings and morphological observations were made at several time points following axotomy to investigate the structural and functional correlates of neural degeneration and renewal in the olfactory epithelium. Slow, transepithelial voltage-transients (Veog(-) and Veog(+)) evoked by odor stimulation decreased in amplitude and disappeared within 10 days. Subsequently, they recovered to 80-100% of the amplitude of the contralateral controls by 100 days following nerve section. Unitary activity was virtually absent 10 days following the lesion, but reappeared within 24-60 days. Analysis of the response properties of newly differentiated olfactory receptor neurons indicated similar odor specificities, latencies, intensity-response functions, and adaptive properties as those observed in control units. Light microscopic examination revealed necrosis and loss of the olfactory receptor cell population by 10 days following nerve section, followed by renewal of the neurons and return of epithelial thickness and apparent nuclear density, as compared with contralateral controls, by 30 days. Specific histochemical staining of secretory products in the apical regions of sustentacular cells suggested no change in the activity or gross structure of these cells throughout the neurogenic process. Physiological activity in the epithelium was observed before macroscopic observation of reconnection of the olfactory nerve to the olfactory bulb. This indicates that functional activity of terminal synapses in the olfactory bulb is not necessary for transduction and action potential production in these neurons. This study also suggests that the presence of olfactory receptor neurons is necessary for maintenance of both components, Veog(-) and Veog(+), of the slow voltage-transient response, and that completely functional, newly differentiated neurons are produced in the olfactory epithelium following olfactory nerve section.

Supported by NIH predoctoral training grant PHS-AM-1113 and NSF grant BNS-76-81404.

432 EFFECTS OF INTRANASAL $ZnSO_4$ IRRIGATION ON OLFACTORY BULB MORPHOLOGY AND BEHAVIOR IN THE RAT PUP. Pauline Singh, Pat Model, George Pappas, and A. Marie Tucker. Albert Einstein Col. of Med., Bronx, NY and Queens Col., Flushing, NY

Morphological changes in the glomerular layer of the main olfactory bulb and latency to suckling were investigated after chemical lesion of the olfactory neurons. Wistar rat pups from 7 litters were subjected to intranasal irrigation with 5% $ZnSO_4$ solution at 7 or 8 days of age. Within each litter 4 pups were $ZnSO_4$-treated (Zn) and 3 were normal or saline controls. Body weights were taken daily, and latencies to suckling on the anesthetized mother were observed. Pups were killed at 1, 4, or 7 days post treatment. The olfactory bulbs of both control and experimental animals were then prepared for light and electron microscopic study.

Light microscopy indicated the following changes in various days post treatment: 1 day, discrete fibers were visible in the medial glomeruli, but most of the peripheral glomeruli appeared disorganized; 4 days, no distinct glomeruli were visible indicating that degeneration had occurred; 7 days, medial glomeruli were again present, although no discrete fibers were visible. This may indicate early stages of regeneration. Electron microscopy showed degenerating terminals with distorted synaptic vescicles, dense cytoplasm, and swollen mitochondria at 1 day post treatment. Some glial-engulfed material and membranous whorls were also present. At 4 days post treatment, few or no degenerating terminals could be distinguished. Instead, glial-engulfed material was present suggesting that the degenerating terminals had been phagocytosed.

The weights of Zn pups were significantly lower than those of control littermates on all days following treatment ($p < .05$). The Zn pups killed at 1 and 4 days post treatment exhibited a deficiency in nipple orientation and attachment. Their median latencies to suckling were 180 sec. (maximum duration of observation), whereas for control littermates they were 45 sec. or less ($p < .05$). At seven days post treatment, there was no significant difference. The behavioral effects of peripheral olfactory deafferentation appear to be correlated with the morphological changes observed at the light and electron microscopic levels.

433 DEVELOPMENTAL STUDIES OF THE OLFACTORY BULB: 2-DEOXYGLUCOSE UPTAKE PATTERNS IN SUCKLING RAT PUPS. Martin H. Teicher*, William B. Stewart, John S. Kauer, and Gordon M. Shepherd. Sections of Neurosurgery, Neuroanatomy, and Gross Anatomy, Yale University Sch. of Med., New Haven, Ct. 06510.

Recent studies have provided behavioral evidence that olfaction is the dominant sensory modality for nipple localization by suckling rat pups (Teicher and Blass, Science 193:422, 1976). These studies have implied that the nipples are coated with a lipid-soluble substance that may act as a pheromone to attract the pups. As part of a study of the functional development of the olfactory system, we have extended the 2-deoxyglucose (2DG) method of Sokoloff to neonatal animals in order to detect sites of uptake in the olfactory bulb correlated with suckling behavior.

Rat pups 5-15 days of age have been used. Following intracardiac injection of ^{14}C-2DG (20 μC/100 g) the pups were placed on their anesthetized mother, in direct contact with a nipple. Attachment occurred within a few minutes, and suckling continued for 45 minutes. Preparation of the olfactory bulbs for autoradiography was by standard methods.

In 12 of 13 animals there was a focus of 2DG uptake in the dorsal part of the main olfactory bulb, at a position just medial to the accessory olfactory bulb. Correlation with the histological sections indicated that in most cases the focus was localized in or near a small group of glomeruli. Scattered foci were also present in medial and lateral parts of the bulb. In control experiments, pups exposed to room air or pure air showed activity in the above regions, but the overall patterns were not as heavily concentrated in the dorsomedial position. Exposure of pups to amyl acetate gave patterns similar though not identical to patterns found in adult rats exposed to this odor (Stewart, Kauer and Shepherd, J. Comp. Neur., in press). Increased 2DG uptake was also observed in the lateral preoptic area of most rat pups in all experimental conditions. Experiments are in progress to further define the specific sites correlated with pheromone-induced activity in newborn pups.

434 MYELINATED NEURONS AND DENDRITES IN THE OLFACTORY BULB OF PRIMATES. Margarete Tigges and Johannes Tigges. Yerkes Regional Primate Research Ctr. and Dept. of Anatomy, Emory University, Atlanta, Georgia 30322.

Numerous myelinated neurons and dendritic segments were found in the olfactory bulbs (OB) of 5 normal squirrel monkey (Saimiri) brains prepared for electron microscopy by routine procedures. Most profiles occurred in the periglomerular region (PGR), but a considerable number were also present in the external plexiform layer (EPL), especially in its uppermost region. The granule cell layer (GCL) contained the least number of myelinated processes. The more than 100 myelinated neurons studied exhibited different cytological characteristics. Since no ultrastructural study of neuronal types in primates exists, criteria established by Pinching and Powell (J. Cell Sci. 9, '71) in rat OB for the classification of different cell types were employed. Although not every cell could be unequivocally categorized, it was possible to discriminate between 4 different types of myelinated neurons. In the PGR and the EPL, myelinated somata resembled external granule cells, and this cell type was the most numerous of all myelinated cells. Neurons with the characteristic appearance of short axon and medium to small tufted cells were also found. These cell types occurred in about equal numbers. The few myelinated perikarya in the GCL were morphologically indistinguishable from adjacent granule cells except for the myelin sheath. Profiles of myelinated dendritic segments were sectioned in both the transverse and longitudinal planes, indicating that they were not running in a preferred direction. Some myelinated dendritic segments were in continuity with somata that resembled tufted or external granule cells. The myelin sheath either completely enveloped a perikaryon or was interrupted by myelin-free gaps in the plane of section. The myelin also varied in thickness, the thin sheaths exhibiting about 8-12 dense lines. Dendrites also displayed gaps in myelination. Frequently, at these gaps, the dendritic segment was engaged in a synaptic relationship and was either in a pre- or postsynaptic position. Occasionally, the synapse was reciprocal. The OB of a 44-year-old chimpanzee also contained myelinated somata and dendritic segments of similar morphology and distribution as the squirrel monkey OB. In the ape, however, myelinated processes occurred less frequently. The functional significance of these myelinated profiles in the primate OB is obscure. Supported by NIH Grant RR-00165 to the Yerkes Regional Primate Research Center and NIH Grant EY-00638.

435 EVIDENCE FOR SUBCORTICAL ADEQUACY IN THE ACQUISITION AND RETENTION OF A SODIUM TASTE-PLACE ASSOCIATION. Celeste R. Wirsig* and Harvey J. Grill (SPON: R. M. Beckstead). Dept. of Psychology, University of Pennsylvania, Phila. Pa. 19104.

The bulk of evidence, in the rat, suggests that neocortical ablation does not produce permanent deficits in regulated ingestive behavior, i.e. sodium appetite, taste aversion learning and taste discriminations. However, it would seem that the absence of the neocortex should eliminate some ingestive function since the neocortical projection area of the gustatory system communicates with each subcortical gustatory nucleus and that the neighboring oral sensory-motor and visceral cortical regions are sites which produce ingestive responses such as salivation, lapping, chewing, swallowing and gagging when stimulated electrically and produce deficits in tongue use when ablated. We therefore reasoned that by using a more sensitive test to examine ingestive abilities of the decorticate rat, some permanent disruption of function might be revealed. To accomplish this we examined the ability of the decorticate rat to remember where and how it obtained sodium even though it was not sodium deficient at the time of tasting NaCl.

Male Sprague-Dawley rats (n=9) were decorticated by aspiration in 1 or 2 stages and recovered 2-3 weeks before training. Each water deprived rat was trained to bar press for water (VI60) during the first phase of the experiment and then for .15 M NaCl. Immediately after the last training session of each phase rats were injected with sodium depleting drugs (DOCA and furosemide) and given salt-free food and water; 24 hrs. later bar presses were counted during a 1 hr. extinction session (Krieckhaus & Wolf, 1969). The results indicate that the presence of the neocortex is not necessary for the salt-trained rat to demonstrate need relevant resistance to extinction. Salt-trained rats pressed the bar at a high rate during extinction while water-trained rats did not at all. In addition, a very brief exposure to saline (1 min. during the last two days of water training) causes resistance to extinction (n=2).

In another experiment the same paradigm was used except that rats (n=3) were trained before a one-stage decortication. After 2½ weeks of recovery rats were injected with sodium depleting drugs and tested 24 hrs. later. Pilot tests had shown that decorticates recover bar pressing by this time and that controls would retain the taste-place association for at least 26 days. Results show that removal of the neocortex does not interfere with the rat's capacity to associate the presurgically tasted sodium with a need condition that was never concomitant with the taste experience. In summary, it was demonstrated that subcortical structures are adequate in the acquisition and retention of a sodium taste-place association. (Supported by NIH AM 21397).

437 A THEORETICAL MODEL OF THE FLY'S CIRCADIAN SYSTEM. Jacob Zabara and Elizabeth Omand, Temple University Health Sciences Center, Depts. of Physiology and Biophysics, Philadelphia, Pa. 19140.

Although the endogenous (autorhythmic) nature of the circadian is generally accepted, little is known concerning its possible basis in neuronal circadian oscillators. Data previously reported from our laboratory is analyzed to present the chemoreceptor neuron as an experimental model of the circadian system of the fly. The observations relating light and feeding interactions on chemoreceptor discharge is summarized graphically and compared to behavioral observations. The circadian clock is described as an endogenous rhythm, possibly genetically determined, composed of an ordered sequence of autorhythmic units summating to a circadian time period. The summation is accomplished by integrating mechanisms which are expressed as endocrine, or central excitatory states. The independent neural units ($A = A_1,\ldots,A_n$) are represented as derivative functions:

$$A_1 = f_1 \frac{de_1}{dz_1}$$

where e = excitation, and z = the equivalent synapse of A. Relating this formalization to the actual discharge of an autorhythmic unit:

$$f \frac{de}{dz} = K_1 \frac{d(I)}{dt} + K_2 (I)$$

where I = interspike interval or spike frequency
and K = proportionality constant
For simplicity we have restricted this formulation to a first order derivative, although higher orders are involved. It is possible to consider the neuro-membrane as simulated by a simple physical model of a variable capacitor (dielectric)-resistance network. Discharge recordings from the chemoreceptor in light and feeding conditions will be presented to illustrate this aspect of the model. The polarized state of the membrane and the condition of its dielectric as well as the channels for sodium and potassium represent critical elements of the circadian system. The average value (S_i) of a time varying excitability factor (E) giving rise to a circadian rhythm over a time interval (0,T) is represented by the following:

$$S_i = \frac{1}{T} \int_0^T E_o(t) \sum_{i=0}^{n} f_i(t)\ (Z_i)dt$$

This formulation, for instance, represents enhanced excitation in a fasting fly where the locomotor activity increases to "override" the ordinary circadian rhythm. (Supported by NIH NS14209).

436 EVIDENCE FOR A CHOLINERGIC PROJECTION TO THE OLFACTORY BULB FROM THE MAGNOCELLULAR PREOPTIC AREA. William M. Youngs, N. Suzan Nadi*, Barry J. Davis, Frank L. Margolis and Foteos Macrides. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545 and Department of Physiological Chemistry and Pharmacology, Roche Institute of Molecular Biology, Nutley, NJ 07110.

Our previous HRP studies have shown that the magnocellular preoptic area (POM; "nucleus of the horizontal limb of the diagonal band") is a major source of centrifugal afferents to the olfactory bulb in the hamster. In the present study we characterized this projection with the autoradiographic tracing technique and examined the possibility that cholinergic afferents to the olfactory bulb originate in the POM. After injections of tritiated amino acids into the POM, labeled axons could be observed to travel rostrally in the medial forebrain bundle, course diffusely through the olfactory peduncle and enter directly into the main olfactory bulb (MOB). A small component of the projection was observed in the medial aspect of the lateral olfactory tract. The projection appeared to terminate in all layers of the MOB, including the glomerular layer. To assess whether the projection contains cholinergic fibers, unilateral electrolytic lesions were made in the POM of fourteen hamsters. Seven additional hamsters were sham-operated. Nineteen to twenty-eight days following surgery, the animals were sacrificed by decapitation and choline acetyltransferase (CAT) activity in the olfactory bulbs was measured by radiometric assay using carbon-labeled acetyl CoA. The CAT activity levels in the bulbs contralateral to the lesions did not differ from levels in the bulbs of sham-operated animals. Activity levels in the bulbs ipsilateral to the lesions were significantly reduced, and for individual animals ranged from 22% to 65% of the levels in the contralateral bulbs. Histological examinations of the extents of the POM lesions indicated that these reductions could not be attributed to an involvement of the vertical limb of the diagonal band. In another set of hamsters, HRP was injected into the ipsilateral bulbs following typical POM lesions in order to evaluate whether damage to fibers of passage might account for the reductions. The nucleus of the lateral olfactory tract and the piriform cortex contained heavily labeled neurons comparable in numbers to those labeled after HRP injections in intact animals. The labeling in the raphe nuclei and locus coeruleus was reduced substantially, but these projections to the MOB are thought to be serotonergic and noradrenergic, respectively. These various results support the hypothesis that the POM is a major source of cholinergic afferents to the olfactory bulb.

COMPARATIVE NEUROBIOLOGY

438 THE ROLE OF PROTOCEREBRUM IN THE MODULATION OF CIRCADIAN RHYTHMICITY IN THE CRAYFISH VISUAL SYSTEM. B. Barrera-Mera, J. Cibrian Tovar*and D.E. García-Díaz*. Depto. de Fisiología, Fac. Med. U.N.A.M. y Colegio de Postgraduados, Chapingo, México.

We have previously demonstrated that bilateral neural connections of crayfish visual system at protocerebrum level have an important role in the central modulatory process of electroretinographic (ERG) circadian oscillations (Brain Res. Bull. 3: 101, 1978; Comp. Biochem. Physiol. 61A: 427, 1978). In order to explore the role of that area of the cerebral ganglion (cg) as the probable site of synthesis and or regulatory releasing of neurosecretions involved in the control of such retinal changes, animals with protocerebrum only, were submitted to continuous recordings of ERG and eye glow area throughout the day. Fig. 1 and figure 2 illustrate typical cases in which we can see the circadian changes of EGA size as well as ERG voltage in animals with protocerebrum only. Notice the clear changes of both EGA size and bilateral ERG rhythm in these conditions in which only 30per cent of cg tissue remains neurally attached to both eyestalks. Since in the animals without cg the rest phase of both ERG and EGA size rhythm was strongly diminished (Barrera-Mera, Physiol. Behav. 17, 59, 1976) one possibility is that protocerebrum is the site of synthesis of hormonal neurosecretions directly involved in the ERG and EGA diminution observed during the rest phase of both rhythms. On the other hand, since the injection of sinus gland extracts obtained from brainless animals induced light adaptation, we believe that protocerebral area of cg controls the releasing of neurosecretion from the sinus gland.

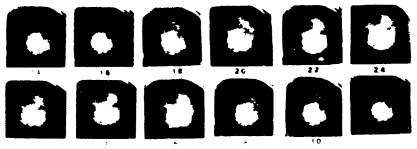

Fig. 2

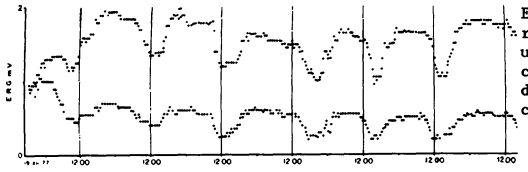

EGA and ERG were recorded under continuous darkness conditions

439 DESTINATIONS OF AFFERENTS AND SOURCES OF EFFERENTS IN VIIITH NERVE BRANCHES OF MORMYRID FISH. Curtis Bell, Neur. Sci. Inst., Good Samaritan Hosp. & Med. Cent., Portland, OR, 97209.

Eighth nerve branches supplying the three canals, sacculus, and lagena were labeled with HRP. The utricular branch was labeled in association with the anterior canal nerve. For comparison, anterior and posterior lateral line nerves were also labeled.

Central structures where afferents ended included; n. descending, n. octavius, n. tangentalis, n. magnocellularis, eminentia granularis, n. anterior, and the cerebellar crest. The last two structures may be considered as a unit. Descending, tangentalis and magnocellularis received afferents almost exclusively from canals and utriculus. Eminentia granularis received input from lateral line nerves and all N. VIII end organs except the sacculus. Octavius received afferents from lateral line nerves and all branches of N.VIII. Saccular afferents went both ipsilaterally and contralaterally to a separate group of cells within this nucleus. Projections to cerebellar crest – n. anterior were noteworthy in that utriculus, sacculus, lagena, anterior lateral line nerve and posterior lateral line nerve went to different regions of the horizontal sheet defined by these cell groups, with afferents from canals overlapping those from utriculus.

The nearly indistinguishable projections of the utriculus and canals are consistent with their common role in equilibrium. The distinct saccular projection with its strong contralateral component and lack of endings in eminentia granularis, a probable cerebellar structure, is consistent with an auditory role. The rather intermediate pattern of lagenar afferents is at least consistent with present uncertainty as to whether this otolith has an equilibrium or auditory role. Our results also indicate that in the mormyrid N. VIII and lateral line nerves project to the same central structures.

Retrograde labeling showed that efferents in the lateral line nerves and all N. VIII branches arise from the same nucleus, a group of large cells above the medial lemniscus. The central course of the axons of these cells parallels that of facial (N. VII) motoneurons and the octavolateral efferent axons exit with the motor root of N. VII. Single efferent axons must branch to supply different end organs since more than half of the ipsilateral neurons in the nucleus were often filled with HRP after labeling single branches of N. VIII or one lateral line nerve.

440 SOME CONNECTIONS OF THE LATERAL OLFACTORY AREA OF THE HORN SHARK. David Bodznick and R. Glenn Northcutt. Dept. Neurosci's., UCSD, La Jolla, CA 92093 and Div. Biol. Sci's., UM, Ann Arbor, MI 48109

The lateral olfactory area (LOA) in the telencephalon of the horn shark (Heterodontus francisci) was reexamined using experimental anatomical and physiological techniques. A relatively large amplitude, short latency (40 msec) positive evoked potential following electrical stimulation of the olfactory tract was recorded from the lateral 1/3 of the ipsilateral telencephalic hemisphere corresponding to the extent of LOA. Fink-Heimer procedures revealed degenerating olfactory tract fibers and terminals throughout the rostral-caudal extent of LOA in animals with unilateral olfactory peduncle transection after 14-21 days at 14° C. Comparable projections were observed with autoradiography following intrabulbar injections of tritiated proline (60 μCi at 20 μCi/μl) and 7 days survival at 14°C. The LOA of Ebbesson and Heimer (Brain Res., 1970) is not a uniform cytological field but can be divided into a dorsal pallial field (lateral pallium) and a more ventral nuclear group (Field A). The lateral pallium is characterized by 3 laminae: a pronounced periventricular lamina of small densely-packed cells, a middle lamina of larger bipolar and polygonal neurons, and an outer lamina of smaller neurons and olfactory fibers. Field A does not possess a pronounced periventricular cellular lamina; it is characterized by an outer fiber layer and an inner zone of scattered cells which ventrally becomes more compact and grades into the cell plate of area superficialis basalis. Injections of HRP (0.1-0.3 μl of 20% Sigma VI) into the lateral pallium revealed that primary olfactory projections arise from 2 distinct populations of olfactory bulb neurons: mitral cells and smaller neurons located within the internal granule cell layer. The injections also revealed additional afferents to the lateral pallium from the ipsi- and contralateral dorsal and medial pallia and from the contralateral lateral pallium. These results suggest that olfactory information reaches the lateral pallium by a direct ipsilateral olfactory projection and an indirect contralateral projection via the contralateral lateral pallium. The latter is also evidenced by a relatively long latency (120 msec) negative evoked potential recorded in the lateral pallium after electrical stimulation of the contralateral olfactory tract. Unilateral injections of HRP (0.5-1.0 μl) into the olfactory bulb revealed projections from ipsi- and contralateral lateral and dorsal pallia but not from Field A. (Work supported in part by USPHS Postdoctoral Fellowship to DB and Rackham Faculty Research Grant (UM) and NIH NS11006 to RGN. Research was performed in accordance with NIH Guidelines, Vol. 7, #17, Nov., 1978.)

441 SOME CONNECTIONS OF THE TORUS SEMICIRCULARIS IN THE BOWFIN, AMIA CALVA: A HORSERADISH PEROXIDASE STUDY. Mark R. Braford, Jr. and Catherine A. McCormick. Department of Anatomy, Georgetown University Schools of Medicine and Dentistry, Washington, D.C. 20007

Following unilateral injections of horseradish peroxidase (HRP) into the torus semicircularis, several populations of neurons were retrogradely labelled. At the level of the obex labelled cells were present in the medial part of the dorsal horn of the medulla. Nearly all of these cells were contralateral to the injected torus. Nucleus medialis of the octavolateralis area receives primary input from the anterior and posterior lateral line nerves. A large number of neurons in this nucleus were labelled following toral HRP injection. Most of the cells labelled in nucleus medialis were the so-called Purkinje-like cells which lie immediately deep to the cerebellar crest into which some of their HRP-filled dendrites ramify. About 90% of these labelled cells were found contralateral to the injection. A few cells more ventrally located in the nucleus medialis were also labelled, again mostly contralaterally. At and rostral to the level of entrance of the eighth nerve, a population of cells was labelled in the central portion of the basal plate. These cells, which may represent the superior olivary nucleus, were labelled predominantly ipsilateral to the injection. In the isthmal tegmentum a group of neurons, termed here the isthmal reticular group, were labelled almost exclusively contralateral to the injection.

Anterograde labelling of fibers and terminals was also present showing both descending and ascending toral efferents. The descending pathway was ipsilateral and formed a compact bundle on the ventral surface of the medulla. Its most prominent terminations appear to be in the superior olivary nucleus. An ascending pathway courses rostrally through the lateral tegmentum and terminates bilaterally in the caudal diencephalon, the contralateral fibers crossing in the supraoptic decussation. The terminal field lies laterally adjacent to the central posterior nucleus of the dorsal thalamus dorsally and over a population of large cells in the glomerulosus complex ventrally. (Supported by NIH Grant 2 R01 NS11006 To R.G. Northcutt and NSF Grant BNS 78-22411.)

442 AFFERENT AND EFFERENT FIBERS OF THE VESTIBULOCOCHLEARIS NERVE OF THE LARVAL ANURAN. D.L. Brown, J.T. Hackett, and S.L. Cochran. Dept. of Physiology, University of Virginia School of Medicine, Charlottesville, VA 22908

Neuroanatomical and electrophysiological techniques were used to study fibers of the vestibulocochlearis (VIIIth) nerve of premetamorphic *Rana catesbeiana* tadpoles. Lesions of selected branches of the anterior and posterior rami were made after opening the otic capsule; horseradish peroxidase (HRP) was applied to the cut nerve. In some experiments HRP was pressure injected into the nerve in place of lesion techniques. The capsules were then sealed. After 1-4 days survival, the brains were processed for the HRP reaction product. Stained primary afferent fibers could be traced from the site of the HRP application through the ganglia of the VIIIth nerve to extensive projections in the rhombencephalon--from the granule cell layer of the cerebellum to the level of the XIIth nerve. Fibers as large as 10 µm could be seen entering the brainstem and turning to form the ascending or descending tracts of the VIIIth nerve, or bifurcating to form both. Collaterals from these tracts could be seen branching perpendicularly into the medial zone of the alar plate. The largest fibers tended to course more medially. More of these fibers were observed from the posterior than the anterior ramus. Neither decussation of fibers to contralateral regions nor differential specificity of projections from various branches was observed. Efferent fibers and somata were labeled in these experiments also. Application of HRP to the anterior ramus revealed a nucleus with more than 20 labeled cells ventral to the sulcus limitans, in the region of the motor nucleus of the VIIth nerve. This efferent nucleus extends from the level of the rostral edge of the VIIIth nerve caudally to the lateral line nerve and is composed of small and medium size cells (8-20 µm). Fine processes from these cells cross the midline into the central grey, as well as ramifying ipsilaterally. Labeling of the posterior ramus showed a different localization of efferent somata. At the level of the VIIIth nerve the cells were found in a more dorsolateral position relative to the anterior ramus efferent nucleus described. Other cells were found in the lateral reticular zone as far caudally as the Xth nerve. Additional evidence for the anterior ramus efferent nucleus was obtained by injecting HRP into cells identified by antidromic stimulation. Location of these cells was accomplished by first identifying the maximum extracellular field potential evoked by VIIIth nerve stimulation. Then a more medial recording site was found where efferent cells could be penetrated. Recovered cells were found in the efferent nucleus, with presumed axons projecting towards the VIIIth nerve.

443 AFFERENT PROJECTIONS TO THE ANTERIOR DORSAL VENTRICULAR RIDGE IN THE LIZARD IGUANA iguana. Laura L. Bruce* and Ann B. Butler. Dept. Anat., Georgetown Univ., Washington, D.C. 20007.

The reptilian anterior dorsal ventricular ridge (aDVR) was traditionally regarded as a homologue of the mammalian basal ganglia. However, recent connectional, histological, and developmental studies indicate that instead it may be a homologue of portions of the mammalian neocortex which receive ascending thalamic sensory projections. To study the projections of the aDVR further, injections of horseradish peroxidase (HRP) into the aDVR of Iguana iguana, processed after deOlmos and Heimer (Neurosci. Let., '77), were used to identify retrogradely labeled cells.

After large injections of HRP into the aDVR, the distribution of labeled cells corresponded to previous descriptions of projections to the aDVR in other reptiles. Thalamic nuclei with labeled cells included nucleus rotundus, nucleus medialis, and several nuclei surrounding nucleus rotundus, such as the nuclei dorsomedialis anterior and dorsolateralis anterior. In addition labeled cells were found in several regions within the lateral mesencephalic tegmentum.

Very small, restricted injections of HRP were also made in various regions of the aDVR. After a small injection limited to the middle third of the rostral aDVR, labeled cells were found in the aDVR ventral to the injection site. Several large cells lying close to and within the lateral forebrain bundle were also labeled. A few scattered cells were labeled in the lateral hypothalamus and in the lateral mesencephalic tegmentum. The labeled fibers course predominantly in the lateral forebrain bundle and several labeled fibers were also in the lateral part of the medial forebrain bundle. When a small injection was limited to the middle third of the caudal aDVR, labeled cells were found in the posterior DVR and in the rostral parts of the aDVR, particularly in the superficial areas. A few labeled cells were scattered in the lateral hypothalamus and in the lateral mesencephalic tegmentum. Labeled fibers coursed along the lateral aspect of the medial forebrain bundle.

444 THE RETINA OF THE WEST INDIAN MANATEE (SEACOW). Joel L. Cohen, Gail S. Tucker* and Daniel K. Odell*, University of Miami, Rosenstiel School of Marine and Atmospheric Science, and the School of Medicine, William L. McKnight Vision Research Center, Miami, Florida 33149.

The retina of the West Indian manatee (Trichechus manatus), an endangered marine mammal, has never been accurately described. In order to determine the cellular makeup of this retina with special reference to photoreceptor cells, eyes were fixed in phosphate-buffered gluteraldehyde (pH 7.3), postfixed in 2% OsO_4, and embedded in Epon 812. Sections were stained with toluidine blue or para-phenylenediamine for light microscopy, and with lead citrate and uranyl acetate for electron microscopy.

Pigment granules were present in the pigment epithelium layer. Two types of photoreceptors were seen. One cell type is typically rod-like with a long cylindrical outer segment and an inner segment of the same diameter as the outer segment. A second cell type has a conically tapering outer segment. Using light microscopy, the nuclei of the two photoreceptor types stain differently with toluidine blue. With the electron microscope, two types of synapses were observed. One type, termed a spherule, is associated with rod-like cells, while the other, a pedicle, is associated with cone-like cells. Typical ribbon and conventional synapses were seen in the inner plexiform layer. The ganglion cell layer is remarkable due to the presence of cells with large perikaryon ($\sim$ 50 µm). This retina can be considered to be anatomically duplex.

445 ORGANIZATION OF SOMATOSENSORY INPUT TO THE MIDBRAIN OF THE FROG. Christopher Comer and Paul Grobstein. Dept. Pharmacolog. Physiol. Sci., Univ. Chicago, Chicago, IL 60637.

The existence of an orderly representation of visual information in the midbrain tectum of the frog has long been known. More recently an orderly representation of auditory inputs in the underlying torus semicircularis has been described (Pettigrew et al., Nature 272:138, 1978). We were interested in whether an orderly representation of somatosensory information is also present in the frog's midbrain. We here report electrophysiological studies on the organization of cutaneous inputs to the midbrain of Rana pipiens.

Multiunit responses to visual, acoustic, and tactile stimuli were recorded with tungsten microelectrodes in adult frogs anesthetized with tricaine methanesulfonate. In some animals the electrode was lowered through the tectum and tectal ventricle, and then into the underlying torus seimcircularis. In others, the tectum was first aspirated permitting direct access to the torus. Significant recording locations were marked with electrolytic lesions and subsequently located in histological sections.

All of the animals recorded from showed similar patterns of sensory responsiveness in the midbrain. Only visual activity was reliably recorded from the optic tectum. In the torus, weak visual activity was occasionally encountered; auditory activity (responses to clicks and snaps) and tactile activity (responses to gentle stroking of the skin) were prominent and reliable.

Penetrations near the midline in the torus yielded purely auditory responses; lateral penetrations, in the region of the magnocellular nucleus of the torus, yielded purely tactile responses. Penetrations between these extremes yielded responses to both modalities. Multiunit tactile receptive fields were large and located primarily on the contralateral body surface. More rostrally in torus, receptive fields were located on the snout and forelimbs; more caudally, receptive fields were located on the hindlimb and flank. There is thus at least a crude topographic map of the body surface in this region.

We conclude that there is a somatotopic representation in the lateral torus semicircularis and hence that not only the visual and auditory but also the somatosensory modality has an orderly representation in the midbrain of the frog. Auditory and somatosensory modalities seem to be principally represented in the torus semicircularis. Our observations suggest an exclusively auditory projection to the medial torus and an exclusively tactile projection to the lateral torus with an overlapping intermediate polymodal region.

446 PREFRONTAL "CORTEX" IN THE PIGEON BRAIN. Ivan Divac. Institute of Neurophysiology, University of Copenhagen, Denmark.

Certain regions of the bird "striatum" are now considered to be comparable to the sensory and motor cortical areas of mammals. It is not known whether the bird brain has a region comparable to the mammalian prefrontal cortex (PFC). In mammals, PFC is defined as the target of the mediodorsal thalamic nucleus which in turn is topographically identified. The bird thalamus, however, has no lamina medullaris interna and thus no topographically definable mediodorsal thalamic nucleus. It was recently discovered that PFC in mammals of three different orders receives uniquely rich dopaminergic innervation. §) Dopaminergic innervation may thus serve as a guide in search for "PF" tissue in the bird telencephalon.

Examination of pigeon brains prepared for catecholamine fluorescence revealed in the posterodorsolateral "neostriatum", just under the ventricle, a somewhat poorly delimited region with rich fluorescent innervation forming perineural nests. This region was clearly distinguishable from the paleostriatum augmentatum, accumbens, and septum. Additional experiments indicated that this "neostriatal" innervation is dopaminergic rather than noradrenergic. Thus, the posterodorsolateral "neostriatum" in the pigeon brain may correspond to PF in mammals.

§) Divac, I., Björklund, A., Lindvall, O. and Passingham, R.E. Converging projections from the mediodorsal thalamic nucleus and mesencephalic dopaminergic neurons to the neocortex in three species. J.Comp.Neurol. 1978, 180, 59-72.

447 HISTOCHEMICAL STUDY OF THE MONOAMINE CELL GROUPS OF THE AVIAN BRAIN STEM. Lorraine Dubé* and André Parent (SPON: R. Boucher). Lab. Neurobiol., Fac. Med., Univ. Laval, Québec, Canada.

The distribution of catecholamine (CA) and serotonin (5-HT)-containing neurons in the brain stem of the chicken was investigated by means of various histofluorescence methods. The monoamine (MA) cell groups were also studied with the help of histochemical procedure for the demonstration of acetylcholinesterase (AChE).

In the mesencephalon of the chick, four CA cell groups are found at the level of the III nerve. First, a few large-sized neurons occur in the periaqueductal gray. These neurons do not display any significant AChE activity. Numerous multipolar CA cell bodies are also present in the tegmental pedunculo-pontine nucleus (TPP). These neurons stain moderately for AChE. Numerous other CA neurons (without AChE activity) are scattered dorsolaterally to the TPP group. Finally, a dense population of large, multipolar, CA cell bodies occurs along the lateral border of the III nerve root fibers. They display a very high AChE activity. More caudally, a CA and a 5-HT cell group are intermingled together within the decussation of the cerebellar peduncles. The CA cells are small, round or oval and display a very high AChE activity. The 5-HT neurons are larger, multipolar and also strongly stained for AChE. At the level of the nucleus of the IV nerve, numerous 5-HT cells occur along the midline and around the MLF. This group is composed of medium-sized and fusiform neurons that stain moderately for AChE. It extends itself laterally and intermingles with the CA cells of the locus coeruleus (LC). The LC is composed mostly of closely-packed and strongly fluorescent cells which also stain intensely for AChE. At metencephalic level, two CA cell groups occur one above the other in the lateral portion of the brain stem. The ventrally located neurons are small and lie in the area of the nucleus of the VII nerve, whereas the more dorsally located neurons are larger in size and are scattered beneath the nucleus of the Vth nerve. Some 5-HT cells are also scattered among the root fibers of the VI nerve, ventrally. At the same level, numerous 5-HT cells are present in the raphe region. These neurons display a moderate AChE activity. More caudally, another group of 5-HT cells is found within the raphe region at the level of the inferior olivary nucleus. Finally, two groups of CA cells can be visualized in the medulla oblongata. First, a few closely-packed CA neurons occur dorsolaterally to the motor nucleus of the X nerve, in an area containing numerous highly reactive AChE neurons. Second, multipolar CA cells are scattered within the central portion of the medulla.

As a whole, the pattern of organization of MA cell groups in the avian brain stem appears complex and somewhat similar to what has been found in mammals. The 5-HT and the CA neuronal systems, however, are more intimately associated one with another in birds.

448 A THALAMIC RELAY NUCLEUS FOR THE LATERAL LINE SYSTEM IN TELEOST FISH. Thomas E. Finger. Dept. Anat., U. Colo. Med. Ctr., Denver, CO, 80262.

The lateral line system in teleosts is a sensory hair-cell system comparable to the auditory and vestibular systems of tetrapods. In fish, the lateral line nerves project to the lateral line lobes in the medulla which in turn give rise to a crossed connection terminating in the torus semicircularis located in the dorsal mesencephalon. However, higher order connections of the lateral line system are largely unknown.

Anterograde transport methods (HRP and tritiated amino acids) were used to determine the projections of the torus semicircularis (mesencephalic target for the lateral line sense) in two species of teleost fish (Carassius auratus and Ictalurus nebulosus). In both species, the torus semicircularis projects to a nucleus in the ventral thalamus possibly equivalent to a portion of the nucleus anterior tuberis of Sheldon (J. Comp. Neur., 1912). A small portion of the toral efferents bypass the ipsilateral thalamic nucleus and cross the midline in a supraoptic (ansulate) commissure to end in the contralateral nucleus anterior tuberis and torus semicircularis. This pattern of connection is similar to that seen in mormyrid fish (Finger, Bell & Russell, in preparation) except mormyrids possess two or three thalamic lateral line nuclei instead of the one seen in goldfish.

Large HRP injections into the lateral half of the telencephalon in catfish (Ictalurus) retrogradely label neurons of the thalamic lateral line nucleus. This thalamic area does not exhibit retrograde label following injections confined to the medial third of the telencephalon and median forebrain bundle. The exact telencephalic target area for the thalamic lateral line efferents remains to be determined. Some of the thalamic neurons are retrogradely labeled following HRP injections confined to the ipsilateral torus. Whether these same neurons also project to the telencephalon could not be determined.

In summary, the central connections of the lateral line system in teleosts appears to be organized similarly to the auditory lateral lemniscus in amniotes. A discrete lemniscal pathway for the lateral line sense can be identified from the lateral line lobes via torus semicircularis and ventral thalamus to finally reach the telencephalon.

449 DIFFERENTIAL PROJECTIONS OF THE AMPHIBIAN AND BASILAR PAPILLAE IN THE LEOPARD FROG (RANA PIPIENS): AN ANATOMICAL BASIS FOR TONOTOPIC ORGANIZATION. Zoltan M. Fuzessery* and Albert S. Feng. Dept. of Physiology and Biophysics, Univ. of Illinois, Urbana, IL 61801

The central projections of the two anuran auditory organs, the basilar and amphibian papillae, were examined using horseradish peroxidase (HRP) tracing technique. The HRP (Sigma Type II) was pressure injected into the roots of individual organs. We modified Mesulam's HRP protocol by directly transferring frozen sections from microtome knife to glass slides, and developing the reaction product on slides. This modification facilitates tissue processing without affecting the sensitivity or resolution of stain development. The majority of fibers from both papillae terminated on the dorsal nucleus; a small portion descended to the solitary nucleus at the XIIth nerve level. Termination sites of the two papillae differed within the dorsal nucleus. Terminals of basilar papilla fibers were restricted to the extreme dorsomedial area. The amphibian papilla termination site was more extensive, occupying discrete dorsal and ventral regions in the lateral two thirds of the nucleus. Terminstion sites of posterior vertical canal fibers were examined as a methodological control. They were limited to the ventral nucleus and lateral reticular zone. In addition, fibers from this organ ascended to the nucleus cerebelli and cerebellar granular layer and descended into dorsal gray at the XIIth nerve level. Since the basilar and amphibian papillae are sensitive to different frequency bands, their separate termination sites in the dorsal nucleus provides an anatomical basis for a rudimentary tonotopic organization. 450 LIVING TOGETHER WITH MINIMAL COORDINATION: COMMUNAL SPIDERS. W. David Hollar* and Peter N. Witt. Mental Health Research, N. C. Department of Human Resources, Raleigh, N. C. 27611

Still photography, time lapse motion pictures, and behavioral observations of a species of communal spiders, Mallos gregalis (M. g.) Simon, were used in examining spatial distribution, activity level and interactions under varied laboratory conditions. M. g. reside together, communally catching prey and feeding, but exhibiting no intraspecific aggression, in a web which may, in natural settings, house several thousand animals. Though other animals (e.g. bees, ants) also live in large groups, M. g. (apparently morphologically isomorphous) do so without obvious behaviorally based castes, division of labor, or other systematic organization. Moreover, the relative lack of interdependence of individual animals has been indicated by naturalistic observations of M. g. in a large terrarium in which separate colonies ranging in population from 2 to 70 have successfully coexisted for months. Measures of animal distribution (inter-animal distances) were used as an index of social organization in artificially created M. g. colonies varying in group size and density. These measures showed variability in distribution approaching randomness among colonies with differing numbers and density, within groups of similar colonies, and within individual colonies. The effects of external factors on group behavior were examined by analyzing films of colonies with and without water present under three conditions: heavy fed, light fed, or dextroamphetamine treated. The presence of water generally increased activity and the number of interactions across conditions. Amphetamine treated groups exhibited relatively more activity and interactions than did heavy fed groups, with light fed colonies being intermediate. These differences, especially the amphetamine related behavioral changes, suggest further experimentation with other drugs in this social context as an extension of studies of psychotropic drug effects in solitary spiders. (This research was supported by National Science Foundation grant BNS 74 09915 to Peter N. Witt).

451 SPINAL AFFERENTS TO THE DORSAL COLUMN NUCLEI IN A GARTER SNAKE. Virgil L. Jacobs and Raymond F. Sis*. Dept. Vet. Anat., Coll. Vet. Med., Texas A&M Univ., Coll. Sta., TX 77843.

An investigation was made of the ascending spinal degeneration to the dorsal column nuclei (DCN) of a non-limbed reptile. Garter snakes (Thamnophis siritalis) received spinal cord hemisections at levels ranging from segment 2 to 31 and were maintained postoperatively for 11 to 28 days. Following perfusion and fixation the brains and spinal cords were processed for degenerated axons according to the Nauta silver methods.

The superficial zone of the dorsal column (DC) contains ascending degenerated axons while caudal to the lesion the deeper zone shows scattered descending fibers. A comparison of the first cord segment of all snakes shows degeneration in the dorsomedial part of the DC following caudal lesions. More rostral cord lesions produce additional degeneration more laterally in the DC. That portion of the DC adjacent to the dorsal median sulcus contains degeneration from all spinal levels. Caudal to the obex degenerated axons from this sulcal zone course ventrally to the nucleus of Bischoff, a paramedian row of cells. This nucleus appears to receive a somatotopic projection from the cord rostral to segment 31.

The dorsal column nuclei (DCN) consist of a thin lamina of cells medially contiguous with a relatively large population of cells laterally. The ventrolateral nuclear portion is wedge shaped and bordered laterally by tractus and nucleus descendens trigemini. The medial boundary at caudal levels is formed by nucleus and tractus solitarius and more rostrally by nucleus descendens vestibuli. A lesion at segment 2 shows dense degeneration throughout the DCN. An overall reduced preterminal degeneration in the DCN follows a segment 13 lesion that is related mainly to the caudal and medial regions of the DCN. Only a couple of preterminals are present in the medialmost cells after a lesion at segment 31. Based on the somatotopic projection of DC fibers to the DCN it appears that these nuclei have homologous features to nucleus gracilis and cuneatus of mammals. Other preterminal degeneration from the DC passes to nucleus descendens vestibuli, nucleus commissura infima and area postrema.

452 THE COURSE OF THE DORSAL LATERAL OLFACTORY TRACT AS AN INDICATOR OF DICHOTOMY IN THE PHYLOGENY OF PLACENTAL MAMMALS. John Irwin Johnson, Robert C. Switzer III, and John A. W. Kirsch*. Neuroscience Program and Zoology, Biophysics and Psychology Depts., Michigan State Univ., E. Lansing MI 48824; Lab. of Brain, Evolution and Behavior, NIMH, Bethesda MD 20014; and Dept. of Biology and Peabody Museum of Natural History, Yale Univ., New Haven CT 06520.

A neuroanatomical feature provides evidence which divides the placental orders of mammals into two major groups, thereby implying common ancestry to each set, and providing a basis for supraordinal grouping which has heretofore been difficult and controversial due to discontinuities in the paleontological record. This dichotomy is concluded from the alternate trajectories taken by the dorsal component of the lateral olfactory tract (LOT) at the level of the accessory olfactory formation (AOF). Our examination of 171 specimens representing 121 species of 15 orders shows that the dorsal LOT passes THROUGH the AOF (separating the large perikarya from the internal granule cells) in rodents, bat (Desmodus), insectivores, colugo, primates, tree shrew and elephant shrew. These orders are in the supraordinal cohorts Unguiculata and Glires in Simpson's 1945 classification, and would be derived from Leptictid-like insectivores in McKenna's 1969 scheme. In the other orders of placentals, Simpson's cohort Ferungulata and derived from Paleoryctid-like insectivores in McKenna's scheme, the carnivores, perissodactyls, hyrax and most artiodactyls, the dorsal LOT passes UNDER the AOF. Marsupials and monotremes exhibit the UNDER condition which leads us to conclude that this is the primitive or plesiomorphic trait and the THROUGH state is the derived or apomorphic trait. These observations indicate the role that developmental heterochrony can play in the evolutionary process. In the primitive state the LOT axons pass UNDER the AOF after the granule cells have migrated into place. In the "new" derived state, the LOT axons pass THROUGH the AOF before the granule cells have completed migration. Both routes are found in edentates and lagomorphs (e.g. of the anteaters Tamandua shows THROUGH and Myrmecophaga shows UNDER), suggesting that these groups may represent intermediate stages wherein the arrival of LOT axons and granule cells arrive nearly simultaneously and minute heterochronic variations switch the adult condition to one or the other trajectories. (Specimens were examined in the collections of the Univ. of Wisconsin Dept. of Neurophysiol. courtesy of W. I. Welker and in that of Georgetown Univ. courtesy of A. Butler and O. Solnitzky, in addition to our own collections.)

453 THE CORTICAL FIELD OF ORIGIN OF THE ANTERIOR COMMISSURE OF THE RHESUS MONKEY. Marc L. Jouandet and Michael S. Gazzaniga. Div. of Cognitive Neuroscience, Dept. of Neurology, Cornell Univ. Med. Col., NY, NY 10021.

The full extent of the cortical field of origin (FO) of the anterior commissure (AC) of the rhesus monkey was mapped by horse radish peroxidase (HRP) histochemistry. Following complete callosal commissurotomies and an eight month survival, two monkeys underwent a second operation involving the massive unilateral injection of HRP into the entire left temporal lobe. Since the AC was the only neocortical fiber system ramifying to the contralateral hemisphere following callosotomy, only the cells giving rise to the AC were labeled in the uninjected hemisphere. Cytoarchetecturally striking pyramidal cells were found whose proximal axons, apical, and basilar dendrites were clearly apparent. The FO extended from the temporal pole to the occipito-temporal sulcus and from the inferior depths of the insula to the parahippocampal gyrus. The FO was not entirely continuous for cells sometimes appeared in clumps separated by quiet zones; more often, however, entire layers were active within certain gyri. The density of pyramidal cells was invariably greatest in the lateral portions of the superior and inferotemporal gyri. In the superior temporal gyrus, pyramidal cells were widely scattered within layer III; in the inferotemporal gyrus, they were restricted to a tight laminar organization, 4 to 6 cells deep, within layer III. The presence of these cells in the insula, the depths of the superior temporal sulcus, and the parahippocampal gyrus appeared to vary with rostro-caudal location. Proceeding caudally, the FO moves progressively out of the inferior half of the insular cortex and down the lateral surface of the superior temporal gyrus, and moves inferiorly and medially into the inferotemporal and parahippocampal gyri. The FO appears to be much more extensive than the terminal projection field of the AC as delineated by previous investigators in rhesus (Zeki, Journal of Comparative Neurology, 148, 1973) and squirrel (Pandya et al., Brain Research, 15, 1973) monkeys. These investigators found the terminal projection field limited to the anterior temporal cortex. If the AC, in actuality, projects in a truly commissural homotopic fashion, then the previous delineations are clear underestimations of the terminal field's true extent. It may be, however, that the extensive FO may project through the AC to a highly compact terminal zone in the contralateral hemisphere. This heterotopic organization would be consistent with Van Alphen's (Acta Anat (Basel), 57, 1969) work on the AC of the rabbit. Aided by USPHS Grant No. NS-15053 and the McKnight Foundation.

454 TRACING THE COMPONENTS OF THE LINGUAL BRANCH OF THE GLOSSOPHARYNGEAL NERVE IN THE FROG BY ANTEROGRADE AND RETROGRADE TRANSPORT OF HORSERADISH PEROXIDASE. F.A. Kutyna and P. Conte*. Dept. of Physiology; Dept. of Anatomy, Uniformed Services University, School of Medicine, Bethesda, MD 20014.

The lingual branch of the IX cranial nerve (glossopharyngeal) of the frog carries in addition to afferent sensory fibers an efferent sympathetic (Chernetski, J. Neurophysiol. 27:493, 1964) as well as an efferent cholinergic (Morimoto and Sato, Proc. IUPS, XIII: Abs. 1563, 1977) component. Electrical stimulation of the first sympathetic ganglion results in enhanced sensitivity of gustatory afferents to chemical stimulation while electrical activation of the cholinergic component results in a depression of IX nerve chemosensory fiber discharge.

Horseradish peroxidase (HRP) was either injected into the crushed IX nerve or applied as a dry powder to both peripheral and central cut ends of the nerve. HRP was transported out to the tongue as well as toward the central nervous system.

The majority of cell bodies accumulating HRP were found in the glossopharyngeal component of the pneumogastric ganglion (g. jugulare) and constitute the sensory component of the IX nerve. A smaller cell type containing HRP was found adjacent to the glossopharyngeal component at the entrance to the ganglion of the sympathetic connective from the first sympathetic ganglion. Very rarely was a cell containing HRP found in the first sympathetic ganglion itself. Electrical stimulation of the IX nerve could evoke ganglionic potentials in the pneumogastric but never in the 1st sympathetic ganglion. This suggests that the IX nerve sympathetic postganglionic fibers originate for the most part outside the 1st sympathetic ganglion and near or adjacent to the cell bodies of the sensory fibers in the pneumogastric g. HRP was never found in cell bodies of the vagal (X) component of the pneumogastric g.

Rarely a motor cell body containing HRP was found in the nucleus of IX. These cells were smaller than their neighbors and of teardrop shape. The axonal processes were seen to travel in the direction of the sensory root of IX suggesting that these may be preganglionic visceral efferents and probably cholinergic. These anatomical findings describe in the frog (Rana pipiens pipiens) the IX nerve with sympathetic, cholinergic and sensory components in agreement with one interpretation of current neurophysiological data.

455 LIGHT ADAPTATION IN THE CRAYFISH EYE INDUCED BY SUSTAINED PHOTIC STIMULATION OF THE HETEROLATERAL EYESTALK WITHOUT RETINAL PHOTORECEPTORS. J. Larriva-Sahd*, J. Cibrian-Tovar*, D.E. García Díaz* & B. Barrera-Mera. (SPON: G. Massieu).
Div. Invest., Deptos. de Histología y Fisiología, Fac. Med. U.N.A.M. y Colegio de Posgraduados, Chapingo, México.

Characterization of extraretinal photosensitivity at several levels of crayfish nervous system (NS) has been advanced by means of electrophysiological (Prosser, 1934; Kennedy, 1958) and behavioral methods (Welsh, 1934; Harris & Stark, 1972). Bilateral influences of extraretinal nature involved in such photosensitivity were studied in these animals in which light adaptation of the retinal shielding pigments, was recorded as a reduction of the eye glow area (EGA). Adult crayfishes without retinal photoreceptors of either eye and with protocerebrum only in which caudal influences of the NS upon the visual system are suppressed were used.

Fig. 1

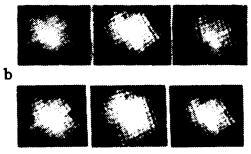

Figure 1 illustrates this changes few minutes after sustained photic stimulation (SuPS) of the heterolateral eyestalk, before (1a) and after (1b) the complete removal of its retina and lamina ganglionaris. Spontaneous variations of the electroretinogram (ERG) amplitude (Fig. 2A), as well as a ERG diminution (15-25 min) after a 60 min, SuPS (↓↑ 2B) were recorded in these conditions. We believe that the first result is probably due to the close relationship of the neuroendocrine system of both eyestalks involved in the control of release of hormon (es) which modulate the retinal sensitivity. On the other hand ERG diminution after SuPS seems to correspond to light adaptation and is probably mediated by extraretinal photosensitivity at the eyestalk level. The histological examination of the eyestalk without retina showed neurosecretory, pigmentary, and osmiophilic cells. The latter with ovoid granules (~ 1.5 µm).

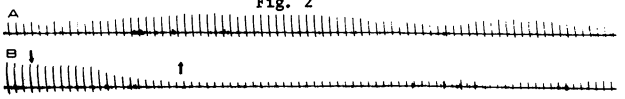
Fig. 2



We postulate that the cells with osmiophilic ovoid granules which probably correspond to lipochondria (Krauhs et al. Biochem. Biophys. Acta, 471, 25, 1977), are involved in the extraretinal bilateral light adaptation of the visual system of these animals.

456 ELECTRON MICROSCOPIC DEMONSTRATION OF CAUDAL AFFERENTS TO THE RAT INTERPEDUNCULAR NUCLEUS. Nicholas J. Lenn and Viviana Wong*. Dept. Neurol. and Ped., Carnegie Labs of Embryol., U. California, Davis CA 95616.

Analysis of the synaptology of the rat interpeduncular nucleus is of interest, amongst other reasons, because of the morphological and biochemical evidence for sprouting of afferents produced by habenular nucleus lesions. Only the synapses arising from the habenulointerpeduncular afferent axons have been identified thus far.

The afferents from the dorsal and ventral tegmental nuclei, which form a tegmentopeduncular tract, have been studied by the electron microscopic degeneration method in adult rats. Electrolytic lesions were placed stereotaxically so as to destroy the tegmentopeduncular tract, as well as various portions of the dorsal or ventral tegmental nuclei. The degeneration of endings in the interpeduncular nucleus was the same in each case. This consisted of: 1.) occasional neurofilamentous type degeneration of axons forming axodendritic synapses at three days' survival; 2.) dense type degeneration of axons contacting either small (0.4-0.8 micron) or large (1.4-2.0 micron) dendrites with synaptic contacts which were symmetrical to moderatedly asymmetrical; 3.) occasional axosomatic synapses also showing dense type degeneration. The dense type degeneration, which was similar at 3 and 4 days' survival, was apparently greatest in the caudal portion of the interpeduncular nucleus.

Equally important were observations of structures which were unaffected by the lesions. These included the S and crest synapses. Some somatic synapses, and apparently normal numbers of flattened vesicle synapses were also seen to be normal.

The present observations clarify at the fine structural level the afferents from the tegmentum caudal to the interpeduncular nucleus. A part of those synapses previously classified as S or somatic synapses, and possibly as F synapses are of this origin. It can be hypothesized that these afferents are amongst those which undergo sprouting caused by habenular lesions. This may involve the formation of heterologous crest synapses, the increase in number of somatic synapses, or both. This hypothesis is amenable to testing in double and triple lesion experiments.

Supported by NIH grants HD 08658 and RR 00169.

457 IDENTIFICATION OF CATECHOLAMINERGIC PROJECTIONS TO AREA X IN THE ZEBRA FINCH (POEPHILA GUTTATA). James W. Lewis, Susan M. Ryan, Larry L. Butcher, Arthur P. Arnold. Dept. Psych. and Brain Res. Inst., UCLA, Los Angeles, CA 90024.

In some passerine birds, song is a behavior which is typical of males but not females, and is controlled by a group of discrete sexually dimorphic brain regions. Area X of the lobus parolfactorius (LPO) is a region which is sexually dimorphic and receives afferents from the caudal nucleus of the hyperstriatum ventrale (HVc), an area known to be involved in the control of song (Nottebohm et al, 1976; Nottebohm and Arnold, 1976). The possible role of Area X in the control of song remains to be determined.

Our injections of horseradish peroxidase (HRP) into Area X confirm the projection from HVc to Area X. Additionally, HRP injections centered in Area X indicate possible afferent projections from midbrain nuclei, either nucleus tegmenti pedunculopontinus (TPc), the area ventralis of Tsai (AVT), or both.

Using the specific glyoxylic acid histofluorescence technique of de la Torre and Sturgeon (1976) we have demonstrated dense fluorescence, due to catecholamine containing nerve terminals and axons, in Area X, LPO, and paleostriatum augmentatum (PA). Catecholamine containing neuronal cell bodies are found in TPC and AVT. Electrolytic lesions of TPc eliminate catecholamine fluorescence in PA, but not in Area X or LPO, when examined 7 days later. A lesion of AVT eliminates fluorescence in Area X and LPO but not in PA. Lesions placed immediately anterior to AVT eliminate fluorescence in LPO, Area X, and PA, presumably by interrupting the fibers to these regions from both AVT and TPc.

The HRP and histofluorescence results, when taken together, suggest catecholaminergic projections from AVT to Area X and LPO, and from TPc to PA. The projection to Area X is sexually dimorphic. In the male, terminal fluorescence in Area X is clearly more intense than that in the surrounding LPO; in the female this distinction is not apparent.

The avian paleostriatal complex, composed of LPO, PA, and paleostriatum primitivum, has previously been suggested to be homologous to the mammalian basal ganglia (Karten and Dubbeldam, 1973). Our results support and extend this homology. Anatomical location and the catecholaminergic projection from AVT suggest Area X - LPO to be the avian homolog of the mammalian nucleus accumbens and/or olfactory tubercle. Identification of sources of afferents to Area X and the neurotransmitters involved will allow further physiological interventions and pharmacological manipulations to assess the functional role of Area X within the paleostriatal complex and its possible significance in the control of song or related behaviors.

458 NEAR-FIELD VISUAL ACUITY IN PIGEONS FOLLOWING LESIONS OF THALAMIC VISUAL NUCLEI. Kathleen A. Macko* and William Hodos (SPON: R. H. Wurtz). University of Maryland, College Park, MD 20742.

In mammals and in birds two ascending pathways, the thalamofugal and tectofugal pathways, conduct information from the retina to the telencephalon. In mammals and birds the response properties and receptive field size of visual neurons within these pathways suggest a functional distinction. The cells of the thalamofugal pathway have relatively small receptive fields and show varying degrees of preference for the orientation of a stimulus. These cells are presumed to be particularly well suited for processing detailed spatial information. In contrast, the cells of the tectofugal pathway show consistently larger receptive fields and a much wider range of receptive field sizes. In general, motion and direction are the preferred stimulus features. These cells appear less well suited for carrying precise spatial information and are presumed to be involved with background events and the location of stimuli within the visual field. Some support for this functional distinction is provided by lesion studies in mammals (rhesus monkey, bushbaby and rat) in which lesions of the thalamofugal pathway produce impairment in visual acuity while lesions of the tectofugal pathway do not.

The present study was designed to determine whether this distinction in functional organization can be applied to the avian visual system. Visual acuity determinations were made for 10 pigeons trained to discriminate high contrast square-wave gratings of successively higher spatial frequencies from a blank stimulus of equal average luminance. The gratings and blanks were presented according to the method of constant stimuli. Video-taped motion pictures of the key-pecking response provided a measure of the eye to stimulus distance. The preoperative results indicated that the mean near-field visual acuity of the 10 pigeons was 2.3' (range 1.6 - 3.6') under conditions of photopic adaptation with the stimulus luminance at 70 cd/m^2. When performance was stable, bilateral electrolytic lesions were placed in 1) the OPT complex (thalamic component of the thalamofugal pathway), 2) nucleus rotundus (thalamic component of the tectofugal pathway) and 3) the OPT complex plus nucleus rotundus. The postoperative data indicated that lesions confined to the OPT complex did not impair resolution threshold. Lesions confined to nucleus rotundus produced permanent threshold elevations. When destruction of OPT was combined with nucleus rotundus the deficit was more severe. The results indicate that in contrast to the mammalian visual system, the integrity of the tectofugal pathway of the pigeon is required for normal performance of spatial discrimination near acuity threshold and demonstrate that wide receptive field neurons are capable of processing detailed spatial information.

459 HISTOCHEMICAL AND ULTRASTRUCTURAL STUDY OF THE PRIMATE CLITORIS. JoAnn McConnell. Dept. Neurobiol. and Anat., U.T. Med. Sch., Houston, TX, 77025.

As with many other genitourinary organs, the structure of the clitoris has not been studied in any detail. The clitoris is formed by two corpora cavernosa which arise from two crura lying on the ischiopubic ramus. Although there is no corpus spongiosum the clitoris is considered to be the "homologue" of the penis in the male. The extent of this similarity, however, is difficult to ascertain since histological data is not available in the current literature.

Tissue for this study was obtained from female cynomolgus monkeys and from patients undergoing a partial clitorodectomy for hormone-related hypertrophy of the clitoris. Each sample was divided into two parts, the first being frozen immediately for use in various light microscopic analyses, and the other being fixed immediately by immersion in glutaraldehyde for EM analysis. Light microscopic techniques utilized included hematoxylin and eosin, phosphotungstic acid hematoxylin, acetylcholinesterase (AChE) and glyoxylic acid (GA) histofluorescence. In addition to routine EM preparations, Wood's (1963) glutaraldehyde-dichromate method was employed for specific localization of adrenergic vesicles.

Preliminary data indicate that the primate clitoris is composed of loose connective tissue with occasional vein-like spaces. Collagen bundles and elastic fibers, along with the other connective elements such as fibroblasts and mast cells, make up the bulk of the stroma. Smooth muscle cells apparently are rarely present, except in the walls of blood vessels. Nerve bundles of various sizes, containing both myelinated and unmyelinated nerve fibers, and small blood vessels can be found traversing the clitoris parallel to the longitudinal axis of the organ. Pacinian and Meissner's corpuscles appear frequently in the subcutaneous tissue.

Presumed adrenergic (GA-fluorescent) fibers are found most often forming plexuses around the small blood vessels, although a few appear in the stroma unassociated with the vasculature. Possible cholinergic fibers (AChE-positive) are found more frequently in the stroma and in both small and large nerve fiber bundles. EM analysis of the neural elements supports these light microscopic results.

The above data suggest that the morphology of the clitoris is significantly different from that of the penis and thus the two are not truly homologous in the adult primate.

460 IDENTIFICATION OF EIGHTH NERVE EFFERENT CELLS IN THE BOWFIN, AMIA CALVA. Catherine A. McCormick and Mark R. Braford, Jr. Department of Anatomy, Georgetown University, Schools of Medicine and Dentistry, Washington, D.C. 20007

Efferent cells of the anterior and posterior rami of the eighth (octavius) nerve were visualized by means of retrograde labelling. In a given animal, one of the two rami was injected with HRP at the level of its ganglion. Labelled cells were seen ipsilaterally after a survival time of four days at 27 C. These efferent cells are found near the branchial motor cell column, with the majority of cells in a periventricular position at or just medial to the sulcus limitans. These cells form a diffuse population, extending from a level just caudal to the entrance of the posterior octavius ramus to a region between the entrance of the anterior vagal rootlets and the glossopharyngeal nerve. The efferent cells are fusiform or multipolar in morphology, with diameters of approximately 50-80 μ and large dendritic extents. The axons of some of these cells emerge from the lateral aspect of the cell and course rostrally toward the entering octavius rami in the descending octavius tract. It also appears that some of the axons course toward the ventral border of the medulla before turning laterally to enter this tract.

Preliminary results on the location of the efferent cells of the lateral line system suggest that these cells occupy a region similar to that of the octavius efferent cells. Supported by NSF Grant BNS 78-22411

461 ANTERIOR AND POSTERIOR THALAMIC AFFERENTS IN THE BULLFROG, Rana catesbeiana. Timothy J. Neary and Walter Wilczynski. Anat. Dept., Creighton Univ., Omaha, NE 68178 and Sect. Neurobiol. Behav., Cornell Univ., Ithaca, NY 14853.

50-150 nl of HRP was injected into either the anterior or posterior thalamus of 14 bullfrogs. Because of diffusion from the injection sites, all injection zones encompassed several cytoarchitectonic fields. Anterior thalamic injections were centered in the anterior nucleus of the dorsal thalamus but spread into the adjacent habenular complex was present in every case. In most of these cases there was further spread into the ventromedial nucleus and into the ventrolateral complex (nucleus of Bellonci, dorsal and ventral ventrolateral nuclei, and superficial ventral nucleus). Structures consistently labelled after anterior thalamic injections include the pre- and supraoptic areas, posterior entopeduncular nucleus, ventral hypothalamus, posterior thalamic nucleus, pretectal grey, and posteroventral tegmental nucleus. In cases where larger amounts of HRP were injected, occasional labelled cells were seen in the medial amygdala, posterior tuberculum, dorsal hypothalamus, anteroventral tegmental nucleus, and a small group of reticular formation neurons medially adjacent to the motor nucleus of V. Numerous cells were also seen in the perisolitary band (Neary and Wilczynski (1977) Brain Res. 138:529). Nearly all labelled cells were ipsilateral to the injection sites. However, most of the labelled cells in the perisolitary band and many of the labelled cells in the pretectal grey were contralateral to the injection sites. Posterior thalamic injections were centered in the posterior thalamic nucleus, with spread into the pretectal grey, posterodorsal nucleus and posterodorsal division of the lateral nucleus. Following these injections labelled cells were seen in the anterior entopeduncular nucleus, pre- and supraoptic areas, ventral hypothalamus, nucleus of Bellonci, dorsal ventrolateral nucleus, optic tectum, and antero- and posteroventral tegmental nuclei. Nearly all labelled cells after posterior thalamic injections were ipsilateral to the injection sites. However, many labelled cells were seen in the contralateral posterior thalamic nucleus and pretectal grey. Anterogradely-filled fibers could be followed from the posterior thalamic injection sites into the dorsal ventrolateral and anterior nuclei.

462 INTERVAL CODING OF TEMPERATURE BY PREOPTIC NEURONS IN SUNFISH. D.O. Nelson* and C. Ladd Prosser. Dept. of Physiology and Biophysics, Univ. of Illinois, IL 61801.

The frequency of discharge of neurons in the preoptic region of many lower vertebrates and mammals is highly sensitive to changes in peripheral and central temperature. These neurons are implicated in thermoregulation. Microstructural neural patterning may be involved in temperature sensing and/or integration necessary for temperature regulation in mammals. Extracellular recordings were made from single cells in medial and lateral preoptic regions of green sunfish, (Lepomis cyanellus), while altering forebrain and skin temperatures. Warm sensitive (22%) and cold sensitive (6%) cells were identified; some of these responded to forebrain temperature changes, some to skin temperature changes and others to both forebrain and skin temperature alteration. In addition, some temperature-insensitive (72%) cells were found. However, examinations of interspike interval patterns of these grossly insensitive cells showed complex alterations from unimodal firing patterns to bimodal patterns. These transitions, which consisted of changes from a continuous random firing pattern to a bursting pattern, occurred at different specific temperatures for different units; in one 25°C acclimated fish, neurons were found which showed transitions at 17.5, 23.0, 25.2 and 28.7°C. The temperatures of transition of different cells appear to comprise a continuum in all fish examined. Such a system of neurons may provide a coded temperature scale which may be used in behavioral thermoregulation. It is suggested that microstructural coding of temperature may be a property found in lower vertebrates as well as in mammals. Investigation of peripheral temperature alterations on firing patterns of preoptic neurons is in progress.

463 COMPARATIVE ORGANIZATION OF REPTILIAN RETICULAR FORMATION. Donald B. Newman* and Antonia Gebert* (SPON: M. B. Carpenter). Dept. of Anatomy, USUHS, Bethesda, MD. 20014.

The brains of snakes of the genera Crotalus, Agkistrodon, and Natrix, lizards of the genera Tupinambis, Basiliscus, Dipsosaurus, and Gecko, turtles of the genera Pseudemys, Chrysemys, and Terrapene, and the crocodilian Caiman were processed using Golgi and Nissl techniqes.

The reticular formation in reptiles is divisible into several distinct fields; an inferior reticular field (RI) in the myelencephalon, a middle reticular field (RM) in the caudal two-thirds of the metencephalon, and a superior reticular field (RS) in the rostral third of the metencephalon: A dorsolateral-ventrolateral metencephalic reticular field (MDL-MVL complex) is present at isthmic levels. The inferior raphe nucleus (RaI) is included with the reticular fomation, as is the middle raphe nucleus (RaM).

In lizards, snakes and crocodilians, RI is subdivided into dorsal vs. ventral portions (RID vs. RIV). Turtles possess only the RID field. In all the reptiles studied, RM, RS, the MDL-MVL complex can be identified in the metencephalon.

The raphe nuclei varied considerably. In snakes, only medium-sized neurons are present in RaI, whereas RaI in lizards and turtles contains large cells, as does RaM in turtles. RaI in crocodilians contains giant cells.

Small reticular neurons (<30μ) have fusiform or triangular somas and bear two to three sparsely-branching dendrites which average 183μ in length. These dendrites exhibit no preferred orientation.

Large reticular neurons (>30μ) have fusiform or polygonal somas which bear three to six sparsely-branching dendrites which average 234μ in length. Dendrites of large neurons in RID show no particular orientation. Dendrites of large neurons in RIV course horizontally. Most dendrites of large neurons in RM course ventrally. RM neurons bear dendritic aborizations which span the dorsoventral width of the brain stem, intersecting the medial longitudinal fasciculus dorsally and touching the pial surface ventrally. Some large RM neurons bear dendrites which cross the midline and enter the contralateral RM field.

The dendrites of both small and large reticular neurons are devoid of excrescences and ramify predominantly in the transverse plane.

The reptilian reticular formation resembles that of mammals in that it consists of distinct sub-nuclei or fields which contain sparsely-branching, "isodendritic" neurons. An unexpected finding was the wide variation observed in the organization of the raphe complex in the various reptilian groups.

464 SOME CONNECTIONS OF THE SKATE DORSAL AND MEDIAL PALLIA. R. G. Northcutt and J. C. Wathey. Div. Biol. Sci's., UM, Ann Arbor, MI 48109 and Dept. Neurosci's., UCSD, La Jolla, CA 92093

Some pallial connections in adult thornback skates (Platyrhinoides triseriata) were revealed with HRP histochemistry (DIA or TMB substrates). Animals survived 8-14 days at 16°C after unilateral pallial injections of 200-400 nl of Sigma VI HRP (20-40%). Retrograde and anterograde transport were apparent. HRP-positive neurons were present in both an ipsilateral and contralateral rostral thalamic nucleus following pallial injections confined to the telencephalic central nucleus and dorsal pallium lying immediately dorsal to the central nucleus. Anterograde fibers could be followed over the caudal pole of the hemisphere where they turned caudally to terminate in the ipsilateral rostral thalamic nucleus that projects to the caudal telencephalic roof. Fibers were also followed from the roof ventrally and caudally where they decussate dorsal to the optic chiasm and terminate in the contralateral rostral thalamic nucleus. The rostral thalamic nucleus projecting to the caudal telencephalic roof has been identified as the lateral geniculate in sharks such as Ginglymostoma (Schroeder & Ebbesson, BBE; 1974). In sharks the LGN projection appears totally crossed, as are the primary optic projections. Skates, however, possess ipsilateral as well as contralateral retinothalamic projections (Northcutt & Boord, unpublished observations) and this difference may account for the bilateral projection of the rostral retinorecipient thalamic nucleus in skates. Pallial injections with greater rostro-caudal extent reveal HRP-positive neurons in an ipsilateral cell group immediately dorsal to area superficialis basalis, and in the septal nuclei and cells of the inferior lobe. Larger injections also revealed two additional cell groups more caudal in the thalamus. The more dorsal group probably corresponds to the central thalamic nucleus of Ebbesson; the second nucleus is more ventromedial and has not been previously named. These larger pallial injections appear to include parts of the medial pallium and reveal pallial efferents comparable to those reported by Ebbesson in sharks (CBP; 1972). Telencephalic efferents terminate bilaterally on the septal nuclei as well as exit the caudal hemisphere where part of the descending fibers decussate in the habenular commissure and supraoptic decussation. Fibers appear to terminate bilaterally in the habenular nuclei, dorsal thalamus, optic tecta, and tegmentum. Descending fibers were also traced to the contralateral inferior lobe where extensive terminal arborizations occur.

465 IDENTIFICATION OF HOMOLOGOUS MUSCLES AND MOTONEURONS IN 2 SPECIES OF SANDCRAB BELONGING TO DIFFERENT TAXONOMIC FAMILIES SUGGESTS ANCESTRY OF SWIMMING BY UROPOD BEATING. Dorothy H. Paul. Hopkins Marine Station, Pacific Grove, CA 93950.

Uropod beating during swimming in Emerita analoga (Hippidae) is attributed to a central neural rhythm generator since the isolated abdominal nerve cord generates power-stroke (PS) motoneuron bursts which are appropriately phased within return-stroke (RS) periods (Paul, 1979, J.Neurobiol.10). But the most prominent feature of the motor program is an intricate pattern of rhythmic activity in motoneurons which innervate the ventromedial muscle (VM) and not bursting of PS and RS motoneurons. VM is a small muscle, a PS synergist and pronator of the uropod. An explanation of the unexpected prominance of VM neurons in the central motor program has emerged from examination of the neuromuscular organization subserving the tailfan of another sandcrab, Blepharipoda occidentalis which belongs to a different family (Albuneidae) and does not swim. Although their uropods have the characteristic sandcrab orientation, the arrangement of muscles in the telson of B.occidentalis resembles that found in decapods with conventional tailfans (e.g., crayfish) as closely as it does the highly specialized anatomy of E.analoga. The probable homologues of all 6 telson muscles of E.analoga have been identified in B.occidentalis by relative position, innervation and, in some cases, soma position and central morphology of motoneurons. Three pairs of homologous muscles in particular reveal striking morphological and function-differences (Table).

muscle*	% of all telson muscles (wet wt.) E.analoga	B.occidentalis	action on uropod E.analoga	B.occidentalis
RS	36	6	retract	elevate
PS	50	24	protract	depress
VM	4	28	protract & promote	none

*terminology as for Emerita

The larger mass of RS and PS muscles in E.analoga attests to the larger angular excursions of the uropods in this species. But the most interesting discovery is that the VM homologue in B. occidentalis is not a muscle of the appendage at all. It is a telson flexor and, therefore, functionally a part of the abdominal flexor system. Thus VM in E.analoga appears to be, historically, an axial muscle. The implication is that the intricate pattern of rhythmic bursting of VM motoneurons in E.analoga, the most prominent part of the central motor program, reflects activity of a neuronal mechanism which may have subserved rhythmic abdominal movements in an ancestral decapod.

466 THE PALEOSTRIATAL COMPLEX IN TURTLES. Anton Reiner. Dept Psychiatry and Behavioral Sciences, Health Sciences Center, SUNY, Stony Brook, N.Y. 11794.

The present study examined the histochemistry and efferent projections of the ventral portion of the reptilian lateral telencephalic wall (paleostriatal complex, PC), the presumed equivalent of the mammalian basal ganglia. Using catecholamine (CA) histoflourescence, acetylcholinesterase (AChE) histochemistry substance P immunocytochemistry, three subdivisions of the PC were recognized in the turtle (Chrysemys scripta). 1) A small-celled zone (paleostriatum augmentatum, PA) occupies most of the basolateral telencephalic wall, extending from the olfactory tubercle to the amygdaloid region. The neuropil of PA is rich in AChE, weakly positive for substance P and contains a fine network of CA terminals similar to that observed in the caudoputamen of mammals. 2) A medial small-celled zone (area d, Riss, Halpern and Scalia, BB and E, 1969), coextensive with PA along the rostrocaudal axis, is interposed between PA and the lateral ventricle. The neuropil of area d is also rich in AChE, but differs from that of PA in that it is more intensely positive for substance P and contains a network of thick CA fibers and terminals. 3) A group of large AChE-rich neurons (globus pallidus, GP) is interspersed with the fibers of the lateral forebrain bundle through intermediate PC levels. The neuropil of GP is rich in substance P, but nearly devoid of CA and AChE.

The efferent projections of the PC were examined using autoradiographic tracing techniques. The most prominent projection of the PC was to a tegmental cell field containing numerous CA neurons. Other targets of the PC included several subthalamic nuclei, the dorsal nucleus of the posterior commissure and parabrachial isthmic regions. Injections of horseradish peroxidase into the tegmental CA cell field indicated that the projection to this region from PC arises from GP and caudal area d. Only a few PA neurons were labeled by such injections. Other research (Parent, Br.Res., 1976) has shown that PA receives an extensive input from the tegmental CA cell field.

The projection of the PC upon the tegmentum is reminiscent of the projections of globus pallidus and nucleus accumbens upon the tegmentum in mammals. The present connectionistic and histochemical data are consistent with the hypothesis PA, GP and area d in turtles are similar to caudoputamen, globus pallidus and nucleus accumbens, respectively, in mammals. I thank Harvey Karten for his support during this research. Supported by USPHS 1 F NS 05682001.

467 AFFERENT AND EFFERENT CONNECTIONS OF THE BULLFROG MEDIAL PALLIUM. Mark C. Ronan* and R. Glenn Northcutt (SPON: M. B. Pritz). Neurosciences Program and Division of Biological Sciences, University of Michigan, Ann Arbor, MI 48109.

Medial pallial connections in adult bullfrogs (Rana catesbeiana) were investigated with HRP histochemistry (DIA or TMB substrates), autoradiography, and Fink-Heimer procedures. Animals were allowed to survive 3-6 days at 23°C after surgery or injection of the tracer. Injections of 100-150 nl of 20-40% HRP (Sigma VI) into the medial pallium revealed both retrograde and anterograde transport. Checks on the medial pallial efferents revealed by HRP were provided by autoradiographic analysis after ^{3}H-proline injections or lesions of dorsal, lateral, and medial pallia processed by Fink-Heimer techniques. The medial pallium receives ipsilateral projections from the dorsal and lateral pallia, lateral and medial septal nuclei, olfactory tubercle, pars medialis of the amygdala, bed nucleus of the pallial commissure, anterior thalamic nucleus, and the midbrain raphe nucleus. The medial pallium also receives contralateral projections from the medial pallium, medial septal nucleus, pars medialis of the amygdala, bed nucleus of the pallial commissure, and anterior thalamic nucleus. The efferent projections of the medial pallium consist of commissural connections with the contralateral medial pallium, and a projection to the contralateral bed nucleus of the pallial commissure, both via the pallial commissure. A precommissural fornix system passess to the ipsilateral lateral and medial septal nuclei, the olfactory tubercle, medial postolfactory eminence, internal granule layer of the olfactory bulb, pars lateralis and medialis of the amygdala, lateral pallium, and preoptic nucleus. Contralateral projections to the medial septal nucleus, olfactory tubercle, pars lateralis and medialis of the amygdala, and preoptic area decussate in the anterior commissure and travel in the contralateral medial forebrain bundle. A postcommissural fornix system consists of medial pallial efferents to the anterior thalamic nucleus and caudal hypothalamus. These postcommissural projections are bilateral and also appear to decussate in the anterior commissure. All telencephalic populations except the striatum, pars lateralis of the amygdala, olfactory bulb, and preoptic nucleus, converge on the medial pallium; the medial pallium forms reciprocal connections with most of these populations and constitutes one of the major efferent pathways of the telencephalon.

(This research was performed in accordance with NIH Guidelines Vol. 7, #17, Nov., 1978. Supported in part by NIH Grant NS11006 to RGN.)

468 EVIDENCE FOR CHOLINERGIC MECHANISMS IN BRAIN REGIONS RELATED TO BIRD SONG. Susan M. Ryan and Arthur P. Arnold. Dept. Psychol. and Brain Res. Inst., UCLA, Los Angeles, CA 90024.

Brain regions thought to be involved in the control of song in the zebra finch, Poephila guttata, were examined histochemically using the Karnovsky and Roots direct-coloring method for the detection of acetylcholinesterase (AChE). In order to control for the possible presence of nonspecific cholinesterase, two substrates, acetylthiocholine and butyrylthiocholine, and several enzyme inhibitors, tetraisopropyl pyrophosphoramide (iso-OMPA), BW284C51, and eserine sulfate, were reacted with the tissue. Manipulations with these compounds demonstrated that most of the reaction product with the substrate acetylthiocholine was AChE. In addition, some of the subjects were pretreated with diisopropylphosphofluoridate (DFP). DFP irreversibly inactivates AChE, which allowed observation of newly synthesized AChE in cell bodies only.

Several brain areas thought to be involved in vocal control in adult males and females contain AChE. These nuclei include Area X (or dorsolateral LPO), magnocellular nucleus of the anterior neostriatum (MAN), nucleus interface (NIF), caudal nucleus of the ventral hyperstriatum (HVc), intercollicular nucleus (ICo), robust nucleus of the archistriatum (RA), and tracheosyringeal portion of the hypoglossal nerve nucleus (nXIIts). In addition, several auditory nuclei, nucleus ovoidalis, dorsal portion of the lateral mesencephalic nucleus (MLd), and Field L also contain AChE. Of the vocal control nuclei, Area X, HVc, MAN, NIF, ICo, and nXIIts contain a denser reaction product than the surrounding tissue. All of the vocal control nuclei, except Area X, contain mostly AChE-synthesizing neuronal cell bodies; however, in Area X an extremely dense reaction product is present in the neuropil, suggesting possible cholinergic input.

Autoradiographic procedures were used to localize binding of tritiated quinuclidinyl benzilate (QNB), a specific muscarinic cholinergic antagonist, in the brain. In both males and females, QNB was localized in high concentrations in the neuropil of Area X (or dorsolateral LPO). This binding was displaced by preinjection with two specific muscarinic antagonists, atropine sulfate and scopolamine hydrobromide, but not by saline, suggesting that the binding is of limited capacity and specific to muscarinic cholinergic receptors. Taken together, the high concentrations of AChE and high level of specific binding of QNB in Area X strongly implicate cholinergic mechanisms in the function of Area X.

Supported by NSF grant BNS 77-05973 to A.P.A.

469 STRUCTURAL CHARACTERIZATION OF THE ANTERIOR AND POSTERIOR PITUITARY OF THE WEST INDIAN MANATEE. Alan Schneyer, Robert Hinkley*, and Daniel Odell*. Department of Anatomy and The Rosenstiel School of Marine and Atmospheric Science, The University of Miami, Miami, Florida 33101.

The pituitary gland of the West Indian manatee, Trichechus manatus, a marine mammal, was examined by light and electron microscopy to determine the cell types present and organization at the ultrastructural level. For light microscopy, paraffin sections were stained by the acid fuchsin-analine blue method to distinguish acidophils, basophils, and chromophobes. The permanganate oxidation-aldehyde fuchsin method was used to demonstrate neurosecretory material in the neurohypophysis. For electron microscopy, tissue was fixed in glutaraldehyde in cacodylate buffer, post-fixed in osmium tetroxide, dehydrated, and embedded in Epon 812. Acidophils, basophils, and chromophobes occurred at relative frequencies of 34%, 22%, and 44%, respectively. Colloid-filled follicles surrounded by a layer of pale-staining cells were present in most sections. Ultrastructurally, at least six cell types, and possibly seven, could be distinguished on the basis of granule morphology. In descending granule size, cell type I contained granules averaging 630 nm in diameter, type II, 515 nm; type III, 410 nm; type IV, 320 nm; type V, 275 nm; type VI, 240 nm; and type VII, 180 nm.

Thin sections of neurohypophysis contain numerous profiles of neurosecretory cell processes and pituicytes. The pituicytes average 7-10 u in diameter, possess lengthy cell processes, and are characterized by one or more well-developed Golgi complexes, vesiculated endoplasmic reticulum, lysosomes, and few mitochondria. Bundles of filaments averaging 9-11 nm in diameter are present in pituicyte cell bodies and processes. The axoplasm of fibers comprising the hypothalamo-hypophysial tract contain numerous filaments, few microtubules, clear vesicles measuring 35-50 nm in diameter, and numerous electron-opaque secretion granules averaging 210 nm in diameter. No Herring bodies were seen in paraffin or Epon sections. Many neurosecretory processes terminate near non-fenestrated capillaries which provide the neurohypophysis of the manatee with a rich vascular supply.

Supported in part by NIH grant GM-25586.

470 THE EFFECTS OF UNILATERAL LESIONS AND IPSILATERAL OR CONTRALATERAL EYE CLOSURE ON THE SOCIAL BEHAVIOR AND ACTIVITY LEVELS OF THE WESTERN FENCE LIZARD. Robert S. Tarr. Physiol. Dept., Chicago College of Osteopathic Medicine, 1122 E. 53rd Street, Chicago, Illinois 60615.

Territorial defense behavior was studied in Sceloporus occidentalis before and after unilateral telencephalic lesions noting the effects after closing either the ipslilateral or contralateral eye. An adult male animal was placed in a large (100 sq. ft.) enclosed seminatural environment. The animal occupied the territory alone for 48 hours, then another adult male was introduced. Activity levels (number of times changing position and number of times changing location) and agonistic behavior (number of assertion displays and challenge displays) were recorded. The animals were removed and the resident was either sham lesioned, lesioned in the anterior DVR, lesioned in the paleostriatum (and nucleus accumbens) or lesioned in the amygdala. All lesions were unilateral. The resident's ipsilateral (to the lesion) or contralateral eye was sutured shut, he was reintroduced into the cage, and 48 hours later the observations were repeated. The animals were again removed and the eye was opened and the other eye sutured shut. Again, 48 hours later the observations were repeated. Animals showing any change from normal were observed for at least one additional observation period. The intruding lizard was the same animal for all the residents. Light, temperature and diurnal activity cycles were all held constant.

Sham lesioning and anterior DVR lesions did not result in a change in activity level or agonistic behavior through either eye. Certain small lesions in the paleostriatum and/or amygdala, resulted in a drop in activity and display behavior when the contralateral eye was open: challenge displays were entirely absent, assertion displays nearly absent, activity was reduced 50% or more and dominance in the territory was lost. These animals could still see and move however, as noted by their normal visual predatory behavior. When the ipsilateral eye was being used social behavior and activity was either normal or reduced but since challenge displays were always present the animal never lost dominance with this eye.

These observations confirm the role of the reptile telencephalon in arousal, attention and agonistic behavior and the functional effect of nearly complete crossing of optic fibers. They further suggest that in these animals the mechanism of arousal is heavily dependent on visually processed information related to social behavior.

471. DISCRIMINATION OF MIRROR-IMAGE SYMMETRICAL STIMULI AFTER LESIONS OF THE VISUAL SYSTEM IN PIGEONS. Susan R. B. Weiss* and William Hodos. Dept. Psych., Univ. of Maryland, College Park, MD 20742

Mammals have been reported to have greater difficulty discriminating between stimuli that are mirror-image (MI) symmetrical than stimuli without such symmetry. Pigeons were trained to perform a simultaneous discrimination task with three pairs of stimuli: laterally MI-symmetrical,  vs.  ; vertically MI-symmetrical,  vs  ; and unsymmetrical, non-MI,  vs  . In contrast to mammals, pigeons had no greater difficulty discriminating MI-symmetrical stimuli than non-MI stimuli.

Following training, bilateral stereotaxic lesions were made either in visual wulst, which is a telencephalic component of the thalamofugal visual pathway or ectostriatum, which is a telecephalic component of the tectofugal visual pathway. After surgery, both groups were retrained to the preoperative criterion. Visual wulst lesions resulted in minor, transient deficits on all three stimulu pairs. MI-symmetrical stimuli showed no greater impairment than non-MI stimuli. Lesions of ectostriatum resulted in moderate to severe impairment in the discrimination of all three stimulus pairs. All subjects with ectostriatum lesions exhibited a greater impairment in the discrimination of lateral MI-symmetrical stimuli than the vertical MI-symmetrical or unsymmetrical stimuli.

Intact mammals require more training to discriminate pairs of MI stimuli than any other type of stimulus pair differing only in spatial orientation. In contrast, intact pigeons learn to discriminate MI and non-MI stimuli at the same rate. Interruption of the tectofugal visual pathway in pigeons results in a differentially greater impairment in the discrimination of lateral MI stimuli than non-MI stimuli. The differences between birds and mammals in their ability to discriminate lateral MI stimuli may be related to differences between them in the organization of their hemispheric interconnections.

472 STRIATAL EFFERENTS IN THE BULLFROG, RANA CATESBEIANA. Walter Wilczynski and R. Glenn Northcutt. Sec. Neurobiol. and Behav., Cornell University, Ithaca, N.Y., 14853, and Div. Biol. Sci., University of Michigan, Ann Arbor, Michigan 48109.

In bullfrogs (Rana catesbeiana) efferents from the thalamic nuclei receiving tectal and toral projections terminate heavily in the striatum (Wilczynski and Northcutt, Anat. Rec., 193: 721, 1979). In order to determine routes by which the striatum could in turn influence midbrain sensory structures, we investigated striatal efferents in adult bullfrogs using autoradiographic and degeneration techniques, and the anterograde transport of horseradish peroxidase (HRP). Results from each technique were essentially identical. Except for the small ventral eminence of the lateral pallium, no pallial area receives a striatal input. The striatal efferents descend in the lateral forebrain bundle (LFB) through the anterior entopeduncular nucleus (AE) where a large fascicle leaves the LFB to cross in the anterior commissure and terminate in the contralateral AE and caudal half of the ventral striatum. A much smaller projection leaves at this level to enter the ipsilateral lateral amygdala. The remaining efferents continue caudal in the ipsilateral LFB, passing through the posterior entopeduncular nucleus. In the diencephalon, small projections to the ventrolateral (pars lateralis), ventromedial, and posterior tuberal nuclei were apparent. A much larger projection leaves the LFB in the pretectum to run dorsally through the lateral nucleus and lateral edge of the posterior nucleus. Striatal efferents continue caudally through the superficial tegmental nuclei (nucleus profundus mesencephali and superficial isthmal reticular nucleus) and into the ventral anterodorsal, lateral anteroventral, and rostral pole of the posterodorsal tegmental fields. A small superficial projection continues caudally to isthmal levels, but not beyond. Tegmental HRP injections reveal retrogradely filled cells in the dorsal and ventral striatum, nucleus accumbens, and AE, and pretectal HRP injections reveal filled cells in the caudal ventral striatum and AE, thus confirming striatal projections to these areas. Striatal HRP injections have failed to demonstrate the source of the commissural striatal connections.

Striatal influence reaches the midbrain roof through several disynaptic pathways: via AE, the pretectum, and the tegmentum, all of which project to the tectum and torus (Wilczynski, Neurosci. Abst., 4: 301, 1978; Wilczynski and Northcutt, J. Comp. Neur., 173: 219-230, 1977). Additional trisynaptic routes are present via AE and its pretectal and tegmental connections, which parallel the striatal pathways.

473 WHAT IS A HOMOLOGY IN THE CENTRAL NERVOUS SYSTEM? GOLGI STUDY OF THE MEDIAL GENICULATE BODY OF THE OPOSSUM AND THE CAT. Jeffery A. Winer and D. Kent Morest. Department of Anatomy, University of Connecticut Health Center, Farmington, Connecticut 06032.

Concepts of homology in the central nervous system of different species are central to comparative neurology. All students of neuroscience rely on such concepts in relating the significance of their findings. Yet there are few critical evaluations of its definition and practical application. The present study explores the premise that the shapes of neurons and axons can be used to demonstrate homologous cell groups in the medial geniculate body of the opossum and cat. Morest (Anat.Rec., 1965, 151, 390) compared the structure and connections of these neurons with the Golgi and Nauta methods to derive homologous nuclei. We have confirmed and extended this work. In the ventral division, the thalamo-cortical neuron in both species has tufted dendrites which are arranged in parallel laminae. A smaller Golgi type II cell with a locally arborizing axon is also present. In the dorsal division, the opossum has two types of principal neurons, as does the cat, and there is close morphological correspondence between the species; in the cat, there are also two kinds of Golgi type II cells, while the opossum probably has only one type. In the medial division, both species have numerous (as many as five) cell types, including Golgi type II cells, and a corresponding richness of afferent inputs. A major difference between the species is the relative abundance of Golgi type II cells in the cat, and their paucity in the opossum in each of the thalamic subdivisions. In addition, certain subdivisions are proportionately expanded or elaborated in the cat (e.g., pars lateralis of the ventral division), while others are relatively more prominent in the opossum (e.g., pars ovoidea of the ventral division.) We conclude that patterns of connectivity, the topographical position of nuclei, their developmental history or functional organization are insufficient to confirm homology in the nervous system; while they can be useful adjuncts in the determination of homology, we propose that a more reliable criterion is neuronal structure.

DEVELOPMENT

474 CONSTANCY OF SPATIAL PREFERENCES OF GRASSHOPPER MOVEMENT DETECTOR NEURONS DURING POST-EMBRYONIC EYE DEVELOPMENT. Tom Abrams* (SPON: J.S. Lockard). Dept. of Zoology, Univ. Washington, Seattle, WA 98195.

The eyes of grasshoppers grow during each instar by adding new ommatidia at their anterior margins. The number of ommatidia increases approximately from 2500 in the 1st instar to 9300 in the adult in Schistocerca americana. Because the field of view of each eye is relatively constant throughout development, the number of ommatidia viewing a given angle in space must increase with age. This was verified by measuring the angle between the optical axes of adjacent ommatidia (interommatidial angle) in particular regions of the retina at different developmental times. The interommatidial angle in the horizontal plane for ommatidia present at hatching was reduced from 5.0° in the 3rd instar to 3.4° in the adult. Any one size stimulus is viewed by 2.2 X more facets in the adult than in the 3rd instar.

The essential piece of information necessary for size discrimination by a visual system is the amount of retina stimulated by an object. If the processing in optic lobe is unchanged during development, then one consequence of the reduction in the area viewed by a given number of facets must be a shift in the size preferences of higher order visual neurons towards smaller stimuli than were optimal for the same cells in younger instars.

I have tested this prediction by determining the size preferences of the Movement Detector (MD) neurons in grasshoppers at various stages of development. The MD cells receive input in the 3rd optic ganglion from across the whole visual field. These neurons are optimally excited by small moving targets, and they selectively fail to respond to stimulation of large areas of the retina. Size preference data were obtained for identified regions of the eye in 2nd and 3rd instar and adult animals. The stimulus used was the motion of a horizontally oriented rectangular grating (11° period; 60°/sec motion). The grating was viewed by the insects through a square window of varying width.

In juveniles, response was maximal with a 5° wide window, and fell off steeply as window size was increased, reaching 1/2 max with between 10° and 15° windows. Response vs. size curves for the same regions of the eye in adults were similar. There was no evident shift of these curves to smaller window widths.

It is concluded that through development, the spatial tuning of the MD system is not simply a constant function of the number of ommatidia stimulated. Compensatory changes must occur to ensure that stimuli of the same size elicit similar responses in different age animals; these may involve a re-distribution in the optic lobe of the connections of those inhibitory interneurons which mediate the discrimination against larger stimuli.

475 A GOLGI STUDY OF THE DEVELOPMENT OF NEURONS IN THE PONTINE NUCLEI OF THE RAT. Catherine Adams*, John G. Parnavelas, Gregory Mihailoff and Donald J. Woodward (SPON: D. J. Woodward). Dept. Cell Biology, Univ. of Tx. Hea. Sci. Ctr., Dallas, TX 75235.

The development of neurons in the basilar pons of the rat was studied using the Rapid Golgi, Golgi-Cox, and Golgi-Kopsch techniques in female albino rats of ages 0, 2, 4, 6, 8, 10, 12, 14, 16, 18, 20, 24, 28 and 90 (young adult) days. This developmental study was undertaken as part of an ongoing effort to examine the development of the cortico-ponto-cerebellar projection and its involvement in visuo-motor processes.

In the adult, the preponderance of neurons are multipolar and exhibit a wide gradation in size and shape. Their dendrites branch extensively and at varying distances from the cell body. The proximal portions of the dendrites are usually smooth while the more distal portions give rise to appendages of varying morphology. A characteristic feature of many of these cells is the presence of conspicuous finger-like projections present at the terminal tips of the dendrites. The axons of these neurons arise from either the cell body or from the proximal portion of one of the dendrites and on rare occasions they give rise to collaterals. A scarce but distinctive type of cell observed in the basilar pons has a bipolar appearance with smooth, sparsely branched dendrites arising from the opposite poles of an elongated cell body.

At birth and for a few days thereafter, the perikarya of the pontine neurons are small and sometimes irregular in shape. Their dendrites are thin, short and beaded, and frequently display bulbous growth cones at the terminal tips. Growth cones are also present at dendritic branch points and along the course of the delicate axons. The cell perikarya are considerably larger at the end of the first postnatal week and continue to grow with time, as do the dendrites, which increase their branching and thickness and resemble those of mature neurons. At this stage a small number of thin appendages appear to arise from the dendrites and cell body surfaces, a feature quite different from the adult morphology. Dendrites continue to grow during the second postnatal week and at the end of this period they appear to achieve their mature arborization patterns. Dendritic thickness continues to increase during the third week and all neurons attain their mature morphological features by the end of the fourth postnatal week.

476 RESPONSE OF INFANT RAT BRAIN TO CHANGES IN PLASMA CONCENTRATION OF BICARBONATE. J.L. Allen*, C.D. Withrow* and C. E. Johanson* (SPON: S.A. Turkanis). Dept. of Pharmacology, Univ. of Utah College of Medicine, Salt Lake City, Utah 84132

There is a paucity of knowledge about acid-base regulation in the neonatal CNS. Recent evidence suggests regulation in the neonate may differ from that seen in the adult (Life Science 19:961, 1976); therefore it was of interest to carry out an ontogenetic study of the response of cerebrospinal fluid (CSF) and cerebral cortex (CC) to metabolic acid-base distortions.

Sprague-Dawley rats 1, 2 and 4 wks of age were bilaterally nephrectomized and injected i.p. with 0.3 mg NH_4Cl, 0.8 mg $NaHCO_3$ or 0.1 mg NaCl, per g body weight. For a given age and treatment, 7-9 animals were used. ^{14}C-DMO was used to indicate intracellular pH. After 2 hr rats were anesthetized with ketamine, arterial blood acid-base parameters were measured, and blood, cisternal CSF, and CC were sampled for analysis of radioactivity. CSF was analyzed for total CO_2.

Plasma HCO_3^- was 24 mM in 1-wk control rats, and 18 and 14 mM in 2-wk and adult animals, respectively. In control animals, blood pCO_2 was higher in 1- and 2-wk rats (57 and 47 torr, respectively) than in adult rats (29 torr). Blood pH was lowest (7.23) in 1-wk control rats and increased with age to 7.39 in adult animals.

Bicarbonate administration increased plasma HCO_3^- only 2 mM in 1-wk rats, and 9 and 13 mM in 2-wk and adult rats, respectively; the consequent metabolic alkalosis increased the CSF HCO_3^- 2 mM in 1-wk rats, and 4 and 2 mM in 2-wk and adult animals, respectively. Thus, although the blood-brain barrier to HCO_3^- is quite permeable in the 1-wk rat, some decrease in permeability is apparent at 2 wk. Metabolic acidosis caused greater changes in blood and CSF HCO_3^- in 1-wk rats than more mature animals.

CC intracellular pH was greater for control 1-wk rats (7.12) than for control adults (7.04). One and two weeks after birth there was regulation of cell pH in CC during both metabolic acidosis and alkalosis. This observation demonstrates substantial buffering capacity in cortical cells despite the leakiness of the blood-brain barrier to bicarbonate in young rats.

Elevated brain cell HCO_3^- has been noted (Am. J. Physiol. 206:521, 1964) in immature rats. This is in part related to the relatively high pCO_2 in the neonate. Despite the ability of HCO_3^- to enter the immature CNS, it appears that there is an adequate homeostasis of cellular pH in the brain in the face of wide fluctuations in plasma HCO_3^-. (Supported by NIH grants NS13988 and GM07579)

477 FETAL RAT BRAIN CATECHOLAMINE CONCENTRATIONS ARE INCREASED FOLLOWING MATERNAL TYROSINE INJECTIONS. Anthony Altar*, Mark F. Nelson*, Carla S. Whitacre*, Edwin Meyer, Jr.*, and Loy D. Lytle. Department of Psychology, University of California, Santa Barbara, CA 93106.

The biosynthesis of a variety of monoaminergic neurotransmitter compounds in adult rats depends to some extent on the relative availability of precursor compounds to brain or peripheral neurons. For example, dietary or pharmacological manipulations which increase the brain concentrations of L-tyrosine produce parallel increases in the rates of synthesis of the catecholaminergic neurotransmitters dopamine and norepinephrine [*C.J. Gibson and R.J. Wurtman, Biochem. Pharmacol. 26: 1137 (1977)*]. Similarly, injections of the essential amino acid L-tryptophan also produce dose- and time-related increases in the brain concentrations of the indoleaminergic neurotransmitter serotonin [*J.D. Fernstrom and R.J. Wurtman, Science 173: 149 (1971)*]. In the present set of experiments we were interested in determining the possible extent to which alterations in the availability of precursor amino acids might cause changes in the abilities of fetal animals to synthesize brain neurotransmitters.

To accomplish this goal, eighteen day post-conception pregnant albino rats were fasted overnight, and then injected subcutaneously with 0, 50, 100, or 200 mg/kg of L-tyrosine (10 ml/kg of 0.9% saline; pH 10.4). Animals were killed 30, 60, or 120 min post-injection and tyrosine concentrations were determined in the maternal plasma, placenta, and in bodies and brains of the fetuses using a fluorimetric assay. Dopamine and norepinephrine concentrations in fetal brain tissues were also measured using the radiometric-enzymatic assay of J.T. Coyle and D. Henry [*J. Neurochem. 21: 61 (1973)*]. Tyrosine concentrations were increased in a dose-related fashion in all tissues examined for up to 60 min post-injection, and returned toward vehicle control values by 120 min. Fetal brain concentrations of dopamine and norepinephrine were increased 30 min or 60 min, respectively, following the maternal tyrosine injections. These results indicate that the synthesis of some neurotransmitters in the brains of fetal animals may be regulated, at least in part, by the relative availability of precursor compounds. (Supported in part by a grant from NIMH).

478 THE FORM OF THE C.N.S ARBORIZATIONS OF SENSORY NEURONS IS GOVERNED BY THEIR EPIDERMIS OF ORIGIN. Hilary Anderson* and Jon Bacon* (SPON: K. Graubard). Dept. Zoology, Univ. Washington, Seattle, WA 98195 and Max-Planck-Institut für Verhaltensphysiologie, D-8131 Seewiesen, Germany.

The head of the locust, Schistocerca gregaria, bears a population of wind-sensitive hairs whose inputs are used for the initiation, maintenance, and control of flight. The hairs themselves are physiologically and morphologically indistinguishable, but hairs in different locations on the head form different neuronal projections within the c.n.s.: hairs on the side of the head send axons to the c.n.s via the ventral tegumentary nerve, and to a small extent the dorsal tegumentary nerve,and form entirely ipsilateral projections within the suboesophageal ganglion and thoracic ganglia; hairs on the top of the head send axons to the c.n.s. exclusively through the dorsal tegumentary nerve and form additional contralateral branches and arborizations in the suboesophageal ganglion and thoracic ganglia.

Are these patterns of projection determined by factors intrinsic to the sensory receptors themselves, or do they primarily depend upon later interactions between their axons and the environment through which they grow in the c.n.s.?

The hairs are formed throughout postembryonic life by the division and differentiation of single epidermal cells. We grafted pieces of epidermis between head locations at a stage when few wind-sensitive hairs had developed. We then examined the projections from hairs which subsequently developed from the grafts by cobalt-filling individual neurons and viewing them in wholemount preparations.

Hairs developing from the grafts were encircled by host hairs developing from the surrounding host epidermis. The graft axons now grew from the epidermis in association with the surrounding host axons and entered the c.n.s. at the host site via the host nerve. However, once the graft axons were in the c.n.s, in no case did they behave according to their altered environment. Rather they all formed projections which were entirely appropriate to their epidermis of origin.

We conclude that receptor cells are assigned, on the basis of early decisions taken by their epidermal cell precursors, an intrinsic developmental programme which specifies their projection patterns.

479 EFFECT OF ENVIRONMENT OF ACH SENSITIVITY OF DEVELOPING NODOSE NEURONS IN VITRO. Paola Baccaglini and Ellis Cooper. Dept. Neurobiol., Harvard Med. Sch., Boston, MA 02115.

Cholinergic synapses form between dissociated neurons from newborn rat nodose ganglia when grown in culture. The formation of these functional synapses as well as the presence of acetylcholine (ACh) receptors depends on the environmental conditions in which these cells are grown. Nodose ganglia (an autonomic sensory ganglion) were dissected from the neck region of newborn rats and mechanically dissociated. All neurons were grown in the presence of NGF; by 24 hrs they attached to the substrate and extended processes. We plated the neurons under 2 different conditions (1) on collagen and in the virtual absence of non-neuronal cells (2) on a preformed layer of skeletal myotubes or myocytes. We recorded from these neurons as early as 10 days after plating. In condition (1) many neurons had spontaneous excitatory postsynaptic potentials (epsps). In addition, in about 20% of randomly chosen neuron pairs in some cultures stimulation of one neuron evoked an epsp in the other. Both spontaneous and evoked epsp's were reversibly blocked by standard cholinergic antagonists indicating that the synapses are cholinergic. In contrast spontaneous or evoked epsp were much rarer events in sister cultures grown in condition (2); they were detected in less than 5% of pairs tested.

One factor that accounts for the failure of at least some neuron-pairs to form cholinergic synapses is the absence of cholinergic receptors. We tested neuronal sensitivity to acetylcholine (ACh) primarily by pressure ejection (similar results were obtained by either bath or iontophoretic application). For each culture dish, which usually contained approximately 500 neurons, we routinely tested 50 neurons chosen at random and scored each one as either sensitive or insensitive. With the concentrations of ACh used a sensitive neuron was one which depolarized by at least 5mV, although most neurons gave responses of 20-40mV; insensitive neurons gave no detectable response (less than 2mV). In experiments where sister cultures were grown either alone or on muscle, 70-90% (n = 130) of neurons grown alone and fed every 2 days were sensitive to ACh whereas only 20-30% (n = 250) of the neurons grown on muscle and fed every 4 days were sensitive. Feeding the 'neurons - alone' cultures every 4 days does not give as many sensitive neurons (50-70%, n = 500) compared to those fed every 2 days, however, the proportions are still significantly different from sister cultures grown on muscle.

We are investigating what factors may be involved in the expression of ACh receptors as well as the pharmacology of these receptors and whether the neurons are sensitive to other transmitter substances. (Supported by the Whitney Foundation, Muscular Dystrophy Association and American Heart Association 78364).

480 ENDURING MORPHOLOGICAL ALTERATION OF HIPPOCAMPUS AND CEREBELLUM IN RATS PRENATALLY-EXPOSED TO ETHANOL. David E. Barnes, Don W. Walker and Steven F. Zornetzer. Dept. of Neuroscience, Univ. of Florida College of Medicine and VA Medical Center, Gainesville, FL 32610.

Pregnant Long-Evans rats were maintained on an ethanol containing liquid diet (40% ethanol-derived calories; 9.7% v/v ethanol) during days 10-21 of gestation. Control groups were pair-fed a sucrose-containing liquid diet with sucrose substituted isocalorically for ethanol or given free access to pelleted laboratory food and water. At parturition, the offspring were culled to 8 males and fostered to additional control mothers. Offspring from the three groups were sacrificed at the time of weaning or 60 days of age. The brains were removed and coded to prevent experimenter bias and hemisected by a midsagittal cut. One half of each brain was embedded in paraffin, sectioned at 4 μm, and stained with cresyl violet. In midsagittal sections the total number of cerebellar Purkinje cells was determined as well as the granule cell population of lobule VIII (pyramis). The number of hippocampal pyramidal cells was determined in sagittal sections 1.5 mm from midline. The ethanol-exposed offspring were not significantly different from controls at birth or 21 days in body or brain weights. At sixty days of age there were large deficits in prenatally-formed neurons in the group prenatally-exposed to ethanol relative to controls. There was a 18% decrease in hippocampal pyramidal cells and a 27% decrease in cerebellar Purkinje cells. In addition, there was a decrease of cerebellar granule cells (9%) which may be a result of the loss of Purkinje cells rather than the exposure to ethanol per se. The results indicate that prenatal ethanol exposure results in an apparently permanent reduction in the number of prenatally-formed hippocampal and cerebellar neurons

(Supported by the Veterans Administration and Grant AA-00200.)

481 A POSTERIOR TO ANTERIOR GRADIENT IN VARIABILITY OF THE STRUCTURES OF TWO IDENTIFIED NEURONS IN CRAYFISH. Michael Bastiani and Brian Mulloney. Depts. of Physiology and Zoology, University of California at Davis, Davis, CA 95616.

The crayfish muscle receptor organs (MROs) monitor the position and movement of the abdomen. A pair of receptors, tonic (MRO_1) and phasic (MRO_2) is associated with each abdominal hemiganglion. The sensory neurons, SN_1 and SN_2 respectively, from these MRDs send axons via the second root into the segmental ganglia; these axons bifurcate and project to the brain and 6th abdominal ganglion.

The anatomy of the sensory neurons which originate in abdominal ganglia one through five was examined in the 6th abdominal ganglion. Microelectrode injection of Lucifer Yellow (Stewart, 1978) into neuropil processes of the SNs was used to determine their structures. Although all the SNs have a characteristic structure, those originating from the more anterior ganglia are much more variable and consistently make what appear to be errors.

Three types of errors commonly occur. The first is inappropriate termination, where the primary branch does not terminate as usual but continues part way back up the connective or into the 6th ganglion and ends in a large bleb. The second is unusual branching patterns. The third, which generally occurs along with the first two, is large (> 5μ) terminal blebs.

The physiology and connectivity of the SNs in the 6th abdominal ganglion has been examined by stimulating selectively SNs from all the abdominal ganglia while recording PSPs in a large number of motor neurons and interneurons. Although there is a very interesting anterior to posterior gradient in synaptic strength, there does not appear to be a correlation between the variability in the structure of the more anterior SNs and missing synapses.

Several hypotheses might account for this posterior to anterior gradient in structural variability. The SNs from the more posterior ganglia are closer to the 6th ganglion and their axons may reach the 6th ganglion earlier in development. This hypothesis predicts that the variability in the anatomy of an identified neuron will be related to its birthday or to the time the synapse forms.

Another hypothesis is that as axons get further from the cell body, there is some loss of control of structural growth. We are now trying to test these two hypotheses.

Supported by US PHS grant NS 12295 and NSF grant BNS 78-10516. We thank Walter Stewart for the gift of Lucifer Yellow.

482 DIFFERENTIAL EFFECTS OF D-AMPHETAMINE ON LOCOMOTOR ACTIVITY IN IMMATURE AND MATURE RATS. Richard H. Bauer, Department of Psychology, Kansas State University, Manhattan, KS. 66506.

In altrical species, such as the rat, biochemical and histochemical studies indicate that catecholamine containing neuronal cell bodies in the lower brain stem are nearly fully developed at birth. During development, axons from these norepinephrine (NE) and dopamine (DA) containing cell bodies grow in a rostral direction, such that successively higher structures are innervated. In the rat, innervation of cortical areas occurs at about 45 days of age.

Since ascending catecholamine neurons in the rat are developing from birth to about 45 days of age, drugs which alter behavior by acting on catecholamines would be expected to have different behavioral effects at different maturational stages. d-Amphetamine is thought to alter locomotor activity and induce stereotyped behaviors by presynaptically increasing the release and reducing the reuptake of NE and DA. Thus, d-amphetamine would be expected to have differential effects on locomotor activity of immature and mature rats. This hypothesis was tested in the present study by recording photo-cell crossings of 15-, 17-, 21-, 36-, 90-, and 275-day-old rats injected with either physiological saline or 0.5, 1.0, 4.0, 8.0, or 16.0 mg/kg of d-amphetamine sulfate. Photo-cell crossings were recorded starting immediately after the injection for a period of 4 hours. The two oldest groups were tested in a 45 x 45 x 45 cm Plexiglas chamber. All apparatus dimensions for younger groups were reduced according to the mean snout to rump length.

For each animal, the number of photo-cell crossing during 15-min intervals was determined. Statistical analyses showed that only the 0.5 mg/kg dose resulted in a slight increase in photo-cell crossings in the two youngest groups. In 21 and 36-day-old rats, there was a positive relationship between drug dose and photo-cell crossings. In the two oldest groups, lower doses increased photo-cell crossings, whereas higher doses reduced crossings. The temporal changes occurring during the 4-hour session also differed as a function of development.

In a second experiment, para-hydroxyamphetamine, which has only peripheral nervous system effects, did not alter photo-cell crossings of immature or mature rats.

The present findings are consistent with the hypothesis that, because of differences in maturation of catecholamine neurons, catecholaminergic drugs would produce differential behavioral effects in immature and mature rats.

483 TEMPERATURE DEPENDENCE OF EARLY INGESTIVE BEHAVIOR: PERCEIVED ENVIRONMENTAL TEMPERATURE VS. BODY TEMPERATURE. Ingrid J. Bennett and W. G. Hall. N.C. Div. of Mental Health, Raleigh, N.C. 27611.

When a food deprived neonatal rat receives a small infusion of milk in its mouth via an intraoral cannula, it ingests a substantial amount of the diet and also shows a dramatic behavioral activation. The feeding and activation only occur when the pup is maintained in a warm environment (Hall, 1978, in press). The present study determined whether body temperature or perceived ambient temperature was the basis for the temperature dependence of early ingestive responding.

Fine polyethylene intraoral cannulas, through which diet could be infused, were implanted in the mouths of six-day-old Charles River CD strain rats. Prior to testing, the body temperature of one pair of pups was adjusted to 33-34°C (for Warm Temperature pairs), while the temperature of another pair was adjusted to 28-29°C (for Cool Temperature pairs). One of the pups in each pair was tested at room temperature (26°C) and the other was tested in a warm (34°C) incubator. A pulse of milk was infused into the pup's mouth through the cannula once a minute for 3 min. Every 30 sec, the pup's activity was rated and a variety of behaviors, including probing and mouthing, were scored. Intake was determined by measuring the change in body weight from the beginning to the end of the test. Warm pups (n = 7 pairs) tested in a warm environment had significantly higher levels of activity, mouthing, probing and intake than warm pups tested in a cool environment. Similarly, cool pups (n = 7 pairs) tested in a warm environment were more active, showed more mouthing and probing, and ingested more diet than cool pups tested in a cool environment (see Table). These findings indicate a significant effect of perceived ambient temperature on the activation and feeding responses of infant rats

However, pup body temperature also had a significant effect, since warm pups tested in a warm environment were more active and ingested more diet than cool pups tested in a warm environment (see Table). Together, these results indicate that the effect of infused diet on the behavioral activation and intake of a deprived pup depends on both contextual cues (e.g. ambient temperature) and physiological conditions (e.g. body temperature).

	Warm Envt. Temp.		Cool Envt. Temp.	
	Warm Body Temp.	Cool Body Temp.	Warm Body Temp.	Cool Body Temp.
Intake (% of infused vol.)	93 ± 7	62 ± 9	56 ± 14	38 ± 7
Activity	11.1 ± .6	8.0 ± .9	6.4 ± .8	4.3 ± .8

484 CELL DEATH IN THE DEVELOPING HAMSTER SUPERIOR COLLICULUS Anne T. Berg* and Barbara L. Finlay Department of Psychology Cornell University, Ithaca, NY 14853

Degenerating cells may be observed with light microscopy in the superior colliculus of the golden hamster during the first nine postnatal days. The number of degenerating cells observable at any point is small. In the period of maximum rate of cell death, postnatal days 3-5, 4-5 degenerating cells can be found per 1000 normal cells; by day 8, only 1-2 degenerating cells per 1000 are visible. As in chick (1) and rat (2), this period of cell death follows neuronal differentiation in the tectum and is coincident with the major period of axon ingrowth and outgrowth.

Within the tectum, the distribution of degenerating cells is fairly uniform. The rate and time course of cell death in tectum may be distinguished from the rate and time course in surrounding structures and other visual structures.

485 BIOLOGICAL CHARACTERIZATION OF A NEW NEURONAL GROWTH FACTOR. Emanuel M. Bloom, Michael D. Coughlin and Ira B. Black. Dept. of Neurol., Cornell Univ. Med. Col, New York, N.Y. 10021.

A new neuronal growth factor(s), derived from medium conditioned by mouse heart monolayer cultures, enhances survival and stimulates development of mammalian autonomic neurons. The factor caused a 2-3 fold increase in neurite outgrowth and tyrosine hydroxylase activity of embryonic mouse superior cervical ganglia (SCG), cultured without added nerve growth factor (NGF). Dose-response analysis revealed that these responses occurred as a saturable function of factor concentration. In addition, choline acetyltransferase activity was also increased in the cultured SCG by the factor.

Antiserum to NGF did not inhibit growth responses to the new factor, suggesting that it was separate and distinct from NGF. Moreover, the new factor enhanced survival of parasympathetic and sympathetic neurons in cell culture, but not sensory neurons, clearly distinguishing the factor from NGF. These results suggest that heart cells in culture are capable of elaborating a new growth factor which fosters survival and differentiation of sympathetic and parasympathetic neurons.

486 GANGLION CELL AXONS MAINTAIN THEIR NEIGHBORS IN THE SELF ASSEMBLY OF THE EMBRYONIC OPTIC NERVE. Neil Bodick* and Cyrus Levinthal. (Spon Malvin Teich) Dept. Bio. Sci., Columbia University, New York, New York, 10027.

Morphological analysis of a developing visual system has been undertaken at the EM level in an attempt to elucidate cellular interactions operative in the formation of the retino-tectal projection. At maturity, the zebrafish (Brachydanio rerio) projects approximately 50,000 fibers from each eye to the contralateral optic tectum. Staged embryos, with relatively few (about 1800) fibers leaving the eye provide the opportunity to examine cells forming the connection to the tectum. Developing cells in the visual system have been reconstructed from serial section electron micrographs using the CARTOS computer graphics system. In the retina, small clusters of adjacent ganglion cell somata spin out axons which, over long distance in the optic nerve, maintain their contiguity. Growth cones of these cells confine their activity to neighboring axonal surfaces.

The retinal surface maps in a systematic fashion into the cross section of the optic nerve. Cell soma position in the retina can be defined by polar coordinates (r,θ), with the choroid fissure at $\theta=0$ and $r=0$ at the nerve head. In the optic nerve, radial position transforms into the Dorso-ventral axis, while angular position transforms into the nasal-temporal axis.

The present study suggests that the optic nerve develops as a highly ordered structure capable of carrying the projection back to the tectum as an organized array of fibers. Such organization is mediated by interactions between and among growing ganglion cell axons which originate from cell bodies which are adjacent to each other in the retina. Details of the ultra-structural interactions will also be discussed.

These studies were supported by NIH grant PCM 78-06636 and Computer Graphics Facility NIH grant 5 P 41 RR-00442-10.

487 PROLIFERATION OF GRANULE CELL PRECURSORS IN RAT HIPPOCAMPUS IS INHIBITED BY HYDROCORTISONE TREATMENT: AN AUTORADIOGRAPHIC STUDY. Martha C. Bohn* (SPON: Kent Morest).Dept. Biobehavioral Sciences, Univ. of Connecticut, Storrs, CT. 06268.

Postnatal genesis of microneurons in the rat brain occurs in both the cerebellum and hippocampus(HP). Neonatal treatment of rats with glucocorticoids has previously been reported to inhibit cell proliferation in neuronal precursor cells in the cerebellum resulting in a permanent deficit in cell number and cerebellar size (Bohn,M.C.and Lauder,J.M.,Develop.Neurosc. 1,250,1978; Cotterrell et al.,J.Neurochem.19,2151,1972).The present study investigated the possibility that postnatal neurogenesis in the HP might also be affected by glucocorticoid treatment.

Rat pups were injected with hydrocortisone acetate(HCA) on days 1-4(200µg/day), sacrificed by perfusion fixation and the brains embedded in paraffin.

For short-survival autoradiography, rats were sacrificed during the first two weeks after birth; each was injected with ^{3}H-thymidine (^{3}H-T)one hour before sacrifice and serial sections of the HP prepared for autoradiography.The total number of cells labeled by ^{3}H-T throughout the dentate hilus and stratum granulosum (sG) was decreased during HCA treatment and recovered to control values during the second week.Decreased labeling was already evident on day 2 in the ventral HP,but was not apparent until day 4 in the dorsal HP.It was concluded that proliferation of granule cell(GC)precursors was transiently inhibited by HCA treatment.

The effect of this inhibition on "birthdays" of GC was investigated by long-survival autoradiography by injecting with ^{3}H-T at various ages and sacrificing at 72 days.The time courses of GC birthdays at ventral and dorsal levels of the sG were determined by plotting the ratio of heavily labeled GC/total GC versus age. Dorsally, the time course for GC birthdays was unaffected. Ventrally, GC birthdays were significantly depressed on day 5 probably reflecting the prolonged inhibition of cell proliferation in this region. This fall was in marked contrast to GC genesis in controls which was maximal on day 5 and resulted in a late peak in GC birthdays at the ventral level in treated rats.

Integrated area measurements in serial sections showed that the total volume of the sG was reduced by 20% in treated rats at 7 days,but was control size at 60 days.Therefore,even though cell proliferation was reduced during the first postnatal week when most GC were formed in controls,this did not result in a permanent reduction in the size of the sG.

These observations of decreased cell proliferation and delay in the peak of GC birthdays during HCA treatment indicate that the rate and pattern of postnatal neurogenesis in the rat HP are altered by glucocorticoid treatment.

488 DEVELOPMENT OF THE TROCHLEAR NERVE FOLLOWING COMPLETE REMOVAL OF THE PERIPHERY. William R. Boydston* and G. S. Sohal (SPON: S. D. Stoney). Dept. Anat., Sch. Med., Medical College of Georgia, Augusta GA 30912.

The aim of the present investigation was to study the development of the trochlear nerve with respect to sprouting in the complete absence of the superior oblique muscle in the white Peking duck embryo. The temporal coincidence between the onset of collateral sprouting in the developing trochlear nerve and the time at which neuromuscular contacts are established had previously suggested that sprouting may be triggered by the periphery. Unilateral optic vesicles along with the surrounding mesoderm were removed on Day 5 of incubation. To ensure complete removal of the periphery, an electric cautery was used to cauterize the extirpation site following removal of the optic vesicle. Embryos were sacrificed daily beginning on Day 11 and continuing through Day 18. Upon sacrifice, experimental and control nerves were fixed for electron microscopy with brains processed for routine paraffin histology. Axon counts were obtained from montages of the nerve while cell counts of the experimental and control trochlear nuclei were done by counting nucleoli in alternate sections. The preliminary results of this investigation based on limited samples indicate that sprouting is essentially absent in the peripherally deprived trochlear nerve. The average axon count on Day 12 of the experimental nerve yields 1639 fibers with an average cell count in the control trochlear nucleus of 1513 neurons. This presents a cell to fiber ratio of approximately 1:1 on this day. This ratio is observed to remain constant through Day 14 (1442 cells, 1827 axons). Subsequently, large numbers of cells and fibers are lost until Day 18 when the experimental nerve and contralateral nucleus are essentially absent. In contrast, cell and axon counts of the control nerves on Day 12 indicate that the trochlear fibers have sprouted. The cell to fiber ratio on this day is 1:4. The ratio is eventually reduced to 1:1 by Day 18 as a result of a loss of cells and fibers between Days 13 and 17. Whether the lack of sprouting in peripherally deprived nerve is due to lack of neuromuscular contacts or the absence of a trophic factor provided to the nerves by the muscle remains to be investigated.

489 THE EMBRYOLOGIC APPEARANCE AND DISAPPEARANCE OF A LITTLE KNOWN TELENCEPHALIC NERVE IN THE BAT. Jerry William Brown. Dept. Anat., Med. Cent., Univ. Ala. in Birmingham, Birmingham, Ala. 35294

Within the few years spanning the turn of the century a ganglionated telencephalic nerve was described by Pinkus and named the nervus terminalis by Locy. In the early decades of this century numerous investigators described this nerve in representatives of all classes of vertebrates; however, in recent years it has received only casual mention. During a study of the development of the telencephalon of insectivorous bats ranging from 6 to 19 mm (near term) C-R length, the ganglionated nervus terminalis was noted to appear first in the 7 mm embryos. As the embryo grows there is a progressive enlargement of the nerve and an increase in the number of associated ganglion cells, reaching the largest size and cell number in embryos of 12 to 12.5 mm C-R length. In the 13 mm embryo the nerve is smaller and fewer ganglion cells are present, some showing degenerative changes. In all embryos older than that of 13 mm the nerve and ganglion cells are absent as in the adult. The origin of these ganglion cells, a matter of some dispute, is clearly a thickened region of the epithelium of the nasal septum of insectivorous bats. Clusters of these cells break away from the epithelium and migrate centrally towards the medial wall of the telencephalon. Even the few intrahemispheric ganglion cells associated with fascicles of the nervus terminalis are most likely of peripheral origin. Between 7 mm, when they first appear, and 12.5 mm, when only one small cluster arises from the epithelium, the cell clusters gradually increase in number, reaching a maximum in the 10.5 mm embryos and then decrease in number. No cells arise from the nasal septal epithelium in embryos of 13 mm and longer. Centrally the nervus terminalis penetrates the brain wall in the region of basal forebrain structures having secondary and tertiary olfactory connections. Evidence will be presented which suggests the functional type of the neurons of the nervus terminalis in insectivorous bats.

490 CHANGES IN BRAIN MORPHOLOGY DUE TO THE EFFECTS OF MALNUTRITION. MB.T. Buschmann, E.M. Burns, L.E. Comerford*, T.W. Kruckeberg*, P.K. Gaetano*and J.M. Meyer*. Dept. Gen. Nurs., College of Nursing, University of Illinois at the Medical Center, Chicago, IL 60612

The effects of protein-calorie malnutrition on the brain is one of the major problems of our time. Malnutrition in animals during early life has been found to cause anomalies in the development of neuronal synapses, reduction in brain size, loss of neuronal cells and other abnormalities. Children who have endured severe malnutrition in early life manifest varying degrees of retarded learning ability. Because of the critical involvement of the dendrites and the synapses in neurological functioning and because of the impaired learning ability noted in severely malnourished children, synaptic morphology was investigated in malnourished and well nourished animals. Further, because of the important regulatory role of the cerebral capillary in the maintenance of an optimal microenvironment of brain cells, the ultrastructure of cerebral capillaries was also studied in these animals.

The purpose of this study therefore was to determine the effect of protein malnutrition on the morphology of brain structures. Dams of the experimental animals were fed isocaloric diets containing either 25% casein (well nourished) or 8% casein (malnourished) for two weeks prior to mating and throughout gestation and laction. Diet regimes were continued after weaning in the young and subsequently the male and female offspring were sacrificed at 35, 100, and 300 days after birth and the brains were fixed for electron microscopy.

Examination of whole brain weight showed a significant decrease in the malnourished animals. Concomitant with the decreased weight was a decrement in synaptic morphology as well as a significant decrease in the number of endothelial mitochondria per cerebral capillary profile. The latter of these implies decreased energy for active transport across the blood-brain barrier.

The results of these studies provide both qualitative and quantitative morphological evidence of a loss of function in the brain due to protein malnutrition. Decreased brain size, loss of mitochondria in the capillary endothelium and altered synaptic structure suggest a functional impairment at the cellular level.

491 THE EFFECTS OF AMPHETAMINE ON ACETYLCHOLINE LEVELS AND SYNTHESIS IN VARIOUS REGIONS OF THE DEVELOPING KITTEN. S.H. Butcher, M.S. Levine, N. Buchwald and C.D. Hull. Mental Retardation Research Center, School of Medicine, UCLA, Los Angeles, CA. 90024.

The development of acetylcholine (ACh) levels and synthesis in the precruciate cortex, caudate nucleus and thalamus of the kitten were measured using stable isotope techniques and a gas chromatographic/mass spectrometric method developed by Jenden et al. (Anal. Biochem. 55: 438, 1973). Kittens were sacrificed using microwave irradiation following a pulsed i.v. injection of deuterium labeled choline ($^2H_9$-Ch). Within the first 24 hrs after birth endogenous levels of ACh were significantly increased when compared to the levels found on the 2nd postnatal day. Since many neuronal input connections are present at birth, this change from the first to second postnatal day may represent a reflection of increases in spontaneous neural activity during this time. The concentration of deuterium labeled ACh ($^2H_9$-ACh) reached adult levels by 40 days postpartum but the concentration of endogenous ACh had not yet attained adult levels within this 40 day period. In order to study the effect of an increased release of endogenous Dopamine (DA) on the developing cholinergic system, kittens were pretreated with amphetamine (5 mg/kg i.p. 30 min prior to sacrifice). Pretreatment with amphetamine produced an increase in the concentration of deuterium-labelled ACh while having no effect on endogenous levels of ACh at any of the early time points measured (5,8,15 and 20 days postpartum). However, on day 40, the synthesis of $^2H_9$-ACh was significantly reduced compared to control levels in all three brain regions studied, while the levels of ACh remained unchanged in the caudate nucleus and thalamus. This latter response is more characteristic of that found in the adult rat (unpublished data). It is possible that this apparent decrease in synthesis is a result of the reduced precursor availability due to the effect of amphetamine on blood flow to these brain regions, or that the newly synthesized $^2H_9$-ACh is being preferentially released.

492 CENTRAL PROJECTIONS OF ANTENNAL SENSORY NEURONS IN MATURE AND DEVELOPING *MANDUCA SEXTA*. Scott M. Camazine* and John G. Hildebrand. Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115.

As a prelude to studies of the organization, physiology, and development of the antennal centers in the brain of the moth *Manduca sexta*, we have examined the normal anatomy of antennal afferents by intracellular staining with cobalt sulfide followed by Timm's intensification of whole-mount or sectioned material.

Axons in the flagellar component of the antennal nerve (largely olfactory) project to the glomeruli of the ipsilateral antennal lobe (AL), to the ipsilateral "dorsal lobe" (DL), and to the ipsi- and contralateral sides of the subesophageal ganglion. Males exhibit a distinct flagellar projection to a macroglomerular complex that is found only in the male AL. This is the only sexual dimorphism that we have observed in the CNS. Cobalt-sulfide staining reveals no neural connections to the AL from the contralateral antenna, the ventral nerve cord, or the nerves of the subesophageal ganglion. Mechanosensory fibers from the Böhm's bristles on the basal segments of the antenna (pedicel and scape) project through and ramify in the DL and terminate in the thoracic ganglia. The projections of these axons are similar to those of the tegumentary nerve fibers, which originate at mechanosensory sensilla on the head. Johnston's Organ, a proprioceptive organ in the pedicel, sends mechanosensory axons to the lateral region of the DL in a distinctive pattern. These fibers terminate in the DL in close proximity to the dendritic arborizations of the antennal motor neurons (of which there are at least 13). This observation suggests that there may be synaptic connections between proprioceptive afferent axons and motor neurons, constituting an antennal-motor reflex pathway.

It thus appears that several classes of mechanoreceptive inputs from the antenna and the sensilla of the head project to the DL, while flagellar chemoreceptive inputs project to the glomeruli of the AL. Other antennal afferents whose sensillar origin and functions have not yet been ascertained terminate in a neuropil region between the DL and the AL and in the protocerebrum.

All of these classes of antennal afferent fibers have reached the CNS of developing adults as early as 2 days after the birth of the flagellar sensory neurons. Over the ensuing 10 days, the density of projections increases dramatically. These findings extend our earlier observation that sensory neurons throughout the antenna are born synchronously and immediately begin to elaborate axons (Devel. Biol. *51* 300, 1976).

493 EFFECT OF LEAD EXPOSURE ON DEVELOPMENT OF HIPPOCAMPAL MOSSY FIBER SYNAPSES. Jerrolynn B. Campbell*, Vijaya K. Vijayan and Dorothy E. Woolley*. Depts. Human Anatomy and Animal Physiology, Univ. Calif., Davis, CA 95616

Postnatal exposure to lead has been shown to mimic traumatic damage to the hippocampal formation and to reduce the normally high levels of zinc in the hippocampal mossy fiber layer. At subclinical exposure levels, thermoregulatory and learning abilities are retarded, and seizure patterns in young animals exposed to maximal electroshock stimulation are altered. In order to correlate patterns of structural development of the hippocampal mossy fiber synapses with the physiologic and biochemical alterations observed following lead exposure, our laboratory has initiated a quantitative morphological study of the suprapyramidal mossy fiber layer in the hippocampal CA3 region of the rat. To minimize variations of development caused by factors other than exposure to lead, all litters were reduced at parturition to 6 pups, and a litter size of 4-6 was maintained throughout the experiment. Following parturition, 0.2% lead acetate was added to the drinking water of the dam. After fixation by intraaortic perfusion of aldehydes, slices from the center of the dorsal hippocampus were processed for quantitative electron microscopic evaluation. Random, non-overlapping fields throughout the suprapyramidal mossy fiber layer were photographed at a magnification of 4,800. A total of 1500 to 3000 u^2 of neuropil area was analyzed from each animal for number, size and structure of synaptic profiles. The typical mature mossy fiber ending appears as the Gray type I ending, with dendritic spines that are deeply embedded in invaginations of the pre-synaptic element. They exhibit dense populations of synaptic vesicles and multiple synaptic contacts, as well as punctata adherens. Gray type II profiles, which display dense vesicle populations and punctata adherens, but lack the deeply embedded dendritic spines, probably also represent mossy fiber endings in which the point of synaptic contact was excluded from the plane of section. The type II endings are interspersed with large bag-like endings and smaller endings with simple or multiple synaptic contacts. The bag-like endings are characteristic of young animals and seem to represent immature forms of the mossy fiber endings, while small, simple endings may be mossy fibers synapsing en passage, or may represent afferents of non-mossy fiber origin. Our initial results indicate that the ratio of type I (mature mossy fiber) endings to other synaptic profiles is directly proportional to the weight of age-matched animals. While there is considerable variation within treatment groups, there is also an average reduction in the number of type I endings per unit area neuropil in lead exposed animals regardless of weight.

494 RETROGRADE TRANSPORT OF NERVE GROWTH FACTOR IN CULTURED RAT SYMPATHETIC NEURONS. Robert B. Campenot*, Edward Hawrot* and Paul H. Patterson. Dept. of Neurobiology, Harvard Medical School, Boston MA 02115.

Nerve growth factor (NGF) is essential for the survival of sympathetic neurons in vivo and in culture. The retrograde transport of NGF to the sympathetic ganglia has been demonstrated in vivo (Hendry et al., Br. Res. 1974). We have begun an examination of the retrograde transport of NGF in rat sympathetic neurons maintained in a 3-chamber culture dish devised by Campenot (PNAS, 1977). Neurons send their axons across a fluid-impermeable seal into 2 separate chambers located on either side of the cell bodies. It is quite common for a single neuron to have axons extending into both chambers. Upon incubating endings in one chamber with ^{125}I-NGF, radioactivity appears in the cell bodies at a time consistent with an axoplasmic transport rate of ~ 3 mm/hr. An apparent steady state was reached in ~10 hrs and was maintained for at least 34 hrs continued incubation. The cell body-associated radioactivity is not due to leakage of ^{125}I-NGF across the seal and direct uptake by the cell bodies since incubating the cell body chamber with excess unlabeled NGF has no effect on the appearance of ^{125}I-NGF in the cell bodies. On the other hand, incubation of nerve endings with ^{125}I-NGF in the presence of excess unlabeled NGF reduces the amount of retrogradely transported radioactivity by >90%. Furthermore, transport is largely inhibited by 20 µg/ml colchicine. SDS gel electrophoresis indicates that the cell body-associated radioactivity migrates as one band with the appropriate molecular weight of NGF. Thus, these findings with isolated neurons in culture confirm the results obtained in vivo. Although ^{125}I-NGF was transported retrogradely to the cell bodies, none of this radioactivity migrated further from the cell bodies in the orthograde direction into endings located in the opposite chamber. This is consistent with the observed local effects of NGF and the transport of NGF into spinal ganglia of the chick embryo (Brunso-Bechtold and Hamburger, PNAS, 1979).

Cultured sympathetic neurons are able to transport ^{125}I-NGF when exposed to concentrations as low as 0.5 ng/ml (2×10^{-11}M) suggesting the existence of a high affinity uptake mechanism in the nerve endings. Retrograde transport appears to be regulated by the external NGF concentration. Neurons starved of NGF for 24 hrs showed a 5-fold increase in the amount of ^{125}I-NGF retrogradely transported. Binding studies performed on dissociated neuronal cultures suggest that this regulation is not at the level of the surface receptor as detected by the low temperature specific binding of ^{125}I-NGF.

495 AN ULTRASTRUCTURAL MORPHOMETRIC ANALYSIS OF THE ORGANIZATION OF THE DEVELOPING OPTIC NERVE OF XENOPUS LAEVIS. Charles Cima* (Spon: G. Hoyle). University of Oregon, Eugene, OR 97403.

A fine structural analysis of the developing optic nerve (ON) of Xenopus laevis was undertaken to determine if and how axons become organized. During early development of the ON there is a lineal addition of small size class axons (0.15-0.75um) from st. 28, when fibers first appear in the optic stalk, through st. 43-44. At this stage a large size class axon (1.0-4.5um) appears in the ON, which consists entirely of unmyelinated axons. At st. 47, the first myelinated axons (less than 100) are found in the ON. This is preceded by the first appearance of glial cells in the central portion of the ON. Myelination seems to begin in the middle of the ON and extend distally and proximally. Myelination is first apparent in the optic chiasma (OC) at st. 50 and the pigmented epithelium (PE) of the retina by st. 52. Myelinated fibers are not seen in the retinal portion of the ON until after metamorphosis. Myelinated axon distribution was analysed at the level of the retina, at the point of exit from the PE, at the midpoint and at the OC. Results show that the number of myelinated axons at the midpoint OC exit from PE retina. Further, this distribution remains constant from st. 47 through 3 months post-metamorphosis (PM). Assymetrical distribution has also been observed in large size class axons throughout the length of the ON during development. Large size class axons (myelinated and unmyelinated) are homogeneously distributed in the portion of the ON found in the retina. At the midpoint of the ON, between the retina and OC, there is a skewing of large size axons to the central portion of the ON. There is further reorganization at the OC which results in accumulation of large size axons dorsally and slightly rostrally. This organization is apparent at st. 44 and remains constant until at least 8 months PM.

The dorsal skewing of large size class axons is the first detectable event in the central pathway which seems to segregate visual fibers. The significance of this fiber shift in ordering connections in visual centers is not known. Several lines of physiological evidence however, suggest that visual centers in the diencephalon may be selectively innervated by large ganglion cells with dendritic arborizations which subtend 10°-15° of the visual field.

496 TECTAL CONNECTIVITY IN THE FROG FOLLOWING EMBRYONIC REMOVAL OF EYE PRIMORDIA. Martha Constantine-Paton and Patricia Ferrari-Eastman. Dept. Biol., Princeton Univ., Princeton, NJ 08544.

In order to determine the degree to which central visual circuitry is dependent upon retinal input we have raised Rana pipiens tadpoles through metamorphosis after either bilateral or unilateral removal of the eye primordia. The operation is performed at Shumway stage 17 before optic nerve axons have entered the brain.

Bilateral eye removals result in a ~70% decrease in post-metamorphic tectal volumes compared to unoperated controls. Tectal layers 1 through 6 remain distinct in these developmentally uninnervated tecta, but layers 7 through 9 are condensed. Volume and lamination changes are qualitatively similar but less pronounced in the contralateral tectum after unilateral eye primordia removals.

The nuclei projecting to these tecta have been identified in post-metamorphic animals using HRP histochemistry. A control analysis on normal animals agrees with those of previous authors (Wilczynski and Northcutt, 1977, JCN 173:219-229) in most respects. After bilateral eye primordia removal small pellets of HRP placed beneath the dorsal tectal surface label all ipsilateral nuclei that project to that region in normal animals. Contralaterally, cell groups in the diencephalon and mesencephalic tegmentum continue to project to these developmentally uninnervated tecta. However, the projection from the contralateral nucleus isthmi (Gruberg and Udin, 1978, JCN 179:487-500; Grobstein et al, 1978, Brain Res. 156:117-123) is absent in all bilateral removals examined. HRP application to the uninnervated tectal lobe in animals with unilateral removals successfully labels cells in both isthmic nuclei.

Axons in the crossed isthmio-tectal tract usually decussate as part of the post-optic commissural system (Gruberg and Udin, 1978; Grobstein et al, 1978). Thus the absence of a contralateral isthmio-tectal projection probably represents a failure of isthmio-tectal fibers to cross the midline when retinal axons are absent from the chiasm region.

The tecto-topic topography of the ipsilateral tecto-isthmi and isthmio-tectal projections (Gruberg and Udin, 1978) is also being examined in this material. Our results to date indicate that these projections are similar in both normal animals and animals that develop without eyes. Our observations are consistent with the idea that central synaptic connections and the gross topography of projections within the frog visual system develop independently of the retinotopic organization normally imposed on the tecta by the optic tracts.

497 EFFECTS OF β-BUNGAROTOXIN INJECTIONS ON THE DEVELOPING MOTOR NEURONS AND THEIR TARGET. Tony L. Creazzo* and G. S. Sohal (SPON: R. K. HOLT). Dept. Anat., Sch. Med., Medical College of Georgia, Augusta GA 30912.

β-Bungarotoxin (β-BTX), a presynaptic blocker, contains two polypeptide chains (M.W. A chain, 15000-17000; B chain, 7000) and has been shown to have phospholipase A_2 (PLA) activity. Chronic application of β-BTX into the yolk sac of avian embryos produces massive destruction of neurons and skeletal muscle. The destructive effects of β-BTX have been postulated to be due to PLA activity. In an attempt to deactivate PLA activity, β-BTX was heated for three minutes in a boiling water bath. About 80% of PLA activity was abolished and the protein consisted of only one subunit (M.W. about 15000). Effects of heated β-BTX on the development of the trochlear nucleus and superior oblique muscle were examined. Either 2 or 4 µg of toxin/day was applied to the vascularized chorioallantoic membrane of the white Peking duck embryo through an opening in the shell. Embryos injected daily just prior to and during the period of maximum embryonic cell death (days 11 to 18) indicate an increase of about 25% of neurons over the control in the trochlear nucleus. Injections of toxin prior to the onset of cell death (days 8-11) indicate that toxin has no stimulatory effect on cellular proliferation of the young trochlear neurons. Similarly, injections of toxin after the period of cell death (days 21-24) indicate that toxin does not cause a transient increase in the number of trochlear neurons. Thus, it appears that β-BTX increases the number of trochlear neurons when applied during the period of cell death, presumably by retarding the magnitude of cell death. β-BTX delays differentiation of the superior oblique muscle. For example, on day 18 the control muscle is composed of myotubes and myofibers and the motor endplates become morphologically identifiable by cholinesterase stain. The toxin-treated muscle on day 18 is composed of myoblasts and myotubes. The motor endplates do not appear until day 22.

(Supported by NIH Grant GM23484).

498 ONTOGENY OF CYCLIC AMP BINDING PROTEINS IN RAT BRAIN. Bruce Culver, Patricia B. Hoyer* and Boyd E. Haley*. Departments of Pharmacology and Biochemistry, University of Wyoming, Laramie, Wyoming 82071.

The cAMP photoaffinity probe [^{32}P]-8-N$_3$cAMP (8-azidoadenosine -3',5'-monophosphate) has been used to study cAMP binding proteins of rat brain. 8-N$_3$AMP specifically substitutes for cAMP and, on photolysis, forms a covalent bond with proteins that bind it. Partial characterization of brain cAMP binding proteins was performed in rats at various stages of development from the twelfth gestational day to 6 months of age. Four different proteins were photolabeled by [^{32}P]-8-N$_3$cAMP. The approximate molecular weights were 127,500; 58,000; 54,000; and 48,000 ± 5% as determined by SDS-polyacrylamide slab gel electrophoresis. Addition of cAMP protected all 4 proteins from photo-incorporating 8-N$_3$AMP. Cell fractionation procedures showed that the 127,500 MW protein (protein A) was found only in the particulate fraction. Protein A exhibited an increase with development, but the function of this protein is not known. The three smaller proteins in order of decreasing MW have been tentatively identified as R_{II}-phosphorylated (R_{II}-P), R_{II} and R_I where R is the regulatory protein of type II and type I protein kinases. These three proteins were found in both soluble and particulate fractions. The R_I protein appeared to increase during development. The R_{II} protein, however, appeared to decrease with age and there was an age-related change in the ratio of R_{II} to R_{II}-P.

The approach of using [^{32}P]-8-N$_3$cAMP as a photoaffinity probe provides a valuable tool to study cAMP-macromolecular interactions. It is proposed that the ontogenic patterns exhibited by different cAMP binding proteins reflects changing physiological roles of components of the cAMP system in the developing brain. The data also suggest that cAMP probably exerts its effects through proteins in addition to types I and II protein kinases.

499 EFFECTS OF PRENATAL AND POSTNATAL NERVE GROWTH FACTOR DEPRIVATION ON THE DEVELOPING MAMMALIAN NERVOUS SYSTEM IN AN AUTOIMMUNE MODEL. Pamela H. Dolkart* and Eugene M. Johnson* (SPON: Thomas Woolsey). Dept. Pharmacol., Washington Univ. Sch. Med., St. Louis, Missouri 63110.

We have previously described an autoimmune model of nerve growth factor (NGF) deprivation whereby adult rats immunized with 2.5S mouse NGF in complete Freund's adjuvant make antibodies which cross-react with rat NGF and which are transferred to offspring in utero and in milk. Anti-NGF activity in the serum of NGF-immunized adults and their offspring, measured in the chick embryo dorsal root ganglia bioassay, is retained in the IgG fraction after ammonium sulfate precipitation and Sephadex G-200 chromatography.

Cross-fostering experiments were used to separate the effects of in utero and in milk exposure to anti-NGF on peripheral sensory neurons, long adrenergic neurons, short adrenergic neurons and adrenal medullary cells. Dorsal root ganglia in 12 week old rats exposed to anti-NGF only in utero were unable to retrogradely transport ^{125}I-NGF injected in the forepaw and had a 20-30% reduction in protein content. Superior cervical ganglia had significant reductions in tyrosine hydroxylase, choline acetyltransferase and protein with either in utero or in milk exposure to anti-NGF. Heart, a tissue innervated by long adrenergic neurons, had greatly reduced levels of norepinephrine with either prenatal or early postnatal exposure to anti-NGF. In contrast, the vas deferens, a tissue innervated by short adrenergic neurons, had no reduction in norepinephrine, and the adrenal gland had no reduction in tyrosine hydroxylase activity. These experiments suggest that a subpopulation of sensory neurons in the rat is dependent on NGF during fetal development for survival. Long adrenergic neurons appear to be NGF-dependent during both prenatal and early postnatal development.

Similar experiments in rabbits indicate that higher titers of anti-NGF are achieved in the fetuses of NGF-immunized female rabbits and greater effects on the peripheral nervous system are observed. 500 ACTH$_{4-10}$ ENHANCES RETENTION OF CONDITIONED TASTE AVERSION LEARNING IN INFANT RATS. Susan M. Dray & Anna N. Taylor. Depts.of Psychol. & Anat., Brain Research Inst., UCLA, Los Angeles,Ca 90024

Previous studies in our laboratory have indicated that neonatal treatment with ACTH$_{1-24}$ has prolonged effects on physiology and behavior. In view of the known effects of ACTH$_{4-10}$ on extinction, we were interested in whether similar organizational effects might accompany neonatal treatment with this peptide. 34 litters of Sprague-Dawley rats (N=288)were cross-fostered the day after birth (d.1) and injected sc on days 7-9 with either ACTH$_{4-10}$(10 ug in saline) or vehicle. On d.12, pups were maternally deprived and kept with littermates in a warm cage (37^{o}) for 6 hrs. Each pup was then stimulated to void, weighed, and given 0.5 ml apple juice by mouth with a syringe while hand held for 5 min, then weighed again. Wt gain was the index of amount drunk. Litters were divided into thirds for reinforcement, with 1/3 injected with LiCl ip (2 ml/100 g bw, .15M) immediately, 1/3 at 1 hr later, and 1/3 24 hr later. Following conditioning, pups were returned to their mothers. On d.15, pups were again 6 hr deprived, weighed, and given 0.5-0.6 ml apple juice. No conditioned taste aversion (CTA) would be expected with noncontingent pairing of taste and illness, and none was seen on d.15 in the 24 hr grp, regardless of ACTH treatment. At d.12, it is unclear whether infants can form aversions with a 1 hr delay, and, likewise, there was no clear CTA in either ACTH or saline pups in the 1 hr grp. Animals given LiCl immediately did learn to avoid apple juice, but again, no additional ACTH effects were seen. To rule out the possibility that the neonate simply is not able to respond to ACTH$_{4-10}$, 6 litters (N=69) were left undisturbed until d.12, at which time they were conditioned and tested as before. This time, however, half of each reinforcement group was injected sc with 10 ug ACTH$_{4-10}$ or saline 15 min prior to the start of the retention trial on d.15. Again, noncontingent reinforcement (24 hr grp) produced no CTA in either ACTH or saline groups. Saline-treated pups drank 184±19% (SEM, N=10) of their d.12 baseline, while ACTH-treated pups consumed 184±17% (N=11). Pups reinforced immediately showed clear aversions, and, likewise, ACTH made no further difference (Saline: 56±7%, N=11; ACTH: 55±9%, N=10). However, in animals given delayed LiCl (1 hr grp), ACTH made a striking difference. Vehicle pups were mildly averted (134±16% of d.12 baseline,N=12), while ACTH pups reduced their intake to 51±7% (N=12). This peptide, then, aided recall of CTA not seen without it. These results indicate that rat pups are sensitive to ACTH$_{4-10}$, and that they are able to learn a CTA with a 1 hr delay of reinforcement. 501 FAILURE OF NGF TO AFFECT FETAL BRAINSTEM CATECHOLAMINERGIC NEURONS IN CULTURE. Cheryl F. Dreyfus, Michael D. Gershon, Edith R. Peterson* and Stanley M. Crain. Dept. of Neuroscience, Albert Einstein Coll. Med., Bronx, New York, 10461 and Dept. of Anatomy, Columbia Univ., P&S, New York, New York 10032.

Catecholaminergic (CA) neurons of the fetal mouse brainstem, explanted from the region of the locus coeruleus, survive in organotypic tissue culture for up to 5 weeks. These neurons exhibit the glyoxylic acid induced histofluorescence (GIF) of CA and their axons become radioautographically labeled by ^{3}H-norepinephrine (^{3}H-NE; Dreyfus, Gershon and Crain, Br. Res. 161, 1979). In the present study we determined whether nerve growth factor (NGF) enhances neuritic outgrowth and/or is necessary for the survival of these central CA neurons. Portions of right and left brainstem, containing the locus coeruleus, were explanted from fetal mice of 13 or 18 days' gestation. Paired sides were grown for 1-3 weeks in either control nutrient media or in media containing NGF (1,10,100 or 1,000 U/ml) or antiserum to NGF (anti-NGF; 1%). The activity of NGF and anti-NGF was bioassayed on cultured dorsal root ganglia. No differences in neuritic outgrowth were detected between control brainstem cultures and their pairs grown with either NGF (up to 100 U/ml) or anti-NGF. Cultures were examined periodically while alive and then were exposed to glyoxylic acid and viewed for CA histofluorescence. A decrease in total neuritic outgrowth as well as the CA component of the outgrowth revealed by GIF, was found in cultures exposed to 1000 U/ml of NGF.

Uptake of ^{3}H-NE was used to evaluate quantitatively the CA neuritic outgrowth. Explants were incubated with ^{3}H-NE (0.5 uM) and nialamide (12.5 uM) for up to 60 min and then washed for 2 hr at 4^{o}C. Uptake was measured into the compartment represented by the slowest single exponential component of the washout curve. Radioautography shows this compartment to be axonal. The uptake process was saturable, temperature dependent, and inhibited by desmethylimipramine (5 uM). No significant differences in uptake of ^{3}H-NE were found between control cultures and their pairs exposed to NGF (100 U/ml) or anti-NGF. Therefore, under these conditions, we could not detect any effect of NGF on the growth or maintenance of cultured fetal central CA neurons. (Supported by the Dysautonomia Foundation and NIH grants NS14990 and NS12969. CFD was a fellow of the Pharmaceutical Manufacturers Association Foundation. Cultures were prepared in Dr. M. Bornstein's laboratory at Einstein.)

502 ALTERED NEURONAL DEVELOPMENT IN HAMSTER OFFSPRING FOLLOWING MATERNAL ETHANOL CONSUMPTION. C.R. Dunmire-Graff* and F.W. LaVelle* (SPON: A. LaVelle). Dept. Anat., Loyola Univ. Stritch Sch. Med., Maywood, IL 60153.

Previous work in this laboratory has described a developmental sequence for the structure of the nucleolus in maturing neurons of the hamster facial motor nucleus. A young neuron initially possesses multiple nucleoli but acquires a single nucleolus as it matures. In the adult hamster this single nucleolus is capped by nucleolar-associated chromatin (DNA) and often contains a central, RNA-rich intranucleolar body (INB) about 1.0 to 2.0 μm in diameter. Among facial motor neurons, many of the cells reach their adult nucleolar appearance by 20 days postnatal age.

In this study, facial motor neurons from 20-day-old hamsters born to control and to ethanol-consuming females were compared at the light microscopic level. The day following mating, female hamsters were either continued on their standard diet of water and laboratory chow (control) or were placed on a regimen of a 15% ethanol solution and laboratory chow (experimental). This regimen was maintained throughout pregnancy and the postnatal suckling period. After weaning, the pups ate and drank the same diet provided to their mother. Twenty-day-old offspring were subsequently weighed, anesthetized with sodium pentobarbital, and perfusion-fixed. The brains were double-embedded and serially sectioned at 4 μm; sections were stained with buffered thionin. Each facial motor neuron exhibiting some type of nucleolar structure was judged to possess either multiple nucleoli (Mult) or a single nucleolus containing no INB (A), a punctate INB (Pu), or a prominent INB (Pr).

Counts in 20-day-old controls yielded the following results: Mult = 14%, A = 9%, Pu = 27%, Pr = 50%. Twenty-day-old offspring of the ethanol-consuming mothers fell into two groups: (1) seemingly healthy animals having a mean body weight close to that of the controls (24 gms), and (2) "runts", which appeared weak, were unable to walk properly, and had a mean weight of 11 gms. Counts of nucleolar structure yielded the following: (Group 1) Mult = 27%, A = 14%, Pu = 20%, Pr = 39%; (Group 2) Mult = 36%, A = 11%, Pu = 25%, Pr = 28%. Group 1 and Group 2 percentages both reflected more immature neuron populations as compared with controls, thus suggesting that ethanol may play a role in retarding the developmental sequence of nucleolar structure in neurons. Central chromatolysis and extensive nuclear infolding were also evident in both experimental groups, indicating further alterations in the synthetic mechanism of developing neurons exposed to ethanol. How much of the increased retardation seen in runts was directly due to ethanol and how much indirectly to malnutrition is not as yet clear.

503 GROWTH AND DEVELOPMENT OF THE OPTIC NERVE IN JUVENILE GOLDFISH. Stephen S. Easter, Jr., Phillip E. Kish*, and Steven S. Scherer*. Div. Biol. Sci., U. Michigan, Ann Arbor, MI 48109.

Previous studies have shown that the retina of juvenile goldfish grows by adding new cells, including ganglion cells, whose axons make up the optic nerve. We describe the optic nerve in young and old goldfish and find structural changes which accompany retinal growth. Optic nerves and tecta were prefixed in situ with buffered aldehydes, osmicated, and embedded in Epon. Semithin sections were stained with toluidine blue and examined light microscopically. Thin sections were stained with U and Pb and examined electron microscopically.

The table gives a quantitative comparison of the optic nerves of young and old fish (ages: 1 and 5 yr; standard lengths: 4 and 12 cm; weights: 1.4 and 67 gm; lens diameters: 1.6 and 4.0 mm.)

Mean values in:	young (N=4)	old (N=3)
Nerve cross section (um^2)	56,780	362,155
Number of myelinated fibers	115,000	179,000

In the orbit, the optic nerve is accompanied by the retinal vessels and a small nerve, containing tens of fibers, which enters the choroid. Glial processes divide the optic nerve into fascicles, the number of which varies depending on the level of section. Small groups of fibers commonly cross between fascicles. In individual nerves, fiber diameters vary by more than tenfold. Within each fascicle, the fiber diameters and myelin sheath thicknesses are relatively homogeneous. Neighboring fascicles are generally more similar in these respects than fascicles widely separated. In small fish, there is always one fascicle which contains nearly exclusively non-myelinated fibers which number a few thousand and measure a few tenths of um in diameter. These are probably the fibers from the new ganglion cells because: 1) new fibers are expected to be non-myelinated and 2) these fibers segregate in the tectum to those regions innervated by peripheral retina, where the new ganglion cells are formed. In the large nerves, there are many fewer non-myelinated fibers, and they are not localized to a single fascicle.

These observations suggest that fibers of the same age fasciculate together in the nerve. The intrafascicular homogeneity of fiber size and myelin thickness probably results because these fibers have all grown and developed over similar periods. The similarity of nearby fascicles suggests that new fibers fasciculate near preexisting fascicles of slightly older fibers. The relative absence of non-myelinated fibers in nerves of large animals suggests that these animals' retinas have stopped adding ganglion cells.

504 FUNCTIONALLY DISTINCT FACTORS SUPPORTING THE SURVIVAL OF CHICK SENSORY AND SYMPATHETIC NEURONS IN CULTURE. David Edgar*, Yves Barde* and Hans Thoenen. Dept. Neurochem. Max-Planck-Institut, D-8033 Martinsried, W. Germany.

Culture medium conditioned by C-6 glioma cells is able to support the survival of sensory neurons from dissociated chick embryo spinal ganglia. This property is also shared by a well characterised protein, the nerve growth factor (NGF), together with media conditioned by embryonic chick heart cells in culture, and extracts of adult rat central and peripheral nervous system. It has been demonstrated that the activities of these conditioned media and tissue extracts are not due to the presence of NGF, as specific anti-NGF antibodies, while able to inhibit the survival and neurite outgrowth induced by NGF, do not inhibit the effects of the conditioned media or tissue extracts. Here we show that the response of sensory neurons to glioma conditioned medium (GCM) differs from that to NGF: culturing neurons from chicks of embryonic ages ranging between day 7 and day 15 in ovo revealed that early in development, NGF is more active than GCM in supporting sensory neuronal survival. However as the sensory ganglia mature, NGF becomes less potent whereas GCM is able to support the survival of an increasing proportion of the neurons plated.

It is suggested that NGF is one of the factors necessary for the early survival of embryonic chick sensory neurons, which subsequently become dependent on factors such as that present in GCM. We further show that the responses of sympathetic neurons, dissociated from embryonic chick para-vertebral ganglionic chains, differ when supplied with NGF or GCM, thus adding support to the concept of functionally distinct factors. That NGF and GCM represent members of two families of factors, differentiated by the developmental stage during which they exert their activity, will be discussed with reference to those activities present in heart cell conditioned medium and extracts of nervous tissue.

505 LASER LESIONS OF EMBRYONIC CRICKET CERCI DISRUPT GUIDEPATH ROLE OF PIONEER FIBRES. John S. Edwards, Michael W. Berns* and SuWan Chen*. Dept. Zool., Univ. Wash., Seattle, WA 98195 and Devel. Cell. Biol., Univ. Calif., Irvine, CA 92717.

The normal development of neuronal connections between embryonic abdominal sensory appendages, the abdominal cerci, and the central nervous system occurs in two phases. The first of these, which occurs at about 50% elapsed time in the developmental sequence precedes elongation of the appendage. Apical bodies of these pioneer fibres underly the epidermis and are associated with glial cells situated along the dorsal and ventral midlines. It is along this pathway that axons from functional sensilla subsequently make their centripetal growth in the final 15% of the developmental sequence.

In order to assess the role of the pioneer fibres as a necessary pathway for the organisation of the cercal nerve within the cercus, embryonic cerci were lesioned in situ by means of a laser microbeam at several stages of development immediately before, during, and after projection of pioneer fibres. Treated embryos were allowed to develop to later stages when neuronal and glial cell populations were examined by transmission electron microscopy.

Apical lesions of cerci that had newly reached full length and had thus completed pioneer fibre formation did not cause significant alteration to the configuration of the dorsal and ventral bundles of functional afferents as sampled in hatchlings.

In contrast, the effect of apical lesions made before the development of pioneer fibre bundles and accompanying glial cells resulted in the subsequent development of multiple bundles of functional fibres within the cercus lumen.

We conclude that the organisation of the neuronal and glial components of the pioneer fibre pathway is necessary for the orderly projection of functional axons. However, once established, the glia alone, having survived the elimination of pioneer neurons appear to be sufficient to organise axon bundles in their normal position.

Passage of axons from the base of the cercus across the hemocoel to the CNS may present more stringent requirements, including intact pioneer fibres. Supported by NIH grants NB 07778 (JSE) and GM 23445 (MWB).

506 STUDY OF PROLIFERATIVE CELL COMPARTMENT IN DEVELOPING CNS BY COLONY CULTURE ASSAY. S. Fedoroff, L. Doering*, B.H.J. Juurlink* and C. Hall*. Department of Anatomy, University of Saskatchewan, Saskatoon, Saskatchewan, Canada. S7N OWO

When the cells of developing CNS are mechanically dissociated and planted in appropriate concentrations in cultures, cell colonies develop. The prerequisite for the formation of a colony is that a cell must adhere to the substratum (plastic) and proliferate. We investigated the possibility of using cell colony formation in cultures as an assay to monitor the proliferative cell compartment during CNS development.

The spinal cord of chick embryos, cerebral hemispheres of mouse embryos at different developmental stages, and the hemispheres of postnatal mice were isolated and the meninges were removed. The basal ganglia and hippocampus were separated from the hemispheres. The spinal cord and hemispheres were then dissociated into cell suspensions which were planted in various concentrations in Falcon plastic dishes. After 7, 10 and 14 days of culturing, the numbers of colonies formed as a function of the size of innocula were determined by direct counts under a light microscope.

The chick embryo spinal cords yielded only few colony forming cells until 4.5 days (E4.5) of development. Between E6.5 and E7.5 there was an exponential increase in the yield of colony forming cells; the peak yield was reached at E11.5.

The youngest mouse embryos used were E11. The hemispheres of such embryos yielded colony forming cells but the peak yield was reached at E15. Postnatally, the yield began to decrease gradually and at P30 only a few colony forming cells were present.

In another series of experiments the mouse cerebral hemispheres were cut into small portions which were divided into two fragments: An outer fragment containing the marginal zone, cortical plate and most of the intermediate zone, and an inner fragment containing a small portion of the intermediate zone, the subventricular zone and the ependymal layer. Such fragments were dissociated and planted in culture dishes. It was found that 75% of colony forming cells came from the subventricular region of the brain. The ultrastructure of the cells forming the epithelial type colonies was similar to that of the "pale" cells of the subventricular zone.

These studies indicate that the colony forming cells are derived primarily from the secondary proliferative zones such as the subventricular zone and that their formation in the CNS and their progression into postmitotic cells can be monitored with the aid of colony culture assay method. This work was supported by Grant MT4235 from MRC Canada.

507 POSTNATAL ONTOGENY OF HYPOTHALAMIC EXTRACELLULAR UNIT ACTIVITY IN THE RAT. Robin S. Fisher and C. Robert Almli. Dept. Psychol., Ohio Univ., Athens, OH 45701.

Extracellular single unit activity was obtained from the lateral hypothalamic area (LHA) and the ventromedial hypothalamic nucleus (VMH) in rats of 1-2, 5-6, 10-11, 25-26, and 90-110 days of age. The following unit activity characteristics were measure for comparison between age levels: spontaneous unit firing rate, unit response to external sensory stimulation (tactile, gustatory and olfactory stimuli), and unit response to variation of interna physiological parameters (hypertonic saline or glucose injection)

No clear or significant ontogenetic trends were found for any of these simple aspects of unit activity. Spontaneous unit firin rates were very low across age levels (X basal rates of 1 spike/sec with over 80% of all units having basal rates below .5 spikes, sec). By the most stringent criterion employed in this study, 69-80% of LHA units were responsive to external sensory stimulati across all age levels. Slightly lower proportions of VMH units were responsive to tactilem gustatory, or olfactory stimulation (54-72% across all age levels). Finally, hypertonic saline or glucose injection altered LHA and VMH unit activity in nearly all age levels. Unit responses to internal and external stimulation were determined by statistical criteria for single stimulus trial or averaged across stimulus trials. Such criteria were highly reliable and indicated that the employed forms of stimulation could either facilitate or diminish firing frequency in both LHA and VMH units. Thus, no typical forms of unit responses to stimulation were noted for particular neural regions or for particular age levels.

Significant age-related trends were found for more complex data interrelationships. VMH units decreased basal firing rate ranges as a function of age while LHA unit basal firing rate ranges reciprocally increased. Furthermore, both VMH and LHA units tended to become responsive to exclusively internal or external sources of stimulation as aging progressed. Therefore, the failure to find ontogenetic trends in the simple aspects of unit activity indicated a qualitative maturity throughout the postnatal life of the rat that correlated well with the age-constant aspects of ingestive behaviors recently elaborated by numerous investigators. The postnatal maturation of more complex characteristics of LHA and VMH unit activity represented a process that would only allow for postnatal "fine-tuning of quantitative aspects of ingestive behavior regulation.

508 IN VIVO AND IN VITRO ONTOGENY OF TORPEDO ELECTROCYTES. G.Q. Fox*, G.P. Richardson* and C.Kirk*(SPON: J.D. LANE). Max-Planck Inst. für biophy. Chemie. 3400 Göttingen, West Germany.

The electric organ of Torpedo marmorata is derived from branchial mesoderm. It is composed of several hundred columns each consisting of vertically oriented myotubes. The myotubes are characterized by myofibrils, diffusely distributed acetylcholine receptors and contractility. With development, the vertical myotubes are converted to horizontally flattened electrocytes. Concurrently myofibrils are broken down and contractility is lost. Acetylcholine receptor becomes localized along the ventral plasma membrane as does cholinesterase. The latter is also found on the ventral basal lamina which forms at this time. The mechanics of transformation can, in part, be explained by the appearance of filamentous structures with possible contractile properties. Synaptogenesis begins upon completion of this cellular transformation with axons from intercolumnar nerves invading the interelectrocyte spaces. The axons course along and form synapses exclusively along the ventral electrocyte membrane. Electrocytes continue to enlarge throughout life with increased multinucleation caused by fusion of satellite cells found along the dorsal surface of each electrocyte.

It is now possible to maintain viable explants of embryonic electric organ and our results suggest that the in vitro system closely parallels many events seen in vivo. For example, with myogenic electric organ explants, myoblasts migrate out, form myotubes and subsequently differentiate into electrocytes. Myofibrillogenesis and breakdown occurs, cells round up, and distinctive regions comparable to in vivo ventral and dorsal plasma membrane form. Acetylcholine receptor and basal lamina are found exclusively associated with ventral plasma membrane. Electric organ explants in which differentiation of electrocytes has occured similarly produce a migration of satellite cells that also form myotubes. Unlike those from myogenic explants these produce substantially more myofibrils. On contact with nerve(i.e. co-cultured electric lobe) contraction is initiated. Experiments are currently underway exploring possible reciprocal differential effects between electric organ and electric lobe explants.

509 NOVEL PERIPHERAL TARGETS OF SENSORY GANGLION CELLS CAN MODIFY CENTRAL PROJECTIONS IN THE SPINAL CORD. E. Frank and M. Westerfield* (spon: R. W. Baughman). Dept. Neurobiology, Harvard Medical School, Boston, MA 02115.

How do sensory neurons establish specific synaptic connections within the spinal cord which are appropriate to the particular muscle or patch of skin that they innervate? One possibility is that a target in the periphery may specify the central connections to be made by the sensory cell that innervates it. We have explored this possibility in developing bullfrog tadpoles by forcing sensory cells to innervate novel peripheral targets.

In normal adult animals, the arm is innervated almost entirely by the 2nd spinal nerve. The 3rd spinal nerve innervates muscle and skin of the thoracic body wall and only occasionally sends a few fibers into the nerve innervating the arm. However, sensory neurons in the 3rd dorsal root ganglion (DRG) will take over the territory of the 2nd DRG, if it is removed at early to middle limb bud stages and the tadpoles are allowed to mature into adults.

Functional innervation of the forelimb by 3rd nerve fibers was first established behaviorally; frogs withdrew the arm on the operated side when it was pinched, and this withdrawal was abolished by severing the 3rd nerve. Later anatomical studies showed that the 3rd dorsal root was often twice its normal diameter. The 2nd and 3rd spinal nerves formed a plexus on the operated side and fiber bundles could be traced from the 3rd spinal nerve into the arm nerve. Central projections of 3rd DRG cells on operated and control sides were traced by backfilling the spinal nerves with horseradish peroxidase (HRP). In most animals, sensory fibers on the operated side projected into the brachial region of the spinal cord (where motoneurons innervating the arm are located) much more extensively than on the control side, or than in unoperated animals. These unusual anatomical projections presumably underlie the arm withdrawal seen in operated animals.

Central rearrangements of sensory projections were not sufficient to produce completely normal function, however. Even though an operated animal could use his arm, the arm was often held in an abnormal position. In several of these animals, central projections of fibers from the 3rd DRG providing sensory innervation of the triceps muscles were traced by backfilling the muscle nerves with HRP. These fibers did not appear to reach the brachial region of the spinal cord where normal triceps sensory afferents (from the 2nd DRG) project. The behavioral and anatomical results therefore show that removal of a dorsal root ganglion can produce distinct but limited alterations in other reflex pathways. NS 00212 & NS 14451.

510 MATERNAL USE OF ALCOHOL, CIGARETTES AND/OR MARIHUANA DURING PREGNANCY: EFFECTS UPON THE OFFSPRING. Peter A. Fried* (SPON: W.G. Webster). Dept. Psychol., Carleton University, Ottawa, Ont. Canada K1S 5B6.

A sample of 200 predominantly middle class women were interviewed once during each trimester and questioned about their usage of alcohol, cigarettes and marihuana. The babies of a number of these women were examined at birth, 2,9 and 30 days of age on a variety of tests that included assessment of behavioral and neurological development. A reduction in birth weight was observed in babies born to mothers who smoked more than 10 cigarettes a day or drank an average of just over a drink or more a day or smoked more than 5 "joints" of marihuana per week. Cigarettes had the most marked effect and a combination of these soft drugs did not greatly potentiate the reduction in birth weight. Cigarettes, and to a lesser degree, social use of alcohol were related to smaller head circumferences in the newborn. A decrease in responsiveness to auditory stimuli was found in the offspring of smokers and habituation rates were slower among babies born to smokers and marihuana users. A very pronounced increase in irritability was observed in the offspring of marihuana users and, to a lesser degree, in the babies of heavy smokers. A large increase in tremors and startles was related to marihuana usage during pregnancy and to a slightly lesser extent were also found in the offspring of heavy social drinkers and/or smokers. The relationship between the social use of soft drugs and subtle neurological abnormalities in offspring are discussed.

511 AGE-DEPENDENCE OF TRANSNEURONAL DEGENERATION IN THE PIRIFORM CORTEX OF THE RAT. B. Friedman* and J.L. Price (SPON: M.B. Bunge). Dept. Anat. & Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

Previous studies of the effect of deafferentation on the piriform cortex have demonstrated growth of the cortical association fibers into the denervated layer Ia following olfactory bulb removal in neonatal rats, and the absence of similar reactive fiber growth in adults. In neonates the expansion of the cortical projection is associated with the continued growth of layer I (composed of the apical dendrites of the cortical neurons) to nearly its normal mature width, while in adults the absence of reactive growth of the association fibers is correlated with shrinkage of layer I and atrophy of the distal portion of the apical dendrites (Caviness, Korde, and Williams, '77; Friedman and Price, '78). In addition, olfactory bulb removal in adult rats produces a severe and rapid transneuronal degeneration in the piriform cortex especially among the cells in the outer part of layer II (IIa). These cells become argyrophilic within 16 hours and subsequently are lost completely (Kalil and Heimer, '78). The present study has examined the response of layer IIa cells to olfactory bulb removal in neonatal rats.

In rats examined 24-48 hours after olfactory bulb ablation on the day of birth (P-1) with the de Olmos Cu-Ag method, no cellular argyrophilia was seen in the piriform cortex, although axonal degeneration was clearly evident in layer I. In contrast, rats examined at the same survival periods following olfactory bulb ablations at P-21 show conspicuous cellular argyrophilia concentrated in layer IIa.

Previous studies in adults using horseradish peroxidase (HRP) as a retrograde axonal marker have also shown that IIa cells can be characterized by distinct connections to the anterior olfactory nucleus (AON), olfactory tubercle (OT) and the lateral entorhinal cortex, and that these cells lack a centrifugal projection back to the olfactory bulb (Haberly and Price, '78). Therefore, other animals were allowed to survive into adulthood following olfactory bulb ablation on P-1, then injected with HRP in the AON or OT and their brains processed with tetramethyl benzidine. Although the cytoarchitectonic distinction of layer IIa is not clear in these animals, cells were demonstrated in the outer part of layer II which had connections typical of the IIa cells. These results indicate that following neonatal deafferentation, the IIa cells do not undergo transneuronal degeneration and survive into adulthood. This is in contrast to other systems where cellular degeneration following deafferentation is more severe in immature animals than in adults.

512 QUANTITATIVE ANALYSIS OF NEURONAL DEVELOPMENT IN THE GUINEA PIG RETINA. Keith R. Fry* and Arthur W. Spira* (SPON: M.A. Bisby) Lions Sight Centre,Division of Morphological Science,Faculty of Medicine,University of Calgary,Calgary,Alberta,Canada T2N 1N4

Differentiation of many of the main components of the guinea pig retina e.g. synapses, outer segments appear well advanced at birth compared to many other species (Spira,Anat.Embryol. 146: 279, 1975). How do populations of neurones change throughout development and when do these populations acheive full differentiation? Quantitative light microscopic techniques have been employed to study neuronal development in the guinea pig. Retinae from animals ranging in age from 35 days post-coitus to 100 days (gestation=65 days) postnatal were processed for light microscopy. Orientation in the retina was maintained throughout the study. Quantitative analysis was performed using a program developed from the Abercrombie method (Anat.Rec. 94:239, 1946) with correction factors for split profiles and underestimation of mean nuclear diameter (Wimer,Brain Res. 133:376,1977). Nuclei of the inner nuclear layer (inl) were classified by their nuclear morphology, location within the inl and the cytoplasmic:nuclear ratio to one of the following categories: (i) horizontal (ii)amacrine (iii) rod or cone bipolar (iv) undifferentiated and Müller. Number of each type of nuclei occupying a column through the retina 10 µm by 10 µm were determined for each age.

Numbers of photoreceptor cells decline throughout fetal life until birth at which time adult levels are attained. Similarly total cell number in the inl declines rapidly until 55 days post-coitus and then undergoes no further change. Analysis of individual neuron types demonstrated that some types do undergo changes in number after birth although total inl counts do not change. Amacrine cells undergo a rapid increase in number between 45 and 60 days post-coitus and continue to increase slowly in number after birth. Rod bipolar cells increase in number rapidly between 50 and 60 days post-coitus and also demonstrate a further gradual increase in number during postnatal life. Cone bipolar cells reach peak levels at 55 days post-coitus but decrease in number slightly until maturity. The appearance of new amacrine and rod bipolar cells must be due to differentiation of undifferentiated neurons. This is substantiated by the observation of significant numbers of undifferentiated neurons at birth which gradually decline until about 100 days postnatal.

The major period of neuronal differentiation in the retina occurs between 45 and 60 days post-coitus. Selected neurons in the inl undergo a second stage of differentiation which continues through the first 1-2 months of postnatal life.

513 ONTOGENY OF THE RETINOTECTAL CONNECTION IN XENOPUS LAEVIS. Steven Glasser, Dept. Ophthal., N.Y. Med. Col., Valhalla, N.Y. 10595.

An ordered projection of retinal ganglion fibers can be found on the tectal surface throughout most of Xenopus larval life. The existence of this ordered retinotopic projection has been taken to imply that ordered retinotectal connections are formed during ontogeny. However, since there are asymmetries in the development of retina and tectum, Gaze, et.al. have proposed that connections between retinal and tectal cells are temporarily formed and later broken. Their hypothesis, further states that during the growth of the eye and tectum there is a continuous caudomedial shift of synaptic contacts between retinal ganglion fibers and tectal cells.

In the present study, I have isolated visually driven postsynaptic tectal unit activity in larval Xenopus laevis. Utilizing standard electrophysiological techniques, postsynaptic visually driven units were isolated and characterized first in the rostrolateral tectum of adult and juvenile Xenopus laevis. These cells, found in the deep tectal layers, responded to larger stimulus targets within larger visual receptive fields than did retinal ganglion terminals. Postsynaptic units, unlike presynaptic fibers, also habituated to the successive repetition of a visual stimulus. Furthermore, the postsynaptic response could be eliminated by the topical application of curare or sodium pentobarbital, whereas presynaptic activity was unaffected by these drugs.

Visually driven retinal fiber terminals were found in the rostrolateral tectum of the youngest animals studied (stage 49). However, on the basis of criteria established in the adult and juvenile preparations, postsynaptic units could be isolated no earlier than stage 52-53.

The implications of these findings will be discussed.

514 ORIGIN, TRANSFORMATION, AND DEATH OF NEURONS FROM AN IDENTIFIED PRECURSOR DURING GRASSHOPPER EMBRYOGENESIS. C.S. Goodman, M. Bate*, and N.C. Spitzer. Dept. of Biology, UCSD, La Jolla, CA 92093, and Max-Planck-Institut für Virusforschung, Tübingen, FDR

We are interested in the differentiation of identified neurons from their birth to their maturation during grasshopper embryogenesis. We have reported that an identified neuroblast gives rise to identified neurons, and described their morphological, physiological, and biochemical differentiation. Here we report on the differentiation of neurons that are the progeny of a different class of precursor cells. There are seven of these cells per segment, called midline precursors (MP 1-7), which lie anterior to the dorsal unpaired median (DUM) neuroblast whose progeny were the subjects of our previous study.

The progeny of the single division of cell MP3 were examined by serial section reconstructions of light microscopic sections, direct observation of cells with interference contrast optics, and intracellular dye injections with Lucifer Yellow. We find that the two progeny are initially bilaterally symmetric. Each sends a single process anterior in the contralateral longitudinal fiber tract which becomes a ventral nerve cord. These processes and those of the progeny of the other MP cells are the first to appear in the embryonic CNS, and have been implicated in the guidance of the axons from the progeny of neuroblasts.

Several days after initial process extension, when there are numerous axons in the longitudinal fiber tracts and commissures, one of the pair of progeny of MP3 in the metathoracic ganglion begins to grow a second process. This second process bifurcates at the posterior commissure, and bifurcates again in each of the longitudinal fiber tracts. These processes then extend in both nerve cords, to the brain and to the terminal abdominal ganglion. Within a few days thereafter the first unilateral process disappears and the cell fully differentiates into the unpaired and bilaterally symmetric identified "H" neuron. Its sibling often dies at this time; when it persists it retains only its original unilateral process.

During the course of embryogenesis, the soma of the "H" cell assumes a position immediately anterior to the oldest progeny of the DUM neuroblast. Thus we have been able to follow the origin and transformation of a single cell which seems to assume two different roles during embryogenesis. It first appears as one of a pair of putative "pioneer" fibers and second transforms into an unpaired identified neuron.

515 TRANSLATION IN VITRO OF RAT BRAIN mRNA CODING FOR A VARIETY OF TUBULIN FORMS. Illana Gozes[1], Annie De Baetselier* and Uriel Z. Littauer*. Department of Neurobiology, The Weizmann Institute of Science, Rehovot, Israel. [1]Present address: Laboratory of Neuroendocrine Regulation, Department of Nutrition and Food Science, MIT, Cambridge, MA 02139.

Tubulin, the subunit protein of microtubules, is present in all eukaryotic cells and has been found to have a variety of structural and dynamic roles in cell shape, division, motility, transport and secretion. In the nervous tissue,neurite outgrowth and axoplasmic transport are thought to be dependent on microtubule integrity. The question therefore arises as to whether changes occur in the tubulin structure upon assumption of different roles within the nerve cell.

We have previously shown that extensive tubulin microheterogeneity is prominent in the brain, whereas tubulin isolated from other organs is less heterogeneous. Mature rat brain tubulin can be resolved by isoelectric focusing into nine distinct components. Different proportions of these nine isotubulins are displayed by various brain regions, resulting probably from the heterogeneity of the brain cell population. Brain tubulin microheterogeneity is developmentally determined, increasing from five to six components (isotubulins 1-6) in the prenatal rat brain to nine components in the mature brain (isotubulins 1-9). It was therefore of interest to determine whether the age-dependent increase in tubulin microheterogeneity is controlled at the RNA level or results from post-translational modifications.

In the present study, mature brain mRNA was translated in vitro in the reticulocyte lysate cell-free system, and was found to direct the synthesis of five tubulin forms, namely isotubulins 1,3,4(or 5),6 and 7. The mRNA species coding for isotubulins 3 and 7 could be partially separated on formamide-sucrose gradients while in the absence of formamide, the mRNA species directing the synthesis of isotubulins 1,4(or 5) and 6 showed differences in mobility. It therefore appears that brain mRNA may consist of five different species coding for distinct tubulin forms. Moreover, a marked age-dependent enhancement in the relative translation of the mRNA coding for isotubulin 7,which is not apparent among the translation products directed by the prenatal mRNA,was detected. Thus, some of the age-dependent increase in tubulin microheterogeneity might be controlled at the mRNA level.

516 EFFECT OF EYE ROTATION ON THE DEVELOPMENT OF OPTIC FIBER PATHWAYS IN XENOPUS LAEVIS. Philip Grant* and PoKay M. Ma* (SPON: D.P.Kimble). Dept. Biol., Univ. of Oregon, Eugene, OR 97403.

The rotation of embryonic eyes is a classic experimental procedure in studying retino-tectal connections in amphibia. The optic fiber (OF) pathways that developed after such operations, however, have not been adequately studied. Conceivably, the manner whereby OF return to the tectum may play an important role in reordering connectivity. To see whether the optic pathways that develop are dependent upon local environmental conditions encountered by growing OF as they emerge from a rotated eye or are determined by factors intrinsic to the eye, we rotated Xenopus eyes at embryonic stages 21/22 to 33 and traced the OF pathways by proline radioautography after mid tadpole stages. Several rotation paradigms were compared, including in situ rotations and isochronic or heterchronic transplantations (eyes transplanted and rotated between animals at the same or different stages).

90% of control animals developed normal optic pathways to the tectum. In all experimental groups however, the pathways that developed seemed to depend upon (1) the stage at which the operation was done, and (2) the local condition around the optic nerve head at the time of the operation. About 65% of eyes rotated at stage 21/22 (optic vesicle stage) developed normal optic pathways. The principal abnormal pathway is the trigeminal pathway. OF grew into and through the ipsilateral trigeminal ganglion to the trigeminal (Vth) root. Most fibers proceeded caudally along the descending tract of the trigeminus into the spinal cord. A high percentage of oculomotor pathway is also observed. OF followed the ipsilateral oculomotor nerve into the ventral tectum, where some crossed to the contralateral tectum. 50-85% of the eyes rotated at later stages developed abnormal pathway, less than 20% followed a normal route via the chiasma. Multiple as well as single (normal and/or abnormal) OF pathways were observed. The early stage operations gave a higher proportion of single pathways than later stage rotations. Most pathways involved the trigeminal and oculomotor pathways.

The high incidence of trigeminal pathways can be explained by the fact that the trigeminal ganglion anlage develops dorsocaudally over the eye. When OF emerge from rotated eyes, they are frequently intercepted by one or more of the several developing trigeminal projections, following these projections into the ganglion and subsequently the Vth root. Other aberrant pathways may develop in a similar fashion. OF display no preferences for specific pathways but tend to follow any accessible fiber pathway.

517 THE DEVELOPMENT OF AFFERENTS AND MOTONEURONS IN RAT SPINAL CORD. Carolyn Smith Grobstein* (Spon: M. Hollyday) Dept. Biology, Univ. Chicago, Chicago, IL 60637.

The morphology of specific populations of motoneurons and afferents in the thoracic spinal cord was examined in fetal and neonatal rats by exposing either the cut dorsal or ventral ramus of a peripheral nerve to horseradish peroxidase. In the adult, each ramus innervates several thoracic muscles and contains afferents for either dorsal or ventral skin. The morphology of the afferents and motoneurons from the 14-18th days of gestation (birth occurs about day 21) was compared with that at postnatal day 10.

At all ages studied, a centro-medial cluster of motoneurons was filled from the dorsal ramus, while the ventral ramus labelled a distinctive lateral pool as well as more medially located cells. This differential distribution of motoneurons was evident in animals in which endplate formation had not yet begun (Kelly and Zacks, J. Cell Biol. 42: 154, 1969). In fetuses a population of cells was also filled in a part of the spinal cord not occupied by motoneurons in older animals. These cells were located more dorsally and medially. They had axons in the ventral root, and, like some motoneurons, frequently had a process which terminated in the ventricular zone. The number of such cells decreased during the prenatal period, and few were seen by day 18. These cells may be migrating motoneurons. The fetal motoneurons appeared immature in that they often had dendrites extending into the ventral white matter and lacked the longitudinally directed dendrites characteristic of more mature motoneurons.

Some dorsal root ganglion cells were filled in fetuses at day 14, indicating the presence of afferent axons in the periphery. Afferent fibers with clearly identifiable growth cones were observed in fetal spinal cords from the 15-18th day. Afferent growth cones were in the vicinity of motoneurons on day 16, and by day 18, afferent contacts with stained motoneurons were frequent. When significant afferent branching in the dorsal horn is first observed, at day 18, both dorsal and ventral ramus afferents have their major arborizations in the restricted regions to which they project in rats 10 days after birth.

These observations indicate that: 1) axons of motoneurons form an adult-like pattern of peripheral innervation before the formation of synapses with muscle begins; 2) afferents contact motorneurons before the motoneurons have attained their mature morphologies and 3) the central processes of afferents in a given peripheral nerve grow preferentially into specific regions of the dorsal horn.

518 THE DEVELOPMENT OF THE CORTICAL COLUMN: A (^{14}C)-2-DEOXYGLUCOSE STUDY IN THE RAT. P. Hand, M. Kossut*, U. Patel*, and C. Goochee*. Department of Animal Biology, School of Veterinary Medicine, and Institute of Neurological Sciences, University of Pennsylvania, Philadelphia, Pennsylvania, 19104; Department of Neurophysiology, Nencki Institute of Experimental Biology, Warsaw, Poland; and Laboratory of Cerebral Metabolism, NIMH, Bethesda, Maryland 20014.

Previous 2-deoxyglucose (2DG) studies of Hand et al., (Neurosci. Abst., 3,4:1977,78) demonstrated that stroking of a facial vibrissa increased glucose utilization in a single, spindle-shaped cortical column which extended from lamina I to lamina VI. The precision of this system makes it a useful model in which to investigate plasticity. Hand et al., produced significant alterations of labeling in the single column after unilateral ablation of all but one vibrissal follicle (C3), 2-4 days postnatally (P-2, P-4). The column activated by C3 stimulation was discernable only in lamina IV. In order to determine if the diffuse labeling of supra-and infragranular layers was the result of a reorganization of developing axonal terminations or that such diffuse connections were in existence at the time of follicle ablation and did not "retract" to the adult columnar configuration, the single whisker stroking paradigm was instituted in rats on P-2, 4, 6, 8 and 12 (PO=birthdate). Briefly, 5uCi of (^{14}C)-2DG was injected intraperitoneally in the unanesthetized, restrained baby rat, the C3 whisker stroked, and the rat sacrificed at 60 minutes and prepared according to Sokoloff et al., (J. Neurochem. 28, 1977). The results were as follows: (1) no increased cortical labeling was detectable in SI cortex on P-2; (2) the column, 250 um in diameter, was detectable on P-4; but was labeled lightly and involved only the superficial - half of the neocortex (presumptive layers I-IV); (3) on P-6 and P-8, the column was more densely labeled, with densest labeling in superficial layers and light labeling in deeper cortical layers; (4) on P-12, supra-and infragranular layers of the column were more equally labeled; (5) on P-4 to 12, the most densely labeled portion of the column was layer IV.

These findings suggest that results in our previous columnar alteration studies were probably due to a reorganization of ingrowing axonal terminations (P-2 rats) or of newly established connections (sprouting?) in P-4 rats. We postulate that lack of labeling in cortical laminae VI and V, containing neurons projecting to thalamus and brainstem-spinal cord, may be responsible (in part) for the lack of cortical control in neonates. 519 THE EFFECTS OF TWO CENTRALLY ACTIVE DRUGS ON THE DIFFERENTIATING RAT CEREBELLUM. Richard S. Hannah*, Sheldon H. Roth and Arthur W. Spira*. Divisions of Morphological Science, and Pharmacology and Therapeutics, University of Calgary, Calgary, Canada.

It is currently believed that many therapeutic agents which can cross the placental barrier may produce subtle effects on the central nervous system of the developing fetus and during the lactation period postnatally, on the neonate. It is our hypothesis that these subtle effects may include a reduction in neuronal population resulting from the action of these drugs on the differentiating neuronal membranes, thus preventing the optimum number or types of synaptic contacts from forming. The two drugs chosen for this study were Chlorpromazine and Phenobarbital. Both agents are capable of crossing all membrane barriers and are frequently administered both pre- and postnatally. Chlorpromazine was chosen as a prototype of the phenothiazine tranquilizers and antiemetics and phenobarbital as a prototype of the barbiturates, sedative/hypnotics. Separate groups of time-pregnant Sprague-Dawley rats were given daily I.P. injections of either 0.6 mg/Kg Chlorpromazine or 0.6 mg/Kg Phenobarbital beginning on day 18 post coitus until they were sacrificed on postnatal days 13, 15, 18 and 21. The pups were anesthetized and perfused with a buffered aldehyde mixture. The cerebella were removed, the vermis dissected free and bisected in the mid-sagittal plane. The tissue was then processed for electron microscopy utilizing conventional techniques. Sections (0.5 µm in thickness) were photographed and quantitated for the number of Purkinje cells per mm^2. Both Chlorpromazine and Phenobarbital produced a statistically significant decrease in total numbers of Purkinje cells below control levels. Large numbers of pyknotic cells were observed in both treated groups. Ultrastructurally, Purkinje cell degeneration was marked by chromatin condensation, increased electron density of the cytoplasm and a paucity of axo-somatic synaptic contacts. The climbing fiber input appeared to be the most severely affected. These results indicate that the Purkinje cell population of the differentiating rat cerebellum is susceptable to the actions of centrally active agents during the period of neuronal differentiation, both pre- and postnatally. (Supported by Alberta Mental Health).

520 EFFECTS OF CELL-SUBSTRATUM INTERACTIONS ON THE SURVIVAL AND DEVELOPMENT OF CULTURED SYMPATHETIC NEURONS. Edward Hawrot* (SPON: Story Landis). Dept. Neurobiology, Harvard Medical School, Boston, MA 02115

The maintenance of low-density, dissociated rat sympathetic neurons for long times in culture requires strong adhesion of the extending neurites to the culture substratum. Several chemically-defined surfaces as well as some cell-derived substrata were examined for their effects on the survival, neurite outgrowth, and neurotransmitter development of sympathetic neurons. In comparison to dried collagen films, both three-dimensional hydrated collagen gels and surfaces coated with basic polymers provided a substratum highly adherent for developing neurons. Good survival was obtained and neurites formed a well-attached network in the absence of Methocel, a viscosity-increasing agent, normally added to the culture growth medium in order to mechanically stabilize the neuronal cultures. Surfaces simply coated with polylysine or polyornithine by adsorption did not support long-term culture (>2 weeks). Polylysine covalently linked with glutaraldehyde to an underlying layer of dried gelatin was, however, suitable for long-term culture in the absence of Methocel.

The neurons also attached strongly to a substratum of killed non-neuronal cells (eg. monolayers of rat cardiac myocytes and associated fibroblasts) that had been fixed with paraformaldehyde, heat, ethanol, or trichloroacetic acid. Such surfaces provided good long-term survival and promoted extensive neurite outgrowth under conditions where dried collagen films alone did not support neurite extension. In addition, an extracellular, substrate-associated material produced by certain kinds of nonneuronal cells promoted the long-term adhesion of growing neurites. The adhesive property of this microexudate was sensitive to trypsin, periodate, alkali, and SDS extraction; but resistant to hyaluronidase, chondroitinase, 0.5 M acetic acid, 8 M urea and mercaptoethanol. The glycoprotein, fibronectin, known to form fibrillar extracellular matrices, has been reported to have several of these characteristics.

All the highly adherent surfaces were examined for effects on development of neurotransmitter characteristics. The choice and development of neurotransmitter function was unaffected by the various substrata tested with one exception. A substratum of non-neuronal cells fixed with paraformaldehyde caused an induction of cholinergic properties similar to that seen with nonneuronal conditioned medium.

This work was supported by the Helen Hay Whitney Foundation, the American and Massachusetts Heart Associations, and the NINCDS.

521 CHANGES INDUCED BY X-IRRADIATION OF THE MID-THORACIC AND LUMBOSACRAL LEVELS OF NEONATAL RAT SPINAL CORD. Jeanne K. Heard* and Shirley A. Gilmore (Spon: E. A. Lucas). Dept. Anat., Univ. Arkansas Med. Sci., Little Rock, AR 72201.

The present report compares histopathological changes in three groups of rats irradiated at three days of age. The irradiated zone was limited to a 5-mm length of mid-thoracic spinal cord (T only) in one group, to a 5-mm length of lumbosacral spinal cord (L only) in a second group, and to 5-mm lengths of both mid-thoracic and lumbosacral spinal cord (T/L) in the third group. A single dose of 4000 R of soft x-rays was administered to each site. Groups of irradiated rats and their sham-irradiated littermates were killed by formalin perfusion from 9 through 60 days post-irradiation (P-I), and the spinal cords were prepared for light microscopic examination. The occurrence of intramedullary Schwann cells and peripheral-like myelin following irradiation of the same levels of neonatal rat spinal cord has been presented previously (J. K. Heard and S. A. Gilmore, 1978) and will not be included.

Irradiation of Mid-Thoracic Area (T only and T/L irradiated groups): The neuroglial population was decreased in the thoracic area from 9 to 13 days P-I. By 15 days this neuroglial decrease was no longer apparent. Scattered hemorrhages were seen in both gray and white matter from 11 to 17 days P-I. Luxol fast blue-periodic acid-Schiff staining revealed that all funiculi were transiently hypomyelinated in both groups. The dorsal funiculus was particularly interesting in that the fasciculus gracilis showed a greater degree of hypomyelination than did the fasciculus cuneatus from 9 through 15 days P-I. These two fasciculi could not be differentiated on this basis by 19 days P-I, and by 60 days the state of myelination in the irradiated thoracic areas appeared the same as that in controls.

Irradiation of Lumbosacral Area (L only and T/L irradiated groups): Lumbosacral spinal cord areas of L only and T/L irradiated animals showed a decrease in neuroglia at all post-irradiation intervals. This neuroglial decrease was most marked from 13 to 17 days P-I. Scattered hemorrhages were seen at 11 days P-I, and from 15 to 60 days some animals showed large areas of hemorrhagic necrosis and cystic degeneration. The dorsal funiculi were affected first, although the gray matter was also involved in a few animals. The lumbar spinal cords were hypomyelinated throughout the experimental period, with the dorsal funiculi being affected most severely. In general, the lumbar area of T/L irradiated spinal cords showed more necrosis, more dysmyelination, and a greater decrease in neuroglia when compared to the L only irradiated spinal cords. (Supported in part by USPHS Grant NS 04761.)

522 BRAIN CATECHOLAMINES AND BEHAVIORAL CHANGES FOLLOWING NEONATAL ASPHYXIA IN THE RAT. Thomas Hedner* and Per Lundborg* (SPON: N.H. Bass). Dept. Pharmacol. and Clin.Pharmacol., Univ. of Göteborg, S-400 33 Göteborg, Sweden.

In the rat brain, almost all the catecholamines-(CA)-containing nerve cell bodies present in the adult are also present at birth. The rate limiting step in the formation of the neurotransmitters dopamine (DA) and noradrenaline (NA), tyrosine hydroxylase, is markedly affected during oxygen deprivation, as molecular O_2 serves as a substrate for the synthesis of the intermediate substance dihydroxyphenylalanine (DOPA). Neonatal rats were exposed to a low oxygen environment (anoxia or 6% O_2) for various time intervals. DOPA accumulation was measured after NSD 1015 to estimate the rate of tyrosine hydroxylation in vivo and DA and NA levels were followed after α-methyltyrosine to study the nerve impulse activity in the CA neurons. During a short period of hypoxia (6% O_2, 30 min) the synthesis of DA and NA was impaired in the brain stem, "midbrain" and striatum regions of the neonatal rats. 6% O_2 over a 2 h interval also caused a reduced nerve impulse activity in the DA neurons but not in the NA neurons, as measured by DA and NA disappearance after α-methyltyrosine. The acquisition of a conditioned avoidance response (CAR) and the effects on CA neurotransmitter synthesis and levels were investigated in 28 days old rats after neonatal oxygen deprivation. A group of rats exposed to 20 min neonatal anoxia did not differ in avoidance responding compared to controls. However, neonatal rats subjected to 6% O_2 for 4.5 hours were markedly inferior in the CAR acquisition than the control group. CA synthesis, measured as DOPA accumulation after NSD 1015, was impaired in the rats exposed to 6% O_2 for 4.5 h but not in the animals exposed to 20 min neonatal anoxia. It is concluded that brief periods of acute asphyxia markedly affect CA synthesis and turnover in the neonatal rat brain. It is also suggested that the permanent behavioral deficits observed after prolonged neonatal asphyxia may be due to an impaired development of central catecholamine mechanisms.

523 SOME CHARACTERISTICS OF PRE- AND POST-SYNAPTIC MEMBRANES DURING THE DEVELOPMENT OF THE ADRENERGIC INNERVATION OF THE CHICK EMBRYO VENTRICLE. D. Higgins* and A. Pappano* (SPON: Y. Grimm-Jørgensen). Univ. of Conn. Health Ctr., Farmington, CT 06032.

Studies employing catecholamine histochemistry have shown that adrenergic axons first appear on the 11th incubation day in the chick embryo right ventricle (RV). We have studied the functional properties of the membranes of the pre-synaptic adrenergic axons and the post-synaptic cardiac muscle cells near the time of synapse formation. Terminals of developing adrenergic axons were characterized by their ability to transport and retain tritiated norepinephrine (^{3}H-NE) and to secrete previously stored ^{3}H-NE. RV were excised from chicks (9 days after fertilization to 1 week after hatching) and were incubated for 1 hour in Tyrode solution containing ^{3}H-NE (0.55μM). They were then transferred to a chamber where passive overflow of ^{3}H was monitored for 60 minutes. Subsequently release was evoked by elevated potassium (K^+, 140mM) or by 60 seconds of electrical excitation (ES) of intracardiac nerves (50V pulses, 5 msec, 30 Hz).

Cocaine-sensitive uptake and reserpine-sensitive retention of ^{3}H-NE were first seen during the third embryonic week. Release of ^{3}H by K^+ or ES was seen as early as the 14th embryonic day. The amount of ^{3}H released per mg tissue by either method increased more than 30-fold from the 14th to the 28th day. Release was blocked by omission of calcium. Blockade of sodium ion channels by tetrodotoxin inhibited release by ES at all ages tested (14, 18 and 28 days). (Preliminary results show the presence of α adrenergic receptors capable of modulating release on the 21st day, the youngest age tested.) It thus appears that membranes of developing adrenergic axons contain many proteins characteristic of mature axon terminals before prolonged contact with the target tissue has occurred. To test for functional β receptors on cardiac muscle cells, superfused RV were paced at 3 Hz and contractions were recorded before and during exposure to Isoproterenol (ISO). As early as the 5th day after fertilization ISO (1μM) augmented twitch tension. From the 8th to 28th day dose-response curves were obtained and the ED_{50} was used as a measure of sensitivity to ISO. A transient subsensitivity to ISO was seen during the 3rd embryonic week (ED_{50}'s for the 11, 18 and 28th day were 3.2±.3, 29±4.3, 2.3±.5nm respectively). Uptake II blockers did not increase the sensitivity of the RV of 18 day embryos, suggesting that the change in sensitivity was post-junctional. Reserpine (10μg/egg) delayed the onset of functional innervation without affecting the change in ISO ED_{50}. Although a subsensitivity coincides with cardiac innervation, they are probably not causually related. (Supported by HL-13339 and Pharm. Manu. Assoc. Fellowship.)

524 DEVELOPMENT OF SENSORY NEURON PROJECTION PATTERNS UNDER NORMAL AND EXPERIMENTAL CONDITIONS IN THE CHICK HINDLIMB. Marcia G. Honig* (SPON: C. Stevens). Dept. Biol., Yale Univ., New Haven, Ct. 06520.

It has frequently been suggested that before axonal outgrowth sensory neurons are unspecified and that they are later specified by contact with their peripheral targets. Alternatively they may somehow be intrinsically specified. The aim of these experiments has been to distinguish between these two possibilities. In addition the pattern of initial afferent outgrowth has been examined to determine whether it is selective or random.

Although sensory neurons projecting out particular cutaneous or muscle nerves in the chick hindlimb are scattered within individual dorsal root ganglia (DRG) (Honig, 1977, Neurosci. Abst. 3:108), they are predominantly localized in 2-3 adjacent DRGs. This segmental pattern of innervation has been used to determine whether afferents project to their appropriate targets initially during development and after experimental manipulations.

Early stages of axonal outgrowth into the limb have been examined by injection of HRP into DRGs, allowing visualization of labelled cell bodies and their axons. Retrograde transport of HRP and spinal nerve stimulation have been used. The segmental projection pattern for both cutaneous and muscle afferents found shortly after axonal outgrowth into the limb (St 27) prior to the period of DRG cell death and before sensory neurons establish their central connections is similar to that found later (St 38) after muscle cleavage and sensory cell death. Thus from the earliest stages, afferents in particular ganglia grow down the appropriate peripheral nerves, and muscle afferents do not show widespread branching throughout the undivided muscle masses.

After several segments of neural tube (prospective spinal cord and DRGs) have been removed at St 15-16, prior to the birth of sensory neurons, the cutaneous and muscle nerves which originate from this region are missing. The remaining ganglion cells grow down only the appropriate peripheral nerves. Furthermore before muscle cleavage, proprioceptive afferents seem to terminate in only appropriate regions of the muscle and do not innervate adjacent uninnervated areas. These results suggest that lumbosacral sensory neurons demonstrate regional differences before reaching their specific peripheral targets and that they do not need to compete with adjacent segments in order to form appropriate projections. In order to determine whether such regional differences are acquired prior to or upon initial outgrowth into the limb, segments LS 1-3 were reversed along the a-p axis prior to neural crest migration. This reverses both the prospective DRG cells and the spinal cord. Displaced motoneurons form appropriate connections in this situation (Lance Jones and Landmesser, 1978, Neurosci. Abst. 4:118). For sensory neurons the pattern of outgrowth is not completely random and projections down appropriate nerves can sometimes be found from displaced ganglia. These results although preliminary are consistent with the hypothesis that at least some sensory neurons may be prespecified to innervate their appropriate targets. (Supported by NIH NS10666).

525 ABERRANT DENDRITIC PROJECTIONS FROM AN IDENTIFIED AUDITORY INTERNEURON ARE INNERVATED BY CONTRALATERAL AUDITORY AFFERENTS. Ronald Hoy and Andrew Moiseff. Sect. of Neurobiology & Behavior Langmuir Laboratory, Cornell University, Ithaca, N.Y. 14850.

When auditory afferent innervation is withheld from an uniquely identified interneuron (interneuron-1) throughout postembryonic development in the cricket Teleogryllus oceanicus, its medial dendrites grow in a peculiar pattern. Normally, the medial dendrites project to the ipsilateral acoustic neuropile and never cross the midline. However, in unilaterally deprived animals the medial dendrites of the deprived int-1 cross the midline of the prothoracic (auditory) ganglion and project to the acoustic neuropile on the contralateral side. Moreover, morphological studies of cobalt-stained preparations suggest that in unilaterally deprived animals the intact auditory axons of the unoperated side innervate the medial dendrites of both the operated and unoperated interneuron-1s (Hoy, Casaday, & Rollins (1978) Soc. Neurosci. Abst. 4.).

Interneuron-1 has a unique response to acoustic stimulation. At sonic frequencies (5-10 kHz) spontaneous activity in the neuron is strongly suppressed; however at ultrasonic frequencies (20-70 kHz) the neuron is strongly and tonically excited. This unusual response serves as a "signature" by which to identify the neuron physiologically, and subsequent staining with cobalt confirms the identity of the unit as interneuron-1 (Moiseff and Hoy, in prep.).

Unilaterally deprived preparations were physiologically tested to determine whether the deprived interneuron-1 could be activated by acoustic stimulation of the intact ear on the contralateral side. We were able to record units from both the deprived and intact sides that responded to sonic and ultrasonic tones in a manner characteristic of interneuron-1. We conclude that deprived interneuron-1s establish functional synapses, through their medial dendrites, with the contralateral auditory afferents.

526 DEVELOPMENT OF CHICK SYMPATHETIC GANGLIA: MORPHOMETRIC AND BIOCHEMICAL ANALYSIS. K.A. Hruschak*, V.L. Friedrich, Jr., M. Marchi* and E. Giacobini (SPON: M. Wilson). Dept. of Biobehavioral Sciences, Univ. of Connecticut, Storrs, Ct. 06268.

Chicks at the four ages: 10 days in ovo (i.o.), 1 day and 30 days after hatching (a.h.) and adult (360+ days a.h.), were fixed by perfusion and the lumbar paravertebral ganglia, L1-L4, were prepared for electron microscopy. The volume of each whole ganglion was determined from area measurements of serial 20-40μm thick sections. Partial volumes of neuronal somas, neuropil, connectives and blood vessels were determined by point hit counting of 2μm thick sections taken at regular intervals. The absolute volume per ganglion of each compartment was determined as the product of the average volume per ganglion from serial sections and the average partial volume of the compartment. Preliminary results are presented here.

The partial volume of the neuropil increases with age from less than 10% at 10 days i.o. to 35% in the adult. The rate of increase is greatest in the interval before hatching and is substantially less, subsequently. By contrast, the partial volume of neuronal somas is greater than 60% at 10 days i.o. and decreases progressively to about 20% in the adult. Total ganglionic volume increases progressively from 0.01 mm^3 per ganglion to 0.8 mm^3 in the adult. Both neuropil and somas increase in their absolute volume per ganglion. The absolute volume of neuropil per ganglion increases during each of the three intervals studied. The ratio of the absolute volume of neuropil to absolute volume of somas also increases substantially during each interval, from 0.3 at 10 days i.o. to 2 in the adult.

Using the radiochemical micromethod of McCaman and Stetzler (J. Neurochem. 1976, 26:996) the levels of acetylcholine (ACh) and choline were also measured in chick lumbar sympathetic ganglia. Data are expressed as pmoles/ganglion. ACh increases over 90 fold (2 to 182 pmoles) from 10 days i.o. to adult. ACh levels are low (3.0) throughout embryonic and early posthatching stages and rise rapidly between 7 days a.h. and adult. Choline levels closely parallel ACh levels at each developmental stage.

Although a general correlation obtains between the amounts of neuropil and of ACh and choline at different ages, the patterns differ in detail. These differences may reflect changes with age in the ultrastructural composition of the neuropil, currently under analysis. Our results show that growth and development of these ganglia continues well into adulthood. This growth is evidenced by substantial increases (at least doubling) in the total ganglionic volume, the absolute volume of neuropil per ganglion, and in the amounts of ACh and choline per ganglion, in the period between 30 days and 360+ days a.h. (Supported by grants NIMH 5 F31 MH07326, NS09904 and UCONN Res. Found.)

528 BIRTH AND DIFFERENTIATION OF SPECIFIC NEURONS IN THE ABDOMINAL GANGLION OF APLYSIA. M. Jacob, S. Schacher* and V. Castellucci. Div. of Neurobiol. & Beh., Columbia U., P&S, New York, NY 10032

The egg of Aplysia is determinate; specific cells of the blastomere differentiate into definitive parts of the adult animal. As a result it should be possible to distinguish the exact part of the blastula which gives rise to precise regions of the central nervous system and thereby to explore the lineage of the identified cells in the various ganglia.

Embryonic development in Aplysia, from fertilization to hatching, takes approximately 12 days. The formation of the abdominal ganglion begins during this period and the anlage of the ganglion is already present at hatching. To examine the origin of the neuroblasts and their differentiation into specific neurons of the abdominal ganglion we exposed egg masses at various developmental stages to 10^{-5} M thymidine, (methyl-^{3}H)-(specific activity 20 mCi/mmol) and 10^{-5} M cytidine in sea water for two days. Following a 24 hour rinse in sea water alone, animals were sampled at definite time intervals relative to their developmental cycle and processed for light and electron microscopic autoradiography.

Exposing egg masses in the gastrula and segmented cavity stage (6&7 days after fertilization, respectively) resulted in the labeling of four or five neuroblasts in both the left and the right quadrants of the abdominal ganglion. At later larval (postembryonic) developmental stages these heavily labeled cells were recognizable as neurons.

Exposing egg masses in the late trocophore stage (8 days after fertilization) resulted in the labeling of fewer cells. At larval stage 1, two of these cells could be recognized as neurons in the left hemi-abdominal ganglion, one in the rostral and the other in the caudal segment. These two cells have been traced throughout the subsequent developmental phases up to adulthood. Preliminary morphological and electrophysiological characterization suggest that these neurons may be the identified cells L_{12} and L_{13}.

Thus, by combining ^{3}H-thymidine labeling with electron microscopic and electrophysiological techniques, it should be possible to study the pattern of differentiation of specific identified neurons of known behavioral function. We are also investigating 1) the origin of the precursor cells, 2) the signals that guide the migration of the neuroblasts and initiate their differentiation following final division and 3) the three-dimensional arrangement of the neurons within the ganglion.

527 TRANSITION FROM A CONTINUOUS TO A DISCRETE DISTRIBUTION OF CALLOSAL PROJECTION NEURONS IN THE RAT PARIETAL CORTEX. Gwen O. Ivy* and Herbert P. Killackey (SPON: E.A. Davis). Dept. Psychobio., Univ. of Calif., Irvine, CA 92717.

In the adult rat, the two cerebral hemispheres are connected through the corpus callosum by neurons which are discretely located in areas of the neocortex. Retrograde tracing techniques have established that the perikarya of callosal projection neurons are found in distinct vertical arrays, with the majority of cells being distributed to layers III and V, and fewer to layers II and VI. During the first few postnatal days, however, the callosal projection neurons are distributed as continuous bands throughout the mediolateral extent of the cortex, as we have reported previously (Anat. Rec., '79, 193:573). The present study focuses on the events occurring during the transition from a continuous to a discrete adult distribution of callosal projection neurons.

Sixty rats of postnatal ages from 0 to 14 days and adults were injected unilaterally in parietal cortex with Sigma VI HRP. Most animals were sacrificed 24 hr post-injection, although some were allowed to survive for from 4 hr to 5 days. All brains were processed according to the technique of Mesulam (J. Hist. Cyt., '76).

From the day of birth, PND 0, through PND 4, two continuous bands of cells extend horizontally throughout the cortex beneath the upper dense cortical plate. These bands are in laminae destined to become layers V and VI in the adult. The Rapid Golgi method reveals that neurons in these laminae are immature pyramidal cells, while cells lying more superficially have not begun to differentiate noticeably. From PNDs 5 through 10, several changes occur. From PND 5 to PND 7, cells of the upper dense cortical plate become labeled in increasing numbers. These labeled cells appear initially as an extension of the band of label in layer V, and later, as a separate lamina above layer IV. Rapid Golgi preparations reveal that superficial pyramidal cells mature in form and acquire basal dendrites during this period. From PNDs 5 through 10, distinct aggregates and bands of cells which lack label become increasingly apparent in layer IV. Also during this period, the density of labeled cells in layer VI declines markedly. The greatest decline appears in areas destined not to be callosally connected in the adult, and in these same areas, labeled cells of the other cortical layers also become much less numerous. Thus, by PND 10, the trend toward the adult distribution of callosal projection neurons is firmly established. Finally, by PND 15, the pattern does not differ significantly from that of the adult.

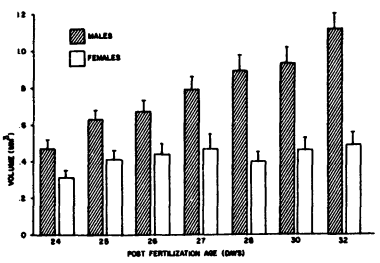
529 ONTOGENY OF THE SEXUALLY DIMORPHIC NUCLEUS OF THE PREOPTIC AREA. Carol D. Jacobson, James E. Shryne*, Fred Shapiro* and Roger A. Gorski. Dept. Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

An area of increased cell density in the medial preoptic area of the adult rat brain which is markedly larger in volume in the male has been named the Sexually Dimorphic Nucleus of the Preoptic Area (SDN-POA). It has been further shown that the presence of the testes or exogenous androgen during the first week of postnatal life significantly increases the volume of the SDN-POA in the brain of the adult. The present study was conducted to describe the time course of the postnatal development of the SDN-POA in the intact male and female rat. Sprague-Dawley females were housed with males on proestrus. The presence of sperm in the vaginal smear on estrus was used to define day 1 of gestation. Male and female pups were sacrificed and perfused with 10% formalin on days 24, 25, 26, 27, 28, 30 or 32 post-fertilization. Following histological sectioning at 60 μ and staining with thionin, 3 investigators independently drew the boundaries of the SDN-POA on successive sections, using a microprojector at a magnification of 43.5. A fourth investigator averaged the 3 drawings; from this average, the nuclear volume was determined with a calibrated planimeter. All drawings and measurements were performed without knowledge of age or sex since the brains were coded according to a random number table. We found that the volume of the SDN-POA was significantly larger in males than in females on days 25 through 32, but no difference was found on day 24. Moreover, the volume of the SDN-POA increased significantly with age in the male, but there was no change in SDN-POA volume in the female (see figure). There was a significant increase in brain weight with increasing age in both males and females, but there was no consistent statistical sex difference in brain weight. Thus, the sex difference in volume of the SDN-POA cannot be accounted for by sex differences or age-related changes in brain weight per se. These data suggest that the development of the SDN-POA (as measured by volume) is itself sexually dimorphic. There are dramatic increases in the male, but not in the female, during a time period which is known to be critical for sexual differentiation of the brain. (Supported by NIH grant HD-01182, and the Ford, Grant and Kroc Foundations.)



530 DENDRITE BRANCH FORMATION AND GROWTH, AND ITS RELATIONSHIP TO SYNAPTOGENESIS ON THE DEVELOPING MAUTHNER CELL OF THE MEXICAN AXOLOTL (AMBYSTOMA MEXICANUM). Jean Jacoby* (SPON: Charles B. Kimmel), University of Oregon, Eugene, OR 97403.

It has been proposed that synaptic contacts during development are intimately involved in directing the course of dendrite growth and branching (Vaughn et al., 1974, JCB 60,664). I have examined the relationship between this growth and synaptogenesis in a case where the dendrite is uniquely identifiable.

The lateral dendrite and the adjoining perikaryon of the axolotl Mauthner cell was studied during a developmental period of about 4 days of the late embryo (Stages 39-43). During this time branch surface increased dramatically, with the cell acquiring its mature pattern of arborization by stage 43. A lesser amount of non-branch growth was also observed. Synapse density (number of synaptic profiles/100 micrometers cell surface) on the cell increased in parallel with the course of growth of the cell's surface, both branch and non-branch. This supports the model of Vaughn et al.

A class of profile termed "quasi-synaptic profiles", which contained features of synaptic profiles but lacking synaptic vesicles associated with the junction, were used to assay very early synaptic contacts. Quasi-synapse density was found to be significantly higher on branches than on non-branch surface at all stages. Quasi-synapse density was highest on branches at the early stages, and decreased with time, as expected for a feature transiently present on newly added surface. In addition quasi-synapse density was low on non-branch surface where growth was also low. Finally, the concentration of both quasi-synaptic and synaptic profiles at branch points was twice as high as that found on the adjacent surface, branch and non-branch. This suggests that a high concentration of afferent contacts stimulates dendrite branch outgrowth.

I conclude that spatiotemporal patterning of dendrite growth in this system is closely associated with patterning of input synaptogenesis. (Supported by NSF grant BNS 77-08685 and NIH grant NS 15001).

531 CHANGES IN RADIOSENSITIVITY ACCOMPANYING GRANULE CELL DIFFERENTIATION. Karl F. Jensen*. (SPON: Joseph Altman) Dept. Biol. Sci., Purdue Univ., W. Lafayette, IN 47907

The developing cerebellar cortex provides an ideal system to evaluate the change in radiosensitivity that occurs in the course of differentiation of granule cells. The proliferative, migratory, and maturational stages of granule cells are present concurrently in anatomically discrete layers and can be histologically quantified.

Ten day old Wistar rat pups were given a single dose of 300 KV whole head x-rays ranging from 25 to 7000 r. The pups were sacrificed 6 hrs after irradiation and the cerebella were embedded in glycol methacrylate. Coronal sections were cut at 3 microns and stained with hematoxylin. All cells were counted in samples of the external germinal layer (EGL), molecular layer (MOL), Purkinje cell layer (PCL), and internal granule cell layer (IGL) of the pyramis. The relative reduction of each cell type across dose was then determined.

Mitotic activity ceased above 250 r. The germinal cells of the upper portion of the EGL and the premigratory cells of the lower portion of the EGL were reduced by 80% at 300 r. The descending granule cells of the MOL and PCL were not significantly reduced until a dose of 1000 r. The basket cells of the MOL did not exhibit significant pyknosis until a dose of 7000 r. Purkinje, Golgi and Bergmann glial cells did not exhibit significant pyknosis at the doses applied. With the exception of the small contribution of the basket cells, the entire pyknotic population can be accounted for by the selective elimination of granule cells at different stages of their differentiation.

The decrease in radiosensitivity occuring with differentiation and associated migration may reflect functional metabolic changes accompanying increased specification. The selective elimination of undifferentiated granule cells can be used to determine their effect on the development of the cells with which they form connections as well as the circuitry in which they are normally involved.

532 THE GERMINAL ZONE IN GOLDFISH OPTIC TECTUM -- WHERE IT IS AND WHAT ITS CELLS LOOK LIKE. Pamela Raymond Johns and Stephen S. Easter. Depts. of Anat. and Zool., Univ. of Mich., Ann Arbor, MI 48109

In the brains of fishes, clusters of dividing cells are seen in several specific locations, called germinal or matrix zones. It is thought that new cells, both neurons and glia, produced at these sites contribute to normal brain growth and to regeneration of damaged tissue. We know from previous reports that the germinal zone of the optic tectum is restricted to the dorso-medial, ventrolateral and caudal edges. But its precise geometry has not been described, nor have the cells that are dividing been examined ultrastructurally. Here we identify the dividing germinal cells and chart their location in the tectum.

When goldfish (about 10 cm in length tip-to-tip) are injected with ^{3}H-thymidine, dividing cells incorporate the label. Labeled germinal cell nuclei are elongated, often lobulated, with prominent nucleoli; cytoplasm is sparse. The germinal cells are at the borders of the tectum, tightly packed between the edges of the periventricular layer and adjacent ependymal cells. A ventricular lumen always underlies the germinal zone. In electron micrographs the distinctive nuclei of the germinal cells are easily recognized.

In dorsal view (reconstructed from serial radioautographs of transverse paraffin sections) the germinal zone is a U-shaped ribbon, approximately 0.1 mm wide and 3.3 mm long, whose base is at the caudal tectal pole. One arm of the "U" lies along the dorsomedial tectal edge and the other arm is on the opposite, ventrolateral edge. The dorsomedial arm extends further rostrally and is 0.65 mm longer than the ventrolateral arm. The "U" opens at the rostrolateral tectal pole; this edge therefore lacks a germinal zone. The tectum receives a topographical projection from the retina, and the gap in the tectal germinal zone corresponds to a nasal segment of visual field subtending approximately 145°. (We compared our anatomical reconstruction with Schwassmann and Kruger's electrophysiological map: J. Comp. Neurol. 124: 113, 1965.) In goldfish retina the germinal zone is not "U" shaped, but rings the entire retinal circumferance. A similar mismatch in loci of cell production in retina and tectum of larval amphibians has led to the proposal that during growth there is a continual readjustment of topographically organized connections between optic fibers and tectal cells. Our results in growing goldfish support this hypothesis.

533 SELECTIVE LOSS OF NORADRENERGIC PHENOTYPIC CHARACTERS IN NEUROBLASTS OF THE RAT EMBRYO. G. Miller Jonakait, Judy Wolf*, Philippe Cochard*, Menek Goldstein and Ira B. Black. Dept. of Neurol., Cornell Univ. Med. Col., New York, N.Y. 10021 and Dept. of Psych., New York Univ. Med. Col., New York, N.Y. 10016.

Noradrenergic phenotypic characters are transiently expressed by neuroblasts in the gut mesenchyme of rat embryos. At 11.5 days of gestation, gut neuroblasts which contain tyrosine hydroxylase, dopamine-β-hydroxylase and endogenous catecholamine (CA) fluorescence, first appear (Cochard, P., Goldstein, M., Black, I.B.: Proc. Natl. Acad. Sci. USA, 75: 2986-2990, 1978; Teitleman, Baker, Joh, Reis: Proc. Natl. Acad. Sci. USA, 76: 509-513, 1979). They increase in number over the ensuing 24 hr. period, but by 13.5 days these noradrenergic characters have essentially disappeared. To define the fate of these cells, we studied formaldehyde-induced fluorescence following specific, high-affinity uptake of norepinephrine (NE). NE uptake, which was apparent in gut neuroblasts at 12.5 days, persisted at least through 17.5 days, long after the other endogenous noradrenergic characters had disappeared. Uptake was inhibited by incubation at 4°C or by inclusion of the highly specific uptake blocker, desmethylimipramine. These observations suggest that (a) high-affinity NE uptake develops as an additional noradrenergic characteristic in these gut cells, (b) the ability to take up NE persists even after the disappearance of other noradrenergic traits, and (c) the loss of noradrenergic characters is probably not simply due to death of the neuroblasts. Consequently, during embryonic development neuroblasts may transiently express transmitter phenotypes.

534 PATHWAY SELECTION BY EMBRYONIC CHICK LUMBOSACRAL MOTONEURONS. Cynthia Lance Jones* and Lynn T. Landmesser. Dept. Biol., Yale Univ., New Haven, Ct. 06520.

In order to examine the distribution of motoneuron axons in the chick hindlimb between the time of their initial outgrowth (St 23-24) and the establishment of specific functional connections (St 27), injections of HRP were made into individual segments of the lumbosacral lateral motor column. This procedure allowed the visualization of HRP reaction product in the motoneuron cell bodies as well as the outgrowing axons. At St 23-24, the spinal nerves projected only to the base of the limb bud, yet clearly were beginning to form distinct crural and sciatic trunks. Labelled axons, projecting from a specific segment of the cord, maintained their relative a-p axial position as far as the base of the limb. No evidence of diffuse outgrowth within the plexus region or limb tissue was found at this or subsequent stages. At St 26 1/2 - 27, prior to the cleavage of individual muscles and the motoneuron cell death period, labelled axons projected via specific anatomical pathways through the plexus to appropriate regions of the muscle mass. These results suggest that a period of diffuse or random axonal outgrowth followed by the death of inappropriately projecting neurons is not involved in the establishment of specific connectivity in the chick hindlimb. Similar characterization of axonal pathways at St 27 - 30 revealed that axons to an individual muscle tended to course in discrete tracts within the plexus and nerve trunks although they could change their topographical position with respect to other axons.

These results, although showing that axonal outgrowth is highly selective, did not allow us to distinguish between possible mechanisms involved in pathway selection. We therefore used similar techniques to trace axon pathways in embryos in which segments of neural tube were either deleted or reversed about the a-p axis at St 15-16.

In deletion experiments, axons from remaining segments followed their original pathways and did not alter their growth to compensate for deleted segments. These results rule out the possibility that axons divide up available peripheral territory on the basis of their relative a-p position, specific pathways being determined by competitive interactions with axons from adjacent segments.

When segments of cord were reversed about the a-p axis, motoneurons projected from the cord via adjacent spinal nerves. They established appropriate connections despite their incorrect order of exit from the cord by altering their original pathways within the plexus and nerve trunks. Labelled axons formed discrete groups as early as St 23 - 24 and never appeared to take random or inappropriate pathways. These results rule out simple mechanical guidance, and rather suggest that axons actively respond to positional cues on the basis of an early central specification. (Supported by NIH Grant NS 10666 and postdoctoral fellowship NS 05990)

535 A BASAL SUBSTRATE PATHWAY DEMONSTRATED BY TRANSPLANTED MAUTHNER AXONS. Michael J. Katz* and Raymond J. Lasek (SPON: H. Gluck) Anat. Dept., Case Western Reserve Univ., Cleve. OHIO 44106

A substrate pathway is a set of similar guidance cues aligned in a discrete route. Previously Katz and Lasek, 1979 (JCN 183:817) used transplanted optic axons to demonstrate a substrate pathway running through the alar region of the developing nervous system in Xenopus (Fig. 1). This alar substrate pathway has also been demonstrated in Rana by Constantine-Paton, 1978 (Br Res 158:31). Here we report that transplanted Mauthner axons have demonstrated a basal substrate pathway.Extra hindbrains were transplanted to various locations in the neural tubes of Xenopus embryos of the same stages.Tadpoles were examined in 10 um Bodian stained paraffin sections at st. 43-47. Among the tadpoles studied we found 10 donor Mauthner axons (M' axons) entering host CNS. 6 of these entered from donor hindbrains implanted in spinal cords in reverse rostro-caudal orientation -- 5 grew rostrally and 1 grew caudally. The other 4 M' axons entered and grew caudally from donor hindbrains attached to host diencephalon or forebrain. 9 of the 10 M' axons grew more than 100 um rostrocaudally in the host CNS, and all 9 followed an essentially identical ipsilateral ventral CNS route (Fig. 2), extending from the developing ventral thalamic region down the developing spinal cord. M' axons always grew along the same discrete route in the basal region, and thus the guidance cues which they followed must be aligned as a substrate pathway. Normally, the MLF may follow this basal substrate pathway.

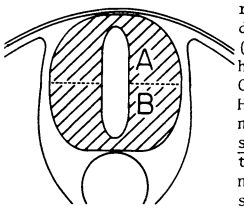

FIG. 1. Developing neural tube. A= alar plate B= basal plate.

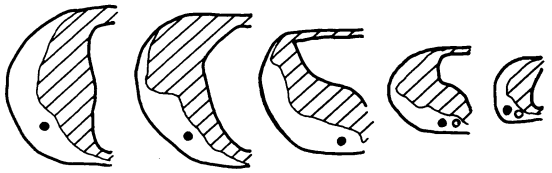

FIG. 2. CNS hemisections (st. 43 Xenopus) showing route of M'axon. L to R: diencephalon, midbrain, rostral hindbrain, caudal hindbrain, spinal cord. (●=donor M' axon, o=host M axon).

536 ORIGIN AND DIFFERENTIATION OF PIONEER NEURONS IN THE EMBRYONIC GRASSHOPPER. Haig Keshishian* (SPON: R.C. Van Sluyters). Neurobiology Group, Univ. Calif., Berkeley, Ca. 94720.

Pioneer neurons (Bate, '76, Nature 260: 54-56) are monopolar afferents found in the lumen of insect embryonic appendages. They may guide sensory neurons to the central nervous system.

The origin of these cells was determined in cultured embryos of the grasshopper Schistocerca nitens undergoing normal appendage morphogenesis. The development of the metathoracic leg and antenna was observed with time-lapse microphotography using differential interference contrast optics, at 30° C.

At the 25-30% stage of development (Bentley et al., J. Emb. Exp. Morph., In press), large (25-30μ) spherical cells can be distinguished in the lumen of the metathoracic leg. These cells give rise to pioneer neurons. The pioneer mother cells (PMCs) have been observed to remain in interphase for as long as six hours before undergoing cell division. During interphase the PMCs sometimes extend and retract 3-5μ cytoplasmic processes, and can undergo small rotations (10-20°). Mitosis of the PMCs is completed in approximately one hour.

PMC daughter cells were identified as pioneer neurons by (1) their location within the lumen, (2) their size, (3) their monopolar morphology, and (4) by a centrally coursing axon. They usually remain quiescent for 30 to 60 minutes following mitosis, after which they begin to sprout fine multiply digitated processes. Although these processes may extend tens of microns, they are often retracted abruptly, followed by a new extension in a different direction. Following this "exploration" of the immediate cellular environment, usually one daughter will migrate in an ameboid fashion along the lumen wall. Velocities of 1-2 microns / minute have been observed for daughter migrations. Axonal sprouting generally follows migration, with the axon spun out behind an elaborately digitated growth cone. Retractions and new extensions of the early axonal processes are sometimes seen. For example, a daughter cell in a 35% stage metathoracic leg was observed to send out cytoplasmic processes first towards the lumen wall, then towards the tip of the leg, and then into the middle of the lumen; finally the cell directed a projection towards the central nervous system which became an axon that grew at least 100-150μ in two hours.

From the 25-30% stage of development onwards some of the PMCs can be individually identified in the metathoracic leg: they occur in fixed number and position in the distal portion of the limb. The PMCs have not been observed to arise from the epidermis, as sensory neurons do, and some evidence suggests that they may be generated centrally and accompany the outgrowth of the appendage.

537 THE ONTOGENY OF EMBRYONIC NEUROBLASTS IS ALTERED BY NERVE GROWTH FACTOR. John A. Kessler*, Philippe Cochard* and Ira B. Black. Dept. of Neurol., Cornell Univ. Med. Coll., New York, N.Y. 10021.

The role of nerve growth factor (NGF) in neuronal phenotypic expression and selective survival was studied in embryonic autonomic neuroblasts in vivo. In the rat, the noradrenergic phenotype first appears in sympathetic ganglion primordia and in neuroblasts within the gut mesenchyme at 11.5 days of gestation (E 11.5), just after neural crest migration. Noradrenergic characters persist in ganglion neuroblasts throughout development, but disappear from the gut by E 14.5.

Transuterine injection of rat embryos with NGF on E 11.5 resulted in striking changes in the ontogeny of the gut cells; noradrenergic numbers were markedly increased. Moreover, injection of NGF caused persistence of catecholamine (CA) neuroblasts in the gut through E 15.5, whereas guts of controls were devoid of these cells at this stage. NGF treatment also increased the number of apparently ectopic neuroblasts in unusual locations such as the liver parenchyma, the somatopleural mesenchyme of the body wall, and the limb bud mesenchyme. In contrast to effects elsewhere, low doses of NGF had little apparent effect on neuroblasts in ganglion primordia. This suggested that the exogenous dose of NGF was too small, in comparison to local endogenous concentrations, to elicit changes in the ganglion primordia. To study the effects of high NGF doses on ganglion ontogeny, the smaller mouse embryo was used, allowing conservation of the protein. Transuterine treatment on E 12.5, during the stage of ganglion aggregation, resulted in a dramatic increase in neuroblast numbers and cell volume in the superior cervical ganglion. NGF treatment also significantly increased ganglionic levels of the CA-synthesizing enzyme, tyrosine hydroxylase.

These observations indicate that NGF can increase the number of noradrenergic neuroblasts in embryonic sympathetic ganglia, as well as the gut and ectopic locations. NGF treatment also caused persistence of noradrenergic neuroblasts in the gut and consequently, local concentrations of endogenous NGF in the embryo may normally determine which neuroblasts survive and/or continue to express noradrenergic characters.

(This work was supported by the NIH, the Dysautonomia Fdn. Inc and the DGRST, France. J.A.K. is the recipient of the Teacher Investigator Award NS 00351. I.B.B. is the recipient of the Irma T. Hirschl Career Scientist Award.)

538 A GRADIENT OF CALLOSAL FIBER DEVELOPMENT IN THE PARIETAL CORTEX OF THE RAT. Herbert P. Killackey and Rebecca M. Akers, Dept. Psychobio., Univ. of Calif., Irvine, CA 92717.

An autoradiographic study of callosal fiber development in the neonatal rat suggests that fibers connecting lateral areas of parietal cortex develop in advance of those directed towards medial parietal areas. Neonatal rats were injected unilaterally in parietal cortex with tritiated amino acids and allowed to survive for 24 hr. Extensive labeling of the entire corpus callosum is evident in animals sacrificed on postnatal day 1 (PND 1). At this stage of development, transported label is evident only in regions of parietal cortex lying adjacent to the rhinal fissure. By PND 2, transported label is evident in the deeper cortical layers of both medial and lateral parietal areas. In lateral areas label extends to the lower border of layer V, whereas in medial parietal cortex it is limited to the lower one third of layer VI. These differences in transport of label are maintained through the first five postnatal days. By PND 4, label in the lateral parietal cortex extends through the deeper cortical layers and reaches the lower border of layer III. In more medial transport sites, label is restricted in most cases to layers V and VI and does not reach the superficial cortical layers until the following day. By PND 6, label extends to the pial surface in both medial and lateral areas of parietal cortex, and regional differences in transport of label are no longer evident.

These findings indicate that the laterally directed callosal fibers may extend through the cortex and reach their superficial terminal fields in advance of fibers destined for the medial parietal cortex. This pattern of callosal fiber development mimics the lateral-to-medial gradient of cell production and migration which has been previously described for the cortex of the developing rat.

Supported by NSF Grant #BNS 78-24655.

539 A STUDY OF THE VITREAL-OPTIC NERVE BARRIER TO DIFFUSION OF HORSERADISH PEROXIDASE IN THE CHICK EMBRYO. Henry B. Kistler, Jr.*and Jennifer H. LaVail. Dept. Anat. UCSF, San Francisco, CA. 94143

Several investigators have described a region immediately beyond the lamina cribrosa of the optic nerve that limits the spread of horseradish peroxidase (HRP) from the vitreous into the extracellular spaces of the optic nerve. The apparent barrier might be explained by apposed membranes of glial cells or neuronal processes, or in the absence of tightly apposed membranes, by a physiological barrier determined by rapid endocytosis of HRP by glial and/or vascular and neuronal elements. As a basis for later study of retrograde transport in developing chick and to determine whether a barrier to vitreally secreted macromolecules might exist, we studied the spread of intravitreal HRP into the optic nerves of chicks ranging from embryonic(E) day 6 to 3 days posthatching. One hr after HRP in saline was injected, the animals were fixed and prepared for histochemical localization of HRP. Light microscopic (LM) examination of 8-10 µm thick longitudinal plastic sections of optic nerve and retina revealed dense reaction product throughout the retina and vitreal surface of the optic papilla. It extended into the proximal optic nerve but not beyond the level of the cartilagenous cuff surrounding the base of the optic stalk. HRP extended farther in the nerve within radially oriented glial septae. Three zones within the nerves of E5, E14 and P3 animals were examined by EM, 1) a proximal zone near the vitreal surface, 2) a zone in the lamina cribrosa where HRP could be detected by LM, and 3)a zone midway between zone 2 and the optic chiasm where HRP could not be detected by LM. In zone 1 there was abundant extracellular HRP and large labeled cytoplasmic organelles in the cell constituents (presumptive glioblasts, astrocytes, oligodendrocytes, and endothelial cells). In E14 and P3 nerves, HRP-filled organelles were seen rarely in axonal profiles. In zone 2, HRP was present extracellularly inbetween the astrocytic processes in radially oriented glial septae. The same HRP-containing cells were present in this zone, but the number, size and density of positive organelles in them were reduced. In zone 3, extracellular HRP was absent. The glial population, composed mainly of presumptive astrocytes, contained few HRP-positive inclusions. In this zone numerous punctate adhesions between apposed astrocytic processes were marked, but tight junctions were never observed. In no zone was there evidence of a transverse network of glial contacts that might form a physical barrier to HRP diffusion. We observed a gradient in the number of positive organelles per astrocytic profile that was inversely related to the distance from the vitreal surface. Our results suggest that the barrier to diffusion of HRP in fetal and early posthatching chicks is a function of uptake of HRP by glial cells that restrict and regulate the concentration of vitreally secreted macromolecules in the developing optic nerve.

540 HISTOGENESIS OF THE INNER NUCLEAR LAYER IN THE RETINA OF XENOPUS LAEVIS. George J. Kokoris and Leslie J. Fisher. Neuroscience Program and Dept. of Anatomy, University of Michigan, Ann Arbor, Michigan 48109

Qualitative and quantitative changes occur in the inner nuclear layer (INL) of the retina of Xenopus laevis as the larvae undergo metamorphosis. That the retina grows by the addition of cells to the periphery is not disputed, but conflicting evidence exists as to the presence of mitotic activity in the older, central retina. Previous investigators have employed paraffin histology, and their different observations may reflect the imprecision of this technique, rather than real differences in their results.

The question of mitotic activity in the central retina was re-examined using plastic histology, which allows more precise identification of nuclei. Xenopus laevis retinae were examined by means of radioautography over developmental stages 55 through 60. Larvae were injected intraperitoneally with ^{3}H-Thymidine and allowed to survive for 24 hours. Eyes were removed, and the tissue processed for radioautography. Under light microscopy, retinae were examined for labelled nuclei within 500um of the optic nerve exit. In addition, nuclear counts were taken over 500um intervals on either side of the optic nerve to ascertain changes in the nuclear density of the INL.

We verify that the INL exhibits a substantial increase in nuclear planimetric density at metamorphosis. The nuclear density of the INL increases significantly ($p<.01$, ANOVA) from stage 55 to stage 60. Furthermore, our experiments confirm Hollyfield's (1971) observation of ^{3}H-Thymidine uptake by nuclei in the differentiated central retina. Though few labelled cells are observed, the changes in nuclear density suggest that mitosis takes place in the central retina, late in larval life.

We present evidence that many of these labelled nuclei are differentiated glial elements (Müller fibers). The precise ultrastructural identification of these new cells is being investigated with electron microscopy.

541 INTRACEPHALIC IMPLANTS OF EMBRYONIC RHOMBIC LIP INTO ADULT RATS PROVIDE MODEL SYSTEMS FOR STUDYING CEREBELLAR DEVELOPMENT. Lawrence F. Kromer, Anders Björklund* and Ulf Stenevi*. Dept. of Neuroscience, UCSD, La Jolla, CA 92093 (L.F.K.) and Dept. of Histology, Univ. of Lund, S-223 62 Lund, Sweden (A.B. and U.S.).

Pieces of embryonic rhombic lip were taken from fetuses with crown-rump lengths (CRL) of 7-25 mm (approximately embryonic days 10-18) and implanted into a cavity in the parietal or occipital cortex in adult female albino rats (180-200 g). The implant was placed adjacent to the severed edge of the host hippocampal formation on the vessel-rich pia covering the thalamus or superior colliculus. Thus, the implant was not in contact with any regions of the host brain that normally have direct afferent or efferent connections with the cerebellum. After survival periods of 1-5 months the host animal was perfused with Bouin's or formalin fixative, and adjacent sections of the host brain containing the implant were stained with the cresyl violet and Klüver-Barrera stains and the Holm's silver method. Pieces of embryonic cerebellar anlage from all gestational stages survived and continued to differentiate within the ectopic site. Individual specimens were observed to contain isolated cerebellar cortex, non-cortical tissue, or both. All implants which developed a cerebellar cortex exhibited a high degree of cytoarchitectonic differentiation. The cortical region was easily identified from adjacent regions of the implant or the host CNS by its characteristic foliation and laminated structure composed of molecular, Purkinje cell and granule cell layers. Since most implants at the time of transplantation contained neuroepithelium with few or no postmitotic neuroblasts, the observations indicate, first, that all different neuron types present in the normal cortex can be generated in the implant, and, secondly, that these cells are able to interact in the isolated implant to produce a highly organized structure. This requires an orderly migration of the cell types involved, especially the granule cells. In addition to the differentiated cortical structure most implants also contain masses of more unstructured neuronal tissue, probably representing brain stem or deep cerebellar structures. This may signify that some of the normal afferent and efferent connections of the cortex can be established within the implant. That such connections are not necessary for cortical differentiation is, however, indicated by cases in which the implant contains only well-differentiated cortex and no or very little brainstem-like tissue.

Thus, it appears that the cell interactions in the fetal brain prior to the dissection and the intrinsic cell interactions occurring within the implant after transplantation are sufficient to produce the characteristic lamination and foliation of the cerebellar cortex. (Supported by UPS grant 5 F32 NS 05528-02).

542 LOSS OF GROWTH HORMONE SENSITIVITY IN BRAIN AND LIVER DURING MATERNAL DEPRIVATION IN RATS. C. M. Kuhn and S. M. Schanberg*. Duke University Medical Center, Durham, N. C. U.S.A.

We have shown previously that maternal deprivation (MD) results in a decrease in brain and heart ornithine decarboxylase (ODC) activity which may be mediated in part by a specific suppression of growth hormone (GH) secretion. To investigate further the relationship between the effects of maternal deprivation and the regulation of tissue development by GH, we tested the ability of GH to stimulate ODC activity in maternally deprived rat pups. Pups were removed from the mother and placed in an incubator for 2 hours, injected with GH (100 µg, s.c.) and liver ODC activity was determined 4 hours later. Littermate controls left with the mother were similarly treated with GH or vehicle. In a separate experiment, maternally deprived and control pups were injected intracisternally with GH (100 µg) and brain ODC activity was determined 4 hours later. ODC activity was significantly lower in liver and brain of deprived pups and was not stimulated by GH, while ODC activity in both brain and liver of control pups increased significantly after administration of GH. When pups that had been maternally deprived for 2 hours were returned to the mother for 2 hours and then injected with GH, significant stimulation of ODC activity in liver was observed. ODC activity did not increase following GH administration in livers of pups placed with a urethane-anesthetized mother although GH did stimulate ODC activity in livers of pups placed with a mother whose nipples had been ligated.

To determine if the loss of tissue response to GH resulted from a specific suppression of GH action, maternally deprived pups were treated with several other inducers of ODC activity. Ovine placental lactogen (oPL, 100 µg), did not stimulate ODC activity in livers of deprived pups, but PGE-1 (50 µg), dibutyryl cAMP (.3 mg) and dexamethasone (0.2 mg) significantly stimulated ODC activity in both maternally deprived and control pups. ODC activity in brains of maternally deprived pups increased significantly following intracisternal administration of dibutyryl cAMP (50 µg).

These findings suggest that maternal deprivation is associated with a specific suppression of tissue response to the growth promoting peptide hormones GH and oPL. This suppression is reversed rapidly when pups are returned to the mother, and appears to be triggered by the removal of active mothering behavior, not by nutritional deprivation or the removal of passive sensory stimuli associated with the mother. (Supported by NIMH grants MH-13683 and MH-06489).

543 RESPONSE OF THE CAT DORSAL LATERAL GENICULATE NUCLEUS TO INFANT VISUAL CORTEX LESIONS. Douglas R. Labar*, Nancy Berman, E. Hazel Murphy. Department of Anatomy and Department of Physiology/Biochemistry, Medical College of Pennsylvania, Philadelphia, PA 19129.

Previous observations indicate that following infant visual cortex lesions in cats, considerable shrinkage of the dorsal lateral geniculate nucleus (LGD) occurs, and the severely shrunken nucleus contains a sparse population of surviving isolated large cells. We looked at the time course of the occurence of these phenomena during the first few post-operative days. Eight kittens were given unilateral visual cortex lesions within 24 hours after birth. Following post-operative intervals ranging from 1 to 9 days, subjects were given a unilateral intraocular injection at H_3-proline, and brains were processed for autoradiography.

Volumes of lesioned and control LGD's were determined from projection drawings. Volumetric changes that occurred in a lesioned LGD were determined relative to the volume of the control LGD of the contralateral thalamus. At two days post-operative, the ratio of lesioned LGD volume to control LGD volume was .92; at four days post-operative, this ratio was .82; at six days post-operative, this ratio was .51; at eight days post-operative, this ratio was .43. These ratios indicate a linear shrinkage of the LGD with increasing survival intervals over the time period studied. Comparisons of volumes of individual autoradiographically demarcated laminae in lesioned and control LGD's showed that shrinkage is not selective for a specific lamina, but that all laminae undergo equal shrinkage, in parallel with the shrinkage at the entire LGD.

Isolated large cells are first seen in the lesioned LGD four days after the lesion. At this time they are located in the A/A_1 and A_1/C interlaminar zones; at the same time, similar appearing large cells emerge adjacent to the interlaminar zones in the control LGD. Isolated large cells appear within laminae A, A_1 and C of the lesioned LGD at 6 to 8 post-operative days; similar large cells are first seen within the cellular laminae of the control LGD at this same time.

The similarity in time of appearance and location of large cells in the normal cat LGD and the isolated large cells present in that nucleus after infant visual cortex lesions suggests that these two populations represent a single class of geniculate neuron. Perhaps the normally large Y cells are able to survive infant cortex lesions.

544 DOES CELL POSITION DETERMINE RECEPTIVE FIELD PROPERTIES OF NEURONS IN THE MOUSE VISUAL CORTEX? Vance Lemmon* and Alan L. Pearlman. Dept. of Physiology and Biophysics, and Neurology, Washington Univ. Med. Sch., St. Louis, MO 63110

During the normal development of the neocortex, the first cells to be produced take positions in deep cortical layers, and later cells are positioned more superficially. Many studies have shown that afferents to the cortex from different sites terminate in specific laminae, that individual laminae have specific efferent targets, and that neurons in the visual cortex within particular laminae have specific receptive field (RF) properties. How important, then, is the laminar position of the various cortical neurons in determining their afferent and efferent connections? This problem can be studied in the reeler mutant mouse, where the positions of cortical cells are grossly disturbed; neurons that are normally located in deep cortical laminae are primarily located superficially in reeler, and vice versa.

We studied the receptive field properties of cortico-tectal (CT) cells because they are located in a single cortical lamina (layer V) in normal mice but are distributed widely in the superficial aspect of reeler cortex. In addition, CT cells have distinctive receptive field properties and can be positively identified by antidromic stimulation with electrodes in the superior colliculus. The properties of CT cells that we studied quantitatively in normal mice and reeler mutants included rates of spontaneous activity, RF size, velocity sensitivity and spatial summation. Statistical analysis of these properties demonstrated no significant differences between CT cells in normal and reeler mice. This finding indicates that the detailed connections underlying the RF properties of CT cells are properly established despite their abnormal cortical locations. (Supported by NIH Grants RO1-EY00621 and T01-EY00092).

545 THE BEHAVIORAL TOXICOLOGY OF LOW CHRONIC DOSES OF HALOTHANE DURING DEVELOPMENT IN RATS. Edward D. Levin * and Robert E. Bowman. University of Wisconsin, Dept. of Psychology, Primate Lab, 22 N. Charter St., Madison, WI 53706.

Chronic, low level exposure of rats during development to the anesthetic halothane has been shown to cause deficits in shock-motivated spatial learning, food-motivated spatial learning and shock sensitivity. (Quimby, Katz and Bowman, Anesthesia and Analgesia, V54(5),p628-33, 1975). We exposed Sprague-Dawley female rats to 12.5 parts per million of halothane in air for 8 hours/day, 5 days/week, from concention through parturition. Mothers and litters, which were pared to 8 pups, were exposed on the same schedule until day 25 when the pups were weaned. The pups alone were exposed until day 30. Male offspring were tested on day 55 for locomotor exploration of a novel T-maze. The halothane-exposed rats (N=12 litters) showed significantly slower speeds than control rats (N=12 litters), in locomoting from the start box at the bottom of the stem into either of the arms. These data indicate that the effects of halothane are descriminable with exposure to only 30 days after birth and that the behavioral effects are not confined to high motivation tasks. Low motivation tasks like locomotor exploration also appear to be sensitive indicators of behavioral toxicology.

MECHANISMS OF AFFERENT LAMINATION IN DEVELOPING HIPPOCAMPUS REVEALED BY OUTGROWTH OF FIBERS FROM SEPTAL IMPLANTS. E.R. Lewis* and C.W. Cotman (SPON: P.T. Kelly). Dept. of Psychobiology, U.C. Irvine, CA 92717

Pieces of embryonic septal tissue were implanted into the entorhinal or occipital cortices of neonatal rat hosts (2-3 days old). The initial outgrowth of fibers originating from the graft and their pattern of termination within the host hippocampal formation was examined using a histochemical stain for acetylcholinesterase (AChE). Fimbrial transections performed in conjunction with the implant surgery eliminated native septohippocampal fibers. When placed in the occipital cortex, septal implants innervate specific laminar zones within the host hippocampus and dentate gyrus; these are the same laminar zones that receive septal efferents in the normal animal. Septal implants placed in the entorhinal cortex also produce a pattern of AChE staining which is similar to that seen in the normal hippocampus. In the dentate gyrus ipsilateral to the implant however, the unstained commissural/associational (C/A) zone is expanded.

Temporal characteristics of the outgrowth of fibers from the implant were studied in animals sacrificed 6, 8, 10, and 12 days after the implant surgery. AChE activity indicative of innervation from the implant is present in 50% of the animals sacrificed 10 days post-implant; by 12 days post-implant all but one animal displayed AChE reaction product in the dentate molecular layer. Processes emanating from cells in the implant were oriented in the direction of the hippocampus throughout the developmental period. In one group of animals, the fimbria was left intact for 27 days after the implant surgery in order to examine competitive interactions between fibers from the implant and native septohippocampal efferents. Extremely light AChE staining is present in the hippocampus and dentate gyrus of animals in this group sacrificed 7, 14, and 30 days after the septohippocampal fibers were severed. When tissues from the striatal region of the embryonic brain were implanted into the entorhinal cortex, AChE reaction product in the hippocampus is restricted to the outer third of the dentate molecular layer.

The position of the afferent source and the time of arrival of the afferent fibers in the target area do not seem to be critical to the mechanisms underlying the development of specific connection patterns in this system. Temporal competition between homologous afferents and a hierarchical scheme of growth possibilities appear to play a role in developmental specificity. In addition, we have proposed that contact between a "critical afferent" (the C/A system in this case) and the target cell might "set" the dendritic membrane for the appropriate patterns of connectivity. (Grants NS 08597 and MH 19691).

A GOLGI STUDY OF DEVELOPING CHICK SYMPATHETIC NEURONS. L. Luckenbill-Edds. Dept. Zoology & Microbiology and College of Osteopathic Medicine, Ohio University, Athens, Ohio 45701

Developing sympathetic neurons in a series of chick embryos were examined in Nissl stained and Golgi impregnated (Stensaas, 1967) preparations. Retroperitoneal tissue blocks containing paravertebral ganglia were prepared from embryos at 7, 11 and 15 days (E7, E11, E15) of development. The general shape and orientation of the neurons, as well as the appearance of dendritic specializations such as end bulbs and claws were recorded.

At E7 when paravertebral ganglia have begun to develop in the mesenchyme, multipolar neurons of two basic shapes are observed. One type has several short thick dendrites that radiate from the cell body and give off fine branches proximally. Growth cones at the ends of the stout dendrites appear as flattened expansions with filaments extending from them. The second type of neuron at E7 has fewer short thick dendrites, some of which terminate in bulbs or claws. This type of cell has other processes which taper into extremely long thin extensions that run parallel to the long axis of the embryo. Occasionally these long thin extensions bifurcate to give rise to thicker processes which terminate in expansions. The long thin extensions do not branch along their course.

At E11 multipolar neurons assume several distinct shapes. One type is a large multipolar neuron with a cell body that is irregular in outline and has stout dendrites radiating from all sides. Some of the dendrites taper and extend distances that are many times the diameter of the cell body, while others remain short and end in claws or bulbs. A second type of neuron has a small oval cell body with fine caliber processes that are restricted to opposite poles of the cell and oriented parallel to the long axis of the embryo. A third type of neuron has a pear-shaped cell body with thick dendrites emanating from the narrower side. After these dendrites branch close to their origin, they turn to run parallel to the long axis of the embryo.

At E15 cell bodies are nearly twice the diameter they were at earlier stages and dendrites have thickened proximally and become more profusely branched distally. The three basic patterns of shapes seen at E11 are maintained in neurons at E15.

These results suggest that when chick sympathetic neurons develop, differences are established in the size and shape of their cell bodies and in their dendritic patterns. Further development involves growth and elaboration of these differences.

Supported by a Grant from Ohio University Research Committee, and College of Osteopathic Medicine.

547 EFFECTS OF EXPOSURE TO HORIZONTAL OR VERTICAL STRIPES DURING REARING ON EVOKED POTENTIALS TO THESE STIMULI AT MATURITY IN RATS. Jill London*, Howard Rowley*, Gregory McCarthy*, and William T. Greenough (SPON: E. Donchin). Depts. Physiol. and Psychol. and Neural & Behav. Biol. Prog., Univ. of Ill., Urbana, IL 61801.

Studies in cats (e.g., Blakemore & Cooper, Nature, 1970,228: 477) indicate that orientation specificity of receptive fields of visual cortex units may be biased toward the orientation of a striped visual field if the cats are exposed exclusively to a single orientation during development. We have examined this phenonmenon in rats, using evoked potentials to stripes in the exposed and orthogonal orientations.

Hooded rats of both sexes were reared from birth in the dark. Beginning at eye opening (approx. 13 d.) and continuing to day 52 rats were exposed for 1 h. per day 5 d. per week to a field of alternating black and white stripes (of variable thickness) oriented either vertically or horizontally. To maintain exposure orientation, the limbs were bound and the animals were wrapped in gauze and placed in boxes with their heads exposed. The boxes were supported by ring stands in (25 cm dia.) drums. Except for these exposure periods, animals were kept in darkness (or dim red light during brief daily maintenance) throughout the experiment.

Stainless steel screw electrodes were implanted unilaterally or bilaterally over areas 17-18 of the cortex on day 52. After 2-7 days, unanesthetized animals were secured to a board facing a vertical or horizontal stimulus field in the dark. Evoked potentials to strobiscopic illumination of the field at 1 sec. intervals were averaged with a Fabritek signal averager and additionally in some cases with a computer averaging program.

N1-P2 peak to peak amplitude was measured from visual evoked potentials to 64 presentations of vertical and horizontal fields from each electrode. For horizontally-exposed animals, 7 of 8 comparisons indicated greater amplitude to the horizontal stimulus with a mean difference of 17% ($p < .01$). For vertically exposed animals, 6 of 9 comparisons favored the vertical stimulus ($\bar{x}$ diff = 10%; $.05 < p < 0.1$). Preliminary work indicates no consistent differences in evoked potential amplitude to the two oriculations in dark and cyclic light reared animals. Studies of evoked potentials to square wave grating reversals at various orientations are in progress.

549 DEVELOPMENT OF ACETYLCHOLINE BIOSYNTHESIS IN CHICK CILIARY GANGLION AND IRIS. Mario Marchi*, Ezio Giacobini, and Douglas W. Hoffman* Lab. of Neuropsychopharmacology, Dept. of Biobehavioral Sci., Univ. of Connecticut, Storrs, Ct. 06268 (Spon: G. Gianutsos)

The ciliary ganglion-iris complex of the chick has been used as an in vivo model system for studying age-related changes in development and aging in the peripheral nervous system. Previous work in our laboratory has described the developmental pattern of acetylcholinesterase (AChE) and cholineacetyltransferase (ChAc) activity as well as α-bungarotoxin binding in the ciliary ganglion and iris (e. Giacobini, in Maturation of Neurotransmission, S. Karger, Basel, 1978; 41-64). The present investigation follows the appearance and variation of levels of acetylcholine (ACh), choline (Ch), and Ch uptake in the same organs during development. The radioenzymatic method of McCaman and Stetzler (J. Neurochem. 26: 669, 1976) was used for determination of ACh and Ch, which are expressed as pmoles/ganglion or iris. ACh was found to be present starting at 5 days of incubation (d.i.) both in the ciliary ganglion (<1) and iris (13.3 ± 2.4). ACh levels per ganglion increase between 7 (1.05 ± 0.1) and 14 (10.7 ± 2.6) d.i. From 14 d.i. to 1 day after hatching (a.h.) this level remains constant but increases again from day 1 a.h. (8.5 ± 1.0) up to 1 yr. (161.2 ± 40.3). In the iris, between 5 and 7 d.i. the ACh level is low and constant (13.3 ± 2.4 to 14.0 ± 4.8). This is followed by a rapid increase up to 14 d.i. (93.2 ± 12.2). Following a small decrease from 14 d.i. to 3 d.a.h. (51.8 ± 10.0) there is a further increase in ACh up to 1 yr. (402.0 ± 42.6). Ch levels closely parallel ACh pattern both in ciliary ganglion and iris (M. Marchi et al., Dev. Neurosci., 1979, in press). Ch uptake is present in the iris starting at 4½ d.i.; and at 5 d.i. the K_m = 1.83 μM and V_{max} = 1.30 pmoles/min/iris. The V_{max} values follow the pattern of Ch and ACh content from 5 d.i. up to 3 months. Recent morphological studies by Aloisi and Mussini (Int. Meet. on Brain Dev. S. di Fasano, 1979, abst.) have confirmed the presence of innervation at 5 d.i. In conclusion our results demonstrate that: 1) ACh and Ch are present both in the ciliary ganglion and iris as early as 5 d.i. Increases in their levels seem to be related to both innervation and synaptogenesis; 2) cholinergic neurons are capable of taking up Ch and synthesizing ACh in their terminals starting at the time of penetration of the fibers into the iris; and 3) Ch levels correlate closely with ACh levels and in addition the changes in V_{max} of Ch uptake during development follow the pattern of Ch and ACh levels. As the V_{max} is determined by the density of transport sites this supports a regulatory role for Ch uptake in ACh synthesis from the earliest stages of development in the peripheral nervous system.

Supported by the Univ. of Connecticut Research Foundation.

550 PHYSIOLOGY AND MORPHOLOGY OF NEURONS IN THE ANTENNAL LOBES OF MATURE AND DEVELOPING *MANDUCA SEXTA*. Steven G. Matsumoto. Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115.

The sensory neurons in the antenna of the moth *Manduca sexta* differentiate and send their axons into the CNS early in the 18 days of adult development. Interneurons in the antennal lobe (AL) of the brain also develop at this time. This study examines the morphological and electrophysiological development of the AL interneurons and their interactions with antennal primary afferents.

Using intracellular recording and dye-injection techniques, we have classified neurons in the AL according to their morphological and physiological properties. Cells in mature moths were tested for their responses to antennal stimulation with female sex pheromone, general odorant (*trans*-2-hexenal), and mechanical stimuli. At least 2 broad categories of interneurons can be discerned morphologically: "local" interneurons with multiglomerular arborizations and no axons, and "output" interneurons with arborizations in single glomeruli and axons projecting out of the AL to the corpora pedunculata. Both of these classes can be subdivided in males with respect to responses to pheromone; no female neurons respond to pheromone. Pheromone-responsive local and output interneurons arborize in a macroglomerular complex found only in the male AL.

Intracellular recordings from AL neurons in developing moths first detect synaptic transmission about day 9 (midway through adult development). The incidence and strength of synaptic transmission increase sharply over the following 4 days, coinciding with the final developmental increase in levels of acetylcholine and choline acetyltransferase activity in the AL (Brain Res. *119* 389, 1977) and with the appearance of mature synaptic profiles in electron micrographs of the glomerular neuropil (L.P. Tolbert, this volume). By day 13 the development of synaptic transmission, as monitored by intrasomatal recordings and electrical stimulation of afferents, is nearly complete. The morphological maturation of the AL interneurons appears to coincide with their electrophysiological maturation. The multiglomerular local interneurons develop by progressive elaboration of their arborizations and the appearance of spine-like structures. The output interneurons initially develop multiglomerular arborizations that subsequently retract between days 12 and 14 to leave a single-glomerular dendritic tuft that continues to increase in density.

551 EFFECT OF RE-INNERVATION, DEVELOPMENT AND DEGENERATION ON MEPP AMPLITUDE DISTRIBUTIONS IN THE MOUSE DIAPHRAGM. C.G. Muniak* and C.G. Carlson* (SPON: N. West) Dept. Physiol., Upstate Medical Center, Syracuse, NY 13210

It has been established that there are two classes of MEPPs in the frog (Kriebel & Gross, 1974, J. Gen. Physiol.) and in the mouse (Kriebel, Llados & Matteson, 1976, J. Physiol.). These two classes of MEPPs have also been seen in the re-innervating cutaneous pectoris of the frog. (Dennis & Miledi, 1974, J. Physiol.).

We have found in the re-innervating mouse diaphragm that the number of small mode MEPPs relative to major mode MEPPs is often greatly accentuated. Some cells which are newly re-innervated show a clear normal distribution of small mode MEPPs and a few with a mean 10-12 times the size of the small mode MEPPs. As the process of re-innervation progresses the percentage of major mode MEPPs increases with respect to the small MEPPs. A gradient is often seen in a single preparation in which the fibers near the point of nerve entry into the muscle have many major mode MEPPs and relatively few small mode MEPPs, while penetrations far from nerve entry give predominately small mode MEPPs.

In preparations partially blocked with cobalt it was found that the unitary evoked response was always greater than the major mode of the MEPPs.

After cutting or crushing the phrenic nerve spontaneous activity ceased within 18 hours. Changes in MEPP distributions in these preparations are rare.

Some MEPP distributions of the newborn mouse diaphragm, show a similarity to the re-innervating preparations described above.

These results indicate that there are two types of release processes at the neuromuscular junction that develop at different rates. (Supported by NIH Grant 11-1524D)

552 DEVELOPMENT OF DOPAMINE AND NEUROLEPTIC RECEPTORS IN THE CNS: *IN VIVO* STUDIES. L. Charles Murrin, Dept. of Pharmacology, Univ. of Nebraska Medical Center, Omaha, NE, 68105

A number of laboratories have demonstrated the feasibility of studying dopamine (DA) and neuroleptic receptors in vivo in adult rat brain by the use of radiolabelled DA antagonists, such as ^{3}H-spiperone (^{3}H-SP)(e.g. Life Sciences 22: 203, 1978). These studies have shown a regional distribution of stereospecifically bound ^{3}H-SP that was consistent with in vitro studies and with known DA innervation of brain regions. The in vivo binding was saturable and was blocked by DA agonists and antagonists. We here report the adaptation of these in vivo binding techniques to the study of dopamine and neuroleptic receptors in the central nervous system of the neonatal rat. Rat pups 5 and 15 days old were administered 250μCi/kg of ^{3}H-SP intraperitoneally. At various times after the injection they were decapitated and the brain was rapidly dissected and frozen. Brain regions were weighed, dissolved in Protosol and analyzed for radioactivity. In 5 day old rat pups there was a regional distribution of ^{3}H-SP binding. The striatum demonstrated the highest level of specific binding followed by the olfactory bulbs. At this age no other brain region (cortex, hippocampus, hypothalamus, cerebellum, thalamus, brain stem) exhibited any specific binding under the conditions used here. Specific binding was defined as radioactivity displaced by (+)-butaclamol (5 mg/kg, i.p., 30 min. before ^{3}H-SP). (-)-Butaclamol had no effect on levels of ^{3}H-SP bound in any region. In the striatum binding reached maximum levels at 1 hour and remained at this level for 4 hours. At 4 hours the striatal/cerebellar ratio was 4:1. In 15 day rats similar results were obtained with striatum again demonstrating the greatest level of binding. By day 15 specific binding could also be demonstrated in olfactory bulbs, cortex, hypothalamus, thalamus and brain stem. Striatal binding reached its maximum at 1 hour and remained at these levels for 2 hours, at which time the striatal/cerebellar ratio was 8:1. Binding in all brain regions at 15 days was reduced to cerebellar levels by (+)-butaclamol and unaffected by (-)-butaclamol. These studies demonstrate the usefulness of i.p. injection for in vivo study of dopamine and neuroleptic receptors in neonatal rats. They are consistent with the general posterior to anterior pattern of dopaminergic development as demonstrated by fluorescence histochemistry. They are also in good agreement with in vitro studies of the ontogeny of DA receptors in the striatum (Brain Res. 125: 376, 1977) showing a large increase in the level of DA receptor binding between day 5 and day 15. The applicability of these data to autoradiographic studies will be discussed. Supported by a seed grant from the Univ. of Nebraska.

553 EMERGENCE OF COORDINATED ACTIVITY BETWEEN FORELIMB AND MOUTH IN RAT FETUSES. C.H. Narayanan and Y. Narayanan*. Dept. Anat., Sch. Med., LSU, New Orleans, LA 70119.

In a previous study, we described three distinct periods in the development of spontaneous oral area activity in rat fetuses: (1) an early phase, beginning from day 17; (2) an acceleration phase, reaching a peak of activity on day 18 through day 19; and (3) a deceleration phase, from late day 19 of gestation age through term. In the present study, we have investigated the sequential appearance of coordinated activity between mouth and forelimb during development as a basis for the analysis of interrelations and control of neural networks involved in this early appearing pattern of behavior. Fetuses ranging from 14 to 20 days gestation age were used in this study. Spontaneous and evoked activity were recorded both quantitatively and qualitatively.

Forelimb movements first appeared as part of a total pattern with head movements until day 16. This was followed by local forelimb movements from day 17 of gestation age. A distinct synchronization of forelimb and mouth activity was observed in fetuses of 18 days gestation age. These movements consisted of alternate flexion and extension of the forelimbs, and face wiping. The forelimb movements were accompanied by mouth opening each time the forelimb was extended in the direction of the head. After day 18, fine digit movements were noticeable with an increasing frequency of synchronized movements of forelimbs, mouth opening and head movements. Evoked responses produced localization of the stimulus when applied to areas innervated by the trigeminal nerves. The results indicate that local actions or units probably represent a minimal unit of centrally initiated motor output during midgestational period. Components of such units presumably provide the substrate upon which complex functions such as suckling, mastication etc., are based.

554 ABNORMAL DIFFERENTIATION OF CERTAIN NUCLEAR CENTERS IN THE BRAIN OF A DUCK EMBRYO ASSOCIATED WITH PARTIAL DUPLICATION OF THE PRIMITIVE STREAK. Y. Narayanan* and C.H. Narayanan (SPON: L.T. Happel), Dept. Anat., Sch. Med., LSU, New Orleans, LA 70119.

Conjoint twins occur occasionally during development in avian species due to duplication of the primitive streak. In a batch of duck embryos raised from incubating eggs, we found a duck embryo of 16 days incubation age with two bills as the only outward sign of duplication. The two bills were of equal size, each with fully developed upper and lower beaks. No beak movements were observed as in normal embryos at corresponding stages of development. The abnormal embryo had two eyes which were normal in outward appearance and were symmetrically placed one on either side of the head. Dissection of the head revealed, however, duplication of the telencephalon, optic lobes and the rhombencephalon. The inner (=medial) half of each of the duplicated embryonic brain division was greatly reduced. Histologic examination of sections through the head revealed the presence of two additional optic primordia each consisting of an undifferentiated mass of tissue representing lens and a much folded epithelium. The orbital muscles except for those associated with the pair of normal eyes were greatly disorganized. Abnormal differentiation of nuclear centers such as the ciliary ganglia, trochlear and accessory oculomotor nuclei and mesencephalic nucleus of the trigeminal nerve was determined by cell counts, and for the non-nervous structures such as the superior oblique and masseter muscles by area measurements. Cell numbers for the four ciliary ganglia, four accessory oculomotor nuclei and two trochlear nuclei appeared to be remarkably proportional to the extent of the peripheral field of innervation. The number of cells in the mesencephalic nucleus was slightly less than normal in spite of the duplication affecting the bill. The masseter muscles did not show a corresponding duplication which could account for the absence of beak movements and for the slight decrease in the number of cells in the mesencephalic nucleus of the abnormal embryo.

555 DEVELOPMENT OF GLOBULAR CELLS OF RAT ANTEROVENTRAL COCHLEAR NUCLEUS FOLLOWING SOUND DEPRIVATION. P. O'Connor and J. Coleman. Depts. Psychol. and Physiol., Univ. of South Carolina, Columbia, SC 29208.

Binaural sound deprivation in mice has been reported to cause an attenuation of growth of globular cells in the ventral cochlear nucleus (Webster and Webster, Arch. Otolaryngol., 1977, 103, 392). The purpose of the present study was to confirm these findings in the albino rat as well as to establish a critical period of sensitivity to monaural sound deprivation. Auditory input was attenuated by surgical ligation of the external auditory meatus. Nine animals from one litter were binaurally deprived at 8 days after birth; 4 control pups taken from 3 other litters were nonoperates and all these subjects survived for a total of 50 days. The monaurally-deprived animals underwent surgery at various ages: 8, 10, 13, 16, 20, 24, 28, 32 or 36 days of age; either the right or left meatus was tied off, and 6 normal animals which were littermates of the operates were used as control subjects. Rats in this series were sacrificed at 70 days after birth. Animals were discarded if the ear canal was not completely closed. Transverse sections were cut and stained with cresyl violet. Globular cells were systematically located throughout the range of the anteroventral cochlear nucleus and measurements of length and width were recorded for each of 6900 cells (50/ear). Results from a repeated measures analysis of variance demonstrate that the binaurally-deprived experimental group had significantly smaller globular cells than the normal control subjects ($p < 0.0003$). The results for the monaural group indicate that age of the subject at the time of surgery was not a significant variable and there was no significant difference between ears. However, when the monaurally-deprived groups were collapsed the effect was significant with operated animals having smaller globular cells in both ears. These findings suggest that surgery per se may account for the observed results; the operation may somehow have interfered with the feeding process and the discrepancy in cell size was perhaps the result of nutritional deficits or some other unaccounted variable occuring during development. The monaural control animals were littermates of the operates and, as such, were perhaps better able to compete for food. In contrast the binaural controls were from 3 different litters, while another entire litter comprised the experimental group. Therefore, all the binaurally-deprived pups had relatively better nutritional opportunities than monaurally-operated subjects. In any case, sham operates should be included in future experiments of this type.

556 INTERACTION EFFECTS OF PRENATAL Co^{60} IRRADIATION AND POSTNATAL NURSERY OR MOTHER REARING ON GROWTH, BEHAVIOR, AND PERSISTENCE OF IMPAIRMENT IN SQUIRREL MONKEY OFFSPRING. J. M. Ordy, K. R. Brizzee, T. Beavers and P. Medart* Tulane University, Delta Regional Primate Research Center, Covington, La. 70433.

For a variety of phylogenetic and logistical reasons, the squirrel monkey has rapidly become one of the more widely used primate species for studying the effects of environmental hazards on brain mechanisms and behavior. Two major complicating factors in the use of this diurnal primate model include: (1) segregation of main effects of hazards from possible interaction effects due to postnatal rearing, and (2) failure to identify one of four possible squirrel monkey phenotypes. The specific aims of this study were to identify and segregate the main effects of prenatal 0, 10, 100 and 200R Co^{60} irradiation from interaction effects of rearing and phenotype, on postnatal growth rates, and behavior in relation to neuronal alterations and/or plasticity in the visual cortex and hippocampus of Colombian and Bolivian squirrel monkey offspring. Differences among nursery and mother reared, as well as Colombian and Bolivian offspring were observed primarily in test adaptation, emotionality and stereotypic behavior rather than sensory, learning, memory, and motor performance. Prenatal 100R Co^{60} irradiation resulted in adverse effects on reversal of original visual discrimination learning at 90, 365, and 730 days after birth. Prenatal 200R Co^{60} irradiation resulted in reductions of neuronal number and dendritic spine counts in the hippocampus and to a lesser extent in the visual cortex. The prenatal 100 and 200R Co^{60} irradiation effects on growth, behavior and brain morphology occurred independent of offspring nursery rearing and phenotype. (Supported by grants NIH HD09942 and NIH RR00164-17).

557 ACETYLCHOLINE RECEPTOR MOBILITY AND LOCALIZATION IN THE DEVELOPING MUSCLE MEMBRANE: MOLECULAR MECHANISMS. Norman Orida and Mu-ming Poo*. Dept. Physiol., Univ. Calif., Irvine, CA 92717

We are studying the movement and localization of acetylcholine receptors(AChRs) in the Xenopus embryonic muscle membrane using intracellular recording and ACh microiontophoresis mapping methods. In previous studies on these spherical, cultured muscle cells plated on clean glass surfaces, we have shown that within 30 min, a small, externally applied electric field(10V/cm) will cause an accumulation of AChRs towards the sides of the cells facing the negative pole of the field as indicated by a post-field asymmetric distribution of sensitivity to iontophoretically applied ACh (Orida and Poo. 1978. Nature 275: 31).

In the present study, the degree of field-induced asymmetric ACh sensitivity was used as an indicator of AChR mobility in the developing muscle membrane between 1 and 8 days in culture. Between 1 and 4 d, exposure to a standard 30 min, 10V/cm field resulted in a ratio of ACh sensitivities at the two poles of the cells of 2.3:1(negative:positive pole). On day 5, the standard field produced less asymmetry in the ratio of the ACh sensitivities and, therefore, AChR distribution on the two sides of the cells. The decline in the side to side sensitivity ratio leveled off and remained constant from day 6 through 8 at about 1.3:1. Pre-treating the cultures with Ca-Mg free saline(CMF) prior to the field (applied in normal Ca-Mg medium) significantly increased the AChR asymmetry over values normally observed when tested on days 2,6, and 8 indicating an increased AChR mobility. CMF treatment is known to remove glycosaminoglycans and other extracellular constituents of the cell coat on cultured cells. In contrast, pretreatment with cytochalasin B and colchicine did not increase the AChR asymmetry on day 2 but significantly increased it on day 6. These results demonstrate a developmental decrease in AChR mobility in the muscle membrane and suggest two possible mechanisms for its basis: (1) An early CMF-sensitive restriction observed from day 2 onwards possibly mediated by the cell coat; and (2) A later-developing constraint mediated by the cytoskeleton.

Localization by the field leads to the formation of stable AChR clusters which persist for hours and are resistant to disruption by various pharmacological treatments. CMF or cytochalasin B and colchicine applied to the cultures after the field failed to disperse the clusters as determined by maintained asymmetric ACh sensitivities at the two poles of the cells throughout the entire period of post-field mapping(up to 5 hrs). These findings indicate that the maintenance of the AChR clusters may involve other mechanisms than suggested above.

Supported by NSF grant BNS 77-04307.

558 QUANTITATIVE ANALYSIS OF ULTRASTRUCTURAL FEATURES IN THE EARLY DEVELOPMENT OF THE CUNEATE NUCLEUS. E.-Michael Ostapoff*, John Irwin Johnson, and Charles D. Tweedle. (SPON:G. I. Hatton) Neuroscience Program and Zoology, Psychology and Biophysics Depts., Michigan State Univ., E. Lansing, MI 48824.

Electron micrographs of 500 μm^2 systematic samples of the dorsal cuneate nucleus near the obex, from pouch young opossums, in the period prior to and during initial synaptogenesis at 8 and 9 days after birth, were analyzed planimetrically. At 3 days postnatal, during the period of epithelial cell division, perikaryal cytoplasm (P) and nuclei (N) accounted for 93% of the identified area in the sample; profiles containing a floccular appearing substance and an electron-lucent background (ELF), possibly dendritic growth cones,were 2%; profiles of processes containing microtubules and ribosomes (MTR), possibly neurites, made up 4%; and profiles containing microfilaments (MF) made up the remaining 1%. At 5 days, when cell migration is under way, P and N made up 39% and 35% respectively, ELF 4%, MTR 11%, microtubule containing processes with no ribosomes (MT) 3%, MF 8%. By 7 days, P and N each accounted for 30%, electron-dense profiles (ED) possibly axonal growth cones and/or degenerating processes were 6%, ELF 18%, MTR 5%, MT 3%, AT less than 1%, ED 6%, and MF 2%. Axonal endings with round vesicles (AT) appeared in appreciable numbers on the 8th day, and large profiles containing a floccular appearing matrix and sparse or clumped synaptic-sized vesicles (ATL) were identified in the 8 and 9 day samples. At 8 days P were 23%, N 19%, ELF 23%, MTR 18%, MT 7%, AT 3%, ATL 2%, ED 4%, MF 1%. At 9 days P were 26%, N 18%, ELF 14%, MTR 11%, MT 12%, AT 4%, ATL 4%, ED 4%, and MF 5%. These findings are consistent with a sequence of events wherein dendritic growth has started on the third day and peaks on the 8th day; axonal growth cones appear on the 5th day and peak on the 7th day; both of these peaks are just prior to synaptogenesis on the 8th and 9th days. Postsynaptic profiles then include MTR, MT, ELF and P; presynaptic profiles are ED, AT and ATL.

559 THE REGULATION OF PLAY: NEUROCHEMICAL CONTROLS Jaak Panksepp. Dept. of Psych., Bowling Green State University, Bowling Green, Ohio 43403

Although there is a vast descriptive literature on the play of animals, the systematic experimental and psychobiological analysis of this behavior remains rudimentary. In this work, we determined that play (as indexed by the frequency of pinning) could easily be measured in laboratory rats and found that through play stable dominance hierarchies were established between animals. Vigorous play started at approximately 18 days of age, increased to 24 days of age, and thereupon remained stable for about 20 days, gradually declining following puberty. The play appeared to be homeostatically controlled in that amount of play increased with social deprivation and decreased with social satiation. For instance, in 28 day old animals, 8 hrs of social isolation increased play by 125% and 24 hrs of isolation increased it by more than 300%. To evaluate the participation of various brain neurochemical systems in the control of play, we studied the effects of a large number of psychoactive drugs. Facilitation of brain serotonin activity with fenfluramine (2.5-10 mg/kg) or quipaaine (5-10 mg/kg) markedly reduced play, while methysergide (5 mg/kg) slightly increased play. Both reduction and facilitation of catecholamine activity (with 1 mg/kg of chlorpromazine and d-amphetamine respectively) reduced play. All of these effects were present in both socially housed and socially isolated animals. The opiate system was the only one of those tested which exhibited opposite effects with respect to social housing conditions. Whereas opiate blockade with naloxone (1-5 mg/kg) reduced play marginally in both isolated and grouped animals, morphine at low doses (.5-1.0 mg/kg) increased play of socially isolated animals while reducing the play of socially housed animals. In general, the results indicated that a systematic analysis of play is a feasible enterprise in rats. The deprivation and satiety functions were as systematic as those obtained with other basic homeostatic motivations such as hunger and thirst. Not only do brain neurochemicals regulate play, but we suspect that activity in certain brain circuits is, in turn, regulated by play.

560 MORPHOMETRICAL ANALYSIS OF DEVELOPING NON-PYRAMIDAL NEURONS IN THE VISUAL CORTEX OF THE RAT. John G. Parnavelas and H.B.M. Uylings*. Dept. Cell Biology, Univ. Tx. Health Sci. Ctr., Dallas, Tx. 75235 and The Netherlands Inst. Brain Res., Amsterdam, The Netherlands.

In this study we sought to investigate with the aid of a computer system the 3-dimensional geometry and development of non-pyramidal neurons in the visual cortex of the rat.

Two to three brains of female albino rats from each of the following ages were treated with the Golgi-Cox technique: 4, 6, 8, 10, 12, 14, 16, 18, 20, 24 and 90 (young adult) days. 617 cells of layer IV were measured with a semi-automated dendrite tracking system[1] at X1,250.

The results show that the cell body size of non-pyramidal neurons, estimated by the projection of the surface area onto the plane of sectioning, increases conspicuously during the early stages of development and reaches adult dimensions at day 16 of postnatal life. This is also the time that the number of primary dendrites and total number of dendritic segments per neuron achieve adult values. However, the total dendritic length per neuron and the radial distance of terminal tips from the center of the cell body increase until day 18. As for the curvilinear lengths of dendritic segments, the analysis shows that they increase markedly until day 18. After this day the lengths of the intermediate segments decline slightly while those of the terminal segments continue to increase at least until day 90. From the morphometrical analysis it is concluded that the dendritic fields of non-pyramidal neurons of layer IV show a preferential orientation in the coronal plane.

561 ORIENTATION OF AXONAL GROWTH OF EMBRYONIC XENOPUS NEURONS BY SMALL EXTRACELLULAR ELECTRIC FIELD. N. B. Patel* and M-m. Poo* (SPON: J. E. Swett). Department of Physiology, University of California, Irvine, CA 92717.

Small extracellular electric fields have been found to influence the neurite growth from chick medulla and dorsal root ganglia explants (Marsh and Beams, J. Cell. Comp. Physiol. 27: 139, 1946; Jaffe and Poo, J. Exp. Zool., 1979, in press). In the present study, we found that an extracellular electric field of about 6V/cm greatly enhanced the axonal growth of dissociated spinal cord neurons towards the cathode within a few hours. Single neural tube cells of 1-day old Xenopus embryos (Stage 17-19) were cultured on a clean, glass surface by previously reported method (Orida and Poo, Nature, 275: 31, 1978). After the cells adhered to the glass substratum, a uniform, steady electric field was applied to the culture via a pair of agar bridges filled with Steinberg's saline. The position of the growth cones with respect to the soma was recorded in polar co-ordinates after the field was removed.

In the absence of an electric field (control), there was a radially symmetrical growth of axons with an average growth rate of 11.7 $\pm$ 0.9 µm/hr ($\pm$ S.E.M., N = 53). When an electric field was applied for 6 hrs, in 3 separate experiments, there was a marked asymmetric growth. The average axonal growth rate towards the cathode was 20.6 $\pm$ 1.5 µm/hr (N = 85); while towards the anode it was 12.6 $\pm$ 1.1 µm/hr (N = 53). It was observed that after the onset of the field, the growth cones of axons previously extending perpendicularly to the field axis gradually changed their direction of growth towards the cathode. In addition, neurons with no previous axonal growth now grew their neurites predominantly from the cathodal pole of the soma. This indicates that the electric field produces its orienting effects both in the rate and direction of axonal growth, and in the initial point of origin of the axon from the soma. Since the electric field used was too small to act directly on the intracellular components, we hypothesize that its effects are mediated through the lateral electrophoresis of membrane-bound growth-controlling components along the plasma membrane.

562 PURKINJE CELL DENDRITIC DEVELOPMENT IN LEAD-TREATED CATS AND RATS. George W. Patrick, William J. Anderson, and Patrick D. Brophy*. Indiana Univ. Sch. of Med., Terre Haute Ctr. for Med. Ed., Terre Haute, IN 47809

Beginning on day 1 of pregnancy (verified by the presence of sperm in a vaginal wash) female rats were given food ad lib mixed with 2% or 5% lead acetate by weight. Control females were also maintained. At birth the litter size was reduced to 8 and half the pups were transferred to a mother of the opposite design yielding 4 experimental groups: control (C), prenatal only (LC), postnatal only (CL), and pre- and postnatally treated (LL). Rats were then sacrificed at 30 days of age and prepared for Golgi analysis. Kittens were obtained from our cat colony. On postnatal day 1, the kittens were given 2 mg/100 g body weight lead acetate dissolved in distilled water at a concentration of 4 mg/ml or distilled water by esophageal intubation for 35 days. They were then sacrificed and prepared for Golgi analysis.

The body weights of rats were (% of control): LL - 31%, LC - 77%, and CL - 54% for the 5% study and LL - 57%, LC - 91%, and CL - 84% for the 2% study. The body weights of cats were reduced by 17% of control. The brain weights of rats were reduced as follows: (% of control) LL - 79%, LC - 86%, and CL - 78% for the 5% study and LL - 62%, LC - 87%, and CL - 75% for the 2% study. Cat brain weights showed no significant differences. The rats in the LL group of the 5% study showed hind-limb paralysis as described by Pentschew and Garro (1966). The other groups of rats showed no observable differences. Some kittens showed hind-limb ataxia and exopthalmia and occasionally displayed cerebral hydrocephalus and herniation of the cerebellum through the foramen magnum. The Purkinje cells in the kittens treated with lead were significantly different in the dendritic arborization. There were fewer tertiary dendrites and they seldom reached the surface of the molecular layer. The LL and CL rats of the 5% study showed significantly reduced dendritic arborization of the Purkinje cells also. The LC rats showed very little reduction.

563 EFFECTS OF AMINO ACID DEPLETION DURING EARLY ONTOGENY ON SUBSEQUENT LOCOMOTOR ACTIVITY AND LEARNING IN RATS. Jim H. Patton*, Richard R. Fritz*, Ernest S. Barratt, and Creed W. Abell*. University of Texas Medical Branch, Galveston, Texas 77550.

The effects of rapid and specific depletion of plasma levels of tyrosine (TYR) and phenylalanine (PHE) between 4 and 8 days of age on subsequent behavior were studied in rats. Phenylalanine ammonia-lyase (PAL) (E.C.4.3.1.3), an enzyme purified from yeast, catalyzes the deamination of PHE and TYR to cinnamic acid and coumaric acid, respectively. PAL rapidly, reversibly, and selectively depletes plasma of these amino acid precursors of catecholamine (CA) synthesis (Abell, et al., 1973; Barratt, et al., 1976). As a result brain levels of CA's are reduced (Barratt, et al., 1976).

Daily injections of 100 units PAL per kilogram body weight (Experimental) and buffer vehicle (Control) were administered I.P. to neonatal rats between 4 and 8 days of age (inclusive). The animals were weaned at 22 days of age and housed multiply thereafter. Locomotor activity testing at 39 days of age revealed that PAL-treated animals were less active in a novel environment initially (first five minute period) but were no different than controls during two subsequent five minute periods. This difference was statistically reliable. PAL rats also defecated less in the test apparatus than controls, a finding which also was statistically reliable. Differences in shuttle avoidance acquisition were marked at 65 days of age. Animals were given five blocks of 10 trials each (50 trials total). The PAL rats made more avoidances responses within each block of 10 trials than controls, although only avoidance differences during the last two blocks of trials were statistically significant. In addition, the PAL group made a significantly greater number of total inter-trial shuttle crossings than controls. No weight differences were seen at time of testing between the groups.

564 EFFECTS OF LITTER COMPOSITION ON BODY WEIGHT, ACTIVITY PATTERNS AND AVOIDANCE PERFORMANCE IN NORMAL AND 6-HYDROXYDOPAMINE (6-OHDA) TREATED RAT PUPS. David E. Pearson*, Martin H. Teicher* and Bennett A. Shaywitz. Dept. of Ped. and Neuro., Yale Univ. Sch. Med., New Haven, CT 06510

We have examined the effects of both environmental alteration and biochemical manipulation on the ontogeny of activity and cognitive performance in normal developing rat pups and littermates administered 6-OHDA at 5 days of age. Such treatment results in a permanent and selective destruction of brain dopaminergic pathways, and behavioral manifestations with many similarities to the childhood disorder known as Attention Deficit Disorder (ADD) with hyperactivity. Litter composition was arranged to examine four different rearing conditions: Homogeneous litters of all 6-OHDA treated pups (T-Homo); homogeneous litters of sham controls (V-Homo); and mixed litters of half 6-OHDA treated and half sham (T-Hetero, V-Hetero). Body weights for V-Hetero were found to be significantly greater than all other groups at all ages, but weights for V-Homo, T-Homo and T-Hetero were not significantly different from each other until 27 days. Activity levels at 12 days of age were lower in 6-OHDA pups, equal at 15 days and 6-OHDA animals demonstrated higher levels of activity thereafter. V-Homo was more active than V-Hetero at 15 days of age, ($p < .001$) and T-Homo more active than T-Hetero at 23 and 27 days of age, ($p < .001$). Over the hour long observation period, V-Hetero exhibited a more rapid reduction of activity (habituation) than any other group. 6-OHDA pups displayed a significantly greater escape latency (indicating an impaired performance) on avoidance tasks at 20 days (T-maze) and 28 days (one-way shuttle box). In the shuttle box task T-Homo exhibited an increased escape latency compared to T-Hetero ($p < 0.001$) indicating that 6-OHDA animals reared with normals performed better than 6-OHDA pups reared with only other damaged pups for littermates. Brain dopamine concentrations in 6-OHDA treated animals averaged 14% of controls levels, compared to norepinephrine levels which averaged 89% of controls. Within a similar treatment (either 6-OHDA or control), no differences in brain catecholamines were found, regardless of assignment to homogeneous or heterogeneous litter type. Our findings that rat pups reared in heterogeneous litters exhibit significantly different patterns of activity and avoidance performance from animals reared in homogeneous litter compositions supports the notion that both environmental and biological factors act to influence the behavioral repertoire of the developing organism. By demonstrating that the effects of 6-OHDA on activity and performance are unrelated to body weight, these results confirm the importance of brain dopaminergic pathways in the ontogeny of behavioral arousal.

565 SYNAPTIC ENDINGS IN THE CHICK TANGENTIAL NUCLEUS: A MORPHOGENETIC STUDY WITH THE ELECTRON MICROSCOPE. Kenna D. Peusner* (SPON: N. Moskowitz). Dept. of Anat., Jefferson Medical College, Philadelphia, Pa. 19107.

This study focuses on the morphogenesis of "spoon" endings of the chick tangential nucleus, part of the lateral vestibular complex. The principal cells selectively receive spoon endings from a special class of primary vestibular afferents, the colossal fibers. Previous studies with the rapid Golgi method showed that one spoon covers 1/4 to 1/3 of the cell's soma in 18 day embryos and that spoon endings undergo a rigid sequence of structural changes in development (Peusner). It was thus of interest to study the ultrastructure of spoon endings in embryos, perfusion-fixed, at ages preceding (8-9 days), during (10-13 days), and following (14-16 days) spoon formation. At 8-9 days colossal fibers may flank the principal cell soma with frequent attachment plaques and occasional vesicular synapses joining them. At the contact site, the colossal fiber contains the ultrastructural components found in developing spoons, namely vesicles, neurofilaments, mitochondria, and microtubules. Boutons with vesicular synapses on the principal cell soma are infrequent at 8-9 days and increase slightly in numbers during spoon formation. At 8-9 days each colossal fiber develops a swelling en passant which contains a dense thicket of neurofilaments, microtubules, and a plethora of mitochondria, with many degenerative profiles, perhaps forewarning the disappearance of the swellings by 11 days. The swelling surface has few if any synaptic contacts. Conceivably, spoon development depends on the formation of the swelling precursor. For at 10 days the swelling is joined near its medial edge by an expansion which becomes a young spoon by 13 days. From 11 to 13 days, the principal cell sprouts lush somatic spines where contact is made with the expansion, which stays in close parallel, for the junction has present attachment plaques and vesicular synapses. At 14 days, this junction contains a new specialization, which has symmetrical cytoplasmic densities and a cleft reduced to about 50 A; its identity needs to be explored. For at 15 and 16 days, the cleft at the junction of the spoon-principal cell shows dilatations, often bordered by gap junctions. The reduced-cleft specializations, attachment plaques, and vesicular synapses are found at the junction as well. In short, the junction of the developing spoon and principal cell is the site of mixed synapses, with vesicular synapses appearing well in advance of gap junctions. Furthermore, it is evident that the spoon ending is the predominant and, moreover, a quite powerful source of synaptic input to the developing principal cell. The morphology and consequent influence of spoon endings in the vestibular system of the mature animal remains to be established.

566 IMMUNOCYTOCHEMICAL LOCALIZATION OF ENKEPHALINE AND SUBSTANCE P IN RAT BRAIN DURING DEVELOPMENT. V.M. Pickel, K.K. Sumal*, R.J. Miller and D.J. Reis, Dept. Neurol., Cornell Univ. Med. College, New York, N.Y. 10021.

Using immunocytochemistry, we sought to determine the presence and regional distribution of neurons containing enkephalin and substance P (SP) at embryonic (E) days 15, 18 and 20, and postnatal (PN) day 1. Adjacent sections of brains were incubated with specific antiserum to enkephalin, SP or control serum and then processed by the peroxidase-antiperoxidase method. The reaction product for both peptides was absent at E15 and present in certain groups of perikarya and fibers at E18. At the latter age, enkephalin-like immunoreactivity (ELI) was localized to perikarya in many regions of the brain which did not contain SP labeled neurons. These include substantia gelatinosa of n. trigeminal, n. tractus solitarius, n. lateral lemniscus, and n. parabrachialis. Other regions such as the n. stria terminals, caudate-putamen, and n. central amygdala contained perikarya for both SP and enkephalin; whereas the n. habenulae lateralis contained only SP labeled perikarya. Fibers, but not varicose terminal fields, showed enkephalin and SP reaction product at the E18 stage. Terminal regions showing both enkephalin and SP were present by E20. The location of terminals and perikarya containing ELI at PN1 was similar to that of adult colchicine treated rat brains (Sar et al., J. Comp. Neurol. 182: 17, 1978). Although the nuclear groups contained more perikarya selectively labeled for the peptides at PN1, their distribution was essentially the same as E20. Both ELI and SP were present in well defined fiber bundles. ELI was noted in numerous pathways, some of which were also common to SP including the lateral lemniscus, medial forebrain, and stria terminals. Other bundles such as the mammillothalamic contained only ELI, while certain fiber systems such as the habenulointerpenuncular contained only SP. There were likewise similarities and differences in the terminal fields labeled with SP and/or enkephalin at PN1. We conclude that neurons containing SP and ENK can be detected immunocytochemically by E18 and that tnese peptides are more evident in perikarya and pathways during development than in untreated adult animals.

567 ONTOGENY OF β-1 AND β-2 ADRENERGIC RECEPTORS IN RAT CEREBELLUM AND CEREBRAL CORTEX. R.N. Pittman*, K.P. Minneman*, and P.B. Molinoff. (SPON: D. Whitlock). Dept. of Pharm., Univ. of Colo. Med. Ctr., Denver, CO.

The β-adrenergic receptor antagonist ^{125}I-iodohydroxybenzylpindolol (IHYP) has the same affinity for β-1 and β-2 adrenergic receptors. Graphical analysis of the inhibition of specific IHYP binding by a variety of drugs selective for β-1 or β-2 adrenergic receptors results in curvilinear Hofstee plots. An iterative computer based method was used to determine the densities of the two receptor subtypes in homogenates of rat cerebral cortex and cerebellum at various times during development. In the cerebral cortex, which contains mainly β-1 receptors, total β-adrenergic receptor density increased sharply between postnatal days 10 and 21. The density of receptors remained fairly constant through six weeks of age though it subsequently declined. The relative proportions of β-1 and β-2 receptors were fairly constant throughout development of the cerebral cortex. Therefore, the development of the density of the two receptor subtypes closely paralleled the development of total β-receptors in the cerebral cortex.

The ontogeny of β-adrenergic receptors in the cerebellum, which contains mainly β-2 receptors, was strikingly different from that observed in the cerebral cortex. Total cerebellar β-adrenergic receptor density steadily increase from postnatal day 5 through day 42. At this time the density of receptors plateaued and remained constant for up to six months. The relative proportions of β-1 and β-2 receptors in the cerebellum changed markedly during development. Between days 8 and 13 approximately 18% of the receptors were of the β-1 subtype. This proportion steadily decreased with age, and in 3 to 6 month old animals only 2% of the receptors were of the β-1 subtype. Therefore, although the density of cerebellar β-2 adrenergic receptors showed an increase similar to that observed for total β-adrenergic receptors, the density of cerebellar β-1 receptors steadily declined between days 20 and 90. The relationship between the development of β-1 and β-2 receptors and various developmental events in the cerebral cortex and cerebellum will be discussed. (NS 13289 and NS 09199).

568 DEVELOPMENT OF WING-FLAPPING AND FLIGHT IN NORMAL AND FLAP-DEPRIVED CHICKS (Gallus domesticus): A STROBOPHOTOGRAPHIC ANALYSIS. Robert R. Provine. Dept. of Psych., Univ. Md. Balto. Co., Catonsville, MD 21228.

A previous study of spontaneous embryonic motility showed that there is a dramatic increase in bilateral wing coordination during the last days of incubation. By the time of hatching, the wings produce low amplitude, bilaterally synchronized, smooth wing movements (Provine, Dev. Psychobiol., in press). The present study extends the developmental analysis of wing movements to postnatal stages by investigating the emergence of drop-evoked wing-flapping and horizontal flight in 1 to 21 day chicks. Wing-flapping movements evoked by dropping tethered chicks 1.9 M were studied using strobophotography (100 Hz). This technique provides information concerning the position of the rapidly moving wings every 10 msec. The capacity for horizontal flight was evaluated by measuring the lateral progress made by untethered chicks when dropped 1.7 M.

Drop-evoked, bilaterally symmetrical wing extension and slow low amplitude flapping were found by the day after hatching. However, flapping rate and amplitude increased up to 13 days after which they leveled off. These developmental changes in wing-flapping behavior were positively correlated with the maturation of drop-evoked horizontal flight between 7-13 days and the development of larger, well feathered wings.

The influence of post-hatching wing movement experience on the development of wing-flapping and flight was evaluated by immobilizing both wings on the day after hatching and testing for drop-evoked wing-flapping and horizontal flight on day 13 immediately after freeing the wings. Day 13 was chosen for testing because adult levels of wing-flapping and horizontal flight are present in control chicks at this stage. The wings were immobilized by binding them to the thorax with elastic bandages. At 13 days, the movement deprived chicks showed amounts of drop-evoked, bilaterally synchronous wing-flapping and horizontal flight similar to unbound 13-day control chicks indicating that wing movement and practice are not necessary for the emergence of wing-flapping and flight. This result is consistent with the earlier finding that muscular correlates of wing-flapping were present in 13-day chicks that had both wings amputated on the day after hatching (Provine, Behav. Neur. Biol. in press).

569 DEVELOPMENT OF β-ADRENERGIC RECEPTORS AND ADENYLATE CYCLASE ACTIVITY IN THE CHICK SPINAL CORD. Walter Prozialeck*, Arlene Pylypiw* and Leonard L. Ross. Department of Anatomy, Medical College of Pennsylvania, Philadelphia, PA 19129.

The chick spinal cord receives a substantial descending adrenergic input from supraspinal levels. It has been recently reported that during development these descending adrenergic axons contain norepinephrine and its synthesizing enzymes, and that they establish their first synaptic contacts with spinal cord neurons at 10-12 days in ovo (Caserta and Ross, Brain Res. 144:241, 1978). In order to further characterize the functional development of these synapses, we studied the development of β-adrenergic receptors and adenylate cyclase activity in homogenates of chick thoraco-lumbar spinal cord. β-adrenergic receptors were measured by the specific binding of ^{3}H dihydroalprenolol (DHA). Receptor density (Bmax) and the apparent dissociation constant (Kd) for DHA binding were calculated by Scatchard analysis. Adenylate cyclase activity was determined by the method of Krishna et al. (JPET 163:379, 1968). The binding of DHA in mature spinal cord homogenates was characterized by a high affinity (Kd = 6.5 nM), saturability (Bmax = 20 fmole/mg tissue), and was 100 times more sensitive to inhibition by l-propranolol than by d-propranolol.

β-receptors were first demonstrated at 14 days in ovo (Bmax = 4.3 fmoles/mg tissue). Few if any receptors were demonstrable in younger embryos. From day 14 to day 20 in ovo the number of receptors increased to 14 fmoles/mg tissue. Receptor density then increased dramatically over the next few days and by the second day after hatching reached a peak of 45 fmoles/mg tissue. Between the second and ninth post hatching days the receptor density declined to adult levels (∿20 fmoles/mg tissue). The affinity of DHA for the β-receptor did not change throughout development, with the Kd remaining ∿6.5 nM. The development of adenylate cyclase activity closely paralleled that of β-receptors with peak activity being reached on the second day after hatching.

Since β-adrenergic receptors are not detectable until 4 days after the formation of the first adrenergic synapses in the chick spinal cord, it appears that the early development of adrenergic synapses might not be dependent on the presence of β-adrenergic receptors on the spinal cord neurons. The role of the adrenergic input in the development and maintenance of β-adrenergic receptors is under investigation.

570 THE ELIMINATION OF REDUNDANT INNERVATION IN NEONATAL SYMPATHETIC GANGLIA. Dale Purves and Jeff W. Lichtman. Dept. of Physiol. and Biophys., Washington Univ. Sch. of Med., St. Louis, MO 63110

Neurons in superior cervical ganglia from neonatal (0-7 day) hamsters are innervated by an average of 11-12 axons arising from 4 different spinal cord segments. Ganglion cells from adult animals, however, are innervated by only 6-7 axons arising from about 3 spinal cord segments. Thus many of the synaptic contacts initially present appear to be lost during development. This elimination of redundant innervation probably occurs during the first few weeks of postnatal life since ganglion cells in 2-3 week-old animals are innervated to an intermediate degree. The overall innervation of the superior cervical ganglion in adult hamsters arises from thoracic segments T1-T5; in spite of the loss of about half of the innervating axon terminals, no additional spinal segments contribute significantly to the innervation of ganglia in neonatal animals. Thus synapse elimination does not occur because some initial innervation arises from inappropriate spinal levels. As in other mammals (see for example Njå and Purves, 1977) the pattern of adult ganglion cell innervation in the hamster is selective in that each neuron tends to receive innervation from a preferred subset of the segments that innervate the ganglion as a whole. This selective tendency is less pronounced in neonatal animals. We conclude that a) the elimination of redundant innervation in early life is not limited to target cells innervated by a single axon in maturity, and b) the loss of redundant contacts refines the selective pattern of synapses made on individual ganglion cells.

571 THE EFFECT OF CORDOTOMY ON DENDRITE BUNDLES AND TREADMILL WALKING IN KITTENS. Patricia Reback* (SPON: R.D. Lindsay). Dept. Kinesiology, UCLA, Los Angeles, CA. 90024.

Dendritic bundles of α motoneurons are present in the spinal segments innervating the forelimbs, but not the hindlimbs of the cat at birth. Since bundles mature in the lumbosacral area coeval with the ability to walk, Scheibel and Scheibel (Exptl. Neurol. 23:106 1970) have suggested that dendritic bundles might be a substation for spinal activity that helped to shape motor control, especially in the coordination of locomotion.

The present study addresses the problem of dendrite bundle formation and maintenance in relationship to treadmill walking of cats, with spinal cord transections at T-12 made during 2 stages of development: 2 weeks postnatal, at which time dendritic bundles and alternating flexor/extensor movements are rudimentary and 12 weeks postnatal, a time when dendritic bundles and walking ability approach that of the mature cat. Each age group was separated into 2 subgroups: those exercised daily for 20 minutes of treadmill walking and those left to spontaneous activity in a limited environment. Kittens were sacrificed 6 weeks or more post-cordotomy. Prior to sacrifice, both nonexercised and exercised groups were rated on a scale of 1-7 for ability to walk on a motorized treadmill at several speeds. At sacrifice the animals were perfused and the cords stained using the rapid Golgi technique. Horizontal cuts were made and the degree of bundling was observed by light microscopy. Spinal segments on coded slides were rated on a scale of 0-5 for presence and complexity of bundles. This data was then compared to the treadmill rating.

Preliminary results suggest that CNS integrity is not always a prerequisite for bundle formation and that dendritic bundle formation and/or maintenance in the lumbar cord are not necessary requirements for treadmill walking. Although there was evidence of bundle formation in 6 out of 8 of the animals cordotomized at 2 weeks (ratings ranged from 1-4), this formation was not correlated to ability to treadmill walk or to spontaneous weight bearing. There was also no correlation between bundle formation and treadmill exercised animals. Cordotomy on the 12 week animal had a detrimental effect on maintenance of the bundles. These animals were all sacrificed after 6 months of age, at which time, ordinarily, bundle formation is within the 4-5 classification (mature). None of the sections examined were rated higher than a 3 on the numerical scale, and signs of degeneration were readily apparent in all sections. Again, no correlation between the treadmill rating and degree of bundling was observed. Initial evidence, however, suggested that daily exercise on the treadmill may slow degeneration of the bundles.

572 BEHAVIORAL COMPONENTS OF THE CLONIDINE RESPONSE IN THE DEVELOPING RAT. Daniel K. Reinstein* and Robert L. Isaacson, Dept. of Psychology, State University of New York, Binghamton, NY 13901.

Clonidine (2, 1 and .5 mg/kg) elicits a response in the 7 and 14 day old rat which is characterized by increases in locomotor, wall climbing and head raising motor patterns. At 21 and 28 days the response to the same dose range is characterized by a form of catalepsy (see Reinstein and Isaacson, 1977. Brain Research).

Increases in open-field activity are observed in 10-20 day old normal rat pups when tested in isolation. One component contributing to this response could be hypothermia. An increase in locomotor activity has been proposed as one thermo-regulatory mechanism available to the infant rat, and clonidine produces hypothermia in the adult rat at room temperature. In the first experiment we undertook to determine if the locomotor response to clonidine before 21 days of age was related to its hypothermic effect. In an open field the behavioral response to clonidine was found to increase with increasing ambient temperatures. At the two lower temperatures (25° and 30°C) the 10 day old animals experienced a 2°C drug-induced drop in colonic temperature. At the high temperature 36°C the animal's temperature rose 1°C after the drug. Control animals at 25° and 30° did not drop core temperature after the pre-injection adaptation period but did experience a 1°C rise in temperature in the 36° environment. This indicates that clonidine-induced locomotor changes in activity are not due to a fall in core body temperature.

In the second experiment the open field response to clonidine at 25°C was observed in 10 day old animals pretreated with phentolamine (2 and 15 mg/kg), phenoxybenzamine (2 and 15 mg/kg) or naloxone (.2 and 2 mg/kg). Phentolamine pretreatment at 15 mg/kg reduced the initiation of wall climbing bouts after clonidine and, at both doses, attenuated the clonidine-induced change in core temperature. Phenoxybenzamine at 15 mg/kg attenuated the decreases in body temperature only. Naloxone had no effects on any of the clonidine-induced behaviors. There were no effects of any of the drugs on locomotion, duration of wall climbing bouts, once initiated, or head raises.

These findings indicate that the temperature reduction produced by clonidine is α-adrenergically mediated but that the locomotor changes found after the drug are not. The reduction in the initiation of clonidine-induced wall climbing seen after pretreatment with phentolamine may reflect actions on a developing adrenergic regulatory mechanism related to spinal cord organization and coordination. The behavioral effects of this adrenergic system may depend on the maturational state of the corticospinal tract.

573 THE DEVELOPMENTAL PATTERN AND LOCALIZATION OF A RAT BRAIN SPECIFIC ANTIGEN (G5) USING MONOCLONAL ANTIBODY. Jane Somsel Rodman* and Richard Akeson, Children's Hospital Research Fdn., Cincinnati, Ohio 45229.

G5 is a monoclonal antibody developed from the fusion of a myeloma cell line (P3-X63-Ag8) and spleen cells from a mouse immunized with rat pheochromocytoma cell line (PC12). G5 reacts strongly with adult rat brain particulate protein and to a lesser extent with rat spleen and bone marrow but not with eleven other cells or tissues as has been previously described (Akeson and Graham, submitted). Using a direct binding assay with antibody excess and ^{125}I-protein A, the presence of G5 antigen in the developing rat brain has been studied. The specific binding activity, as well as, total amount of G5 antigen is very low in the newborn rat brain (30 ng IgG bound/mg brain particulate protein). G5 binding increases rapidly with age until day 28 to levels of 300-400 ng IgG bound/mg brain particulate protein. After this time, G5 specific binding activity increases slowly to adult levels of 400-500 ng IgG bound/mg brain particulate protein. The total G5 binding to brain increases 150-200 fold from birth to age 60 days.

The macroscopic localization of G5 antigen has been studied using the direct binding assay on homogenates of regions of the dissected adult rat brain. It has been found that G5 antigen is concentrated in the cerebral cortex gray matter which contains ten-fold more G5 antigen than cerebellum, cerebral cortex white matter, brain stem or spinal cord.

Additional studies to determine the cell type specificity and molecular composition of G5 antigen will be reported.

574 A MORPHOMETRIC STUDY OF SYNAPSE FORMATION IN THE CHICK SYMPATHETIC GANGLION FOLLOWING SPINAL CORD TRANSECTION. Leonard L. Ross and Leo Cosio*, Department of Anatomy, Medical College of Pennsylvania, Philadelphia, PA, 19129.

We have previously described by morphometric analysis (Ross et al. 1978) that few synapses are found in the chick lumbar sympathetic ganglia prior to hatching. Beginning at two days post-hatching, there is a rapid proliferation of synapses and adult levels are attained by 21 days. We have also reported (Ross, Smolen and Cosio, 1977) that spinal cord transection in the chick embryo at the presynaptogenic stage (8 days in ovo), while reducing the afferent input to the preganglionic nucleus (of Terni) by 40%, does not affect either the number or the morphological development of the neurons of this nucleus.

To determine the effects of supraspinal input to the preganglionic neurons on the development of peripheral ganglionic synapse formation, the spinal cords of two days old chicks were transected at cord level T3 and the animals were allowed to survive until 21 days. At this time the chicks were perfusion fixed and the lower thoracic spinal cords and the lumbar ganglia were prepared for ultrastructural morphometric study.

In the spinal cord transected chicks, the synaptic density in the ganglia was reduced by 60% when compared with controls of the same age. Although the ganglia of the spinal cord transected animals were considerably smaller than those of the controls, the density of neurons was not significantly different. These observations provide a morphometric extension of the biochemical observations of Hamill, Bloom and Black (1977) and confirm the existence of a transynaptic influence on the formation of ganglionic synapses. That is, a neuron may require an intact afferent input for the formation of a normal complement of its own axonal terminals. The quantitative aspects of this phenomenon in the spinal cord are being determined by a morphometric analysis of the synaptic input and neuronal population of the nucleus of Terni of these post-hatch animals.

575 DIFFERENTIATION OF ENTERIC NEURONS FROM UNRECOGNIZABLE PRECURSORS WITHIN THE MICROENVIRONMENT OF CULTURED FETAL MOUSE GUT. Taube P. Rothman, Cheryl F. Dreyfus and Michael D. Gershon. Dept. of Anatomy, College of Physicians & Surgeons, Columbia University, New York, New York, 10032.

In the developing mouse gut neurons cannot be detected morphologically by light or electron microscopy prior to day 12 of gestation. Before this time the gut consists of an apparent mesenchymal tube surrounding a layer of stratified mucosal epithelium and encompassed by a single layer of serosal epithelial cells. The gut shows no neuronal properties. It fails to synthesize ^{3}H-acetylcholine (^{3}H-ACh) from ^{3}H-choline; it fails to specifically take up ^{3}H-5-hydroxytryptamine (^{3}H-5-HT), and neither 5-HT nor norepinephrine (NE) can be shown by formaldehyde-induced histofluorescence. Neurons first appear morphologically in the small intestine at 12 days' gestation, at 13 days in the stomach and proximal colon, and at 14 days in the distal colon. Coincidentally, with the appearance of neurons, synthesis of ^{3}H-ACh from ^{3}H-choline appears and uptake of ^{3}H-5-HT becomes radioautographically demonstrable in the primordial myenteric plexus. When any region of the gut is explanted in organotypic tissue culture prior to neuron formation, neurons subsequently develop in the cultures. This can be shown in gut explanted as early as 10 days' gestation but also occurs at later ages. In the cultures the epithelium degenerates but two layers of smooth muscle form, properly oriented into an inner circular and an outer longitudinal layer. A myenteric plexus forms between the two layers of smooth muscle and exhibits typical neuronal perikarya and a neuropil. Within the neuropil of the myenteric plexus there are axons that specifically take up ^{3}H-5-HT and can be shown by radioautography. (Uptake is blocked by fluoxetine.) There are also abundant cell bodies that show the typical yellow 5-HT fluorescence when the cultures are treated with glyoxylic acid or formaldehyde gas. Therefore, neuronal precursor cells invade and colonize the gut substantially before neurons can be recognized chemically or morphologically. This indicates that differentiation of enteric neurons occurs within, and is probably dependent upon, the enteric microenvironment. (Supported by a Basil O'Connor Starter Research Grant, National Foundation - March of Dimes and NIH Grant #NS12969).

576 ORDER IN THE OPTIC NERVE OF GOLDFISH. Anne C. Rusoff* and Stephen S. Easter, Jr. (SPON: M. W. Dubin). University of Michigan, Ann Arbor, Michigan 48109

We have demonstrated that retinal ganglion cell axons are distributed non-randomly in the optic nerve of goldfish, and that one of the rules for their ordering is: axons from ganglion cells of the same age, that is, located the same distance from the optic disc, are together. The non-random distribution of axons in the optic nerve was demonstrated with small injections of HRP into the retina. Injections were made peripherally so that axons from a localized region, rather than axons of passage, were filled. Fish survived 2-8 days, depending on their size; retinas were prepared as whole mounts, and optic nerves and tecta were sectioned longitudinally; the tissue was reacted with H_2O_2 and o-dianisidine. Stained ganglion cell axons were traced from the injection site across the retina, into the optic disc and throughout the length of the nerve and tract. Stained axons remained in a bundle throughout this length. In one example, the same axons were followed for 0.8mm, and the distance between the most peripheral axons was 63μm ± 11μm (mean ± S.D.). Thus, axons from one location on the retina are together in the optic nerve.

The converse experiment--making a small injection of HRP into the optic nerve--was also done. HRP was injected into the optic nerve just behind the eye. Fish survived 20 hr; then the tissue was prepared as described above. When HRP injections were localized to a single bundle in the nerve, an annulus of ganglion cell bodies was stained in the retina. The annulus was centered on the optic disc. Stained axons radiated from the disc, but did not extend peripherally beyond the annulus, and scattered stained ganglion cells were found neither more peripheral nor more central than the annulus. Injections in separate fish, presumably filling different bundles of axons in the nerve, produced annuli at different distances from the disc. In goldfish the retina grows by addition of cells at the peripheral margin so all the ganglion cells in an annulus are the same age. Therefore, bundles within the optic nerve are composed of axons from ganglion cells of the same age. (Supported by EY05294 to A.C.R. and EY00168 to S.S.E.)

577 STEREOTAXIC PLACEMENT IN THE BRAIN OF NEONATAL SWINE (SUS SCROFA). M.-E. Salinas-Zeballos* and P.M. Gootman, Dept. of Physiology, Downstate Medical Center, SUNY, Brooklyn, N.Y. 11203.

The use of neonatal swine in a variety of maturational studies, especially in cardiovascular regulation (Gootman et al., Chapt. 4, In "Fetal and Newborn Cardiovascular Physiology", Vol. 1, edited by L.D. Longo and D.R. Reneau, Garland STPM Press, pp. 93-152, 1978), has made necessary the development of an atlas correlating the growth of the skull with the underlying structures of the maturing brain. 33 piglets aged 3 hr-12 days (0.74-3.65 kg) were used for this study.

The major modification of the Kopf piglet stereotaxic apparatus (Gootman et al., Am. J. Physiol., 222: 994, 1972) was the use of straight ear bars directly into the ear canal. These ear bars permitted the head to be held in a consistently reproducible position.

The position of the brain was standardized by keeping Lambda and Bregma at the same vertical level from stereotaxic zero by lowering or raising the palate-nose piece, in this way the surface of the brain remained parallel to the horizontal zero of the stereotaxic instrument.

Growth of the skull and brain was measured as distances between Lambda, Bregma and Nasal sutures to the stereotaxic zero. Lambda corresponded to the caudal tip of the occipital lobe, Bregma to the level of the medial thalamus and the Nasal suture to the anterior tip of the frontal lobe.

Four major groups were found to have significant differences in brain size:

Ages (days)	Weight (kg)	Lambda (mm)	Bregma (mm)	Nasal (mm)
≤ 1	1.4 ±0.09	-10.95±0.62	+8.35±0.52	+43.28±0.72
2-5	1.19±0.07	-10.77±0.37	+11.47±1.39	+44.37±1.29
6-9	1.8 ±0.18	-10.11±0.93	+13.53±0.91	+49.51±1.61
10-12	2.95±0.31	-14.47±1.64	+12.68±1.35	+49.72±2.34

The map containing these values will facilitate stereotaxic localization of brain structures in piglets of different ages. (Supported by NIH Research Grant HL-20864).

578 NICOTINE AFFECTS THE FETAL NIGROSTRIATAL DOPAMINE (DA) SYSTEM OF THE RAT. M. Schlumpf, R. Maire * and W. Lichtensteiger, Inst. Pharmacol., Univ. Zürich, Zürich, Switzerland.

Various types of interactions between cholinergic neurons and the nigrostriatal DA system exist in the adult rat. The prenatal development of cholinergic influences on these DA neurons was first investigated with nicotine. This drug increases the firing rate of nigral DA neurons in adult rats in doses of 0.25-1 mg per kg. DA nerve cells become detectable by fluorescence histochemistry in the mesencephalic flexure of rat fetuses at embryonic day (ED) 13 (ED 1 = 24 h after mating). Their projections reach the neostriatum at ED 15-16.

Nicotine (0.4 mg/kg s.c.) was administered to the mother rat at ED 18 3/4 or 19 3/4. At this developmental stage the catecholamine fiber innervation of the neostriatum is fairly dense but shows the immature patchy pattern. The fetal brains were dissected 10-40 min after drug injection. DA was determined in midbrain and caudate-putamen by radioenzymatic assay. DA concentrations were markedly elevated in both regions after nicotine. Preliminary experiments revealed an influence of the drug also after direct injection into the fetus. These observations demonstrate that fetal nigrostriatal DA neurons are responsive to nicotine. However, the biochemical characteristics of the reaction differ from the adult state where DA concentrations remained unchanged in the somatodendritic and terminal areas. First experiments on neonatal rats point to differences between pre- and postnatal animals in the nigral response to nicotine. Biochemical and histochemical observations on fetuses in the last third of gestation indicate that the nigrostriatal DA system is also influenced by chronic nicotine treatment during pregnancy. The biochemical aspects of these drug effects are further investigated.

Our results show that nicotine affects a prenatal central catecholamine system, the nigrostriatal DA neurons. A direct assessment of drug effects in the fetal period may contribute to a better understanding of the relationship between prenatal influences and their possible consequences for postnatal life.

579 DEVELOPMENT OF THE ANTENNAL SYSTEM OF *MANDUCA SEXTA* FOLLOWING TRANSPLANTATION OF IMAGINAL ANTENNAL DISCS. Anne Schneiderman. Dept. of Neurobiol., Harvard Med. Sch., Boston, MA 02115.

Each antenna of the moth *Manduca sexta* develops during the 18 days of metamorphic adult development from an imaginal disc that has grown but not differentiated within the cranium of the larva. At pupation the disc everts, and with the initiation of adult development, antennal sensory neurons arise mitotically and send axons into the head along pre-existing "pupal antennal nerves" that run from cells near the tip of the extended, everted disc to the brain (Roux' Archiv *178* 71, 1975; Devel. Biol. *51* 300, 1976). As the antennae and antennal lobes of the brain develop, sexual differences become apparent in their structure (Camazine and Hildebrand, this volume; Matsumoto, this volume). Male antennae possess sensilla and associated olfactory neurons that are specialized to detect the female sex pheromone and are not present in female antennae. Male antennal lobes contain a macroglomerular complex that is missing from females and receives arborizations from interneurons that respond to pheromonal stimulation of the antenna. The present experiments begin efforts to explore the role of the pupal antennal nerves in the centripetal growth of adult antennal axons and the role of appropriate neural interactions in the ontogeny of the sexually dimorphic components of the antennal lobe.

We have surgically interchanged antennal imaginal discs between late-instar larvae of the same age and opposite sexes. In many cases the transplanted disc develops into a functional, partial or complete adult antenna with morphology characteristic of the donor's sex. Sensory neurons in the transplanted antenna differentiate and grow into appropriate regions of the brain, although pre-existing neural connections between the disc and the brain have been unambiguously severed. The macroglomerular complex in the male antennal lobe develops irrespective of the "sex" of the antenna associated with it. Histological, electrophysiological, neurochemical, and intracellular staining studies of these surgically chimeric antennal systems are in progress and will be described.

80 DEVELOPMENT OF ADRENAL STRESS RESPONSIVENESS IN THE RAT. Nancy M. Schoenfeld*, Jamshid Rabii and James H. Leathem. Dept. of Physiology, Rutgers University, Piscataway, NJ 08854.

The concept of a refractory period of responsiveness to ether stress in the neonatal rat has been questioned. Since the original determination of this stress non-responsive period had been based on the relatively insensitive fluorometric assay of corticosterone (B), we decided to re-evaluate this phenomenon using the more sensitive technique of competitive protein binding assay. Serum and adrenal B were measured 15 min after exposure to a 1-min ether (E) stress, as well as to subcutaneous injections of ACTH (A, 20 I.U./100 gm b.w.) and saline (S) in rats 5, 7, 9, 11, 13, 15, 20, and 25 days of age. Furthermore, the time course of the response to E was determined in 9- and 15-day old rats, at 0, 15, 30, and 60 min following the exposure to E. Significant elevations in serum and adrenal concentrations of B were measured at all ages following the treatments; the serum B values (µg/100 ml) are shown in the table:

AGE:	5	7	9	11	13	15	20	25
B	.33 ±.05	.11 ±.02	.42 ±.03	.24 ±.04	.60 ±.07	1.50 ±.27	2.23 ±.33	3.11 ±1.11
E	1.91 ±.56	1.10 ±.20	1.72 ±.13	2.66 ±.35	3.93 ±.21	11.58 ±.67	16.48 ±.92	40.04 ±3.76
A	3.92 ±.20	1.98 ±.16	1.95 ±.14	3.11 ±.23	3.75 ±.22	9.79 ±.31	16.35 ±1.17	39.56 ±4.56
S	2.81 ±.24	.29 ±.05	1.04 ±.12	1.08 ±.17	2.69 ±.26	4.72 ±.69	7.88 ±.59	21.90 ±4.16

The serum and adrenal response to E was maximal by 15 min in the 9-day old animal. In the 15-day old rat serum response continued to rise thru 60 min, whereas the adrenal response became maximal at 15 min. We concluded that the neonatal rat is capable of a significant response to ether as well as to ACTH and saline at all ages studied. Furthermore, the 9-day old rat does not show a delayed response to stress as evidenced by the significant rise in corticosterone levels observed 15 min after ether.

581 MATURATION OF WALLERIAN DEGENERATION: AN EM STUDY IN THE DEVELOPING OLFACTORY TUBERCLE. Thomas A. Schoenfeld, Christine K. Street* and Christiana M. Leonard. Dept. Neurosci., Univ. Fla. Coll. Med., Gainesville, FL 32610

Previous work has demonstrated that Wallerian degeneration argyrophilia (DA) shows qualitative and quantitative changes with age. In immature systems, DA develops between 8 and 16 hours of axon transection and, in many systems, has disappeared by 72 hours. With age, DA becomes long-lasting, increasing in density and extent during the first few days after a lesion. We have investigated the ultrastructural correlates of short-latency and long-lasting degeneration, using the olfactory tubercle of the golden hamster as a model system. Unilateral olfactory bulbectomies were performed in 5 and 19 day old pups, which were then sacrificed at 24 and 72 hour survivals and the brains removed and processed for routine electron microscopy.

Dark (electron-dense) profiles apposed to postsynaptic densities, typical of degeneration in the adult, were abundant in the superficial plexiform layer both 24 and 72 hours following bulbectomy at Day 19. The width of the plexiform layer was the same on both control and lesioned sides. At 24 hours after bulbectomy at Day 5, by contrast, the plexiform layer had shrunk by 50% and contained only a few dark or cystic profiles. By 72 hours, the layer had regained normal size and had a normal synaptic density (about 5/100 μ^2), suggesting that non-olfactory bulb afferents had come to occupy the vacated terminal space. The paucity of degeneration found after Day 5 lesions corresponds to the lack of degeneration argyrophilia seen at the light microscope level. It is possible that the rapid clearing of degenerative debris is associated with glial hypertrophy or proliferation. Numerous large dark, lysosome-containing processes occupied a substantial portion of the neuropil at 24 but not 72 hours after a Day 5 lesion.

Curiously, the density of synapses after a lesion at Day 19 was the same as after a lesion at Day 5, even though half of the synapses in the older pups were represented by degenerating synaptic profiles. The innervation of deafferented regions by the process of collateral sprouting may be limited by the presence of degenerating terminals, which, though non-viable, contribute to the total volume of terminal space. Such conservation of synaptic density in the olfactory tubercle, in conjunction with the occurence of short- or long-lasting degeneration, may account for known differences in neuropil reorganization after bulb lesions at different ages.

582 THE HALTERE-LIKE PROJECTION OF SEGMENTALLY TRANSLOCATED WING RECEPTORS IN DROSOPHILA HOMEOTIC MUTANTS. Margrit Schubiger* and John Palka, Dept. Zoology, Univ. Washington, Seattle, WA. 98195.

When sets of sensory cells are experimentally moved from one location to another, their axons often assume a distribution within the c.n.s. that characterizes their place of origin, as when the ganglion cells of an inverted amphibian eye project to the tectum according to their original orientation relative to the body. Certain receptors on the wing of Drosophila behave in this way when their axons are caused to enter the c.n.s. in the metathoracic segment by the mutation bithorax which transforms the halteres into a second set of wings. However, each investigated class of wing receptors responds differently to such a segmental translocation [Palka, J., Lawrence, P.A., and Hart, H.S., Develop. Biol. 69, 549-575 (1979)]. We present here an analysis of the small campaniform sensilla whose axons, instead of going "home" to the mesothorax, follow the paths of the haltere receptors they have replaced.

The wings and halteres of wild type flies both carry small campaniform sensilla. Their morphologies are similar but not identical and their central pathways are likewise very close to each other in many places but are not overlapping; in certain locations they are entirely distinct. The small campaniform sensilla of halteres homeotically transformed into wings follow the path of wild type haltere fibers in every respect we have examined, even though they come from wing tissue and their external morphology is clearly of wing type.

A more wing-like projection might be obtained from these fibers if the normal mesothoracic wings were removed prior to the time when sensory fibers reach the c.n.s., thus leaving a substrate vacant and ready for occupancy by the homeotic wing fibers. We have produced wingless flies both genetically by using a wingless; bithorax stock, and surgically by extirpating one wing disc in bithorax prepupae. In silver-intensified cobalt fills we have not been able to detect any differences in the course of the homeotic fibers in flies with and without normal wings. Thus, an occupied wing substrate does not appear to be responsible for the haltere-like course taken by the axons of the small campaniform sensilla of the homeotic wing.

583 DEVELOPMENTAL SPECIFICATION OF COLUMNAR AND RETINOTOPIC STRUCTURE OF RETINO-GENICULO-STRIATE SYSTEM VIA A MOVING BOUNDARY VALUE DIFFUSION DECAY SYSTEM. H.Schwartz* & E.L.Schwartz (SPON: E. R. John) Brain Research, Dept. of Psychiatry N.Y.U.

In previous work, it has been shown that the pattern of afferent input to striate cortex may be described in terms of a concatenated complex logarithmic mapping (Schwartz,1977a), and that receptotopic structure in general may be characterized in terms of solutions to a variational problem in which the magnitude of the magnification factor is minimized,subject to prescribed boundary conditions imposed by retinal cell density and cortical anatomy (Schwartz,1977b). In the present work, it is shown that the moving boundary value diffusion-decay system that has recently been proposed as a phyllotactic mechanism by Lindenmeyer and Veen (1977) may be adapted by a conformal transformation to specify the columnar and retinotopic structure of the retino-geniculo-striate system. The solution to the modified Lindenmeyer-Veen equation possesses the correct spatial structure to describe the receptive field density of LGN direction columns on a local scale, as well as retino-cortical inhomogeneity on a global scale. Remapping this spatial pattern to the cortex via the variational principle proposed in Schwartz(1977b) results in an accurate model of local and global retino-geniculo-striate functional architecture. Ocular dominance and orientation column structure are provided with the correct relative column scale factors, and it is shown that the Ising model method allows an analytic study of the (phase) transition from overlapped to columnar ocular dominance pattern. Finally, a general variational principle for fiber sorting is proposed, which includes most other models as special cases, and which is implimented by a convenient computer algorithm which may be used to solve the general receptotopic encoding problem. This work indicates that the details of retino-geniculo-striate map development may be simulated quantitatively and analytically, and that the variational principle-field theoretic approach to developmental specification(Schwartz,1977b) may provide a comprehensive description of receptotopic formation.

584 PSYCHOPHARMACOLOGICAL EFFECTS OF APOMORPHINE DURING ONTOGENY. Ismail A. Shalaby* and Linda Patia Spear. Dept. Psychology, SUNY-Binghamton, Binghamton, N.Y. 13901.

Behavioral time-sampling methods were used to assess the ontogenetic patterns of psychopharmacological responsiveness to the dopaminergic agonist, apomorphine. Male and female Sprague-Dawley rats were given 0, 0.05, 0.1, 1.0 or 3.0 mg/kg apomorphine hydrochloride and tested on either postnatal day (P)7, 14, 21, 28 or 35. During the first two weeks of life, all doses of apomorphine markedly increased wall climbing behavior (forepaw treading against walls) and the number of matrix crossings. At these ages, only slight amounts of sniffing behavior were seen even after the highest doses of apomorphine. By P28, the adult pattern of apomorphine responsiveness was seen. At this age, 0.05 and 0.1 mg/kg apomorphine decreased the number of matrix crossings, presumably a result of preferential activation of autoreceptors at these low doses of apomorphine (e.g., Martres et al., Br. Res. 136 (1977, 319). Also at P28, administration of either 1 or 3 mg/kg apomorphine increased matrix crossing behavior and induced marked stereotyped sniffing, gnawing, or licking behavior.

Apomorphine-induced wall climbing behavior was seen only during the first two postnatal weeks. We have also observed that the α-noradrenergic agonist clonidine similarly induced wall climbing behavior only during this postnatal interval, although the noradrenergic reuptake inhibitor cocaine did not induce wall climbing at any age (Spear & Brick, Behav. Neural Biol., in press). Moreover, wall climbing can also be induced by footshock (Fish, personal communication) or wall shock (Stehouwer & Campbell, Develop. Psychobiol., 1979, in press) at early postnatal ages. Possible explanations of these similarities in insult-induced behavior at early postnatal ages, and their subsequent decline during ontogeny, will be discussed.

585 DEVELOPMENT OF PIONEER AND SENSORY AFFERENT PROJECTIONS IN THE GRASSHOPPER EMBRYO. Marty Shankland* (SPON: D. Bentley) Neurobiology Group, Univ. Calif., Berkeley, Ca. 94720

The embryonic formation of a sensory projection will be described in the grasshopper, Schistocerca nitens. Cobalt diffusion staining (silver intensified) of the cercal nerve depicts sequential ingrowth and central branching of both pioneer and sensory axons.

Pioneer neurons (Bate, '76, Nature 260: 54-56; Edwards and Chen, Roux's Arch. Dev. Biol., in press) in the cercal lumen establish the nerve prior to sensory axon differentiation. I have stained the central processes of pioneer axons as early as 50% of embryogenesis. At this stage many central neurons have not yet differentiated, and the neuropil is restricted to pairs of segmental commissures linked by two bilateral longitudinal fiber tracts (LFT). At least five pioneer axons are seen in the cercal nerve. They enter the LFT at its junction with the most posterior commissure and form numerous fine processes. Two or three thicker axons that end in growth cones travel several segments anterior as part of the LFT. These axons do not branch, but bear short, fine processes which later disappear. The four posterior ganglion rudiments fuse at 60% of embryogenesis. Sensory axons enter this fused ganglion at 65% and obscure the projection, but the pioneer neurons still persist. Unbranched, multisegmental longitudinal axons are present even in the adult. Furthermore, a cobalt fill into the hatchling cercus stains not only epidermal sensory cells but also a pair of neurons within the lumen (pioneers) whose dendrites do not contact sensilla. Hence, at least some pioneer neurons survive after embryogenesis.

The pioneers have been described as pathfinders, leading sensory axons into the ganglion. Cobalt stains show that some sensory axons continue to follow the pioneer tract within the ganglion, but the majority diverge upon entry. At 65% they form two ipsilateral patches of dense arborization which demarcate the eventual cercal glomerulus. The Medial Giant Interneuron is first visible in silver stained sections at this same age. The giant is a major synaptic target for the sensory afferents, and the glomerulus develops as a paraboloid sheet of afferent arborization around its main dendrite. By 80% the embryonic projection resembles the adult projection in all main features. The neuropil continues to expand, but no new tracts are added by the postembryonic ingrowth of new axons.

The regional characteristics of this sensory projection are thus established during embryonic formation of the neuropil. Pioneer and sensory axons grow along specific paths within the ganglia and contribute to the structural differentiation of the neuropil.

586 THE DEVELOPMENT OF ORDERING IN THE OPTIC AXONS OF Rana pipiens. Sansar C. Sharma. Dept. Ophthalmology, New York Medical College, Valhalla, N.Y. 10595.

The time of origin of ganglion cell fibers in the developing Rana pipiens retina has been studied using electronmicroscopy, silver stained sections and whole mount preparations. The first ganglion cell axons appear at Shumway stage 17-18. The developing fibers group together and form a fascicle. The individual fibers within the fascicle are directed towards the optic disc and travel into the optic stalk, which is still intact at stage 18. Subsequent to the formation of the initial optic fascicle, more fascicles appear in later stages, and they are also oriented towards the optic papilla. In later stages a fan-like network of fascicles appears which joins at the optic papilla. The initial nerve outgrowth is not dependent upon the choroidal fissure, which develops later. Instead, first-formed axons and their fascicle formation act as a guiding source for the new fascicles. These fascicles maintain parallel alignment in the optic nerve and are apparently responsible for the retinotopic order in the optic nerve and subsequent termination in the optic tectum.

587 Birthdates Of Ocular Motoneurons In Rabbits. Marjorie D. Shaw*, and Keith E. Alley. Dept. Anat., Case Western Reserve University, Cleveland, Ohio 44106.

Temporal gradients constitute a critical variable in many developmental processes. A knowledge of neuron birthdates (time of final mitosis) may reveal new principles in the developmental construction of brain pathways and nuclei.

Injections of 12 uCi of tritiated thymidine into the large rabbit blastocyst demarcate all newly emerging neurons with heavy radioactivity. On the ninth day of gestation, such an injection reveals the earliest beginnings of ocular motoneuron formation. By day 13, production of ocular motoneurons ceases.

The generation of the oculomotor, trochlear and abducens nuclei proceed on similar timetables. Heavily radioactive cells form approximately 1% of the total neurons of each nucleus in specimens injected on day 9. The percentage rises to about 5 on day 10, peaks at 20 on day 11, then falls to 5 again on day 12. The neurons of the accessory abducens nucleus (recently recognized as the motoneurons for the retractor bulbi muscle of the eye) emerge at a faster rate. On day 10, 30% of the cells show heavy labelling, but by day 12 all label disappears.

In the oculomotor nucleus, the earliest neurons tend to settle most rostrally, while later forming cells migrate preferentially to the caudal end. A rostro-caudal gradient emerged clearly within the oculomotor nucleus, but appears less marked between the nuclei.

588 GUIDANCE AND TOPOGRAPHIC PATTERNING OF RETINAL GANGLION CELL AXONS. Jerry Silver* (SPON: G.A. Kevetter). Dept. Anat., Sch. Med., Case Western Reserve Univ., Cleveland, Ohio 44106

In order to examine the factors that may guide the earliest developing optic axons in mice, the stretch of primitive neuroepithelium located along the potential route of the pioneer optic nerve fibers has been examined in three dimensions with the use of computer graphic reconstruction of serial, 1μm sections. The study has revealed a system of wide-bored intercellular channels (averaging about 25 μm^2 in cross sectional area) within the marginal zone of the primitive retina and continuing without interruption into the underside of the optic stalk (adjacent to the optic fissure) and toward the presumptive optic chiasm. The spaces appear well in advance of the morphological differentiation of the retinal ganglion cell neurons.

The openings are arranged with a definite directionality. Thus, the spaces at the region of the prospective optic disc appear to coalesce and form segregated sets of long, interconnecting tunnels oriented in the direction of the stalk. More peripherally, toward the back and rim of the cup, the spaces form blind, radially arranged pockets. Previous studies have established that the first developing retinal ganglion cells with axons are generated immediately dorsal to the optic stalk (Mann,'69; Kahn, '73), that is, at the junction between the open tunnels and closed pockets. Given the constraints of their extracellular surroundings it is conceivable that the earliest optic axons may be confronted with alternative environments depending on their direction of movement and may literally be compelled to exit the eye in the proper direction. Indeed, the path taken by the first outgrowing optic fibers is identical to the one previously established by the intercellular tunnels and always in the direction of the stalk.

Over their entire course, the tunnels in the region of the disc strictly maintain their positions in relation to the optic fissure and, thus, particular segments of the retina become connected by continuous openings with equivalent regions in the stalk. As the later forming optic axons (those near the back and periphery of the cup) add on sequentially, perhaps by fasciculation, they are never given the option of growing towards the pupil since the pockets interposed between them and the rim of the cup always remain closed. Providing that the first optic axons approach the disc in register, the layout of these specialized extracellular spaces may not only provide directional information to the first forming optic axons but topographic cues as well.

589 THE BLUEPRINT HYPOTHESIS OF CENTRAL NEURITE PATTERNING DURING REGENERATION AND EMBRYOGENESIS. Marcus Singer, Ruth Nordlander* and Margaret Egar*. Dept. Anat., Sch. Med., and Dev. Biology Ctr., CWRU, Cleveland, OH 44106.

The tail of the lizard and of the newt including the spinal cord regenerates after amputation. The spinal cord is formed at first by outgrowth of the ependyma from the amputated end of the cord, forming a tube which ends blindly. Fibers descending from the cord stump follow the primitive ependyma; and in the case of the newt the ependyma also gives rise to new central neurons and glia. The ependymal cells, oriented around the central canal, have radiating processes which contact the basal lamina beneath the developing pia mater. Between these processes there are "spaces" which are in register to form longitudinal channels and descending axons are located in these channels. A salient fact is that the channels form in advance of the first neurites; and it is, therefore, these channels or their internal surfaces which guide the neurites toward the as yet undeveloped target. A similar mechanism of guiding neurites was observed during embryonic and larval development in the newt and in other animals. These observations led us to propose the so-called blueprint hypothesis of neurite patterning which states that the primitive ependyma and its derivative primitive glia provide the itinerary directing the pioneer neurites to their destination. The hypothesis includes the concepts of trace pathways on the epithelial surfaces, the ability of neurites to follow specific traces and the possibility that growing axons may act as evocators of the blueprint.

590 MORPHOLOGY OF RETINOTECTAL CONNECTIONS IN FETAL MOUSE EXPLANT CO-CULTURES. Neil R. Smalheiser, Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Electrophysiologic studies of retinotectal co-cultures (Smalheiser and Crain, Br. Res. 148:484,'78) have now been extended by horseradish peroxidase (HRP) tracing of retinal ganglion cell axons within tectal (superior collicular) explants. Extracellular iontophoretic HRP injections (Smalheiser, Crain and Peterson, Soc. Neurosci. Abstr. 4:479,'78) resulted in a solid Golgi-like filling of cell bodies and neurites. Using 13-15 day fetal mice, retinal halves were placed adjacent to, or ~ 0.5 mm away from, whole tecta. In the latter case a collagen gel overlay (Elsdale and Bard, J. Cell Biol. 54:626,'72) enhanced organized "optic nerve" outgrowth. HRP injections into the retinal or tectal explants filled retinal ganglion cells whose axons entered the optic fiber layer and converged to the site of the optic nerve head, as occurs in situ. In co-cultures, some of these axons often became myelinated after 2-3 weeks in vitro. The axons formed long fascicles that emerged from the retina during the first few days in vitro. The majority of ganglion cell axons that did not reach the tectal explant degenerated after the first week. If they entered the tectum, many of them survived for at least five weeks. Within the tectum, the retinal fibers tended to be smooth, with few swellings; pursuing a wavy course, usually with few bifurcations. Thin stems came off at frequent intervals which varied from simple short thorns to long, thin preterminal ramifications bearing elaborate nests of boutons. The existence of these terminal arborizations had, in fact, been predicted from our earlier analyses of retinally-evoked action potentials within the tectum. Ganglion cell axons surviving upon collagen or nonneural cell layers showed no arborizations -- at most, bouton-like swellings along the fibers. Oriented co-cultures are being analyzed after HRP injections to evaluate whether retinal fiber growth or arborizations from retinal halves are preferentially located in correct tectal regions as occurs in situ.

Neurites also grew out from retinal interneurons, emerging radially from the retinal explant after the first week in vitro. These had 'en passant' varicosities and bouton-like structures, and were tipped with growth cones (even after several weeks in vitro). Their appearance was similar whether growing within the tectum or upon inert collagen substrates. Some of these neurites showed catecholamine fluorescence.

These morphological observations further demonstrate the potential of retinotectal co-cultures for exploring mechanisms of synaptic specificity.

591 LATE DEVELOPMENT OF DENDRITIC STRUCTURE IN N. LAMINARIS D.J. Smith and E. W Rubel. Neuroscience Program and Dept.s of Otolaryngology and Physiology, Univ. Virginia Med. Ctr., Charlottesville, VA. 22908.

N. laminaris (NL) is a third-order auditory nucleus in the avian brain stem. It is composed of a monolayer of cell bodies, and two neuropil regions, one dorsal to the cell bodies, and one ventral. The dorsal neuropil receives tonotopic input from the ipsilateral cochlea via the ipsilateral n. magnocellularis (NM), and the ventral neuropil receives matching input from the contralateral NM. The dendritic structure of NL cells is such that they have a dorsal and a ventral group of dendrites, with few dendrites issued laterally. The dendritic organization of NL in 5 day-old chicks has been previously described (Smith and Rubel, J. Comp. Neur. in press). At this age, NL has been functional for two weeks. At 5 days the total dendritic length (the sum of the dorsal and ventral dendritic lengths) of NL cells increased 3.5-fold from the rostromedial to the caudolateral poles of the nucleus. The gradient of this increase is identical to the gradient of tonotopic organization in NL, and accounted for 50% of the variance in total dendritic length. Separate analyses of the dorsal and the ventral dendritic lengths revealed divergent gradients for the dorsal and ventral dendrites; each was symmetrically skewed to either side of the frequency gradient. The cell-by-cell correlation of dorsal with ventral dendritic lengths was 0.47.

In this study the late development of dendritic structure in NL was examined in 25 day-old chickens. Camera lucida drawings of Golgi-Kopsch impregnated cells were analysed for dendritic length and number of primary dendrites. The gradient of total dendritic length across NL remains in correspondence with the tonotopic gradient, and accounts for 72% of the variance: there is a 10-fold increase in total length from rostromedial to caudolateral NL. The dorsal and ventral length gradients become identical by 25 days, and both gradients correspond to the tonotopic organization. The cell-by-cell correlation of dorsal with ventral dendritic lengths is increased to 0.84.

Thus, during the postnatal period the degree of change in dendritic length from rostromedial (high Hz) to caudolateral (low Hz) NL becomes greater. Also, the lengths of the dorsal and ventral dendritic trees become more closely correlated: the orientations of the dorsal and ventral length gradients realign to coincide with the gradient of tonotopic organization. These data indicate that the organization of dendritic size is progressively tuned to a greater correspondence with the tonotopic organization, emphasizing the importance of afferent organization in determining the organization of dendritic structure. (Support: NSF #BNS 78-04070; Deafness Research Found.; NIH #MH-05949)

592 KINETICS OF ^{22}Na AND ^{36}Cl DISTRIBUTION IN THE POSTNATAL RAT CHOROID PLEXUS. Quentin R. Smith, Conrad E. Johanson, and Dixon M. Woodbury. Dept. Pharmacology, Univ. of Utah College of Medicine, Salt Lake City, Utah 84132.

Maturation of the blood-CSF barrier involves changes in the transport properties of the choroid plexus (CP). Notably, CP vascularity and fluid production increase while permeability decreases. To evaluate the effect of these alterations on two ions (Na and Cl) closely linked to fluid elaboration, the kinetics of ^{22}Na and ^{36}Cl distribution in the postnatal choroid plexus were analyzed. The data for ^{36}Cl are reported herein.

Four-hr nephrectomized rats (1 wk, 2 wk, and adult) were sacrificed 1/12, 1/6, 1/4, 1/2, 1, 2, 4, and 8 hr after i.p. injection of 100 uc/kg ^{22}Na or ^{36}Cl. Samples from the central nervous system (CP, CSF, cerebral cortex, and cerebellum) and the periphery (skeletal muscle, plasma, submaxillary salivary gland, and thyroid) were assayed for radioactivity. Values were reported as a space (%) = 100 x (dpm/g tissue)/(dpm/g extracellular fluid H_2O). The uptake of ^{36}Cl by the 1 wk rat CP was markedly slower than that of the adult, though similar steady-state values were obtained (~54%). For example, the 5, 10, and 15 min post-injection spaces (which reflect the filling of the CP extracellular space) were ~35% those of adult values. In contrast to the CP, ^{36}Cl spaces of the 1 wk rat cerebral cortex were equal to or greater than those of the adult at all time periods. Because of the greater extracellular volume, the cerebral cortex steady-state space of the neonate was larger than that of the adult. Comparable results were obtained with the cerebellum.

The slower rate of uptake at early time periods by the 1 wk rat CP compared to the adult may reflect the less developed vascularity of the neonatal CP. Similarly, the steady-state Cl content of the 1 wk CP may indicate that mechanisms for accumulating Cl are present in the CP at that age. In the cerebral cortex and cerebellum, differences in ^{36}Cl uptake with age may be explained by a larger extracellular space and a greater membrane permeability in the neonate. (Supported by NIH Grant GM07579, NS13988, and AM20935.)

593 DEVELOPMENT OF HYPOTHALAMIC LHRH AND SERUM LH, FSH AND PROLACTIN IN INTACT AND NEONATALLY GONADECTOMIZED MALE AND FEMALE RATS AND NEONATALLY ANDROGENIZED FEMALE RATS. W.E. Sonntag*, A.A. Gerall, J.C. King and A. Arimura*. Department of Psychology, Tulane University, and Veterans Admin. Hospital, New Orleans, LA 70118.

Hypothalamic LHRH, serum LH, FSH and prolactin were measured by RIA on days 10, 20, 29, 36 and 52 in intact and castrated male and female rats and in intact females injected with 1.25 mg testosterone propionate on dav 3. LHRH was assayed in rostral (MPOA-OVLT) and caudal (arcuate-median eminence) areas. In intact animals, LHRH content was higher on day 20 and 52 than other davs. No sex differences in LHRH content were observed in either hypothalamic area until dav 52 when estrous females had lower LHRH than either males or diestrous females (P<.01). On day 10, LHRH content was not different among any groups. About day 20, gonadectomized females had a lower hypothalamic LHRH content in caudal areas compared to intact controls (P<.05). A similar difference was not observed in gonadectomized males until day 25. In androgenized females, LHRH content was similar to that in intact animals until days 36 and 52 when it exceeded that in intact animals (P<.01). Although LHRH was substantially lower in rostral than in caudal areas, their developmental pattern was similar. Serum LH was uniformly low in intact and androgenized animals throughout development. Gonadectomized animals had similar serum LH as intact animals on day 10, but these LH values increased around dav 20, and stabilized around day 29 to a level above that in intact animals. Serum FSH was elevated in intact females compared to intact males between days 10 and 20 (P<.01, each), but serum FSH in intact males was significantly higher than in intact females on days 29, 36 and 52 (P<.01. each). Androgenized females had FSH values intermediate to intact males and females at all ages. Although gonadectomized animals had higher serum FSH concentrations from days 10 to 52 than intact animals (P<.01), high est values were found around day 20. Serum prolactin concentrations increase from day 20 to dav 29 and then decrease in all animals except androgenized and estrous females.

Despite differences in serum FSH concentration between males and females and between intact and gonadectomized animals as early as day 10, differential hypothalamic LHRH content between intact and gonadectomized animals was not evident until after day 10 in female rats and after day 25 in male rats. Androgenized females do not demonstrate an increase in LHRH content until the peripuberal period. This increased hypothalamic LHRH might be related to the tonic secretion of estrogen or possibly, to the high concentrations of prolactin occurring after puberty in the androgenized animals.

594 DEVELOPMENTAL CHANGE IN AUDIOGENIC SEIZURE SUSCEPTIBILITY IN DBA/2J MICE, POSSIBLY MEDIATED BY SEROTONIN RECEPTOR MODIFICATION. David L. Sparks* and N.S. Buckholtz, Depts. of Biochemistry and Psychiatry, Medical Univ. of S.C., Charleston, S.C. 29403

DBA/2J mice are maximally susceptible to AGS at 21 days of age and demonstrate almost no AGS Susceptibility (AGS-S) at 28 days. AGS-S in the DBA/2J mouse is possibly a result of reduced neurotransmitter levels leading to reduced receptor interaction. 5-HT system may mediate the seizure attenuating action of the drugs chlorimipramine (CIMI), pargyline, and certain ß-carbolines by increasing 5-HT interacting at its receptor or by the drugs themselves acting directly at the 5-HT receptor.[1] It would thus seem that the 5-HT receptor agonists Quipazine or 5-Methoxy-DMT would block AGS, but they do not.[1] This report presents evidence that the effect of these drugs on AGS changes developmentally and this may be due to a modification in the 5-HT receptor.

AGS testing was done by placing drug or saline injected DBA/2J mice, one hour post injection, into a bell jar and engaging a bell (119 ± 2 db). AGS was scored for the following components: wild run, clonic seizure, tonic seizure and death. Saline injected control animals demonstrated the expected developmental reduction in AGS-S starting after 24 days of age. The receptor agonist 5-MeO-DMT (10 mg/kg) was shown to block the death, tonic, and clonic components of AGS in DBA/2J mice from 22 to 26 days of age after which time it increased AGS-S as compared to control animals. The receptor agonist Quipazine (10 mg/kg) blocked death and the tonic seizure component until age 26 after which time it increased clonic and tonic components as compared to control animals. The selective 5-HT re-uptake inhibitor CIMI (25 mg/kg; which would increase 5-HT levels at its receptor) demonstrated the same phenomenon, whereas the monoamine oxidase inhibitor pargyline (100 mg/kg; which would increase 5-HT intraneuronally) did not.

These results suggest that a developmental change in the 5-HT receptor occurs at day 26 or 27, which can be observed by increased AGS-S in response to increased 5-HT or 5-HT like activity at post synaptic receptors. One might speculate that the post-synaptic 5-HT receptor or a specific pool of these receptors undergoes a shift in functionality or maturation which may be related to the isozymal shift in activity of Ca^{2+}-Mg^{2+} dependent ATPase activity at 25 days in DBA/2J mice.[2] This would lead to an hypothesis that decreases in neurotransmitter levels contribute to the severity of AGS but it is the presence of unmatured receptors that imparts susceptibility to AGS in DBA/2J mice.

595 DISTRIBUTION OF ENZYME ACTIVITIES AND AXONALLY TRANSPORTED GLYCOPROTEIN IN HAMSTER OPTIC NERVE SYNAPTOSOMES DURING POSTNATAL MATURATION. Susan Corey Specht and Teresa Candelas*. Dept. Pharmacol., Sch. Med., Univ. Puerto Rico, San Juan, PR 00936.

Optic nerve endings of golden hamsters were labeled by axonal transport following intraocular injection of ^{3}H-fucose at postnatal ages 12 days (P12), P16, 3 wks and adults. Synaptosomal subfractions were separated on a 4-step sucrose gradient by the method of Cohen et al. (J. Cell Biol. 74:181, 1977) and analyzed for acid-precipitable label or enzymatic activity. Incorporated radioactivity was measured 1, 7 and 15 days following injection. At both P12 and P16 over 75% of K^+-dependent, ouabain-sensitive p-nitrophenyl phosphatase and 5'-mononucleotidase activities were found in subsynaptosomal fractions layering at 0-0.85 M (A) and 0.85-1M (B); cytochrome oxidase activity was divided between the 1-1.2M (C) interface and the pellet (D). In 3 wk and adult hamsters the membrane markers were concentrated at the denser B and C interfaces; cytochrome oxidase activity was concentrated in D. The proportion of total synaptosomal protein in these fractions increased only slightly during development. Incorporated ^{3}H-fucose was recovered predominately from the C and D fractions in adults and from the less dense A and B fractions in P12 hamsters. In P16 hamsters synaptosomal label was initially distributed according to the P12 pattern but shifted to resemble the adult pattern 7 and 15 days after intraocular injection. Label disappeared from adult synaptosomes at the same rate as from other optic nerve fractions but was accelerated in synaptosomes isolated from hamsters injected at P12 and P16. The results demonstrate a maturational shift of membrane marker enzymes into denser fractions. ^{3}H-fucose incorporated at P16 showed a similar shift, suggesting that incorporation by retinal ganglion cells at P16 may be directed principally to plasma membrane precursors which appear first in light fractions and are later inserted into the heavier membranes. At P12 incorporation may be directed to less dense synaptosomal components. Active synaptic remodeling in neonatal optic nerve endings is suggested by the relatively more rapid turnover of synaptosomal ^{3}H-fucose. (Supported in part by NIHPHS grant EY02334.)

596 PHYSIOLOGICAL DEVELOPMENT AND SEGMENTAL DIFFERENCES OF NEURONS FROM AN IDENTIFIED PRECURSOR DURING GRASSHOPPER EMBRYOGENESIS. N.C. Spitzer, M. Bate*, and C.S. Goodman. Dept. of Biology, UCSD, La Jolla, CA, 92093, and Max-Planck-Institut für Virusforschung, Tübingen, F.D.R.

The "H" neuron, one of the two progeny of the midline precursor cell 3 (MP3) in the grasshopper, undergoes a morphological transformation early in embryogenesis. During this transformation in the metathoracic ganglion it acquires many of the same physiological properties as the first progeny of the DUM neuroblast in the same ganglion, at the same time that the latter cells are differentiating. The transformation of the "H" cell takes place while still electrically coupled to its mitotic sibling. The original process appears inexcitable throughout the course of its transient existence. This cell becomes uncoupled from its sibling and loses its original axon. The onset of electrical excitability is first seen in the new processes and shortly thereafter in the soma. It stains with neutral red, is depolarized by ACh, and receives spontaneous synaptic input. In those cases in which the sibling persists, its axon but not its cell body becomes electrically excitable.

Although all of the segmental ganglia come from relatively similar sets of embryonic precursor cells, there are striking differences in the number and properties of the neurons in the mature ganglia. In the meso- and metathoracic ganglia (T2 & T3), one of the two progeny of MP3 is transformed into the "H" cell. In many of the abdominal ganglia, beginning with the fourth (A4), both MP3 progeny disappear, at the time of the transformation of the "H" cell in T2 and T3. A gradient of transformation and cell death is seen in the first three abdominal ganglia (A1-3), at the boundary between thorax and abdomen. From A1 to A3 the MP3 progeny acquire fewer of the morphological phenotypes of the "H" cell: they lose the original process less often, and extend fewer of the new axons. There is also variability in the apparent gradient of the number of progeny persisting from A1 to A3. Finally, the acquisition of only a fraction of the morphological phenotypes is paralleled by the partial acquisition of the physiological phenotypes: the progeny of MP3 in A1 to A3 develop excitable axons but do not develop overshooting soma spikes.

Thus cells that are the progeny of the same precursor cell in different segments can develop different morphological and physiological properties. In contrast, cells which are the progeny of different precursor cells in the same segment can develop similar phenotypes.

597 SELECTIVE OPTIC FIBRE PROJECTION FROM COMPOUND EYES TO THE TECTUM DURING DEVELOPMENT IN XENOPUS. Charles Straznicky[1,3], R.M. GAZE[2]* and M.J. KEATING[2]*. [1]Sch. Med., Flinders Univ of South Australia, Bedford Pk. 5042, Australia. [2]Natl. Inst. Med. Res., London NW7 1AA, UK.

Compound eyes were formed in Xenopus embryos at stage 32 by the fusion of two nasal (NN), two temporal (TT) and two ventral (VV) halves of the eye blastema. ^{3}H-proline was administered both into the operated right and the left intact eyes at stages 50, 52, 56, 60, 63, 66 and 2 and 6 weeks after metamorphosis and animals were killed 24 hours after injection in order to map the retinotectal projections autoradiographically. The visuotectal projections in animals from stage 56 onwards were also mapped electrophysiologically to demonstrate the success of the compound eye operation.

The projection from TT eyes was deficient in comparison with the normal side in that only the rostrolateral part of the tectum was innervated. In the autoradiographic time series the TT eye projection gradually expanded caudiomedially and finally reached the caudomedial tectal margin about 6 weeks after metamorphosis. Optic fibres from VV eyes initially projected, via the medial branch of the optic tract, to the medial portion of the developing tectum. At later stages this projection gradually expanded laterally reaching the lateral tectal margin only after metamorphosis. In contrast to TT and VV eye projections, optic fibres from NN eyes projected across the entire normally innervated extent of the tectum at all developmental stages.

These observations suggest that the initial tectal distribution of fibres from a compound eye is selective at least as far as concerns the polarity of the projection. Secondary spreading of the projection over the whole extent of the tectum then occurs. The extension of the NN projection over the whole tectum at all stages of development reflects the fact that the first part of the tectum to be innervated is the rostral part, even for nasal retina. In normal animals this rostral innervation by nasal fibres is pushed caudally during development by incoming temporal fibres; but with an NN retina there are no such fibres and the nasal innervation persists.

598 NEUROTRANSMITTER-SPECIFIC PROTEINS OF SYMPATHETIC NEURONS. Kathleen J. Sweadner and Sarah J. Braun*. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Sympathetic neurons from superior cervical ganglia of neonatal rats can be maintained in dissociated cell culture in the absence of non-neuronal cells, where they develop into mature, differentiated neurons. The choice of neurotransmitter they synthesize, store, and release at synapses can be controlled: they develop as adrenergic cells when grown in depolarizing media, and as cholinergic cells when grown in media conditioned by certain non-neuronal cells (Walicke, Campenot, & Patterson, PNAS 74: 5767, 1977). We have examined the protein composition of adrenergic and cholinergic cells to identify transmitter-specific proteins involved in the formation and function of these two types of synapses.

Transmitter specific proteins might be found in the plasma membrane, in the extracellular matrix, in synaptic vesicles, and as soluble proteins free to diffuse between cells. To separate and characterize the transmitter-specific proteins, we have analyzed each of these subclasses of neuronal proteins separately: (1) Membrane glycoproteins were labeled either metabolically, by incorporation of [^{3}H] sugar precursors, or at the cell surface, by oxidation with periodate or galactose oxidase, followed by reduction with [^{3}H]BH_4^-. Both methods labeled a similar group of proteins. (2) Extracellular glycoproteins are left bound to the collagen substratum after the neurons are removed. These were then labeled by periodate or galactose oxidase and [^{3}H]BH_4^-. (3) Proteins are released into the culture medium when transmitter release is evoked by depolarization, Ba^{+2}, or black widow spider venom. These were labeled metabolically by incorporation of [^{3}H] leucine. (4) Soluble proteins are secreted and/or shed into the culture medium under normal growth conditions. These were also labeled metabolically by incorporation of [^{3}H]leucine.

Proteins were analyzed by high resolution one dimensional (SDS) and two dimensional (isoelectric focusing/SDS) gel electrophoresis and autoradiography. Data will be presented that shows that each of these subclasses of cellular proteins is distinct. Each contains from five to more than twenty different polypeptides. It has been possible to identify adrenergic- and cholinergic-specific proteins in each subclass, and a preliminary characterization of these will be described. Determination of neuronal transmitter choice thus involves not only the enzymes required for transmitter synthesis, but also a number of other proteins which are extracellular or exposed on the surface of the cell.

599 DIFFERENTIATION OF PNMT IN CULTURED ADRENAL GLANDS FROM RAT EMBRYO. Gladys Teitelman, Dong H. Park, Tong H. Joh and Donald J. Reis (SPON: R.A. Ross). Lab. of Neurobiol., Dept. of Neurol., Cornell Univ. Med. College, New York, NY 10021.

In the rat embryo, the prospective adrenal medullary cells (phaeochromoblasts), of neural crest origin, reach the adrenal cortical anlage between prenatal days 15 and 16. At this stage, the CA synthesizing enzymes tyrosine hydroxylase (TH) and dopamine-β-hydroxylase (DBH) are detected in these cells by immunohistochemical techniques. However, it is not until day 18 (d18) of development that the enzyme required for adrenaline synthesis, phenylethanolamine-N-methyl transferase (PNMT), is first expressed (Teitelman et al., PNAS 76:509, 1979). To study some of the possible factors responsible for the initiation of PNMT synthesis within the phaeochromoblasts, we have sought to determine: a) whether PNMT would be expressed in adrenal glands removed from the embryo at day 16 and cultured in vitro; b) if the time course of appearance of PNMT in vitro is similar to that in vivo; and 3) whether ACTH and/or glucocorticoids are required for the initiation of PNMT synthesis in vitro. Adrenal glands were removed from 16d rat embryos, bisected, transferred into culture flasks and incubated. At different times in culture, the tissues were fixed in 4% paraformaldehyde, embedded in sucrose and cut in a cryostat microtome. Using the PAP technique, the sections were stained with specific antibodies to the enzymes TH, DBH, or PNMT. After 2 days in vitro, the adrenals contained many cells stained for TH and DBH. On the other hand, PNMT was detected in only a few cells, as in 18d in vivo. After 5 days in culture, the number of cells containing PNMT had increased greatly. The distribution of cells stained with either TH, DBH or PNMT was similar: after 5 days in vitro, they tended to aggregate into several large groups and, in many cases, surrounded the unstained adrenal cortex. To determine whether the expression of PNMT was due to ACTH or glucocorticoids in the culture media, adrenals removed at d16 were cultured in medium containing dialyzed serum, which presumably lacks these molecules. Incubation in dialyzed serum did not modify the time of the appearance of PNMT nor the subsequent increase in the number of cells containing the enzyme. We conclude: a) PNMT can be expressed in embryonic adrenal medullary cells in vitro; b) such differentiation is not a consequence of small molecules present in the culture medium; and c) the time course of appearance of PNMT in vitro is similar to that in vivo. The cultured embryonic adrenals may serve as a useful model for the analysis of the factors involved in the initiation of PNMT synthesis.

600 SYNAPTOGENESIS IN THE DEVELOPING ANTENNAL LOBES OF THE BRAIN OF THE MOTH *MANDUCA SEXTA*. Leslie P. Tolbert. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

The antennae and antennal lobes of the brain of the moth *Manduca sexta* arise during the 18 days of metamorphic adult development, and therefore provide a convenient preparation in which to study the developmental interactions between neurons that will come to be synaptically related. As a basis for a detailed understanding of the correlation between the neurochemical and cytological maturation of the antennal lobes, we have undertaken a study of the synaptic connections in the adult antennal lobe and of the formation of synapses in the developing antennal lobe.

In the antennal lobe, the antennal sensory axons synapse with second order cells in light-microscopically identifiable regions of condensed neuropil, the glomeruli. Electron-microscopic examination of these glomeruli in adult moths reveals that they comprise tightly packed neuronal processes, most of which contain vesicles. Several types of synaptic processes can be distinguished on the basis of the sizes and shapes of their vesicles and whether they are presynaptic or postsynaptic or both. Following removal of the antenna, profiles containing round, electron-lucent vesicles exhibit degenerative changes, suggesting that these profiles represent the primary afferent input to the lobe.

Although growing antennal axons begin to reach the antennal lobe on about day 3 of adult development, synapses do not appear until much later. On day 10, many neurite profiles contain vesicles; only a few have begun to elaborate small, weakly staining membrane specializations. During the next two days of development, membrane-associated densities expand and acquire their adult staining characteristics; synaptic vesicles in the presynaptic elements cluster around the presynaptic densities. By day 12, mature synaptic complexes are distributed throughout the glomeruli. Previous studies in our laboratory (Dev. Biol. *52*: 105, 1976; Brain Res. *119*: 389, 1977) have shown that the antennal axons appear to use acetylcholine as neurotransmitter. On day 12, when morphologically mature synapses are first seen, levels of ACh and its synthetic enzyme, choline acetyltransferase, in the antennal lobe are just reaching their mature levels, suggesting that the newly formed synapses may be functional. Intracellular recordings by S.G. Matsumoto (this volume) corroborate this idea. They show that synaptic transmission in the antennal lobe develops between days 9 and 13 of development.

601 PATTERNS OF NEUROGENESIS IN THE VENTRAL LATERAL GENICULATE NUCLEUS OF THE CHICK. C. J. Uchwat* and W. J. Crossland, Department of Anatomy, Wayne State University School of Medicine, Detroit, Mich. 48201.

This study was conducted to determine the temporal and spatial patterns of neurogenesis in the chick ventral lateral geniculate nucleus (GLv). A single injection of 20 µCi of ^{3}H-thymidine was applied to the yolk sac of 49 chick embryos from stage 17 through stage 36. The embryos were sacrificed at stage 42 or 43 and the brains embedded in paraffin. Since the ^{3}H-thymidine is available to the embryo from the yolk for some time, a cumulative labeling analysis was employed.

The results of our autoradiographic studies indicated that the lateral diencephalic nuclei are produced before the medial nuclei. Similarly, ventral nuclei precede dorsal; caudal nuclei precede rostral. These patterns are similar to those already described for mammals.

Neuronal proliferation is somewhat late in the GLv in spite of the ventrolateral position of the nucleus in the diencephalon. A detailed analysis of cell production in the GLv was made by determining the percentage of unlabeled cells in both GLv lamina (internal lamina and neuropil lamina) from thionin stained autoradiographs. Two gradients of cell production were apparent. 1) Neurons in the caudal GLv were produced before the rostral GLv neurons. 2) Although unlabeled cells appeared in both GLv laminae at stage 21 and both laminae were unlabeled by stage 34, the internal lamina became unlabeled more rapidly than the neuropil lamina. Thus the GLv has an "inside-out" (dorsomedial to ventrolateral) gradient of cell production in contrast to the over-all "outside-in" (ventrolateral to dorsomedial) pattern in the diencephalon.

Planimetric measurements of camera lucida-traced neurons in a stage 25 embryo showed that unlabeled cells in both GLv laminae have a larger mean area than labeled cells. Furthermore, the mean neuronal area in the internal lamina is significantly greater than the mean neuronal area in the neuropil. Thus the pattern of neurogenesis in the GLv appears related to cell size rather than to the general gradients of cell production in the diencephalon.

602 ALTERED ISTHMO-TECTAL TOPOGRAPHY AFTER EYE ROTATION IN XENOPUS TADPOLES. Susan B. Udin and M.J. Keating*, National Institute for Medical Research, Mill Hill, London NW7 1AA, England.

In normal Xenopus, the tectum receives a direct visuotopic input from the contralateral eye and an indirect input from the ipsilateral eye. Each eye projects directly to the contralateral tectum; in turn, each tectum projects to its ipsilateral nucleus isthmi (NI) and the NI then projects across the midline to the tectum ipsilateral to the eye of origin. The tectal projections from the two eyes are in register with each other; each point in the binocular visual field is represented at a single point in each tectum via both eyes.

If one eye is rotated during mid-larval stages, each point on the retina still projects to its appropriate site in the contralateral tectum; thus, the visuotectal map on the contralateral tectum is rotated. The indirect ipsilateral visuotectal map from the normal eye develops in such a way that the two visuotectal projections are in register, i.e., the indirect ipsilateral projection from the normal eye becomes rotated. On the other tectum, the normal eye still produces a normally-oriented direct visuotectal map; and again, the indirect ipsilateral projection is in register, i.e., the rotated eye produces a normally oriented ipsilateral projection. We have studied the tecto-isthmo-tectal pathway in an attempt to reveal whether this plasticity comes about by means of rearrangements of the terminals of the crossed isthmo-tectal projection.

To test this hypothesis, we have made localized horseradish peroxidase (HRP) injections in the tectum to determine the topographic relationship between the tectum and the NI in normal and eye-rotated frogs. Our results show that in normal Xenopus, each tectal HRP injection labels a discrete group of tecto-isthmic fibers in the ipsilateral NI. This tecto-isthmic topography appears to be identical in eye-rotated frogs. In normal frogs, each injection also labels a discrete group of cells in the contralateral NI. In eye-rotated animals, however, a single HRP injection usually labels two groups of cells in the contralateral NI. One group corresponds to the normal population; the other consists of cells which normally would be labelled by an HRP injection in a different tectal site. We interpret our results to mean that a new population of crossed isthmo-tectal cells is arborizing at the injection site and that the original population is labelled because they are either passing through their original positions en route to new sites or are forming physiologically inactive arbors at their original sites. Thus, it appears that the anomalous topography of the indirect ipsilateral projection results from alterations in the termination sites of the crossed isthmo-tectal fibers.

603 FEMALE SEXUALITY: PREDICTION BY FETAL LEVELS OF TESTOSTERONE IN SERUM AND AMNIOTIC FLUID OF MICE. Frederick vom Saal* and Claude Desjardins* (SPON: L.W. Hamilton). University of Texas, Austin, Tx

Androgen exposure during fetal life produces changes characteristic of the masculine phenotype in mice as evidenced from developmental anomalies and the administration of exogenous androgen. In sharp contrast, a novel approach to the study of sexual differentiation has involved the examination of a naturally occurring phenomenon in multiple-birth species; namely, the effect of intrauterine proximity of females to male fetuses (vom Saal and Bronson, 1978). Specifically, female mice that develop in utero between two male fetuses (2M females) and females that are not contiguous to a male fetus (0M females) differ in a variety of characteristics: for example, 0M females are more sexually attractive to males, have shorter estrous cycles as adults, and enter puberty later when grouped; 2M females, on the other hand, are more aggressive in a variety of situations and have larger anogenital spaces at birth. It was hypothesized that androgen produced by a male fetus might be transfered to an adjacent female fetus via the amniotic fluid and thus be present in higher concentrations in both the amniotic fluid and blood of a 2M female relative to a 0M female. To test this hypothesis, mouse fetuses were delivered on Day 17. Amniotic fluid was collected on filter paper, and blood serum was taken from 75 2M and 75 0M females. Testosterone, progesterone and 17β-estradiol were measured by radioimmunoassay after chromatographic separation.

Significantly higher levels of testosterone were detected in the serum and amniotic fluid of 2M females (serum: 2M females = 1,090±66 pg/ml; 0M females = 878±43 pg/ml; $t = 2.7$, $p < .05$, df=8; amniotic fluid: 2M females = 128±2 pg/fetus; 0M females = 102±6 pg/fetus; $t = 4.0$, $p < .01$). Estradiol and progesterone levels in amniotic fluid and serum did not differ ($p > 0.1$). The results support the hypothesis that 2M and 0M females differ as a result of 2M females being exposed to androgen produced by contiguous male fetuses. The findings from previous studies involving the intrauterine-position phenomenon demonstrate that many androgen-mediated characteristics, traditionally considered sexually dimorphic (e.g. aggressiveness), exhibit considerable variability within a population of females. Rather than consider these characteristics as dimorphic, in terms of male vs female, it now appears to be more appropriate to consider that a continuum exists for females with regard to characterististics such as aggression and sexual attractiveness. The implications of the present findings are that the point on a continuum of these characteristics that a female occupies is correlated with serum levels of testosterone during prenatal development.

vom Saal, F. & Bronson, F. Biol. Reprod., 19: 842-853, 1978.

604 CONSIDERATION OF Ca^{2+} AND CYCLIC AMP AS SECOND MESSENGERS IN THE EFFECTS OF ELECTRICAL ACTIVITY ON NEUROTRANSMITTER CHOICE BY SYMPATHETIC NEURONS. Pat Walicke* and Paul Patterson (SPON: E. J. Furshpan). Dept. Neurobiology, Harvard Med. Sch., Boston, MA 02115

Sympathetic neurons taken from superior cervical ganglia of neonatal rats and maintained in cell culture can develop either adrenergically or cholinergically depending on culture conditions. Both chronic depolarization and electrical activity can stabilize the choice of adrenergic development, even in the presence of the cholinergic inducing factor secreted by certain nonneuronal cells. Blockers of Ca^{2+} influx (Mg^{2+}, D600, EGTA) inhibit this effect of depolarization, indicating that Ca^{2+} may be the coupling factor. Depolarization elevates neuronal cAMP content, and exposure to dibutyryl cAMP or agents elevating cAMP (adenosine, PGE_1, dibutyryl cGMP) also stabilize the adrenergic choice, suggesting that cAMP may be the second messenger.

To clarify the roles of Ca^{2+} and cAMP, some of their interrelationships were studied. When neurons were depolarized in the presence of Mg^{2+} or D600, no increase in cAMP was seen. On the other hand, EGTA, diphenylhydantoin, and theophylline did not alter the elevation in cAMP but did reverse the developmental effect of depolarization. Thus Ca^{2+} appears to be more directly involved in the depolarization effect, since manipulating its cellular distribution can uncouple the cAMP increase from stabilization of the adrenergic choice. Mg^{2+} and D600 are probably more efficient than the other agents at blocking Ca^{2+} influx through voltage-dependent channels, so their additional effect on cAMP could indicate that the increase is in response to this type of Ca^{2+} entry. α and β adrenergic blockers and adenosine blockers had no influence on cAMP, so release of these substances is not an intermediate step.

Restricting Ca^{2+} availability with EGTA also reversed the effect of dibutyryl cAMP on transmitter choice. Furthermore, neurons exposed to adenosine, PGE_1, or dibutyryl cGMP in the presence of EGTA responded with a normal increase of cAMP but failed to remain adrenergic. These results are consistent with the interpretation that these agents are acting by increasing neuronal Ca^{2+}, though the possibility remains that Ca^{2+} and cAMP act additively at a later step controlling transmitter choice. In summary, the Ca^{2+} and cAMP systems of these neurons appear to be multiply interconnected, but Ca^{2+} appears to be more directly linked with the control of transmitter choice. (Supported by a NINCDS grant to Paul Patterson.)

605 FURTHER OBSERVATIONS ON POSTNATAL NEUROGENESIS IN THE SNAKE'S VOMERONASAL EPITHELIUM: USE OF ^{3}H-THYMIDINE AUTORADIOGRAPHY TO TRACE THE DIFFERENTIATION, MATURATION AND MOVEMENT OF BIPOLAR NEURONS. R.T. Wang, A. Vagvolgyi*, B. Mendelsohn* and M. Halpern. Dept. of Anatomy and Cell Biology, SUNY Downstate Medical Center, Brooklyn, N.Y. 11203.

The vomeronasal epithelium of adult garter snakes is capable of postnatal neurogenesis under normal conditions and following vomeronasal axotomy (Wang et al., Society for Neuroscience Abstracts 3:85, 1977; 4:93, 1978). The undifferentiated cells (UD)--the precursors of bipolar neurons (BP)--can be labeled with ^{3}H-thymidine and identified using autoradiographic techniques (Wang et al., 4:93, 1978). Application of this technique to animals with long postinjection and post lesion survival times has permitted us to trace the genesis of the BP in the epithelium.

Four groups of adult garter snakes (3 snakes in each group) were injected intracardially with ^{3}H-thymidine (1 μCi/gm body wt). On the day following injection, unilateral vomeronasal nerve lesions were made in snakes in three of the experimental groups. The fourth group was sacrificed 24 hours following injection without being subjected to the lesion-making procedure. The remaining snakes survived 2 weeks, 4 weeks or 8 weeks following surgery. The heads of all animals were processed for light microscopic autoradiography.

Graded movement of ^{3}H-thymidine-labeled cells from the basal, UD layer toward the apical region of the BP layer was observed in both the normal VN organ and the deafferented VN organ at different survival times. Cell migration distances were positively correlated with post operative survival time in both normal and deafferented organs. However, the apical labeled cells in the deafferented VN organ always progressed further than their counterparts in the normal VN organ at each respective survival time. Labeling in cells at the migrating front was very heavy at all survival times, but the labeling in the basal UD cells was gradually diluted at long survival times.

Despite the difference in distance of cell migration which occurred between the normal VN organ and the deafferented VN organ at each survival time, labeled cells which had been tagged for 2 weeks in both organs were still in the undifferentiated stage. The apical labeled cells underwent further neuronal differentiation in 4 weeks and subsequently became mature neurons in 8 weeks. (Supported by NIH contract NO1RR82139).

606 DO CATECHOLAMINES MONITOR BRAIN DNA SYNTHESIS ? Claude G. Wasterlain†, Matilde Fando* (SPON: R. Lolley). Epilepsy Research Laboratory, VA Hospital, Sepulveda, CA 91343, Dept. Neurol. and Brain Research Institute, UCLA Sch.Med.

Catecholamine agonists and antagonists can have lasting effects on the developing brain. Since L-DOPA is used in treating cerebral palsy, and since cAMP and/or catecholamines monitor the rate of cell division in many systems, we investigated the relationship between L-DOPA treatment and brain DNA synthesis in immature rats. L-DOPA (30 to 500 mg/Kg) inhibited DNA synthesis in forebrain in a dose-dependent fashion. A DOPA-decarboxylase inhibitor (RO4-4602, 800 mg/Kg), which raises brain L-DOPA but not catecholamines, blocked the inhibition of DNA synthesis by L-DOPA, while monoamine oxidase inhibitors potentiated this effect. This inhibition was maximal in the first 10 days of life in forebrain, but was not manifest until 10 days in cerebellum, suggesting that it depended on the stage of maturation of the tissue. In vitro, norepinephrine and dopamine in concentrations sufficient to elevate cAMP (0.1 to 1 mM) and dibutyryl cyclic AMP inhibited DNA synthesis in brain slices.

These results suggest that therapeutic amounts of L-DOPA can alter brain DNA synthesis and presumably brain development; whether this effect is mediated by catecholamines and cAMP requires further investigation. Until that hypothesis is ruled out, the possibility of adverse effects on development should be kept in mind when using neurotransmitter precursors, agonists or antagonists in the neonate.

Supported by Research Grant NS 13515 from NINCDS and by the Research Service of the Veteran's Administration

607 THE DEVELOPMENT OF β-ADRENERGIC RESPONSIVENESS IN CNS MOUSE REAGGREGATE CULTURES

J. M. Wehner* and J. R. Sheppard, University of Minnesota Dight Institute for Human Genetics, 400 Church Street S.E., Minneapolis, MN 55455, U.S.A.

Mouse CNS reaggregate cultures were prepared using fetuses after 17 days of gestation. Whole fetal brains were removed and mechanically dissociated into single cells as described by Honneggar and Richelson (Brain Res. 109:338, 1976), and maintained in DMEM + 15% horse serum. The development of β-adrenergic hormone responsiveness was examined as a function of time in culture. The time course of cAMP synthesis (using intact reaggregates) in response to 10^{-7}M Isop. revealed that a major peak of cAMP production (after 10 min of hormone exposure) appeared at 11-13 DIV (equivalent to 8-10 days after birth). This corresponds to the development of catecholamine response in cerebral cortex described by Harden et al. (Brain Res. 125:99, 1977). The stimulation of cAMP production was dependent upon the dose of Isop. (10^{-9} - 10^{-5}M), and was blocked by the addition of β-propranolol. Adenylate cyclase activity was also measured using homogenates prepared from reaggregates at 4, 14, 21 DIV. Basal and fluoride-stimulated activity increased as a function of time in culture. Isop. (10μM) or GTP (50μM) did not stimulate adenylate cyclase activity in homogenates of 4DIV reaggregates. However, adenylate cyclase activity was stimulated 2-3 fold by Isop. or GTP and 7-8 fold by Isop. + GTP at 14 & 21 DIV. These experiments indicate that β-adrenergic responsiveness appears in reaggregate CNS cultures at approximately the same time that such a response appears in vivo. (Supported by NIH Grant NS-14436.)

608 DEVELOPMENT OF THE PARASYMPATHETIC INNERVATION OF THE CHICK HEART. Thomas A. Weidman*, Margaret L. Kirby, John W. McKenzie*. Dept. Anat., Sch. Med., Medical College of Georgia, Augusta, GA 30901.

There have been several studies of the development of parasympathetic innervation of the heart using silver impregnation techniques. The results of these experiments are conflicting and indicate that the heart is innervated either on the 3rd or 5th day of incubation. Using electron microscopy and the Holmes silver impregnation for light microscopy, we have determined the sequence of innervation of the chick heart. At 72 hours of incubation cardiac ganglion cell precursors were aggregating adjacent to the bulbus arteriosus and were partially encapsulated. The cells appeared to be streaming lateral to the pharynx into the bulbar region. No neuronal processes were seen ultrastructurally and no preganglionic fibers could be found either in silver preparations or in electron micrographs. Preganglionic axons were traced from the neural tube to the cardiac ganglia on the 6th day and in electron micrographs preganglionic terminals could be seen in the region of the cardiac ganglia. The earliest synapses of preganglionic axons were observed at 8 days. The ganglion cells sprouted on the same day, and postganglionic nerves were found in the heart. The terminals contained clear vesicles of the type associated with cholinergic transmission. On the 9th and 10th days the number of postganglionic nerves increased and en passant synapses were present on cardiac muscle fibers. These results correlate very well with physiological studies which have shown that cardioinhibition between the postganglionic neurons and sinoatrial pacemaker cells can be detected first on the 12th day of incubation. In the presence of physostigmine, a cholinesterase inhibitor, cardioinhibition can be elicited on day 10 of incubation. The effect of physostigmine has been attributed to inhibition of cholinesterase which allows the small amounts of released acetylcholine to reach postsynaptic receptors in concentrations sufficient to inhibit pacemaker activity (Pappano AJ, Pharmacol Rev 29:3-33, 1977).

609 CELL LINEAGE AND REGULATION DURING LEECH NEUROGENESIS AS REVEALED BY ENZYME INJECTION OF IDENTIFIED EMBRYONIC CELLS. David A. Weisblat*, Seth Blair*, and Gunther S. Stent. Dept. Mol. Biol. UCB, Berkeley, CA 94720.

Glossiphoniid leeches are highly suitable for neurodevelopmental studies because the early embryo and the segmental ganglia of the adult nerve cord both consist of large, identifiable cells, readily accessible to observation and experimental manipulation. The egg of these leeches undergoes stereotyped cleavages that produce an early embryo containing three macromeres (A, B, and C), one bilateral pair of mesoteloblasts (M) and four bilateral pairs of ectoteloblasts (N, O, P, and Q). The teloblasts give rise to columns of stem cells, that merge to form left and right germinal bands; the germinal bands migrate ventrolaterally across the surface of the embryo, eventually coalescing in a rostrocaudal progression on the ventral midline to form the germinal plate, from which the segmental tissues, including the nerve cord ganglia, arise.

Lines of descent of cells comprising the ganglia have been ascertained by injection of horseradish peroxidase (HRP) into identified cells of early embryos of the glossiphoniid leech Helobdella triserialis. Such experiments show that the central nervous system has a complex embryological origin. Most of the neurons of the hemilateral segmental ganglia derive from the ipsilateral N ectoteloblast, but a spatially coherent fraction derives from the ipsilateral OPQ ectoteloblast precursor. Some, possibly all, of the segmental neuroglia derive from the mesoteloblast M, whereas the cells of the frontmost, supraesophageal ganglion derive from the A, B, or C macromeres. The position of the boundary between unstained (rostral) and stained (caudal) tissues in preparations in which N teloblasts were injected after initiation of stem cell production showed that each hemiganglion contains the descendants of more than one, probably two, primary N-derived stem cells.

In normal embryos, HRP-stained ganglionic cell bodies are found only ipsilateral to the injected teloblast progenitor, indicating that innervation of the contralateral musculature by segmental motor neurons is attributable to a developmental decussation of their axons, rather than to an initially uncrossed projection followed by reciprocal migration of homologous cell bodies across the midline. However, if, following HRP injection of one N teloblast, the contralateral N teloblast is killed by intracellular injection of Pronase (Parnas and Bowling, Nature 270: 626, 1977), stained cell bodies are present on both sides of the segmental ganglia, indicating a regulative contribution by the surviving N teloblast to the contralateral nerve cord.

610 A GOLGI ANALYSIS OF EARLY DIFFERENTIATION OF MOTOR NUCLEI IN THE HINDBRAIN OF THE MOUSE EMBRYO. Lee E. Wentworth. Dept. Anat., Sch. Med., Univ. of California, San Francisco, CA 94143

To this date no one has described the very early differentiation of mammalian cranial nerves using the Golgi technique. Last year, using a modified Golgi technique, we described (Anat. Rec., 190: 580-581) neuronal differentiation throughout the CNS in a mouse embryo of ten days gestation (E10; E0=vaginal plug). Cells from younger and older embryos have been successfully impregnated since then. At E9-9 1/2 axons of hypoglossal neurons exit in a direct line with the ventral roots of cervical nerves. By contrast, axons of cells of the nucleus ambiguous complex, facial motor nucleus, and trigeminal motor nucleus exit at the level of the sulcus limitans. Their cell bodies are located in a position similar to that of spinal accessory neurons at this age, i.e., ventromedial to somatic efferent neurons, e.g., the hypoglossal nucleus. The bulbar portion of C.N. XI and the vagus nerve appear to be part of a continuous complex at this age. A few of the cells of the trigeminal motor nucleus have started to migrate towards their existing root. By E10 the hypoglossal nerve is well developed and some cells are becoming multipolar. The majority of the cells of the nucleus ambiguous complex still reside ventral to hypoglossal neurons. Occasionally a cell is seen located ventral to and projecting a process into the exiting root of the vagus. These cells may be early cells of the dorsal motor nucleus of the vagus. A row of motor neurons of the trigeminal nerve extends along the lateral border of the neural tube from a most ventral position to almost the level of exit of the motor root. Although many of the most ventral cells are still oriented radially, some of the cells which have migrated closer to the exiting root have reached the bipolar stage. By E11 some cells of the X-XI nucleus ambiguous complex have migrated dorsolaterally to the level of exit of the hypoglossal nerve. A well-developed facial nerve passes between the facial ganglion laterally and the acoustic ganglion medially. Occasionally a cell that may belong to the developing superior salivatory nucleus is seen ventromedial to the exiting root of the facial nerve. A few exiting fibers of the abducens nerve make their first appearance during E11.

611 SYNAPSE DEVELOPMENT IN OLFACTORY CORTEX. Lesnick E. Westrum and Elizabeth Miller.* Departments of Neurological Surgery and Biological Structure, Univ. of Washington, Seattle, Wa. 98195

Layer I of rat prepiriform cortex (area 51A) is being studied electron microscopically at several consecutive postnatal ages from birth to adulthood, emphasizing the maturation of synaptic patterns. Previous qualitative studies have suggested that dramatic increases in numbers and changes in proportions of synaptic types occur during the first two weeks of life (J. Neurocytol. 4:713). Attempts have now been made to quantify these estimates. Consecutive non-overlapping micrographs were taken throughout layer I starting at the olfactory tract and finishing at the cell body layer II. Three animals were used at each of the ages of 1, 3.5, 4.5, 7, 14, and 30 days after birth. Mature synapses were counted in all of the micrographs and averages were determined for density of contacts and proportions of the major types of synapse. With rare exceptions, the area contains two major types of synaptic contact: presynaptic terminals with primarily round synaptic vesicles (R) and presynaptic terminals with mainly flattened or elliptical synaptic vesicles (F). The R terminals usually form asymmetric contacts and the F form symmetric appositions. Thus far over 10,000 total synaptic contacts (R + F) have been counted in approximately 900 electron micrographic fields (of 140 sq. μm each). At 1 day of age, there are approximately 5½ total synaptic contacts per field studied (about 0.038 synapse/sq. μm or 3.8/100 sq. μm) and 10% of these are F synapses. The numbers of total synaptic contact increase gradually over the first week to about 9 per field at 7 days of age (0.063/sq. μm or 6/100 sq. μm) with 11-12% of these being F contacts. A striking finding, however, was the relative proportion of F contacts seen at 3-4 days of age forming approximately 20% of the total contacts. By 14 and 30 days of age, the density of all synapses increases to 16-20 per field (0.12-0.15 synapse/sq. μm) with the proportion of F terminals decreasing to about 10% of the total. The thickness of layer I increases from about 60 μm at birth to about 150 μm at 14-30 days of age. The observations document the increase in total number and proportions of synaptic contacts during the first month after birth, and suggest a critical age range (3-5 days) during which there is an accelerated maturation specifically of the F type of synaptic contact. This is followed at 5-14 days by a proportionally greater maturation of the R synaptic contacts. These patterns may be related to developmental sequences in specific pathways of this region. (LEW is an affiliate of the CDMRC. Aided by NIH Grants NS09678, NS04053, and DE04942).

612 CENTRAL CONTROL OF ULTRASONIC VOCALIZATIONS OF NEONATAL RATS: BRAIN STEM MOTOR NUCLEI. Daniel M. Wetzel, Darcy B. Kelley, and Byron A. Campbell. Department of Psychology, Princeton University, Princeton, N.J. 08544.

Ultrasonic vocalizations of rodents show dramatic developmental changes. This system may prove a useful model to study maturational changes in the mammalian brain and subsequent effects on behavior. Neonatal rats emit pulses (≅ 100 ms duration) of intense (59-85 dB re 2 x 10^{-5} NM^{-2}) ultrasound (≅40 kHz) in response to cold stress. The rate of ultrasounding declines as the pup matures, from a high of >100 pulses/min on postnatal day 10 to <10 pulses/hr by day 20. To elaborate the possible neural bases of this change, the laryngeal nerves controlling the production of ultrasounds and the motor nuclei of origin of these nerves were investigated.

Transections of the laryngeal nerves were used to study the laryngeal production of ultrasounds. Bilateral and unilateral transections of the inferior laryngeal (IL) and superior laryngeal (SL) nerves were made on postnatal day 8, as were sham operations. Ultrasounds were elicited on day 10 by placing the pups in a sound isolation chamber with an air temperature of 0°± .1°C. Both unilateral and bilateral transections of the IL reduced ultrasounds to undectable levels, while sham animals were no different from controls. The harmonic structure of audible squeaks,elicited by tail pinch, was only slightly affected by bilateral transections of the IL. Transections of the SL reduced the intensity (86 dB to 77 dB) and increased the fundamental frequency (from 40 kHz to 49.5 kHz) of the ultrasounds; bilateral transections more so than unilateral. Squeaks remained unchanged after SL transections. It appears that the ultrasound is produced by the actions of the muscles innervated by the IL on the airflow, while the muscles innervated by the SL act to further modify the ultrasounds' physical characteristics.

The motor nuclei of origin of the IL and SL were explored with retrograde transport of horseradish peroxidase (HRP). On day 8 bilateral injections of HRP were made into the intrinsic muscles of the larynx with only one IL or one SL intact, and all other laryngeal nerves cut. After 48 hrs survival, brain sections were reacted with tetramethylbezidine. Cells heavily labeled with HRP reaction product were consistently found in the dorsal formation of the nucleus ambiguus ipsilateral to the intact IL. A few lightly labeled cells were also found in the dorsal motor nucleus of the vagus; possibly gamma motor or secretomotor neurons. The ventral formation of the nucleus ambiguus contained heavily labeled cells ipsilateral to the intact SL. The results suggest that the dorsal and ventral formations of the nucleus ambiguus are the cranial motor nuclei controlling the laryngeal production of the ultrasonic vocalizations of rat pups.

613 DEVELOPMENTAL CHANGES OF MEMBRANE-BOUND NEURAMINIDASE ACTIVITY IN PRE- AND POSTNATAL STAGES OF WILDTYPE MICE AND ALTERATIONS IN NEUROLOGICAL MUTANTS. Wolfgang Wille* and Ekkhart Trenkner Dept. of Neuroscience, Children's Hospital Med. Ctr., Harvard Medical School, Boston, MA 02115

Mouse cerebellum cells change their cell surface carbohydrate pattern during their development as shown with carbohydrate specific antibodies (Trenkner & Sarkar, J. Supr. Struct., 6:465, 1977). In the cerebellar mutant 'staggerer' (sg/sg) neuraminic acid containing sugar polymers pertinent to prenatal cell surfaces are maintained throughout early postnatal development (Trenkner, Nature, 277:566, 1979). In this study we focus on the enzyme neuraminidase which is presumably involved in alterations of cell surface carbohydrates.

Neuraminidase (N-acetylneuraminate glycohydrolase, =sialidase, EC 3.2.1.18) is, at least in one form, a plasmamembrane-bound glycosidase which cleaves N-acetylneuraminosyl linkages. In our test system we used the substrate α-D-N-acetylneuraminosyl-(2'→3')lactit[^{3}H]ol. After cleavage the free lactitol was separated from uncleaved neuraminlactitol on ion-exchange column (Bio-Rad AG1-X2, formate). The eluted radioactivity was related to the protein concentration of the enzyme containing membrane fraction of the homogenized tissue.

Neuraminidase activity was determined in cerebellum, cerebrum, and liver. The age-dependent changes of neuraminidase activity in all the tissues show only one significant maximum. While three days before birth (E16) the specific activities were low (liver: 5.0, cerebellum: 2.5, and cerebrum 1.5 nmoles cleaved neuraminlactitol/mg protein/3 h at 37°C and pH 4.0) the maximum activity was reached within 5-6 days (4 fold). The activities then decreased rapidly to values equivalent to E16 at approx. 20 days after birth (P20). The order of tissue specific activities as seen at E16 remained unchanged throughout development.

In contrast neuraminidase activity of the 'staggerer' cerebellum was considerably higher (2 fold at P7, 5 fold at P17) than wildtype whereas activities in cerebrum and liver remained unchanged. The cerebellar mutant 'weaver' (wv/wv), on the other hand, did not exhibit significantly different neuraminidase activities compared to normal littermates.

614 ^{3}H-THYMIDINE LONG-SURVIVAL AUTORADIOGRAPHY AS A METHOD FOR DATING THE TIME OF ORIGIN IN THE CHICK EMBRYO: DEVELOPMENT OF THE LOCUS COERULEUS-CEREBELLAR SYSTEM. L. Yurkewicz*, J. M. Lauder, E. Giacobini and M. Marchi*. Dept. of Biobehavioral Sci., Univ. of Connecticut, Storrs, CT. 06268. (SPON: E. Shaskan).

Since the chick embryo offers numerous advantages for developmental studies, we are attempting to establish a model system to explore the interactions between noradrenergic (NA) neurons and their target cells during brain development in this experimental animal. As investigated by histofluorescence, the locus coeruleus (LC) has been reported to project to the cerebellar cortex of the adult chicken (Mugnaini and Dahl, J. Comp. Neurol. 162 (4):417, 1975). In the present study we have confirmed this report using the horseradish peroxidase tracing technique. In the rat LC-cerebellar system, the time of origin (last cell division) of LC cells precedes that of cerebellar Purkinje cells by several days (Lauder and Bloom, J. Comp. Neurol. 155 (4): 469, 1974), a pattern we have now examined in the chick. The amount of ^{3}H-thymidine (^{3}H-T) (s. a. 57 Ci/mMol) available to the embryo at various survival times following a single injection (25 uCi) into the yolk sac at 1-2 days of incubation (d. i.) was determined by thin layer chromatography of acetic acid extracted yolk, white or embryonic brain tissue. Contrary to previous assumptions, results of this study indicate that ^{3}H-T is not continuously available to the chick embryo after a single injection, but rather constitutes a 1-2 day pulse. This finding permits the use of long-survival ^{3}H-T autoradiography in chicks to date the time of last cell division within a 2 day range using the adult brain rather than that of the embryo, greatly facilitating accurate identification of cell populations in discrete brain regions. Therefore, we have used this method to determine the time of last cell division of LC cells and cerebellar Purkinje cells in the chick. A single dose (25 uCi) of ^{3}H-T was injected into the yolk sac of fertilized eggs on day 1, 1.5, 2, 2.5, 3, 4, 5, 6, 7 or 8 d. i. Chicks were sacrificed between 29 and 44 days posthatching and the brains prepared for autoradiography. Cell proliferation ceased in the chick LC from 2-6 d. i., with a peak of heavy labeling between 3-5 d. i., whereas this event occurred in the Purkinje cell precursor population from 3-7 d. i. with a peak of heavy labeling between 4-6 d. i., indicating that the chick LC begins to develop prior to the cerebellar Purkinje cells in a manner similar to that observed in the rat. This finding, together with our data confirming a specific LC-cerebellar projection in the chick, provides the basis for the use of this system as a model for examining NA neuron target cell interactions during avian embryonic development. Supported by U of Connecticut Research Foundation.

615 POSTNATAL BRAIN DEVELOPMENT FOLLOWING PRE- AND POSTNATAL EXPOSURE TO TRITIATED WATER FOR 5 GENERATIONS. Stephen Zamenhof and Edith van Marthens*. Mental Retardation Res. Cntr., and Brain Res. Inst., Sch. Med., UCLA, Los Angeles, Ca. 90024.

In view of the anticipated increased use of atomic energy in industry, in continuation of our previous work (Radiation Res. 77, 117, 1979) we studied the possible long term effect of chronic radiation exposure. Rats were given tritiated drinking water (3 μCi/ml) before pregnancy, during pregnancy and thereafter, continuously through 5 generations (F_1 to F_5); females were mated with control males. The average total daily intake was 57 μCi. At this dose, no signs of radiation illness were observed. In each generation, 30 day old male and female pups were sacrificed and their brains assessed for accumulation of radioactivity and for development.

Radioactivity significantly increased through generations: as compared with F_1, the radioactivity in F_3 and subsequent generations was up to 136% higher in the blood and up to 88% higher in the cerebral cortex; the highest increase was in the cerebellum (209%). The highest specific activity was in the cortical DNA fraction (up to 85000cpm/mg); in the protein fractions the highest specific activity was in the diencephalon (up to 2000 cpm/mg) and brain stem (up to 1780 cpm/mg).

The damages to the developing brain were also significantly intensified through generations: as compared to the control, the decrease in DNA (cell number) and protein in F_5 was 3 to 4 times more severe than in F_1. The most severe decreases were: DNA (cell number) of brain stem (-31%), diencephalon (-25%), cerebral cortex (-23%) and cerebellum (-18%); protein of diencephalon (-32%), brain stem (-30%), cerebral cortex (-28%) and cerebellum (-27%); all these differences were statistically highly significant ($p < 0.001$); on the average for both DNA and protein they were 1½ times more severe in diencephalon than in the cortex. These damages at 30 days were also 2 to 3 times higher than in the newborns.

Several phenomena may account for all these results. Postnatally proliferating cells (glia in cerebral cortex, most neurons and glia in cerebellum) may be more sensitive to radiation damage than the prenatally proliferating neurons. RNA involved in protein synthesis (mostly postnatal) is repaired less efficiently (if at all) than the prenatally proliferating neuronal DNA. (Supported by DOE grant EY-76-S-03-0034 and NIH grants HD-05615 and AG-00162).

EPILEPSY

616 **DIFFERENTIAL EFFECTS OF ANTICONVULSANT DRUGS ON CORTICAL- AND AMYGDALA-KINDLED SEIZURES IN THE RAT.** Penny Albright* and W. M. Burnham. Dept. of Pharmacology, Univ. of Toronto, Toronto, Ontario, Canada.

Previous studies involving the kindling model have indicated that seizures kindled from the cortex and from the amygdala respond differentially to therapeutic drugs. The present study was designed to explore this difference in more detail and to determine whether the amygdala-kindled seizures might resemble human temporal lobe epilepsy in terms of their drug response. No good pharmacological model for temporal lobe seizures exists at present.

Rats with well-established seizures of the amygdala- or cortical-generalized type were therefore injected with multiple doses of the following anticonvulsant drugs: carbamazepine, clonazepam, diazepam, ethosuximide, methsuximide, phenobarbital, phenytoin, and sodium valproate. The effects of these drugs were analyzed on two components of the seizure: 1) the long generalized convulsion 2)and the partially generalized and focal seizure. With respect to the generalized component all the anticonvulsant drugs with the exception of ethosuximide suppressed this aspect of the seizure at non-toxic doses. Thus the kindling model responds appropriately to antiepileptic drugs and appears to be a viable model of grand mal epilepsy. Furthermore there were no differences between amygdala and cortical groups in the suppression of the generalized convulsion by drugs. This finding coincides with the hypothesis that the generalized seizure is similar in mechanism regardless of the location of the stimulated focus.

Analysis of the focal and partially generalized component revealed dramatic differences between amygdala and cortex. Epileptic activity in the cortical focus was easily inhibited by drugs at doses only slightly higher than those required to block the generalized convulsion. The amygdala focus was extremely resistant to anticonvulsant action however and was never fully suppressed by drugs. In addition the drugs most successful in treating human temporal lobe epilepsy were also most effective at suppressing amygdala-kindled seizures in the rat. These results suggest that the amygdala-kindled seizure may provide a useful pharmacological model for temporal lobe epilepsy.

617 PROCAINE-INDUCED SEIZURES IN MONKEYS WITH BILATERAL HIPPOCAMPAL ALUMINA FOCI. Thomas L. Babb, Kent M. Perryman*, Jeffrey P. Lieb, David M. Finch and Paul H. Crandall. Depts. Neurology, Neurosurgery and Brain Research Institute, UCLA, Los Angeles, CA. 90024.

Intravenous injections of local anesthetics at low doses have been shown to depress central nervous system functions (Livingston and Perrin, 1972; Julien, 1973; Demetrescu and Julien, 1974) and has been recommended for treatment of status epilepticus (Bernhard and Bohm, 1955; French et al., 1957). However, at higher doses a variety of cocaine derivatives precipitate seizures in animals (Wagman et al., 1967; Julien, 1973; Munson et al., 1969) and man (de Jong and Walts, 1966). This paradoxical activation of central synapses has been attributed to a selective conduction block of inhibitory fibers (Warnick et al., 1971). Furthermore, it has been suggested that anesthetics such as lidocaine and procaine preferentially activate the limbic system before affecting the neocortex (de Jong and Walts, 1966; Wagman et al., 1967; Racine et al., 1975). For these reasons, de Jong (1970) and Livingston (1978) have proposed that lidocaine and procaine may induce typical auras and electrographic seizures in patients with subcortical limbic epilepsy while preventing secondarily-generalized seizures, which are a common threat when using seizure-provoking drugs such as pentylenetetrazol.

Intravenous procaine HCl given at low doses (0.5-2.5 mg/kg) to two monkeys with bilateral alumina hippocampal foci depressed interictal spiking or had little effect. At 5.0 mg/kg unilateral limbic activation occurred. At 10.0 mg/kg unilateral or bilateral limbic activation and generalized seizures could be evoked within 3-10 minutes. At higher doses (15 and 20 mg/kg) bilateral limbic activation or brief (one minute) generalized seizures occurred. The unilateral-onset psychomotor seizures were not identical to spontaneous psychomotor seizures, and the generalized seizures never occurred spontaneously in these monkeys. However, these results do indicate that procaine challenges may selectively activate limbic epileptogenic areas without activation of debilitating generalized tonic-clonic seizures.

618 ANTAGONISM OF GAMMA-HYDROXYBUTYRIC ACID INDUCED FREQUENCY SHIFTS IN THE CORTICAL EEG OF RATS BY DIPROPYLACETATE. Larry J. Bearden and O.C. Snead, III. Neurosciences Program and Dept. Pediatrics, Univ. Ala. in Birmingham, Birmingham, Ala. 35294.

Gamma-hydroxybutyric acid (GHB) is an endogenous neural constituent, of undefined significance. This compound has been shown to produce EEG and behavioral alterations in animals which closely resemble the changes observed in human petit mal epilepsy. Moreover, previous studies have also demonstrated that the neurophysiologic effects of GHB are alleviated by anticonvulsants which have shown clinical success as specific anti-petit mal agents (Godschalk, et al., Neurosci. Lett. 3:145, 1976; Snead, Neurology 28:1173, 1978). The present experiments indicate that within two minutes after the intraperitoneal injection of gamma butyrolactone (i.e. the lactone of GHB; 4 mmole/kg), intermittent bursts of hypersynchronous waves (300-500 μV, 3-6 Hz) coinciding with a behavioral depression are observed. This pattern is quickly followed by a continuous hypersynchrony, during which rats are flaccid and immobile. Similar electrical and behavioral changes, but with a more gradual onset, were observed when an equimolar dose of GHB (4 mmole/kg) was given as the acid salt. The hypersynchrony produced by GHB could be prevented or aborted by dipropylacetate (300 mg/kg, i.p.), a petit mal anticonvulsant. However, when given at the end of the GHB induced hypersynchronous phase, dipropylacetate did not reverse the effects of GHB. These findings corroborate previous observations, and provide additional quantitative evidence characterizing the neurophysiologic effects of GHB and petit mal anticonvulsants. Both the development of the GHB induced hypersynchrony, and the antagonism of the hypersynchrony by dipropylacetate were clearly observable by means of frequency analysis of the ECoG. The frequency analysis technique employed offers the advantages of simplicity and flexibility for studies of this type.

619 CHRONIC IRON-INDUCED EPILEPTOGENIC FOCI: AN ULTRASTRUCTURAL STUDY IN RATS. A. B. Butler, L. J. Willmore, and G. W. Sypert. Dept. of Neurosurgery, University of Virginia, Charlottesville, VA 22908, and VA Hospital and Dept. of Neurosurgery and Neuroscience, University of Florida College of Medicine, Gainesville, FL 32610.

Chronic focal epilepsy can be produced in rat sensorimotor cortex by subpial injections of 5 μl of 100 mM $FeCl_3$ (Wilmore et al., Science 200: 1501, 1978). Five weeks after subpial injections of ferric chloride in 10 rats (Sprague Dawley, 200-300 gm) transcardial perfusion fixation with aldehydes was performed, after which samples of sensorimotor cortex including the injection site and surrounding brain were prepared for electron microscopy using standard techniques. Light microscopic examination of plastic embedded thick (1-2 μ) sections of these tissues reveal a cavitary lesion (zone I) extending inferiorly from the subpial layer to include the majority of all cortical laminae. The neuropil immediately adjacent to the cavitary lesion (zones II,III) contains numerous swollen cell processes admixed with an increased number of glial cells and macrophages. Examining more peripherally (zone IV), the cortical neuropil gradually assumes the structural characteristics of normal cortex. Electron microscopic examination of the cortical neuropil immediately adjacent to the cavitary lesion reveals a narrow band of altered tissue (zone II) in which most cells and processes are either severly swollen or totally disrupted. Cell organelles are frequently present within the extracellular space. In the adjacent peripheral zone of tissue (zone III), the major cytopathologic alterations of cortical elements are confined to astrocytes and dendrites. These changes are characterized by dispersion of cytoplasmic organelles and a markedly electron-lucent cytoplasm. Dendrites exhibit increased intermicrotubular spacing, dilitations of smooth endoplasmic reticulum, and periodic increased swelling of the dendrite shaft (varicose swelling). Neuronal perikarya are relative less swollen whereas astrocytes exhibit a pale watery cytoplasm containing extensive bundles of glial filaments. Pleomorphic, electron dense inclusion bodies are numerous and are contained within astrocytes, macrophages and neuronal perikarya. Swelling of synaptic terminals in this tissue zone is uncommon. No alteration of myelinated or unmyelinated axons has been demonstrated. Within zone IV, a gradual transition in cytopathologic alteration is noted characterized by gradual diminutions of cytoplasmic swelling in astrocytes and dendrites associated with a decreasing number of pleomorphic electron dense inclusion bodies as more peripheral areas within this zone are examined.

620 RELATIVE ANALGESIC AND EPILEPTIC POTENCIES OF VARIOUS OPIATE DRUGS. J. T. Cannon, R. L. Nahin*, S. M. Ryan, A. S. Moskowitz, and J. C. Liebeskind. Dept. Psychol., UCLA, Los Angeles, CA 90024.

The discovery that the enkephalins, β-endorphin and morphine cause a characteristic pattern of epileptiform EEG seizures after intracerebroventricular (ICV) injection in rats has generated considerable interest in the possible role of endogenous opioids in certain seizure phenomena. That naloxone can block such seizures suggests that opiate receptor mechanisms are involved in their expression. The following experiments sought to provide additional evidence on this point.

Rats were chronically prepared with skull screw EEG electrodes and lateral ventricle guide cannulas. ICV injections (10 µl) of levorphanol (LEV) and dextrorphan (DEX) tartrate failed to cause seizures at any dose between 58-300 µg. All doses of LEV and 100-300 µg DEX produced naloxone reversible EEG synchrony. LEV and DEX caused tail-flick analgesia at 100-300 µg. LEV analgesia was more robust, longer lasting and naloxone reversible. Naloxone (164 µg, ICV) also caused brief analgesia. For some rats, 200-300 µg LEV proved lethal.

In preliminary work, ICV injections of 3 benzomorphans (cyclazocine, ketocyclazocine and WIN-35, 197-2) also failed to cause seizures throughout a dose range in which EEG synchrony, analgesia or death could all be observed. These drugs have been shown by others to be potent agonists for σ and/or κ opiate receptors. On the other hand, we have recently found that ICV levorphanol (100 µg) can cause seizures of the same sort previously seen with opioid peptide or morphine injections if sufficient potassium sulfate is added to produce an equimolar sulfate concentration to that present in a 100 µg dose of morphine sulfate. This preliminary finding is consistent with recent evidence of the opiate-like actions of sulfate ions (LaBella et al., 1979).

621 INTRACORTICAL EVOKED RESPONSES RECORDED FROM PERI-FOCUS ELECTRODE SITES FOLLOWING PENICILLIN-INDUCED EPILEPTIC DISCHARGES IN CAT VISUAL CORTEX. A.B. Chatt and J.S. Ebersole. Neurology Service, V.A. Medical Center, West Haven, CT 06516 and Dept. of Neurology, Yale University School of Medicine, New Haven, CT 06510.

NaCl-filled microelectrodes were positioned in area 17 of the visual cortex of paralyzed, anesthetized cats at varying distances from a Na-penicillin filled microelectrode through which epileptic foci were induced by pressure-injection. In any one animal, only one pair of electrodes was positioned (a focus and peri-focus, or surround, electrode) and the distances between these electrodes was different for each animal. Recordings were taken from these electrodes to ON-OFF stimuli delivered to the preferred (center) receptive field positions of both electrodes before and after the microinjection of Na-penicillin.

Following drug injection at the focus electrode, variations in the normal visual evoked response (VER) recorded from the peri-focus electrodes were noted from those surround electrodes positioned nearest to the focus electrode (2 and 4 mm). No evidence of any influence from the epileptic focus was seen at the most distal peri-focus electrode position (7 mm). These alterations in VERs associated with the development of an epileptic discharge at the focus electrode, and recorded at the peri-focus electrode, were also dependent upon the receptive field (RF) site stimulated. Stimulation of the focus electrode RF center produced a secondary component (60-150 ms) at the peri-focus electrode simultaneous with the development of an epileptic discharge at the focus electrode with no change in the primary latency component (40-50 ms) at the peri-focus electrode, if one existed. Stimulation of the surround electrode RF center produced the following alterations at the peri-focus site in succession: 1) an enhanced secondary component as the epileptic focus developed at the electrode, followed by 2) an enhanced primary response.

Though it is generally agreed that the primary component of a VER is the result of local, summated, direct thalamo-cortical influences, it is hypothesized here that the secondary components reflect projected intra-cortical activity. The enhanced secondary responses, then, recorded at the peri-focus electrodes (always in synchrony with the occurrence of the epileptic focus at the focus electrode) may represent projected intracortical input from the cell population in the area of the focus electrode. The enhanced primary component recorded from the most proximal surround electrodes during peri-focus center stimulation probably reflect the actual physical spread of the convulsant drug to these recording sites. 622 ROLE OF FOREBRAIN CATECHOLAMINES IN AMYGDALOID KINDLING. Michael E. Corcoran and Stephen T. Mason. Dept. of Psychology, Univ. of Victoria, Victoria, B.C., and Div. Neurol. Sci., Univ. of British Columbia, Vancouver, B.C., Canada.

Previous evidence has suggested that central catecholamines play some role in kindling, a permanent increase in susceptibility to seizures after intermittent electrical stimulation of the brain. Specifically, it has been reported that amygdaloid kindling was facilitated by intraventricular injections of 6-hydroxydopamine (6-OHDA) that produced marked depletion of noradrenaline (NA) and dopamine (DA) throughout the neuraxis. The relative contribution of NA and DA to this effect is unclear, however, as is the anatomical locus of the critical amine. We therefore examined the effects on amygdaloid kindling of selective depletion of NA and separately of DA by bilateral intracerebral injections of 6-OHDA into the ascending axons of these neurons.

NA-depleted rats received bilateral injections of 6-OHDA into the ascending NA axon bundles; controls received vehicle injections. DA-depleted rats were pretreated with desipramine (DMI) and received bilateral injections of 6-OHDA into the nigrostriatal bundle; controls received DMI and vehicle injections. Electrodes were implanted bilaterally into the amygdala one week later, and kindling began two weeks later. The threshold intensity of stimulation for local amygdaloid afterdischarge was first determined, and all rats were then kindled at a fixed suprathreshold intensity of stimulation.

There were no differences in the thresholds for amygdaloid afterdischarge in NA-depleted, DA-depleted, or control rats. The rate of amygdaloid kindling was significantly enhanced in NA-depleted rats, however, but there was no difference from controls in DA-depleted rats. When stimulation was subsequently applied to the contralateral (secondary-site) amygdala all rats showed a facilitation of kindling rate (transfer), and once again this was significantly greater in the NA-depleted rats.

These results indicate that depletion of forebrain NA and not DA results in a marked facilitation in the rate of kindling, presumably by disinhibition of the spread of seizure discharge from the stimulated amygdala. Conceivably a lessening of seizure-suppressant NA activity in the forebrain is part of the mechanism underlying kindling.

623 EFFECTS OF CORTICAL EPILEPTOGENIC ACTIVITY ON DEVELOPMENT OF RECEPTIVE FIELD PROPERTIES IN THE VISUAL CORTEX OF YOUNG RABBITS. John W. Crabtree*, K.L.Chow, Louis H. Ostrach, H. Dale Baumbach, and Bryann S. Bromley*, Dept. Neurol., Stanford Univ. Sch. Med., Stanford, CA 94305.

A previous study (Chow, et al., Brain Res., 146: 151, 1978) showed that normal development of receptive field properties in cells of the lateral geniculate nucleus in young rabbits was disrupted during chronic epileptogenic discharge in the visual cortex. In the present study, the effects of a chronic epileptogenic focus in one visual cortex on development of receptive field properties of visual cortical cells were examined.

In 7 to 8 day old rabbit pups a stainless steel cannula was implanted over each visual cortex so that the cannulae rested on dura which covered the monocular visual areas. Beginning on the day after surgery epileptogenic activity was induced unilaterally in each pup by the application of penicillin (200,000 µ/ml) to the dural surface through one cannula. Penicillin applications were administered twice a day for 17 to 23 consecutive days. Following each penicillin application, interictal spiking was observed within 10 minutes on the EEG monitor and lasted for 6 to 12 hours. Concurrent with the penicillin applications, a mixture of equal proportions of penicillin and penicillinase was applied through the other cannula. This second application served to control for possible physical damage to the visual cortex due to cannula implantation and the administration and presence of drugs. No cortical spiking was observed in the hemisphere which received the control drugs. Drug applications were terminated 24 hours before recording sessions. Responses of single units in the visual cortex were recorded on the rabbits' 25-31 postnatal day. This age range is after the time at which percentages of receptive field types of visual cortical cells have attained adult values in the rabbit (Mathers, et al., Exp. Brain Res., 19: 20, 1974). Interictal spike activity was not seen during recording sessions.

The percentages of receptive field types of cells in the visual cortex recorded up to 5 mm away from the cortical epileptogenic focus were clearly abnormal. Relative to adult values in the rabbit, a significant increase in the proportion of unresponsive cells and cells with indefinite receptive fields was found concurrent with a significant decrease in the proportion of cells with linearly oriented receptive fields. The cells sampled from the visual cortex contralateral to the epileptogenic focus showed normal percentages of receptive field types. (Supported by NIH grants EY 00691, EY 05176, NS 12151 and NS 07012).

624 KAINIC ACID ELICITS ELECTROGRAPHIC EPILEPTIFORM ACTIVITY AFTER CENTRAL AND PARENTERAL ADMINISTRATION TO AWAKE RATS. I.L. Crawford and W.C. Wooten*. VA Epilepsy Ctr. and Depts. Neurology and Pharmacology, Univ. Texas Hlth. Sci. Ctr. at Dallas, TX 75216.

Parallels between the neuronal excitatory actions and the neurotoxicity of kainic acid (KA) have not yet been fully delineated in concurrent experiments. We compared the histology and electrophysiologic effects of intracerebroventricular (icv) and systemic (i.p.) doses of the ascaricide. Adult male Sprague-Dawley rats (300±25 gm) were implanted with an icv cannula, and monopolar epidural electrodes were placed over the frontal (F) and parietal (P) cortex on each side. One week later, bipolar recordings were made bilaterally between F and P, and transcoronally from F to F and P to P. Low, threshold doses of KA (10-30 nanograms, icv; or 10 mg/kg, i.p.) shifted the predominant frequency to 20-30 Hz (β activity) and produced an active, alert behavioral state for 1.5 to 2 hr. A similar initial increase in β activity caused by 50 ng icv KA was followed within 4 min by spikes (<80 ms duration) and bidirectional sharp waves prominent in parietal areas. This electrical activity continued without motor convulsions, up to 2 hrs after injection then ceased. Severe electrographic seizures induced by KA (100 ng, icv; 30-50 mg/kg, i.p.) began within 2 min as spike-bursts lasting 40-80s separated by 30-50s interictal periods often associated with 'scratching' and 'wet dog shakes'. In the early stages of seizure development rats were immobile during the paroxysms, one hr later salivation, myokymia and myoclonus preceded head nodding, rearing and forelimb clonus. These ictal episodes continued to cycle and developed into prolonged (6-8 hr) electrographic seizures with occasional tonic-clonic motor convulsions. Abnormal slow wave activity (1-3 Hz) in the frontal leads and parietal spikes with afterdischarges or sharp waves persisted for 5 to 7 days after treatment; chromodacryorrhea and hematuria appeared one day after systemic injections. High doses (300 ng,icv) caused generalized seizures, status epilepticus and, without anticonvulsant treatment, death marked by tonic contracture within 1 hr. Histologically, CA3 hippocampal pyramidal cells were destroyed only in brains from rats given 100 ng or more. In addition to death of other CA pyramidal neurons, high doses (300 ng) also destroyed scattered cells in the thalamus, amygdala, and olfactory cortex. Our results provide support for KA as a potent excitatory agent, and suggest that its cytotoxic actions correspond more closely with subsequent long-lasting epileptogenicity than with acute, dose-related electrographic seizures. (Supported in part by VA Grant MRIS 1604).

625 TRIMETHADIONE AND SEIZURE SUSCEPTIBILITY IN EPILEPTIC FOWL. H.L. Davis*, D.D. Johnson and R.D. Crawford* Depts. of Pharmacology and Animal and Poultry Science, Univ. of Sask.,Saskatoon, Saskatchewan, Canada S7N 0W0.

Phenobarbital, phenytoin and primidone at plasma drug concentrations which closely parallel those required in human epilepsies will prevent seizures induced in epileptic fowl by stroboscopic stimulation. Dipropylacetic acid abolished seizures but the plasma concentrations required were approximately double those required for control of absence seizures in humans. However ethosuximide, the agent of choice in absence seizures, was without effect at plasma concentrations approximately 5 times those effective in humans. The present study was performed to further characterize epileptic fowl as a pharmacological model of human epilepsy and was designed to determine if the seizure process in epileptic fowl was sensitive to the anticonvulsant effect of trimethadione (TMO) and to determine the relationship of any observed reductions in seizure incidence to the plasma drug concentrations achieved. TMO dissolved in DMSO was administered to groups of 10 epileptic chickens in doses of 100, 200 & 300 mg/kg in a cross-over design. Chickens in the control groups received DMSO. All chickens were tested for seizure susceptibility in response to stroboscopic stimulation 1,3,6,8,12,24 & 48 h after TMO administration. Blood samples were obtained prior to each determination of seizure susceptibility for determination of drug concentrations by GLC. TMO produced significant reductions in the incidence of seizures 1,3,5 & 8 h following 200 mg/kg and for up to 48 h following the 300 mg/kg dose. As in other species TMO is metabolized to dimethadione (DMO), an active metabolite. Significant reductions in the incidence of seizures occurred when the total plasma drug concentration (TMO & DMO) exceeded 210 µg/mL. The maximum reduction in seizure incidence, without overt manifestations of acute neurological toxicities, was obtained at mean plasma drug concentrations of 442 µg/ml. DMO alone (200 mg/kg) produced a significant reduction in the incidence of seizures when the DMO plasma concentration exceeded 300 µg/ml. The data indicates that epileptic fowl are sensitive to TMO and DMO, and that plasma concentrations required to control seizures are somewhat lower than those required in absence seizures in humans. The finding that TMO has anticonvulsant activity in epileptic fowl indicates that epileptic fowl do not represent a specific pharmacological model of grand mal epilepsy.

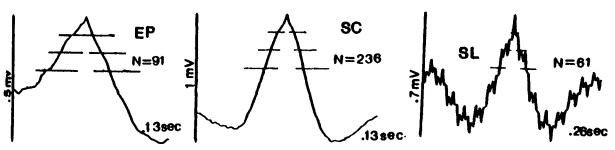
626 COMPUTER RECOGNITION OF EEG SPIKES FROM NORMAL, SCHIZOPHRENIC, AND EPILEPTIC SUBJECTS. David F. Dean, M.D., Herbert E. Longenecker, Jr., Ph.D., Valery Koss, Ph.D., Chi-Ming Huang, Ph.D. Departments of Neurological Surgery, Pharmacology, and Physiology, College of Medicine, University of South Alabama, Mobile, Alabama.

Reported methods for spike analysis in EEG have utilized Fourier analysis or correllation analysis. Both of these methods require complex instrumentation and large amounts of computer time. Neurologists examining epileptic EEG's will notice abnormality but obtaining a consensus from multiple encephalographers regarding all 'epileptic spikes' in the record is difficult. Computer alogrithms for high frequency analysis of monopolar scalp electrodes were developed which demonstrate epilepsy as well as in subjects with diagnoses of schizophrenia that were not seen in a population of normals. These waves also appear randomly in sleep in all tested subjects as well.

Monopolar electrode recordings were fed to a Grass (DC to 10 kHz) amplifier whose output was FM recorded in 17 subjects. The recorded output (DC to 3 kHz) was then fed to a Varian 73 Computer System for the analysis program. Data was sampled at 1 msec. continuously for up to 30 minutes and stored for analysis on magnetic tape. Arbitrary intervals of contiguous 330 msec. were analyzed for the occurrence of spikes.

Clustering techniques with multiple parameters demonstrated a high degree of success in identification of cortical potentials. A random spike wave activity occurred in both schizophrenics and epileptic patients. The average rate of occurence of the 'spike' potentials was 0.05 to 0.3 per second. Both interval and joint interval histograms of interspike intervals suggest a random order of potential occurrence. Muscle spikes were clearly differentiated from these potentials. The normals, however, did not show any of this degree of random spiking.

Examples of the clustering technique, alogrithms, and computer analysis will be shown. This study is part of an initial program in an on-line computer automated analysis system for inpatient continuous EEG monitoring.



627 ALTERATION OF INTRACORTICAL EVOKED POTENTIALS DURING FOCAL PENICILLIN EPILEPTOGENESIS IN CAT VISUAL CORTEX. J.S. Ebersole and A.B. Chatt. Neurology Service, Epilepsy Center, V.A. Medical Center, West Haven, CT 06516 and Dept. of Neurology, Yale Univ. School of Medicine, New Haven, CT 06510.

The interictal spike has been viewed as the basic field potential manifestation of the epileptic state. Its neuronal basis, the paroxysmal depolarization shift (PDS), is presumed to result from abnormal interactions among neurons of the epileptic aggregate. One would expect that evoked field potentials (EP), themselves a reflection of cell population activity, should show changes with epileptogenesis and perhaps help delineate its stages of development.

Potentials, recorded through micropipettes, were evoked from discrete regions of visual cortical area 17 in cats by 1° square ON-OFF stimuli before and after pressure-injection of Na-penicillin from the electrode. Stimulation at an optimal visual field location evoked a large amplitude potential of primary afferent latency (40-50 ms) with small or no secondary components. Stimuli presented progressively eccentric to the "receptive field" center (2°-10°) elicited increasingly smaller primary latency components while also recruiting longer latency secondary responses (60-150 ms). These secondary potentials appear to represent interactions of surrounding cortex with the recorded region, since the displaced stimuli evoking them preferentially activate adjacent cortical populations.

Micro-injection of Na-penicillin pathologically altered the normal visual evoked responses (VER) in a reliable and reproducible fashion. The initial alteration was an enhancement by 40-120% of its primary component to center stimuli which most likely is due to the direct effect of penicillin on neurons in the immediate vicinity. This was followed by the gradual development of a secondary component that exceeded the amplitude of the primary response and grew into a full-blown interictal spike potential. Although near complete reversal of this pathologic process followed a single injection within minutes, recurrent injections using controlled parameters could maintain a given stage of epileptic response abnormality.

During the period of penicillin action, eccentric stimuli produced altered VERs as well. Primary EP components were elicited by peripheral stimuli that were previously ineffective. The receptive field of the recorded neuronal population enlarged, as reflected by an increased range of stimulus displacement over which EP components could be elicited, particularly the pathologically enhanced secondary response. These later effects are probably a manifestation of more peripheral neurons being recruited into abnormal and enhanced interactions with the newly created epileptic focus. (Supported by Veterans Administration)

628 EXPERIMENTS ON HIPPOCAMPAL "KINDLING" IN THE RABBIT. C.L. Ehlers*, P.C. Chappus*, D.I. Whitmoyer* and C.H. Sawyer. Dept. Anat. and Brain Res. Inst., UCLA, Los Angeles, CA 90024.

The process of "kindling" is a phenomenon in which a progressive increase in neural and behavioral responsivity is produced by spaced and repeated epileptogenic stimulation of specific brain sites. In the present study we have investigated the development of kindling following electrical stimulation of the dorsal hippocampus (DHPC) of the rabbit and the ability of various drugs to modify kindled electroencephalographic and behavioral responses. Five New Zealand White rabbits were stereotaxically implanted with concentric bipolar electrodes aimed at two sites in the DHPC and one in the amygdala (AMY), as well as screws placed in the calvaria over frontal and limbic cortices (CTX). The kindling stimulus (1 msec biphasic square wave pulses, 60 Hz frequency, 200 μA current, 1 sec train) was applied once daily until 3 fully-kindled convulsions (chewing, rearing, falling) were noted. The initial stimulations produced only brief behavioral arrest and DHPC afterdischarge (AD) which did not spread to CTX or AMY. However, with repeated stimulations a sequela of "psychomotor" behaviors emerged which included sniffing, darting of the head from side to side, facial twitching, wet dog shakes, posturing, grooming of the face and violent hindlimb thumping associated with urination ($\bar{X}$ = 11.6 days). During this time ($\bar{X}$ = 10.4 days) independent interictal discharges in DHPC appeared which were enhanced during rest and slow-wave sleep, and were blocked during attention. With repeated stimulation AD was seen to spread to AMY and frontal CTX; following this the animals began to show typical rhythmic chewing characteristic of AMY kindling ($\bar{X}$ = 24.6 days). Animals showed fully-kindled responses soon thereafter ($\bar{X}$ = 29.0 days), although they remained "partial" in nature, i.e., the chewing and rearing were ipsiversive to the focus and animals would show brief falling and usually only contralateral forelimb clonus. First-trial stimulation of AMY or another DHPC electrode 2 or 4 mm from the focus in fully-kindled animals produced a similar seizure; however, the order of presentation of behaviors appeared different. Single doses of phenobarbital (30 mg/kg IP), carbamazepine (20 mg/kg PO) and Diazepam (5 mg/kg IP) all attenuated or blocked fully-kindled responses, although some of the "psychomotor" behaviors remained. Chlorpromazine (10 mg/kg IM) had no effect on fully-kindled responses, although it did block some of the "psychomotor" behaviors. None of the drugs blocked independent interictal discharges in DHPC. (Supported by NIH, the Ford Foundation and the Gianinni Foundation.)

629 ON THE SITE OF CONVULSANT-INDUCED ENHANCEMENT OF SENSORY RESPONSES OF RETICULAR NEURONS: IONTOPHORETIC STUDIES. C.L. Faingold, W.E. Hoffmann* and D.M. Caspary. Divisions of Pharmacology and Neurobiology, Dept. Medical Sciences, Southern Illinois University School of Medicine, Springfield, IL 62708

Our previous studies indicate that the responses of reticular formation (RF) neurons to sensory stimuli are greatly enhanced by subconvulsant doses of three very different convulsants. This phenomenon was suggested to be involved in the action of the 17 different convulsants which enhance sensory evoked field potentials (Faingold, Prog. Neuro-Psychopharmacology, 2: 401-422, 1978). Possible brain sites at which convulsants could act to produce RF response changes include 1) peripheral sensory receptors, 2) primary sensory neurons, 3) RF neurons, and/or 4) descending pathways which modulate RF activity. These studies utilized locally anesthetized paralyzed cats, or chloralose anesthetized white rats, and neuronal responses were evaluated using poststimulus time histogram analysis. Field potentials and single unit responses in the RF evoked by electrical stimuli in cochlear nucleus or lateral geniculate nucleus were greatly enhanced after administration of subconvulsant doses of pentylenetetrazol (PTZ). This suggests that the convulsant does not produce enhancement by acting predominantly on sensory receptors. PTZ administration results in only a modest increase in responsiveness of primary visual neurons in the lateral geniculate nucleus (mean 38%) (Faingold and Stittsworth, Neurosci. Abs., 3:139, 1977), while mesencephalic RF neuronal firing is increased by a mean of 310%. This suggests that effects of this convulsant on primary sensory neurons are not sufficient to explain the extent of RF response enhancement. The effects of microiontophoretic application of PTZ or strychnine directly onto mesencephalic or bulbar RF neurons were also examined. The sensory responses of RF neurons were enhanced extensively after iontophoretic application of strychnine (40-380 nA) or PTZ (65-190 nA). Following application of strychnine, the enhanced responsiveness often lasted for up to 30 min. However, the prominent and repetitive spike bursting pattern observed with systemic administration of strychnine (Faingold and Stittsworth, Soc. Neurosci. Abs., 4:142, 1978) was not observed with iontophoresis. In some cases the enhancement of RF neuronal firing by convulsant could be reversed by iontophoresis of the inhibitory amino acids glycine and GABA. Since iontophoresis of convulsants produces RF response enhancement, a major portion of the effect of systemic convulsant on RF neuronal responses may be exerted directly on the reticular formation. These data further support the theory that actions of convulsants on the reticular formation are important to the development of drug-induced generalized seizures. (Supported in part by the S.I.U. Foundation.)

630 REDUCTION OF THE EPILEPTOGENIC EFFECT OF INTRASTRIATALLY INJECTED KAINIC ACID (KA) BY TAURINE (TAU). Ruggero G. Fariello, Gregory T. Golden, Kathleen M. Kantak, James A. Black*. Dept. Neur. and Psych., University Wisconsin and Waisman Center, Madison, WI 53792

It has been suggested that symptoms of Huntington's Disease (HD) may partially result from the excitotoxic action of glutamate which is poorly counterbalanced by hypofunctioning inhibitory systems. Intrastriatal injection of KA offers at the present time the closest biochemical, and possibly pathogenetic model of HD. Seizures occurring in the first 5 hrs after intracaudate administration of KA are a behavioral index of the excitotoxic action of KA. Conceivably agents capable of reducing such excitotoxic effect may be candidates for the palliative treatment of HD. Taurine is a naturally occurring inhibitory amnioacid (AA), 3 aminopropane sulfonic acid (3APS) is a powerful gabamimetic agent that systemically injected can block focal epileptiform discharges (Fariello, Exp Neur in press). In the present study we have tested the effects of these inhibitory AA on the behavioral changes and the seizures induced by bilateral intracaudate injection of KA. Two groups of rats were pretreated for four days with IP 3APS or Taurine (500 mg/Kg/day). These two groups plus a third non pretreated group were then injected with 1 ul of 4.7 nM KA in both caudate nuclei. Behavior and seizures were then continuously monitored in all animals for 6 hrs. At 26 and 48 hrs after injections animals were sacrificed and their brains histologically examined. The mean number of seizures during the 5 hrs post injection are reported below for each group.

Control KA	94
3APS	73
TAU	36

In the taurine group seizures were also of less severe intensity and shorter duration. Hyperactivity, excessive grooming, jumping and wet dog shaking behavior were maximally prominent in the 3 APS group, followed by KA and only moderatly present in taurine rats. Taurine seems to offer significant protection against the epileptogenic and hyperactivity inducing effect of KA. The results are further discussed in light of the histological findings in the various groups at different times after KA administration.

631 NEOCORTICAL EPILEPTOGENESIS IS NOT REDUCED BY TRANSVERSE CORTICAL LESIONS. John H. Ferguson * and Howard Williams. Div. of Neurology, Case Western Reserve U. Sch. of Med. and Cleveland VA Hospital, Cleveland, Ohio 44106.

To test the hypothesis that transverse cortical lesions (TCL) would raise afterdischarge threshold (ADT), ADT and duration (ADD) were measured in suprasylvian gyrus (SS) acutely in 35 cats. ADT and ADD were determined in each half of each SS (4 quadrants) in 19 controls and 16 cats with various TCL made 0-48 days before testing. We had found no differences in ADT among control and TCL animals using surface stimulation (Williams et al, Neurosci Abstr 3:148, 1977) but found ADT was lower in controls using intracortical stimulation (0.13±.006 ma vs 0.63±.03 ma for surface stimulation). We repeated the TCL studies with intracortical stimulation.

The results are: 1. In cats with 4 parallel TCLs in one SS quadrant, ADT was significantly elevated (0.43±.05 ma) compared to the non-lesioned quadrants (0.17±.02 ma, $p < .001$). 2. In cats with an additional 4 TCLs (8 TCLs) in an adjacent quadrant, and in animals with 4 TCLs forming a box in one quadrant, a slight ADT elevation in the lesioned quadrants was not significant compared to non-lesioned quadrants but both were significantly elevated compared to controls, (0.38±.05, 0.19±.03 ma vs 0.13±.006 ma). 3. ADD as in previous experiments with surface stimulation, was elevated in lesioned quadrants compared to non-lesioned . Grouping all lesioned animals, it was significantly elevated in lesioned (13.8±5.23 sec) and non-lesioned (10.6±3.3 sec) quadrants in lesioned animals compared to control (4.5±0.4 sec). 4. The results occur immediately after the lesions (sham lesioned cats show no change) and are not time dependent within the 48 days.

Sectioning horizontal cortico-cortical connections affects epileptiform activity even in non-lesioned cortical areas. Although some support for the hypothesis is gained, epileptogenesis may be enhanced because of these lesions as shown by prolonged duration of afterdischarge.

632 ULTRASTRUCTURE OF THE MOSSY FIBER ENDINGS IN THE HIPPOCAMPUS OF THE CONVULSIVE MONGOLIAN GERBIL. I. Fried*, L. Paul*, K. Watanabe*and A. B. Scheibel (SPON: A. B. Harris). Dept. of Psychology, Neurology, Psychiatry and Anatomy, UCLA, Los Angeles, CA 90024.

The Mongolian gerbil (Meriones unguiculatus) has been proposed as a model for the epilepsies (Loskota et al., Epilepsia 15:109, 1974) and strains of seizure-sensitive and seizure-resistant gerbils have been established by several laboratories. Previous research has indicated structural differences between the two strains in CA3 zone of the hippocampus (Paul et al., Neurosci. Abs. 4:145, 1978). The main differences, as observed with the light microscope using Golgi techniques, were in the distribution of spines on CA3 pyramidal cells and in the shape and size of the mossy tufts of dentate granule axons. These changes have been now further studied with the electron microscope and several observations seem worthy of description. 1) Synaptic vesicles in mossy sacs in seizure-sensitive gerbils appear to be densely and homogeneously distributed throughout the tuft rather than clustered near a synaptic thickening as observed in seizure-resistant gerbils. We wonder whether the vesicle-crowded tuft in the seizure-prone gerbil may not reflect the disordered ictal state. 2) The seizure-sensitive gerbils exhibited evidence of ongoing degenerative changes in pre- and post-synaptic elements in CA3 and CA4 zones of the hippocampus. These changes appeared as electron dense profiles with most of the contained membranous components degenerated.

In view of similar degenerative changes observed in previous Golgi and electron microscope studies in temporal lobe epilepsy in man (Brown, UCLA Forum in Medical Sciences, 17:339, 1973; Scheibel et al., Epilepsia 15:55, 1974) further studies are underway to compare the structural changes in the latter disorder with similar changes in the convulsive gerbil.

633 DIPHENYLHYDANTOIN: INTERACTION WITH [^{3}H]DIAZEPAM BINDING SITE IN BRAIN AND ANTICONVULSANT ACTIVITY. Dorothy W. Gallager, Pierre Mallorga*, and John F. Tallman. Biological Psychiatry Branch, NIMH, Bethesda, MD 20205

Using extracellular recording and microiontophoretic techniques, the anticonvulsant agent diphenylhydantoin (DPH) was found to increase the efficacy of benzodiazepines when tested on dorsal raphe neurons in the anesthetized rat. This increased biological effect could be correlated with an enhanced specific binding of [^{3}H]diazepam ([^{3}H]DZ) in brain following pretreatment of rats with DPH. Enhanced [^{3}H]DZ binding could be demonstrated in an in vitro assay using cortical membranes from animals pretreated with DPH in vivo. In addition, using an in vivo labeling technique, DPH pretreatment significantly enhanced the amount of specifically bound [^{3}H]DZ in brain. Increased binding (of approximately 15% when measured at 0.25 nM [^{3}H]DZ) following treatment of rats with DPH is due to an increase in the affinity of the brain-specific benzodiazepine receptor for its ligand. However, this enhanced binding does not appear to be a direct effect of DPH on [^{3}H]DZ binding or due to an increase in brain GABA levels.

Increases in [^{3}H]DZ binding were found to be dose-dependent following anticonvulsant doses of DPH, while not significantly altered by subconvulsant doses of DPH. In developing rats, effects on brain-specific [^{3}H]DZ binding were found to parallel the time course for the development of the anticonvulsant activity of DPH. In rats younger than 3 weeks, treatment with DPH resulted in non-significant decreases in [^{3}H]DZ binding, while in rats 3 weeks of age and older, significant increases in [^{3}H]DZ binding were seen as compared to vehicle-injected littermates.

Since DPH, the benzodiazepines and several other agents which cause alterations in benzodiazepine binding site affinity are active as anticonvulsants, the data suggests that the benzodiazepine binding site in brain may be involved in some of the anticonvulsant properties of these drugs.

634 GLIAL DEPOLARIZATION AND EXTRACELLULAR POTASSIUM CHANGES EVOKED BY DIRECT CORTICAL STIMULATION AND AFTER DISCHARGE. Robert S. Greenwood*, Michiaki Takato*, and Sidney Goldring. Dept. Neurol. and Neurol. Surg., Washington U. Sch. Med., St. Louis, Mo. 63110.

Although invertebrate glial cells appear to respond to changes in extracellular potassium concentration, $(k^+)_o$, in a manner predicted by the Nernst equation, variable results have been obtained in studies of the response of mammalian glial cells to $(k^+)_o$ changes (Somjen, 1975; Futamachi and Pedley, 1976). In feline neocortex we simultaneously recorded intraglial potentials and adjacent $(k^+)_o$ changes induced by direct cortical stimulation (DCS). A series of stimulus trains, each train of greater intensity than the previous trains, was administered until after discharge (AD) was produced. We found that at the height of glial depolarization following DCS, the slope of the relationship between glial depolarization and $(k^+)_o$ changes was 52.9 mV membrane potential change for a 10 fold change in $(k^+)_o$. During AD, however, the relationship between glial depolarization and $(k^+)_o$, changed significantly, AD associated glial depolarization larger than that occurring during DCS was seen in only 3/14 instances despite $(k^+)_o$ rises which invariably exceeded the levels reached during DCS. These observations suggest that glial depolarization is related to $(k^+)_o$ in a manner approximating that predicted by the Nernst equation when measurements are made just after the termination of DCS, however during AD the relationship between glial depolarization and $(k^+)_o$ changes. Factors accounting for this change in relationship will be discussed.

635 DISTINCTION BETWEEN NORMAL AND EPILEPTIC RHYTHMS IN RODENT SENSORIMOTOR CORTEX. E.J. Hammond*, H.J. Villarreal*, and B.J. Wilder Medical Res. and Neurology Service, VA Med Ctr, Gainesville, FL 32602.

The rat is extensively used in experimental models of epilepsy, and several reports describe the appearance of induced electrographic seizures in rat cortex. We have recorded bursts of epileptiform activity over sensorimotor cortex in chronically-implanted rats and guinea pigs, in both brain-lesioned and unlesioned animals. In monopolar recordings these bursts consist of a negative wave followed by a higher amplitude negative spike at a frequency of 8-12 hz. Bipolar recordings produce quite dramatic spike activity. These bursts closely resemble those which are often reported as being electrophysiological correlates of epilepsy. These waves appear in fusiform "spindles" over sensorimotor cortex. They are concomitant with behavioral inactivity. They are accentuated by low doses of sodium pentobarbital and are abruptly terminated by a loud acoustical stimulus, and thus appear to be related to arousal mechanisms. These waves in unanesthetized, unlesioned animals appear similar in wave form to the artificially-induced recruiting and augmenting responses. Although thalamocortical valleys undoubtedly play a role in the genesis of epileptic brain rhythms, these particular epileptiform spindles do not appear to be a reflection of epilepsy. A comparison was made between these bursts and epileptic spiking arising from cobalt foci in the same animals. Although spindle waves and epileptic spikes look somewhat similar in waveform, the latter are aperiodic, particularly when unaccompanied by behavioral manifestations and do not present the 8-12 hz. fusiform burst configuration. Higher amplitude spikes from foci in sensorimotor cortex are synchronous with clonic limb movements.

636 THE USE OF HOMOCYSTEINE-INDUCED SEIZURES IN THE STUDY OF EXPERIMENTAL EPILEPSY. R.W. Hurd*, E.J. Hammond*, F.J. Thompson, and B.J. Wilder (SPON: A.J. Dunn). Dept. of Neuroscience, Univ. of Fla., and Neurology Service, VA Hospital, Gainesville, FL 32610.

Although the occurrence of homocysteine-induced behavioral seizures in animals has been reported, the use of this agent in the study of experimental epilepsy has not been fully exploited. We believe that this model has theoretical and practical advantages over models which rely on introduction of foreign substances into the brain, and systemic injections of substances with dubious clinical relevance. Homocysteine is structurally-related to methionine sulphoximine (MSO), a commonly studied convulsant, but unlike MSO, homocysteine occurs endogenously as a metabolite of methionine, and some patients with elevated plasma levels of homocysteine have been reported to have seizures.

With i.p. injections of homocysteine, dose-related electrographic and behavioral seizures are observed. The seizures are recurrent and semi-chronic. Doses of 1-2 mMoles/kg activate latent cobalt foci in rats. Focal spiking in the electrocorticogram (ECoG) is observed. At doses of 3 mMoles/kg activation of limb musculature is observed in synchrony with the ECoG spiking. At higher doses, electrographic and behavioral seizures are also seen in unlesioned animals. Doses of 5.5 mMoles/kg (ED_{50}) cause massive tonic-clonic seizures (latency 20-30 minutes) characterized by generalized high amplitude spiking in synchrony with clonic limb movements. The seizures recur within 30 minutes.

We have further studied a possible mechanism of these seizures in mice. A major pathway for homocysteine metabolism occurs via the methionine synthetase reaction which requires N^5-methyl tetrahydrofolic acid (N^5MTHFA) and vitamin B_{12}.

Pretreatment of animals with N^5MTHFA (.3 mg/kg), tetrahydrofolic acid (4 mg/kg) or methotrexate (4 mg/kg) decreased the latency to homocysteine-induced seizures ($p < .05$). Chronic pretreatment with vitamin B_{12} (5 µg/kg per day) increased the latency and decreased the severity of seizures.

These results have a clinical correlate, as previous reports have indicated a decrease in severity and number of seizures when epileptics were administered a combination of folate plus B_{12} rather than folate alone in treating the hematological complications of anticonvulsant therapy. Prophylaxis was also observed following pretreatment with therapeutic doses of the anticonvulsant drug phenobartital ($p < .01$); the anti-petit mal drug ethosuximide had no effect on seizure latency or duration. This paradigm therefore might serve as a useful animal model for assessing the efficacy of anticonvulsant drugs used in the treatment of convulsive seizures.

637 POSTWEANING HOUSING CONDITION AFFECTS SEIZURE ACTIVITY IN THE MONGOLIAN GERBIL. Harriett Kaplan. Inst. Bas. Res. in Ment. Retard. Staten Is., N.Y. 10314

Seizure prone Mongolian gerbils undergo epileptiform seizures when placed in a strange environment. These seizures appear to be triggered by stressful stimuli. I have previously shown that events occurring during the preweaning period can effect seizure latency and postseizure recovery time (Neuropsychologia 16: 649, 1978) as well as other seizure parameters. To determine whether postweaning manipulations would also affect subsequent seizure activity, housing condition was varied using a split litter technique. After weaning at 4 weeks of age, half of each litter was group housed. The other half was housed singly, so that these subjects could see, hear, and smell, but not touch other gerbils. Starting at 6 weeks of age, all subjects were tested for seizures, at first weekly and then biweekly, in our standard seizure test: placing the subjects into a large, empty cage for 3 minutes. Testing continued for 7 months. Results indicated that postweaning housing condition had a significant effect on seizure activity. Single-housed gerbils underwent seizures less frequently than group-housed gerbils. In addition, their seizures were less severe and of shorter duration. These rather surprising results are interpreted as indicating that housing gerbils alone may act as a mild form of stress, possibly increasing stress response threshold or affecting emotionality or arousal levels so that these gerbils can handle increased or stressful input more effectively. Further experiments are underway to determine more precisely the relationship between early experience, extra stimulation, and seizure activity in the gerbil.

638 DEPTH SPIKING RELATED TO SLEEP STATE AND SEIZURE FOCI IN PATIENTS WITH TEMPORAL LOBE EPILEPSY. Jeffrey P. Lieb, Jean P. Joseph*, Jeffrey Walker* and Paul H. Crandall. Reed Neurol. Res. Ctr. and Brain Res. Inst., Schl. Med., UCLA, Los Angeles, CA 90024.

The statistical properties of interictal EEG spike activity recorded from medial temporal lobe sites (amygdala, hippocampal gyrus and pes hippocampi) were evaluated using computer spike recognition techniques in all-night sleep records obtained from 10 patients with medically refractory TLE. For each patient, 1 all-night sleep record was chosen for analysis. Each sleep record was manually staged by 2 observers according to standard criteria. Sleep stages were classified into 1 of 4 groups: wakefulness, REM sleep, light sleep and deep sleep. Deep sleep was not observed in 1 patient and 5 patients did not demonstrate uniform periodic REM episodes due to many shifts from REM sleep to light sleep. An ongoing theta rhythm (4-8 c/s) was observed cortically in 1 or more states in 6 patients. Sleep spindles were not observed in 3 patients. Despite these abnormalities, the relative proportion of REM sleep, light sleep, and deep sleep was, on the average, close to that reported for normals.

Spike activity was observed to be most frequent during deep sleep in 7 of the 10 patients. Maximal spike rate was found to be most frequent during light sleep in the 3 remaining patients. In occasional sites, maximal spike rate was observed during waking or REM sleep.

All 10 of the patients reported in this study were considered to be suitable for temporal lobectomy as judged from the distribution of locus of seizure onset. In contrast to the results obtained in a previous study, the side with a site or sites demonstrating maximal mean spike rate during waking, light sleep, deep sleep, or REM sleep did not significantly correlate with the side chosen for lobectomy. However, the side with a site or sites demonstrating a minimal activation in mean spike rate in light sleep or deep sleep relative to waking did significantly correlate with the side chosen for lobectomy. In those patients in which spike properties yielded an apparently false lateralization with respect to side of seizure onset, decreased background activity was usually evident throughout the seizure-initiating side. Additionally, the mode of seizure initiation and propagation was found to differ in these patients. The results obtained here indicate that an analysis of sleep-induced changes in depth spike activity can be useful in improving predictions concerning the predominant side of seizure initiation but that a concurrent analysis of background activity would improve predictive power.

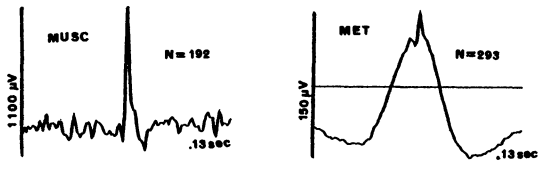
639 Computer Recognition of Spikes in the EEG of Metrazole Treated Rats using Fixed Interval Analysis and Clustering Techniques. Herbert E. Longenecker, Jr., Valery Koss, David F. Dean, and Chi-ming Huang. Departments of Pharmacology, Neurosurgery and Physiology, College of Medicine, University of South Alabama, Mobile, AL. 36688.

Classic methods for spike analysis in EEG records utilize Fourier analysis or correllation analysis. Both of these methods require either complex instrumentation or vast amounts of computer time. Even with the advent of microcomputers it does not appear feasible for recognition of spikes in an online and continuous multichannel mode with these methods. Here, we report a very simple computational technique that detects and facilitates classification and other analysis of spikes with a high degree of accuracy which can be implemented with only a minimal computer.

High frequency EEG (DC to 10KHZ) was FM recorded (DC-3kHZ) from monopolar leads from a cortical electrode. Data was presented to an A/D converter and sampled at 1 msec intervals. Contiguous 330 msec. epochs were examined, The following parameters were computed from each epoch: L, the length of the entire voltage excursion; T, the time between the min and max amplitudes; and D, the amplitude between min and max signals. Empirical observations were that clustering occured in either the L vs D plot or L vs T plot. By chosing windowed values of these parameters it was possible to detect a spike. The parameters Wn, the width the spike at n percent of the spike height were used for spike classification according to the following table:

Spike Type	D-uV	L-mV	T-msec	W86	W72	W57-msec
MUSCLE	180-650	00-30	00-65	$\leq$4.0	$\leq$9.5	$\leq$13.0
CORTICAL	180-650	00-30	00-65	$>$4.0	$>$9.5	$>$13.0

Once an epoch was found to contain a spike, the peak of the spike was aligned to mid screen and and the record could be signal averaged. The potentials below represent averaged muscle and cortical spikes as per the above selection algorithm.



10 OUABAIN CAUSES DIFFERENT MOTOR SEIZURE PATTERNS ACCORDING TO BRAIN REGIONAL SITE OF MICROINJECTION. James L. Minnich and +Theresa Page*. Dept. Physiol., Fac. Med., Univ. of Manitoba, Winnipeg, Canada R3E 0W3. +Biol. Dept., TWU, Denton, TX 76204.

Ouabain injection into brain ventricles induces reproducible motor seizure patterns (Canad. J. Biochem. 51: 198, 1973). In the present study ouabain was injected directly into selected brain regions of adult male Sprague-Dawley rats through indwelling stainless steel cannulas (26 gauge). Each rat had bilateral placement of cannulas into one brain region (N=9-11 for each region studied). Control injection of 1 µl of 0.3 M sucrose was done in the brain region on one side, and ouabain injection (10 µg in 1 µl of 0.3 M sucrose) was done on the contralateral side at 2 weeks and 3 weeks, respectively, after cannula implantation. The control injections of vehicle did not alter motor behavior. Histological verification of cannula tip location was done. The motor behavior of each animal was observed for 30 min after each intracerebral injection. Seizure activity was categorized as in a previous communication (ibid.). Analysis of variance (for repeated measures and unequal groups) was done between brain region injection sites for the occurrence of various seizure categories, and Duncan's multiple range test was applied to the mean difference obtained for each comparison between regions. The most severe seizure patterns were seen after injection of ouabain into the raphe nucleus and lateral thalamic nucleus. Less severe seizures (localized to head and neck) resulted from ouabain injection into sensorimotor cortex. The following table shows the seizure categories and the brain region where ouabain caused their highest occurrence. In every case the occurrence shown here was significantly ($P<0.05$) higher than in other brain regions.

Seizure category	Brain region with highest ouabain-induced seizure occurrence
Clonic (4 legs)	Raphe
Tonic flexion (legs)	Raphe
Clonic (hind legs only)	Lateral thalamic nucleus
Tonic flexion (body and head	Lateral thalamic nucleus
Running and leaping	Lateral thalamic nucleus
Clonic (head and face)	Sensorimotor cortex

Ouabain microinjection into the lateral septal nucleus caused vocalization. Brain regions in which ouabain caused seizure activity only at lower levels included dorsal hippocampus and caudate-putamen. Earlier work (ibid.) has shown altered serotonin levels associated with ouabain-induced seizures; the raphe region is the origin of ascending serotoninergic systems. The lateral thalamic nucleus is thought to project to the cortex in the rat, so that activation of widespread cortical areas might possibly result from ouabain stimulation of this diencephalic region.

12 PERSISTENT INCREASE IN HIPPOCAMPAL NEURONAL EXCITABILITY PRODUCED BY DAILY INJECTION OF PENTYLENETETRAZOL. A.P.Oliver, B.J.Hoffer, and R.J.Wyatt. Laboratory of Clinical Psychopharmacol., DSMHR, NIMH, Saint Elizabeths Hospital, Washington, D. C. 20032.

Repeated injection of chemical convulsants are reported to induce progressive lowering of seizure thresholds, a phenomenon known as "kindling". Epileptiform activity was studied in guinea pig hippocampal slices to examine the physiological changes which may be involved. Interictal spike (IIS) frequency was used as the primary parameter. Slices from normal guinea pigs, perfused with 7-8 mM K^+, will develop spontaneous IIS only when suitable concentrations of a chemical convulsant (i.e. 3000 U/cc penicillin) are added to the medium. In contrast, slices from animals injected daily for 5 days with 50 mg/kg pentylenetetrazol (PTZ) manifested clearcut IIS in 8 mM K^+, without addition of a convulsant drug. This increase in excitability was found for up to twelve days following the last drug injection. The rate of IIS discharge in the "kindled" animals perfused with 8 mM K^+, about 14 IIS/minute, is similar to that seen in normal animals perfused with 8 mM K^+ + 3000 U/ml penicillin. The configurations of the IIS are also similar in the two groups. The kindled animals convulsed about 80% of the time following PTZ injection. However, no spontaneous convulsions were seen during drug-free periods. Taken together, these results suggest that chronic administration of chemical convulsants induce long-term increases in neuronal excitability, which persist far beyond the time of drug exposure.

641 BRAINSTEM AUDITORY EVOKED POTENTIAL (BAEP) ALTERATIONS DURING INDUCED AND SPONTANEOUS GENERALIZED SPIKE-WAVE ACTIVITY IN ANIMALS AND HUMANS. Allan F. Mirsky, Boston University Medical Center, Boston, MA; James J. Stockard, Mayo Clinic, Rochester, MN; Barry F. Skoff*, Boston University Medical Center; & T.A. Jones, University of California (Davis).

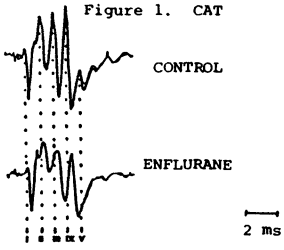
Preliminary data from animals and humans studied in our laboratories indicate that BAEPs are altered during certain types of seizures associated with generalized spike-wave activity.

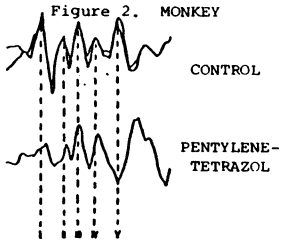
Figure 1 illustrates BAEP changes seen in the cat during administration of enflurane at a dose producing bisynchronous spike-waves. There is an increase in I-IV interpeak latency of 8 standard deviations. There was no significant change in interpeak latency with administration of equipotent doses of all non-epileptogenic anesthetics studied to date: halothane, thiopental, nitrous oxide, or isoflurane (the isomer of enflurane).

In the monkey, there is a significant increase in I-V interpeak latency, as shown in Figure 2, with administration of pentylenetetrazol in doses producing an electro-clinical model of petit mal epilepsy.

In addition to the animal data, there is evidence for BAEP alterations during spike-wave bursts in patients with "absence" seizures. For one of the patients seen (Boston), there was an increase of over 2 standard deviations in I-IV/V interpeak latency during spike-wave activity. In another patient (Rochester) induction of 3 per second spike-wave discharges with photic stimulation was associated with highly significant transitory prolongation of I-V interpeak latency that persisted for a short period after the spike-wave activity.

In summary, there appear to be alterations in functioning at the level of the rostral brainstem, as indicated by BAEP changes, during generalized spike-wave activity induced by drugs in animals, and accompanying absence seizures in humans.





643 ON STRUCTURAL SUBSTRATES OF EPILEPTIC BEHAVIOR IN THE MONGOLIAN GERBIL. L. Paul*, I. Fried*, K. Watanabe*, and A. Scheibel. (SPON: R. Schain). Departments of Physiological Psychology, Pediatric Neurology, Anatomy and Psychiatry, University of California, Los Angeles, CA 90024.

Extending work previously begun in our laboratory, we have investigated possible structural correlates of seizure behavior in the Mongolian gerbil (Meriones unguiculatus). A seizure-sensitive (SS) and a seizure-resistant (SR) strain have been selectively bred in the laboratory of Dr. R. Schain. Investigations were performed using anatomical, histochemical and lesioning techniques. Quantitative analysis of Golgi-impregnated material using improved tissue-blocking and staining methods enabled a clear visualization of hippocampal CA3 pyramidal cells. Dendritic spine counts performed on selected 45 µ segments (2 apical and 2 basilar segments per cell) in the cells and in neocortex revealed the following:

MEAN SPINE COUNTS
(Number of spines/45 µ dendritic segment)

	Hippocampal Pyramidal Cells[1]	
	SS (n=19)	SR (n=24)
Basilar	63.3	75.6 * $p<.025$
Apical	72.3	80.1 * $p<.05$
	Neocortical Pyramidal Cells	
	SS (n=14)	SR (n=14)
Basilar	71.8	76.5 N.S.
Apical	76.9	74.2 N.S.

[1]n=number of cells

The loss of spines in CA3 may indicate only that we are not observing a generalized metabolic deficiency. Results from transmission electron microscopy reported elsewhere at this meeting indicate differences between SS and SR animals in several parameters. Structural variations in mossy tuft terminals impinging on these pyramids have also been noted. We are examining the brains of developing animals, bracketing the age at which seizures first appear (about 2 months). Two other major approaches are being utilized: histofluorescence methods compare SS and SR animals, as well as brains before and after seizures in SS gerbils. Finally, based on a "deafferentation" hypothesis as explanation for the spine loss, seizure behavior in SR animals is carefully monitored following lesions in sites with heavy input into CA3. The spontaneous nature of seizure behavior in these rodents provides an interesting laboratory model of epileptic behavior. It is possible that our findings could illuminate some small portion of the human epilepsy picture.

644 EVALUATION OF INTERTRIAL INTERVAL ON DEVELOPING AND DEVELOPED KINDLED SEIZURES. Steven L. Peterson*, Timothy E. Albertson and Larry G. Stark*. Dept. of Pharm., UCD, Davis, CA 95616.

The interval between each kindling stimulus and the presentation of massed stimulations has been shown to have an important effect on kindling. In this study, a grouped trial session (GTS) consisting of 5 daily stimulations, one hour apart, was used to determine the effects of a repeated massed stimulation paradigm on kindling. All rats were stimulated electrically in the right amygdala with a 60 cps, 400 μA stimulus of 1 sec. duration. Seizure intensity was determined by afterdischarge (AD) duration and behavioral response (BR) classifications characteristic of kindled seizures in rats. The effects of repeated GTS sessions on kindled rats were determined in Group I by presenting 6 consecutive days of GTS to rats previously kindled by one stimulation per day. These animals had kindled normally with consistent AD's and BR's when stimulated once daily, but exhibited reduced AD's and inconsistent BR's during the GTS days. Within 5 days of returning to daily stimulations all animals (Group I) responded with pre-GTS seizure intensity. The effects of GTS on the development of kindling were tested by stimulating the animals in Group II using only the GTS paradigm. These animals never showed the consistent AD duration or BR characteristic of rats kindled with just one stimulation per day. For comparison, Group III rats were stimulated once hourly for 32 hours during which the AD duration increased normally, but BR's were inconsistent with only 4 of 9 animals showing occasional Class 5 seizures. When reduced to daily stimulations, the group AD and BR response was greatly diminished compared to the hourly stimulation period, but all animals exhibited consistent kindled seizures within 11 days. These findings suggest that a prolonged inhibition of kindled seizures result from repeated massed stimulation and that animals kindled with repeated hourly stimulations may not share all the neurophysiological characteristics of those kindled with stimulations once a day.

645 **QUANTITATIVE EVALUATION OF PINOCYTOTIC ACTIVITY WITHIN BRAIN ENDOTHELIUM DURING EXPERIMENTAL SEIZURES.** **C.K. Petito* (SPON: D. Levy). Cornell University Medical College. New York, N.Y. 10021.**

During experimental seizures, increased vascular permeability to horseradish peroxidase (HRP) occurs via enhanced vesicular activity within the endothelial cells of small parenchymal vessels. In order to determine the relative contribution by small arteries, arterioles, and capillaries to the increased permeability, pinocytotic activity was assessed quantitatively in 6 paralyzed, ventilated rats whose blood pressure and arterial blood gases were monitored during the experiment. Intravascular HRP was allowed to circulate for 5 min and was followed by a series of 20 consecutive electroshocks (100 mamps, 1 sec duration) every 30 sec. The animals were anesthetized with ether and sacrificed by perfusion-fixation with paraformaldehyde-glutaraldehyde. A mid-coronal section through the third ventricle was incubated for peroxidase activity and prepared for light and electron microscopy. Light microscopy of the serial 1μm sections from 3 additional animals showed the presence of small arteries within each focus of HRP extravasation. Endothelial cytoplasmic area was determined by planimetry from electron micrographs taken at a constant magnification. The number of HRP-containing vesicles per 1 mm^2 endothelial cytoplasm was quantitatively evaluated. Mean pinocytotic activity within the endothelium of the different vessels was: capillaries (211), 83.71 vesicles/mm^2; arterioles (11), 159.87 vesicles/mm^2; and small arteries (37), 244.05 vesicles/mm^2. These results show that significant blood-brain barrier permeability occurs within small arteries and arterioles as well as within capillaries and that the small arteries may be the initial site of the increased vascular permeability that occurs during seizures.

646 LOCAL CEREBRAL GLUCOSE UTILIZATION IN LIDOCAINE-KINDLED SEIZURES. R. M. Post, C. Kennedy, M. Shinohara,* K. Squillace,* M. Miyaoka,* S. Suda,* D.H. Ingvar,* and L. Sokoloff. NIMH, Bethesda, MD 20205

Repeated daily injections of subconvulsant doses of lidocaine in the rat eventually evoke major motor seizures resembling those seen following repeated electrical (kindling) stimulation of the amygdala (Life Sci. 17: 943, 1975). The lidocaine seizures progressively increase in severity and duration. Animals also undergo progressive behavioral changes, becoming omniphagic and extremely aggressive following repeated lidocaine seizures. In the current study the ^{14}C-2-deoxyglucose method was used to measure local cerebral metabolic rates and to identify neural systems involved in the progressive lidocaine effects on behavior and development of seizures. Twenty-one male Sprague-Dawley rats weighing 250-300 gm. were administered lidocaine (65 mg/kg, i.p.) or saline once daily (5 times a week) for 12 to 43 days. Eleven of the 13 lidocaine-treated animals eventually exhibited 1 or more seizures (maximum = 28; median = 9) lasting several seconds to as long as 30 minutes with salivation, chewing, and perioral movements followed by intermittant clonic movements of head, trunk, and forepaws; Straub tail phenomenon; and rearing and falling. Lidocaine and saline treated animals were prepared and studied in pairs. One femoral artery and vein were catherized under light halothane anesthesia and the animals were partially immobilized in loose fitting pelvic plaster casts and allowed to recover at least 2 hours from anesthesia. The animals were then injected with lidocaine or saline i.p., and approximately 10 minutes later the measurement of local glucose consumption with ^{14}C-2-deoxyglucose was carried out, as previously described (J. Neurochem. 28: 897, 1977). Compared to chronic saline treated controls, all lidocaine-treated animals had 15%-25% lower rates of metabolic activity in all areas of brain including cortex, striatum, brainstem, and cerebellum. In animals without or with only mild seizures lidocaine treatment also reduced the metabolic rate throughout limbic structures. In animals exhibiting prolonged lidocaine seizures, however, striking increases in glucose utilization were observed in hippocampus, dentate gyrus, amygdala, septal nuclei, and entorhinal cortex. The increase in average glucose utilization over the 45 minute period of measurement correlated positively in all these limbic areas with seizure duration ($p < .05$). Inverse correlations between metabolic rate and duration of seizures were observed in several other regions, such as the thalmus and medial and lateral geniculate bodies ($p < .05$). The current studies demonstrate that limbic structures, particularly hippocampus, amygdala, septal nuclei, and entorhinal cortex, are intimately involved in the convulsive and behavioral aberrations associated with lidocaine-kindled seizures which appear to offer an experimental model for temporal lobe epilepsy.

647 ELECTROPHYSIOLOGY OF HUMAN EPILEPTIC NEURONS. D.A. Prince and R.K.S. Wong. Dept. of Neurology, Stanford Univ. Med. Sch., Stanford, CA 94305

We have recently examined data obtained from eight human cortical biopsies using the in vitro slice technique in order to determine whether abnormal patterns of neuronal activity were present in biopsies from patients with focal epileptiform discharges. A total of 28 neurons were analyzed. These cells all had stable high resting potentials with overshooting spikes and input resistances which were as high as 50 Mohms, suggesting that they were relatively "healthy." Intracellular current pulses as well as orthodromic activation were applied in each case. Six neurons from two biopsies of cortex which was normal, (i.e., remote from sites of cortical pathology or abnormal EEG epileptiform discharge), showed patterns of activity similar to those recorded in guinea pig neocortical cells. Single orthodromic stimuli evoked EPSP-IPSP sequences usually associated with single spikes. Synaptic events could be graded with the intensity of the stimulus. Six cortical biopsies were studied from areas which were known from prior EEG studies or electrocorticography to be capable of generating focal epileptiform activities. Twenty of 22 neurons from such cortex generated bursts of 3-7 spikes with orthodromic stimulation. Intracellular recordings revealed that depolarizing potentials with amplitudes of up to 25 mV or more and durations as long as 100 msec served as generators for bursts of fast spikes. Occasionally spikelets resembling fast prepotentials were intermixed within the fast spike bursts. The slow depolarizations had many of the characteristics of depolarization shifts (DSs) described in acute neocortical foci. They were often triggered at long latency (ca. 50-60 msec), and arose abruptly in an all-or-none fashion following threshold orthodromic stimuli. With increasing stimulus intensity, latency became shorter, but the DS configuration remained unchanged. In some cells DSs could be regularly evoked by low frequency stimuli (ca. .75-1 Hz) but would "alternate" when stimuli of higher frequencies (2 Hz) were used. DSs increased significantly in amplitude during hyperpolarizing current pulses and were never blocked by this maneuver. DSs and bursts could not be evoked in any neuron by direct depolarization (up to ca. 1.0 nA). These limited data suggest that human epileptic neurons generate DSs which are very similar to those in other models. In light of recent findings in guinea pig cortex and hippocampus, we would speculate that these all-or-none depolarizations are intrinsically generated. Neurons of chronic epileptogenic cortex appear to maintain abnormal features in the in vitro environment, a finding which will be important in further studies of the pathophysiology of epilepsy. (Supported by NS 06477 and NS 12151 from the NINCDS).

648 HEMOGLOBIN INDUCED EPILEPSY. Arthur D. Rosen and Natalie V. Frumin*. Dep't. Neurology, State Univ. of New York, Stony Brook, New York 11794.

Recent reports have demonstrated that both the di-and-trivalent forms of iron are potent epileptogenic agents when in contact with the cerebral cortex. The present study was carried out to test the hypothesis that ionic iron released from hemoglobin plays a role in the development of seizures following intracortical bleeding. Adult Sprague-Dawley rats were anesthetized with sodium pentabarbital and secured in a stereotaxic apparatus. A 2mm hole was drilled through the skull over the left occipital cortex and with the aid of a micro-injection syringe fitted with a 30 gauge needle, 10 ul of a 13 mg% solution of purified hemoglobin in saline injected 1.5mm below the cortical surface. The animals were permitted to recover and maintained for periods of up to two months. EEGs were recorded, using needle scalp electrodes, daily for the first week and twice weekly thereafter. All recordings were done under sodium pentabarbital anesthesia and continued until the animal showed signs of awakening. At varying intervals after hemoglobin injection animals were anesthetized and killed by transcardiac perfusion with neutral buffered formalin. Histological verification of the extent of the lesions was carried out. High amplitude focal spike activity was recorded from 24 of the 27 rats injected with hemoglobin (89%) and in none of the four animals injected with saline alone. 50% of the animals showed spikes within 48 hours. The spike focus, when present, became relatively stable within two days after it was noted and in all cases persisted until the animal was sacrificed. No clinical manifestations of seizures were seen.

649 EPILEPSY: A PREDICTIVE MODEL OF SEIZURE BASED ON THE TIME DISTRIBUTION OF EEG SPIKING. Bernard Saltzberg, Texas Research Institute of Mental Sciences and Baylor College of Medicine, Houston, Texas; Peter Kellaway, Baylor College of Medicine and Methodist Hospital, Houston, Texas; William D. Burton, Jr.*, Texas Research Institute of Mental Sciences, Houston, Texas; and James D. Frost, Jr., Baylor College of Medicine and Methodist Hospital, Houston, Texas.

A mathematical model is developed which accurately approximates the cumulative distribution of the focal EEG spike discharges occurring during a night's sleep. This model provides a quantitative as well as an intuitive phenomenological basis for understanding the relationship between focal EEG spiking and the state of the epileptic patient. The EEG spiking events in this model are considered the realization of a stochastic point process; that is, a process which is characterized by the points in time at which such spiking events occur. Using the model, it is postulated that a single descriptive parameter of the cumulative distribution of EEG spiking events provides a predictive measure of risk of convulsive seizure or a measure of the degree of control which is produced by anti-epileptic drugs. A two parameter model characterizing the distribution of spiking events is derived and regression equations are developed to fit the model to empirical data. The initial findings are based on EEG sleep recordings obtained from a population of ten patients (a total of thirty-one sleep nights). The spiking profiles which are derived by visual analysis of each of the thirty-one sleep nights were subjected to regression analysis to derive numerical values for the regression parameters. The curvature of the cumulative distribution is represented by one of the regression parameters and it is shown that this parameter alone provides a predictive measure of seizure risk.

650 EFFECTS OF VENTROBASAL THALAMIC LESIONS ON KINDLED SEIZURES AND ASSOCIATED SLEEP DISTURBANCE IN CATS. M.B. Sterman, P. Hauri* and M.N. Shouse*. Sepulveda VA Med. Ctr., Sepulveda, CA and Depts. of Anatomy and Psychiatry, UCLA, Los Angeles, CA 90024

Lesions placed in ventrobasal thalamus (VB) have been shown to reduce susceptability to seizures both in man and in various experimental animal models of seizure disorders. In previous studies we have shown that such lesions protected cats against drug-induced seizures and facilitated sleep, which is typically disturbed with the development of seizures. In the present study the effect of VB thalamic lesions was examined in relation to chronic seizures induced by amygdaloid kindling and the disturbance of sleep which also accompanies the development of seizures with this model. Two groups of cats were prepared for basolateral amygdala kindling and standard sleep-waking state evaluation. Animals in both groups were monitored polygraphically during 12-hr recordings of EEG, EOG and EMG activity before and at intervals after daily stimulation of amygdala with a one-second train of biphasic square waves (1 msec pulse duration, 60 Hz, at currents just sufficient to elicit afterdischarge). After initial afterdischarge thresholds were established animals in one group were subjected to bilateral electrolytic lesions of ventrobasal thalamus. Both groups were then studied until generalized tonic-clonic seizures were obtained with kindling stimulation or for a maximum of 75 days.

Animals in the non-lesioned group demonstrated kindled seizures within 19-25 days and a progressive decrease in both slow wave and REM sleep. In contrast, animals with VB lesions required a minimum of 61 days for kindling or showed no generalized seizures within the 75 day period of study.

Both groups of animals showed a disturbance of sleep during initial afterdischarge threshold determinations. This disruption of sleep was extended and sustained in animals without lesions during subsequent kindling but recovered completely within 30 days in animals with VB lesions. Animals in the latter group which failed to develop generalized seizures showed both remarkably stable afterdischarge thresholds and sleep state distributions.

These findings support the body of data indicating that thalamic lesions protect against seizures. Further, they suggest that conduction of abnormal discharge through sensorimotor thalamic circuits is involved in the propogation of seizure activity and the development of generalized seizure disorders of subcortical origin.

651 A QUANTITATIVE STUDY OF THE REDUCTION OF INHIBITION NECESSARY TO CAUSE SPINAL SEIZURES. G.L. Tribble*, P.C. Schwindt*, W.E. Crill (SPON: H.D. Patton). Dept. Physiol. & Biophysics, & Medicine, Univ. Washington, Seattle, WA 98195.

Several recent studies using a variety of model neural systems have shown that convulsive drugs such as penicillin, pentylenetetrazol, and others reduce inhibitory postsynaptic potentials (IPSP's). These results suggest that the epileptogenic action of these agents may depend on a common mechanism, reduction of inhibition. To evaluate this mechanism in the mammalian CNS, it is essential to know how much inhibition must be reduced in order for a seizure to occur. As a first step, we have investigated the amount by which postsynaptic inhibition must be reduced by the well-known glycine antagonist, strychnine, in order for spinal seizures to occur. Experiments were conducted on cats anesthetized with pentobarbital or chlorolose, or decerebrated (unanesthetized). In each case, the spinal cord was transected at the L4 or C1 segments. In each cat, a motoneuron was recorded before and during incremental I.V. injections of strychnine. Reduction of the disynaptic group Ia IPSP or the Renshaw IPSP was observed as doses of strychnine were incremented until seizures developed. Seizure initiation was characterized by the appearance of high frequency bursts of action potentials occurring synchronously among many motoneurons in the recorded segment. Although the strychnine dose producing a seizure varied among the preparations, in all cases the IPSP's were reduced to at least 25% of their control values before the first sign of seizure activity appeared. These results suggest that if other drugs such as penicillin cause seizures in the mammalian CNS by decreasing postsynaptic inhibition, then a large, easily observable reduction in IPSP amplitude should be seen prior to seizure onset. Equivalent experiments on a GABA-mediated IPSP are in progress. Supported by VA Research Grant MRIS 1610.

652 ENDORPHIN EVIDENCE AGAINST THE SYNAPTIC BARRIER MODEL OF KINDLING. Roy A. Wise and Anita Rackham Center for Research on Drug Dependence, Psychology Department, Concordia University, Montreal, Canada H3G 1M8.

Kindling refers to the progressive lowering of local afterdischarge (AD) thresholds and the progressive development of convulsive responses to initially innocuous electrical stimulation of limbic and other structures. It has been traditionally thought to reflect the breakdown, by repeated bombardment, of synaptic barriers between the site of stimulation and the motor systems. Studies of the epileptigenic effects of intraventricular injections of β-endorphin do not fit with this model, however. Injections of β-endorphin (10 μg) caused limbic epileptiform activity in rats which was not expressed in behavioral convulsions even when given to animals that had had their presumed limbic-motor synaptic barriers broken down by prior electrophysiological kindling. This was true whether amygdala, hippocampus, caudate, or dorsomedial thalamus was kindled to the stage of full clonic convulsions. The electrophysiological AD in the kindled hippocampus had greater amplitude than the ictal episodes caused by β-endorphin in kindled animals, but the biphasic pattern of response was the same; thus the two epileptiform events seem to have had qualitatively similar limbic effects. That the difference in amplitude might account for their differential effectiveness seems unlikely since the initial ictal episodes had greater amplitude than ADs at the begining of kindling. That the amplitude of the ADs increased as a result of electrical kindling while the amplitude of the ictal episodes from β-endorphin did not indicates that there must be some difference between the two events which is more than a simple difference in amplitude. These data indicate that if synaptic barriers account for the failure of β-endorphin to cause behavioral convulsions in association with limbic ictal episodes, then the synaptic barriers involved must differ from those that block similar behavioral expression of ADs elicited by limbic electrical stimulation.

EVOKED POTENTIALS AND EEG

653 EVALUATION OF WIENER FILTERING APPLIED TO BRAINSTEM AUDITORY EVOKED POTENTIALS. J. R. Boston, C. A. Younger*, and P. J. Ainslie*. Biomedical Engineering Program, Carnegie-Mellon University, Pittsburgh, PA 15213.

The application of Doyle's version (ECN 38:533, 1975) of a Wiener filter for averaged evoked potentials to the brainstem auditory evoked potential (BAEP) was evaluated as a means of reducing the number of stimulus-response pairs necessary to obtain a consistent estimate of the BAEP. Averaged responses based on 256 individual evoked potentials were processed using the Wiener filter and a simple narrowband filter (200-1600 Hz). (This narrowband filter had previously been found to improve the identification of waves in the BAEP without distorting the waveform.) The resulting waveforms were compared to both the unfiltered averaged potential based on 256 individual potentials and an averaged potential (from the same subject) based on 2048 individual potentials. Subjectively, the Wiener filtered potentials were much more consistent from run-to-run than the narrowband filtered responses based on 256 individual potentials. The Wiener filter reduced the mean square error of the waveform, and the reduction was greater than that obtained with the narrowband filter. (The mean square error was estimated as the difference between the filtered waveform and the averaged potential based on 2048 responses.) The variability of latency and amplitude (peak-to-following trough) measures of waves I through V obtained from averaged potentials based on 256 individual responses was also reduced by the Wiener filter. Although the resulting variability was larger than the intersession variability of averaged potentials based on 2048 responses for a given subject, it was about the same as intersubject variability. The "goodness" of the spectral estimate of the evoked potential signal was observed to be an important factor in reducing the variability in the latency and amplitude data, as has been discussed in the literature. Finally, the Wiener filter appeared to severly distort the waveform in many cases; although waves I through III were usually enhanced, wave V was often significantly reduced in amplitude. This problem appeared to be due to the magnitude of the signal spectral estimate in the frequency range of 200-300 Hz., but the cause of the problem has not been identified.

654 RELIABILITY OF THE HUMAN AUDITORY EVOKED POTENTIAL AMPLITUDE-INTENSITY FUNCTION. Carl P. Browman, Helen T. Sullivan*, and Marie A. Fullerton*. Rush-Presbyterian-St. Luke's Medical Center, Chicago, IL 60612 and St. Louis University, St. Louis, MO 63103.

This study was designed to assess the test-retest reliability of auditory evoked potential (AEP) amplitude-intensity functions. Male and female volunteers were tested on consecutive and nonconsecutive days. Averaged AEP waveforms were obtained from bipolar recordings. Ten levels of stimulus magnitude, ranging from 60 to 87 dB SL in steps of 3 dB SL, were presented at each session. AEP amplitude-intensity functions per session were computed by the method of least squares. F tests were used to compare intersession residual variances, regression coefficients, and amplitude measures.

There was no statistical difference in residual variances across sessions. Similarly, individual regression coefficients were statistically unchanged from day to day. Periodic significant differences in AEP amplitude thus indicated a shift of the entire function. The duration of the test-retest interval had minimal effect. These results demonstrate the relative reliability of AEP amplitude-intensity functions.

655 MUSCLE INPUT TO HUMAN MOTOR-SENSORY CORTEX. William F. Brown. Dept. Clin. Neur. Sci., University Hospital London, Ontario.

There is clear evidence in sub-human primates for projection of muscle length receptors to the sensori-motor cortex. This sensori-motor input may function as part of the transcortical system to adjust motor output from cortex in response to unexpected changes in muscle length or load. In the human, there is a strong body of evidence to support the presence of such a 'transcortical reflex' but muscle afferent specific inputs to sensori-motor cortex have not been identified. To investigate the latter, a method has been developed to excite muscle stretch afferents, exclude the cutaneous input and measure the ipsilateral and contralateral voltage distribution for the evoked scalp potential. Healthy subjects have been instructed to contract the first dorsal interosseous (IDI) muscle in an isometric manner at various force levels. Measurements of the IDI EMG, ulnar, median and radial nerve action potentials and the evoked potentials from the ipsilateral and contralateral scalp in response to mechanical taps delivered to stretch the IDI were made. The cutaneous input from the skin over the IDI muscle and the 1st, 2nd and 3rd digits could be removed by local anaesthetic block of the median and radial nerves. The anaesthetic block was proven complete by a combination of nerve stimulation and the absence of radial or median but preserved ulnar nerve action potentials in response to the taps. A low voltage initial surface positive potential could be detected, localized primarily to the contralateral scalp hand area. The shortest latencies to the initial positive voltage deflections were 20-22 ms and were correspondingly shorter for taps delivered to more proximal muscles. This method has, therefore, provided evidence for muscle, probably length afferent, input to the human sensori-motor cortex, a measure of the latencies for this input and a possible method for investigation of this input in relation to changes in muscle length and contraction force in the periphery.

656 RESEARCH APPLICATIONS OF A QUANTITATIVE STANDARDIZED EEG AND EVOKED POTENTIAL ANALYSIS SYSTEM (MINICEARS). Donald G. Brunet*, Reginald G. Bickford, Kenneth R. Hanson*and Virgil Rochowansky*, Dept. Neurosci., Sch. Med., UCSD, La Jolla, CA 92093

The field of CNS macro potential analysis is largely characterized by fragmented and unstandardized approaches to computer analysis. An impetus towards standardization has come from the clinical field with the development of the ACE test (Automated Cerebral Electrogram) which combines EEG and evoked potentials into a single procedure. Efficient processing of test data has been made possible by use of the MINICEARS computer system (LSI-11, 32k memory, 2 floppy disks, 100k sample A-D, X-Y and graphics printer output.) Apart from clinical uses this system has wide ranging research applications. The functions include: 1) spectral programs producing 16 channel spectral analysis displays (compressed spectral arrays) sampled over 2 minutes; 2) plots of spectral averages in the form curves for each electrode; 3) bin microvoltages (delta, theta, alpha, beta, or selectable ranges) are generated and statistical programs provide significance tests for homologous electrodes and for normal populations matched for age; 4) area display programs make voltage contour plots of bin data (delta, etc.) or "time slices" of evoked potential fields at selected latencies following the stimulus; 5) recognition of patterns (i.e. spikes) is performed on 16 channels and the data assembled as "spike pack" graphics. By aligning primary spike data (recognized as "probable spike" by the computer algorhythm) for final visual validation; 6) evoked potential averaging proceeds on 16 channels (brainstem response 4 channels) and computer programs recognize peaks and assign latency and amplitude automatically; 7) monitoring of EEG or evoked potentials over long periods and the construction of a "somnogram" or "comagram" can be achieved. The system formats reports on the printographic terminal and can be used for data gathering, word processing, etc. Single unit processing algorhythms are under development and customized software development will be available. Cost economy has been the major consideration in developing the system which is manufactured by Plessy Peripherals of San Diego. (Supported by NIH Grant USPHS/NS 08962-11.)

657 Computer Classification of Somatic Evoked Potentials Using Euclidean Distance and Cross Correlation.
E. Carlton, S. Katz, and L. Martin.* Department of Physiology, Medical University of South Carolina Charleston, South Carolina 29403

Computer classification of somatic evoked potentials (SEP) obtained from monkeys subjected to different spinal cord lesions was based on two different discriminant functions: cross correlation and Euclidean distance. Prototype SEPs were chosen arbitrarily from each lesion class. Each unknown SEP was classified according to its relationship with the prototype. In the minimum distance classification procedure, the Euclidean distance between the unknown and each prototype is calculated. The unknown is then assigned to the class of the prototype for which this distance is minimum. In the cross correlation classification, the correlation coefficient between the unknown and each prototype is calculated. The unknown is then assigned to the class of the prototype for which this coefficient is maximum.

In a series of experiments, monkeys were subjected to 3 different spinal cord lesions (anterolateral, hemisection, and central). Prior to the lesion three control SEPs were recorded from electrodes implanted in the skull overlying upper limb and lower limb SSI. A week after the lesion three SEPs were again recorded from each of these areas. For each lesion, the SEPs from three different monkeys were used for computer classification. Two of the three recorded SEPS from each monkey were taken as prototypes from each class. The third SEP was the unknown to be classified. Thus, the classification programs were asked to assign each of 18 unknowns to one of four classes: normal, anterolateral lesion, hemisection lesion, and central lesion. Both procedures classified over 90% of the unknowns correctly. The Euclidean distance program made more correct classifications than the cross correlation program, indicating the significance of both size and shape parameters in the decision-making process. (Supported partly by research grant NINDS NS11066).

658 VISUALLY EVOKED POTENTIALS AND AFTER-DISCHARGE AS A FUNCTION OF AROUSAL AND FRONTAL LESION IN RATS.
Peter G. Como*, Rhawn Joseph*, D. Fiducia*, J. Siegel and J. Lukas*. Dept. Psychology & Instit. for Neuroscience & Behavior, Univ. Delaware, Newark, DE 19711

Differences in tendencies to augment or reduce, defined as the increments or decrements in amplitude of visually evoked potentials (VEP) to increasing intensities of light stimulation (Lukas & Siegel, Science, 198: 73, 1977) are believed to be related to level of arousal. Since frontal cortex has been implicated in control of arousal, two experiments were conducted to determine augmenting/reducing patterns in primary VEPs, N1-P2, and the 1st component of the photic after-discharge, N3-P4, preceeding and following lesions to area 8. In addition, behavioral responsiveness of lesioned and control Ss was measured and compared with the electrophysiological data.

In Experiment 1, Ss were implanted with electrodes over area 17, and following recovery were tested on two separate occasions. Five intensities were presented in random blocks of 30 flashes (1 per 5 sec.) and computer averaged. Slopes for peak to peak amplitude of the first (N1-P2, 30 msec) and third (N3-P4, 115 msec) components were computed and compared. In Experiment 2, all Ss were lesioned bilaterally in area 8 (2 mA for 20 sec.). Rats were then tested on the 1st, 7th and 37th day post lesion as described in Exp. 1. Subjects were found to demonstrate either augmenting or reducing of the first component. However, following lesion, VEP reduction was reversed such that all Ss yielded characteristic augmenting of the primary component. In addition it was found both pre- and post-lesion in response to increasing stimulus intensities and thus arousal, that the after-discharge component of the VEP showed corresponding decreases in amplitude, and in most Ss completely dropped out at the highest intensities.

In Experiment 3, to assess behavioral correlates of the electrophysiological effects of frontal lesion, 12 additional rats received either lesion or sham operations as described for Exp. 2. For 4 days beginning on the 7th and again on the 37th days following surgery Ss were tested in a closed field apparatus (Joseph, et al. Behav. Biol. 24: 364, 1978) to assess differential responsiveness and activity in a complex, novel environment (Joseph & Gallagher, Devel. Psychobiol. 1979, in press). It was found that the lesioned rats were significantly more active and responsive than the sham operated rats on the first 4 and last 4 testing days. Surprisingly, no subsequent decreases were found in activity as a function of testing sessions. Viewed together the electrophysiological and behavioral data suggest that lesions to area 8 result in or maintain the augmenting VEP and results in increased behavioral responsiveness. These findings suggest that VEP augmenting/reducing and degree of behavioral responsiveness are both functions of frontal pole control of arousal level.

659 FREQUENCY RESPONSE CHARACTERISTICS OF THE SOMATOSENSORY EVOKED RESPONSE SYSTEM.
D. E. Dallman,*J. Trimble and D. J. Smith*, USVA Hospital, Research Service, RER&D Center, Hines, IL 60141

Somatosensory evoked responses to transient stimuli (SERs) have received widespread application in diagnosis of somesthetic disorders. Such disorders frequently alter SER latency, amplitude or waveform. However, this is not always the case, and it is often difficult to correlate SER changes with the underlying neurophysiology (Hume, A.L. and Cant, B.R., EEG. Clin. Neurophysiol., 45:361-875, 1978). One reason for this is the difficulty in describing the complex SER waveform.

Recently, Namerow, et.al., (EEG. Clin. Neurophysiol., 37:11-21, 1974) introduced a method utilizing high-frequency stimuli which produces a sinusoidal SER (steady-state SER or SSER) quantifiable by two parameters: amplitude and latency or phase. They report a relation between stimulus frequency and response amplitude (frequency-response curve or FRC) which changes with diseases such as multiple sclerosis.

We have utilized a variation of this method to study the FRC for the somatosensory system, as well as FRC changes with disease. Five neurologically normal adults were tested on three occasions. Pulsatile stimuli at frequencies from 5 Hz to 50 Hz were delivered transcutaneously to either median or peroneal nerves at current levels between 2 and 6 mA. The SSER was recorded bipolarly from electrodes at Fz and Pz using a reference at Cz (10/20 system). Potentials were amplified by $2x10^5$ with a passband of 1 Hz to 1 kHz, and stored on FM tape for off-line analysis by digital computer (DEC PDP 11/10).

Recorded data were digitized at 200 pts/sec. Ensemble averages were computed for 50 responses with a sample epoch of 400 msec. The ensemble averages were then filtered with a high-Q, narrow-band digital filter centered at the stimulus frequency. The SSER magnitude was estimated from the root-mean-square value of the filtered ensemble average. The FRCs were then made by plotting SSER magnitude vs. stimulus frequency.

In the frequency range tested, for normals, the FRCs for median nerve stimulation show bandpass characteristics with a center frequency near 20 Hz. The FRCs for peroneal nerve stimulation show lowpass characteristics with a cut-off frequency between 5 and 10 Hz. Three patients with sciatica were then tested. Their neurological exam was unremarkable. The transient SER for one patient showed increased onset latency to L_5 stimulation. For all patients, the FRCs from the affected side were abnormal. With peroneal stimulation there was a marked decrease in the magnitude of the low-frequency portion. In one case, this change correlated with surgical findings. For median nerve stimulation, the FRC peak shifted to lower frequencies. Our results suggest the FRC may be an important measure of somatosensory function.

660 DEVELOPMENTAL CHANGES IN NEGATIVE COMPONENT (N2) OF EVENT-RELATED POTENTIALS RECORDED DURING REACTION TIME TASK.
Jorge H. Daruna, Rathe Karrer, Randall Cone*, and Charles Warren*. Illinois Inst. for Developmental Disabilities and Dept. of Psychology, Univ. of Illinois at Chicago Circle, Chicago, IL 60680.

Event-related-potentials have been recorded from children (6-8 yrs), preadolescents (10-13 yrs), and adolescents (16-18 yrs) engaged in a variety of information processing tasks, as part of a project investigating the changes in brain activity which accompany normal mental development and retardation. We report here on data obtained during a reaction time task.

A light flash presented at random intervals between 10 to 18 sec served as the stimulus. The subject responded by pressing a button with his dominant thumb. EEG was recorded DC from a vertex lead referred to linked ears. Eye movements were monitored by electrodes placed above and below the left eye. The data was digitized (250 pts/sec) and edited offline using a PDP 11/10.

Individual subject averages were computed using the ten trials with the fastest reaction times. For each subject's waveform it was possible to identify a prominent negative peak preceeding the maximum positive peak evident during the first 500 msec of the epoch. This negative component resembles the N2 component observed by Ritter et al. (Science,203:1358,1979) and may thus reflect a decision process related to sensory discrimination or stimulus identification.

Reaction time, measured from stimulus to thumb EMG, showed an inverse relation to age. The N2 component had the longest latency for the children ($\bar{X}$=246 msec,SEM=10,N=23). Its latency did not differ for the preadolescents ($\bar{X}$=177 msec,SEM=10,N=17) and the adolescents ($\bar{X}$=183 msec,SEM=05,N=22). N2 always preceeded the response for both the children and the preadolescents, but not the adolescents. Correlations between N2 and reaction time were as follows: children ($r=.74$, $p<.01$), preadolescents ($r=.65$, $p<.01$) and adolescents ($r=-.24$, n.s.).

The findings suggest that during a simple reaction time task the older subjects can dissociate response initiation from the sort of stimulus identification reflected in the N2 component. In contrast, the younger subjects must identify the stimulus before responding. This highlights the changes in subjective task demands with cognitive and motor development.

(Supported by NICHD grant HD 08265)

661 EFFECT OF ENVIRONMENTAL SCALE OF SUBJECTS ON SPECTRAL EEG OUTPUT. Alton J. De Long* and Joel F. Lubar. Sch. Arch., Dept. Psych., Univ. Tenn., Knoxville, TN 37916

Three studies were conducted varying the environmental scale of subjects. The purpose was to assess changes in neurological functioning as postulated by a theory of experiential space-time relativity.

Environmental scale was manipulated three-dimensionally, two-dimensionally, and perceptually through color. Each study involved a comparison between large and small scale conditions. In the first study scale contrast consisted of exposure to the full-size laboratory environment, and a 1/12 scale-model replica of this space. In the second study, subjects viewed different image sizes of projected slides, the smaller being 1/3 the scale of the larger. In the third study scale contrast was provided perceptually by presentation of receding(cold) and approaching(warm) colors.

Neurological functioning was measured through absolute and percent power output of the left and right central cortex across seven EEG spectral bands comprising the range of 0-27 Hz. Scalp electrodes were placed bilaterally over the motor cortex with active electrodes placed 10% and 30%, measured from the vertex to the ipsilateral ear with an ear-lobe ground. Data were analyzed according to a spectral program employing the Fast Fourier Transform.

Results of all three studies indicate two principal effects of reduced environmental scale on spectral EEG output: 1)an increase in absolute power output across all spectral ranges, and 2) a selective increase in percent power output across the higher frequencies (16-27 Hz).

These findings are consistent with the theory of experiential space-time relativity which postulates that the rather precise mediation of temporal experience by spatial scale (De Long,1978, Technische Universität Berlin--Dokumentation, 6:344-358) should exhibit neurological correlates. The selective increase in percent power output for higher frequency ranges seems compatible with the experience of time passing more swiftly for subjects under scale-reduced conditions. The increase in absolute power output across all spectral ranges still eludes interpretation, but appears consistent with reports by subjects that the compression of temporal intervals under scale-reduced conditions is experienced as being intense -- the temporal intervals feeling densely packed.

When considered in conjunction with the space-time theory,these findings suggest environmental scale may play a central role in mediating changes in neurological functioning associated with maturational development. Current studies are examining the potential role of environmental scale in maturational development and the etiology of hyperkinesis. [Research supported by The Office of Graduate Studies and Research, University of Tennessee]

662 THE SOMATOSENSORY EVOKED POTENTIAL IN THE NORTH AMERICAN OPOSSUM: EFFECTS OF INTERACTION OF PERIPHERAL NERVE INPUTS. R. M. Dom*, J. G. Blackburn, R. K. Simpson and S. Katz. Depts. Anat. and Physiol., Medical Univ. South Carolina, Charleston, SC 29403.

Alterations of the somatosensory evoked potential (SEP) resulting from interaction of peripheral nerve inputs were studied in adult opossums anesthetized with alpha chloralose. In all cases, the averaged SEP was recorded from the forepaw area of the cerebral cortex (Lende, J. Comp. Neur., 121: 395-404, 1963) with the superficial peroneal nerve being stimulated (conditioning stimulus) at different time intervals prior to stimulation of the superficial radial nerve (test stimulus). Maximal interaction was present at stimulus delay intervals ranging from 100 to 200 msec. The primary component of the SEP is most attenuated at 100 msec, whereas the secondary responses remain depressed for a longer time interval.

The similarity of the interactive responses in the opossum to prior observations in the cat and monkey indicates that interaction may be a cortical phenomenon characteristic of mammals. Because of the potential usefulness of interaction studies in evaluation of spinal trauma, the relatively nonspecialized central nervous system of this pouched mammal may prove to be a useful model for spinal cord injury studies.

663 ADVANCES IN CLINICAL NEUROPHYSIOLOGY. PSYCHIATRIC RELEVANCE. B. Dubrovsky. Allan Memorial Institute, McGill University, Montreal, Quebec, Canada.

Recording of event-related slow potentials (ERSP) during activities that require the active engagement of subjects has turned out to be a useful, atraumatic method of exploration of brain activity in psychiatric populations. From the various ERSP, the contingent negative variation, CNV, has been one of the most extensively studied. While in normal control populations the resolution of the CNV, that is the return of the negative wave to the baseline level occurs immediately after S_2, a significant number of psychotic patients show an apparent prolongation of the negativity which extends for more than 2 sec. after S_2. Different brain reactivity to peripheral stimuli during persistence negativity suggest that neural activity generating it is at least partly independent from the CNV per se. Dongier (In Biol. Diagn. of Brain Disord. S. Bogoch Ed. p. 47; 1973) has named this prolongation post-imperative negative variation (PINV). Moreover, metabolic changes (varying concentrations of CO_2 measured in the expired air) selectively affect PINVs (Dubrovsky et al. Biol. Psychiat. 11 535; 1976) without significantly affecting amplitude and duration of CNV waves per se. In other context, significant differences viz. larger CNV amplitude, abnormally prolonged PINVs and shorter reaction times were found when using phobogenic stimuli as S_2 in patients suffering from specific phobias. After successful treatment with relaxation desensitization therapy, the CNVs of the patients were within normal limits. These results led us to propose a neural mechanism for relaxation desensitization therapy. Regions in the hypothalamus and limbic system mediate, at least in part, certain global emotional reactions such as fear. Most animals form associations as long as the modality to which the association is made is a limbic modality (Gershwind, Brain 88; 237, 1965). We propose that the pairing of a pleasurable condition (relaxation) with phobogenic stimuli establishes a new association, presumably in limbic structures involved in these emotional states. Limbic frontal connections (Nauta, Psychiat. Res. 8; 167, 1971) can then act in part as modulators of frontal regions from where CNVs are mainly generated. The functional connections between the relaxed condition and phobogenic stimuli established through the desensitization treatment, possibly involving limbic regions, would then affect the gain of the threshold mechanism for CNV generation in frontal regions (Loveless and Sanford, Biol. Psychol. 2; 217, 1975) and consequently affect CNV amplitude and duration. For us mental pathology is the result of regional disorganization of neural activity rather than "dissolution" or "regression".

664 NEUROPHYSIOLOGICAL LOCALIZATION OF DYSLEXIA. Frank H. Duffy, and Martha B. Denckla* (SPON: M. Duchowny). Seizure Unit and Department of Neurology, Children's Hospital & Harvard Med. Sch. Boston, MA 02115.

EEG and evoked potential data were recorded from 8 dyslexic and 10 control children aged 9-11. Data were collected during test situations designed to activate the left hemisphere (reading, listening to speech), right hemisphere (recognizing geometric forms, listening to music), both hemispheres (sound-symbol association, phonemic discrimination), or neither hemisphere, (resting EEG and evoked response). EEG spectra and evoked potentials were formed from 20 electrodes and the resultant waveforms were processed into topographic maps of brain electrical activity. Separate topographic maps of the average (mean) electrical activity for the control and dyslexic groups was formed for each test state. Topographic maps of group difference were formed following statistical tests and were used to delineate regions of the brain where the 2 groups differed. In addition to a large area of group difference overlying the left temporal and parietal regions, prominent differences were found over both hemispheres, in the frontal lobe overlying left Broca's area and the bilateral medial supplementary motor area. Thus, dyslexia appears to involve more cortex than would be predicted by analogy to adult-onset aphasia. The areas implicated above are analogous to regions shown by others to be active in normals during reading and speech (isotope radiography). We suggest that dyslexia represents a "system deficit" rather than an isolated "lesion."

665 SELECTIVE ATTENTION, P300, AND POSSIBLE REGIONAL CEREBRAL BLOOD FLOW CORRELATES. Dragoslav Ercegovac*, Richard C. Josiassen*, Richard A. Roemer and Charles Shagass*. Eastern Pennsylvania Psychiatric Institute and Temple University Health Sciences Center, Philadelphia PA 19129.

There is growing acceptance that selective attention to task-related sensory stimuli which resolve a subject's uncertainty elicit a cerebral evoked potential (EP) of 250-500 msec peak latency, namely the P300. The first section of this report examines somatosensory EPs elicited by random sequences of electrical stimulation of four different fingers, where the subject is instructed to attend only to the number of stimuli delivered to one finger which has been designated the "target finger". Electrical stimulation of non-target fingers is to be ignored. Following the work of Desmedt et al (1977), the authors have replicated the finding that reliable P300 components may be obtained using this selective attention task. Robust P300 components were recorded over the central-parietal region contralateral to target finger stimulation.

The experimental group was comprised of 25 normal adult volunteers. All subjects were screened for disorders of skin sensation, bone fractures, head trauma, and brain disease.

It is the hypothesis of this report that these obvious somatosensory EPs are accompanied by systematic changes in regional cerebral blood flow. This hypothesis is based on the general observation that mental activity increases circumscribed regional cerebral blood flow. Using impedance plethysmography procedures (rheoencephalography), it is possible to calculate a blood flow index which is highly correlated with cerebral blood flow. The rheoencephalographic method used in this study follows the procedure of Jacquay et al (1974).

Within the context of the identical selective attention paradigm, rheoencephalographic data were obtained to test the hypothesis that mental activity which elicits robust cerebral electrical potentials is accompanied by measureable cerebral blood flow changes.

666 AUDITORY EARLY, MIDDLE AND LONG LATENCY EVOKED POTENTIALS IN CAT. Glenn R. Farley* and Arnold Starr. Depts. of Psychobiology and Neurology, Univ. of Calif., Irvine, Irvine, CA 92717.

We are studying early, middle, and long latency (1-650 msec) averaged evoked potential (AEP) components of muscle-paralyzed cats to define their relationship to evoked potentials recorded from man. We are using behavioral paradigms designed to control arousal and attentional state. In behavioral "habituation," 500 msec noise bursts are presented once every 25-65 sec against a background of continuously presented (1/sec) clicks. In "sensitization," clicks and noise are presented as above, along with a tail shock once every 25-65 sec. The shock has a random temporal relation to the noise. "Conditioning" is similar to sensitization except that the tail shock invariably follows noise onset by 5 sec. The behavior indicating learning of this association is a pupillary dilation that is temporally related to the noise. Averaged evoked potentials are recorded from each of 17 skull electrodes to clicks immediately preceding and following the noise, and to the noise itself, during each of the behavioral paradigms. Multivariate statistical analyses are applied to these waveforms for determination of AEP components. Factor scores of the AEP waveforms for each component are derived, and subjected to further analysis to find which experimental manipulations control each component. Results show that various components vary differentially with the physical parameters of the stimuli (clicks, noise), the behavioral context in which the stimuli are presented, and the topographical distribution of the potentials across the skull surface. These results suggest that some of these components may be useful models of some human auditory evoked potential components which show similar controlling factors.

667 EEG CORRELATES OF TEXT THEMATIC STRUCTURE. E.Françozo* and A.F.Rocha* (SPON:C.Timo-Iaria) Dept.Phys.Bioph., UNICAMP, 13100 Campinas, SP, Brasil.

Text structures can be studied through the notions of *theme* (information on which the text is built up) and *rheme* (what the text informs about its theme).This conceptual pair can be viewed as the counterpart of the pair *topic* and *comment* at the level of sentences. Linguistic stimuli have already been demonstrated to evoke EEG responses correlated to functions and properties of natural languages. Our purpose here is to report the existence of correlations between evoked responses and thematic structures of texts, the dynamics of such correlations and their linguistic relevance.We presented a previously recorded text to the subjects while their EEG was recorded and, immediately after, asked them to reproduce it in written and then to point to its theme. The whole procedure was repeated twice within an interval of 30 minutes. Results can be thus summarized: i) two context dependent strategies were used by the subjects during text reproduction: a *divergent* one, in which the theme was given in the first sentences of the reproduction, and the rheme followed, and another, *convergent*, in which a set of arguments was given first, and theme followed; ii) the thematic structure defining elements evoked a characteristic electrical activity pattern; iii) the EEG activity reflected accurately the syntactic or semantic performance of the subjects; iv) in the subject's convergent approach to the text, only comments evoked marked patterns in the EEG, while when a divergent strategy was used both topics and comments evoked responses.The above data seem to indicate: a) the existence of responses evoked in the EEG by the thematization and topicalization structures of natural languages; b) that the relationship between such structures depends on a context dependent strategy; c) that relevant linguistic data can be obtained from the EEG by means of an adequate methodology which takes into account pertinent theoretical parameters.

668 EFFECT OF CHRONIC HALOTHANE EXPOSURE ON SENSORY EVOKED POTENTIALS IN FREELY BEHAVING RATS. G.N. FULLER, B.M. RIGOR*, R.C. WIGGINS and N. DAFNY. Depts. of Neurobiol. & Anat. and Anesthes., Univ. of Texas Med. Sch., Houston, TX 77025.

Chronic halothane exposure has been implicated in pathologic changes in several peripheral organs. The present study was initiated to determine if chronic halothane exposure has any effect on bioelectrical activity recorded simultaneously from two different deep brain nuclei. Sensory evoked field potentials were employed as a measuring tool to assess halothane induced alterations in bioelectrical activity. The target nuclei in the present study were the mesencephalic central gray and the nucleus parafascicularis, two deep structure mediators of analgesia and anesthesia. Permanent semimicroelectrodes (60μ diameter) were implanted stereotaxically under pentobarbital anesthesia several days prior to experimentation. The averaged acoustic evoked response (AAER) following 32 repetitive click stimuli was recorded from both regions in halothane naive freely behaving rats on day 1. The rats were subsequently exposed to 0.25% halothane delivered through a vaporizer (Fluotec 3) with compressed air for 3 hrs per day, 5 days a week. AAER recording was resumed at 28 and 56 days after the initial daily exposure of halothane. The AAER consists of a positive (P_1)-negative (N_1) spike followed by a positive-negative-positive (P_2-N_2-P_3) wave. The last three components were consistently observed within and between animals and were therefore quantitated and compared to naive values. After 28 days of chronic exposure, no significant changes were observed in the recording obtained from the central gray as compared to the day 1 recording. In contrast to this, in the nucleus parafascicularis the P_2 and P_3 components showed a statistically significant ($p<0.01$ and 0.05 respectively) increase in amplitude (paired t test). Following 56 days of halothane exposure, the N_2 and P_3 components of the central gray AAER were statistically increased ($p<0.05$ and 0.005 respectively) over naive values. In the nucleus parafascicularis, the P_2 and P_3 components remained increased as at 28 days but with a more significant value for P_3 ($p<0.005$). Thus although a general increase in AAER amplitudes is seen in both regions examined, the time course and individual components affected vary markedly. These data demonstrate a pronounced alteration of sensory evoked potentials following chronic halothane exposure. (Supported in part by USPHS grant no. NS-14355.)

669 EEG CORRELATES OF SEX AND SCHIZOPHRENIA. Duilio Giannitrapani. Veterans Administration Medical Center, Perry Point, MD 21902.

EEG sex differences, with particular reference to power, phase angle and coherence spectra, were compared to those found in schizophrenia. Eighteen males and 18 females, 11 to 13 year-old right preferents, were selected. Subjects were administered an EEG during which spectra were obtained from 16 brain areas between 2 and 34 Hz in 16 frequency bands, each 2 Hz wide.

Power spectra show overall greater power in the males except in the left occipital area in the 2 - 10 frequency range where the opposite was true for the females. The areas in which the females show greater power slowly broaden with increasing frequency. The broadest distributions occur in the 19, 21, 29 and 33 frequency bands, possibly indicating a broader distribution of the 2nd and 3rd harmonic of dominant activity in females, also found in schizophrenics by this investigator.

In the phase angle analysis in the 13 Hz activity, males show predominant significant anterior leading while females show significant posterior leading. A similar pattern has already been shown by this investigator for schizophrenics and normal adults respectively.

Coherence in general is higher in females in anterior areas and in males in posterior areas bilaterally. An exception is the 29 and 33 Hz activity, showing higher coherence in females in all comparisons, also found by this investigator in schizophrenics.

The 13 Hz phase angle finding and the 29 Hz power and coherence spectral finding are in contradiction in regard to the hypothesized sex-relatedness of schizophrenia. The 13 Hz finding is consistent with greater vulnerability toward schizophrenia in males while the 29 Hz data for the females correlates with higher power and coherence found by this investigator among schizophrenics. An attempt is made to coordinate the data from the three parameters studied and relate them to the known unequal distribution of psychopathological incidence among the sexes.

The data points to a physiological substratum of schizophrenia. Inferences could be made for the genesis of the underlying morphological differences which would have to go back to the early ontogenetic development of the brain when it still consists of a neural tube. The manner in which the ablateral holosphere becomes bilateral and develops into lobes as we know them would be at issue.

670 INTRACRANIAL DISTRIBUTION OF SOMATIC AND AUDITORY EVOKED POTENTIALS DURING SLEEP IN MAN. W.R. Goff, T. Allison, G.D. Goff*, C.C. Wood* and P.D. Williamson*. Neuropsychology Lab, West Haven VAMC and Dept. Neurol., Yale Sch. Med., New Haven, CT.

Analysis of morphological and topographical relationships between scalp and intracranially recorded evoked potentials is fundamental to inferring the cerebral origins of scalp activity. One approach is to record from the two areas under conditions known to alter scalp potentials and to determine the effects of these conditions upon intracranial potentials. Scalp recorded somatic (SEP) and auditory (AEP) evoked potentials undergo dramatic changes during sleep. Therefore we are comparing scalp and intracranial recordings during waking and different stages of sleep. To date five patients have been studied; they had up to six multicontact depth probes chronically implanted bilaterally in frontal, central, and occipital regions as part of an evaluation for possible neurosurgery to relieve intractable epilepsy. Simultaneous recordings were made from 16 contacts selected from up to 108 available contacts on the probes. In all patients, the gross morphological changes from waking to sleep seen in scalp potentials were also observed intracranially. In four patients, long latency SEPs and AEPs had different scalp-depth relationships during waking whereas scalp-depth relationships were similar for the two modalities during sleep. Emphasizing the tentative nature of data from a few patients with abnormal brains, these results are consistent with our previous suggestion (Goff et al., 1966) that long latency potentials occurring during waking and sleep reflect activity of different neural generators.

671 A MICROPROCESSOR SYSTEM FOR CORTICAL AND BRAINSTEM EVOKED RESPONSES. Steve H. Graham and M. E. Miner. Division of Neurosurgery, University of Texas Medical School, Houston, Texas 77030.

Recent advances in large scale integration have brought computer technology within the budget of almost every electrophysiological laboratory. The microprocessor, due to it's programability may be used to replace an assortment of electronic devices at a fraction of their cost. We have developed a microcomputer system to signal average up to 14 channels of cortical evoked potentials and one channel of brainstem evoked responses.

The system consists of a commercially available Z80 microcomputer with 64K RAM, dual 8 inch floppy disk, a CRT conversion, interval timers, interupt logic, and a parallel port. Using the interrupt timers, the system is able to perform three tasks simultaneously: acquire signal averaged data, display waveforms on an oscilliscope, and run the BASIC program that controls the sampling interval, number of points and number of repetitions to be averaged. Maxima and minima of the evoked potentials may be identified and their latencies from the stimulus computed. The peaks determined by the computer are displayed on the oscilliscope; manual review of the waveform and positioning of a cursor allows for correction if necessary. The waveforms and other data are stored on the floppy disk for later review and analysis. The A/D converter utilized has 8 bit resolution; therefore, one must compromise between maximal resolution and the possibility of the A/D converter being saturated. We have partially resolved this dilemma by not including any data in the sum if any of the channels contain a saturated data point. The parallel port is used to control external devices such as stimulators, allowing the microprocessor to supercede delay timers. Stimuli intervals may be randomized to prevent habituation.

672 EFFECTS OF GENOTYPE, AGE, INTERSTIMULUS INTERVAL (ISI), AND BINAURAL SUMMATION ON COCHLEAR AND AUDITORY BRAINSTEM EVOKED RESPONSES (BSER's) IN THE LABORATORY MOUSE. Kenneth R. Henry. Dept. Psychol., University of California, Davis, Ca. 95616.

Several recent studies have shown that, as the ISI is decreased, the amplitudes and latencies of the various components of the BSER show differing recovery rates. These responses also differ in the human neonate, adult, and geriatric adult (Fujikawa and Weber, 1977). A binaural occlusive effect also occurs with P_{IV} in the cat (Huang and Buchwald, 1978) and P_V in man (Blegvad, 1975).

Mice of the C57BL/6 and CBA/J strains, from 20 to 380 days of age, were used for these studies. The former genotype expresses a progressive postpubertal hearing loss, while the latter maintains its hearing throughout its life (Henry, 1979).

As the ISI was decreased from 100 to 50 to 25 to 12.5 msec, latencies increased by 66, 141, 163, 188, and 356 μsec for P_I-P_V, respectively, regardless of age and genotype. For the CBA genotype, decreasing the ISI reduced all amplitudes by approximately 45%. The C57BL/6 mouse also had this same 45% amplitude decline for P_I, P_{II} and P_{IV}, but its P_{III} and P_V responses only declined by 25% with decreasing ISI.

When monaural and binaural responses were compared, all ages and genotypes showed the same effect. For P_{I-III}, binaural stimulation produced the same responses as did summing the responses obtained by monaurally stimulating the two ears. For P_{IV} & $_V$, however, binaural stimulation reduced the amplitude by 25% and 60%, respectively.

673 SPATIAL AND TEMPORAL DISTRIBUTIONS OF NARROW AND WIDE BAND SOMATICALLY EVOKED FIELDS IN HUMANS. A. Joseph Lipton*, Lloyd Kaufman*, Samuel J. Williamson*, and Douglas Brenner. Neuromagnetism Laboratory, Depts. of Physics and Psychology, NYU, New York, NY 10003.

A Superconducting Quantum Interference Device (SQUID) demonstrating high spatial resolution in measurements of evoked cortical activity was used to elucidate the spatial and temporal distributions of somatically evoked fields (SEF) associated with median nerve stimulation in humans. Reliable narrow and wide band measurements were made over the somatosensory areas with both contralateral and ipsilateral stimulation. 1 msec transcutaneous pulses were delivered at 20 Hz for the mapping aspects of the study. Detectable evoked fields were clearly distributed over the contralateral cortex only. Within the 1 cm spatial resolution of the system, activity was well modeled by a single current dipole oriented normal to the central gyrus, although evidence for other nearby sources was found. For both steady-state and transient measurements a 180^{o} polarity reversal of the field occurred within a 3 cm scan through the hypothesized dipole with response amplitudes reduced to 50% of peak values within 2 cm. Simultaneously recorded narrow and wide band magnetic responses at stimulation frequencies between 1-12 Hz allowed the comparison of waveform and latency derived from wideband somatically evoked potential (SEP) measurements with those derived from wide as well as narrow band SEF measurements. Although the basic components of the wideband SEF, characterized by early components followed by a much longer and slower component, were similar to the earliest cortical components of the SEP their respective onset latencies of 70 and 30 msec did not agree. No unique latency could be derived from narrow band measures, as derived latency varied over different ranges of measurement.

674 THE RELATIVE CONTRIBUTIONS OF PERIPHERAL NERVES TO THE SOMATOSENSORY EVOKED POTENTIAL. Joel Myklebust*, Joseph Cusick. Med. Coll. of Wis. and Wood V.A. Med. Ctr., Milw., WI.

The relative contributions of cutaneous and muscle afferents to the somatosensory evoked potential (SSEP) are not well established. In this study, the SSEP elicited by mixed nerves (the common peroneal at the fibular head, and the posterior tibial at the ankle) and primarily cutaneous nerves (the deep peroneal nerve distal to the bifurcation of most muscular branches, and the sural nerve at the ankle) were compared in man and in the stumptail macaque monkey.

In the human, stimulation was applied through stainless steel disc electrodes, and recordings were made from needle electrodes placed in the scalp over the somatosensory cortex. In the monkey, the nerves were surgically exposed and stimulated with hook electrodes. Recordings were made with platinum disc electrodes placed epidurally over cauda equina (CE), conus medullaris (CM), thoracic spinal cord, and sensory-motor cortex (SMC).

In the human, the response to stimulation of common peroneal (mixed) nerve at levels below the motor threshold was almost identical to that obtained with supramaximal stimulation of the sural and deep peroneal (cutaneous) nerves. With increased stimulus intensity, the common peroneal response appeared at a shorter latency and, in some cases, with an altered waveform. In contrast, no threshold effects were observed with stimulation of the sural or deep peroneal nerves. Stimulation of the tibial nerve at levels below motor threshold produced a response at approximately the same latency as that for the sural and deep peroneal nerves. Increased stimulus intensity produced an earlier response with an altered waveform.

In the monkey, low level stimulation of all four nerves elicited a complex tract response at CE. Increased stimulus intensity on the common peroneal and tibial nerves produced an earlier, large triphasic potential. At CM and the thoracic cord, the tibial and common peroneal responses had shorter latencies and were more compressed temporally than with sural nerve stimulation. At SMC, the responses from the tibial and peroneal nerves were shorter in latency than the sural nerve response.

These results indicate that, with mixed nerve stimulation, the fast, early portions of the SSEP are probably due to muscle afferents, while the later, slower components result from cutaneous fibers.

675 RELATIONSHIP BETWEEN INTRACRANIAL PRESSURE AND LATENCY SHIFT IN VISUAL EVOKED POTENTIAL. Morris Pulliam, Donald H. York, Clark Watts and John G. Rosenfeld*. Dept. of Physiology and Section of Neurosurgery, School of Medicine, University of Missouri, Columbia, MO 65212. Previous studies have suggested that increases in intracranial pressure (ICP) as a consequence of hydrocephalus may compress the visual radiation fibers as they course through the lateral ventricle. The present study was designed to test the hypothesis that increases in ICP would cause consistent shifts in latency of waves constituting the visual evoked potential (VEP). An initial pilot study was undertaken on a 16-year-old head injury patient who had a pressure transducer placed epidurally to monitor ICP. Visual evoked responses were conducted over a 10-hour period to provide 18 independent assessments. The VEP was measured by differential recording from surface electrodes at O_1, O_2 (International 10-20 system). The stimulus was a strobe flash delivered to the eyes at a rate of 1/sec. Each flash generated a VEP which was averaged in a computer of average transients for 75-100 successive responses. The peak of each major positive and negative going wave component was identified by subsequent analysis in a microprocessor which assigned latency values to each peak. Latency values for eight component peaks of the VEP up to 256 msec were then correlated at 21 different intracranial pressures over the 10-hour time period. The results show a linear correlation (r=0.68) of ICP with increased latency of the N70 peak. This would suggest that VEP measurement may provide a non-invasive estimate of intracranial pressure. The second part of the study sought to examine this relationship by studying the VEP response in children with hydrocephalus or symptoms of raised ICP. Using age matched controls of normal children as baseline, 9 of fourteen children demonstrated an increase in latency of N71 wave, whereas all 14 also showed an increase in latency of N138 wave. These findings taken together with the pilot study conducted with ICP monitoring suggest that the VEP may provide an important clinical tool for the assessment of raised ICP.

676 BRAINSTEM AUDITORY EVOKED RESPONSE AS A TOOL IN NEUROTOXICOLOGY AND OCCUPATIONAL MEDICINE. Charles S. Rebert. Neuroscience Laboratory, SRI International, Menlo Park, CA 94025

Event related potentials are becoming increasingly useful in assessing the integrity of the nervous system, and so are of potential benefit in evaluating the effects of exposures to neurotoxins--perhaps especially in indexing sub clinical deficits. Advantages of ERP methods include their objectivity, situational versatility, unique information content, cultural nonspecificity and usefulness in both animals and humans. The brainstem auditory evoked response (BAER) is most useful because of its consistency, ease of recording, relatively well known genesis, need for minimal patient cooperation, homology of animal and human responses, demonstrated sensitivity to clinical dysfunction and separability of peripheral and central components.

Little use has been made of BAERs in the evaluation of chemical toxicity although it has been shown to be modified by alcohol (Squires et al. 1978) and by triethyltin (Shah et al. 1978). To further evaluate the efficacy of the BAER as an index of neurotoxicity, chronically implanted young Fischer rats were administered misonidazole, a neurotoxic radiation-enhancing compound of possible use in cancer therapy.

Five rats were given ip injections of 300 mg/kg 5 days/week and 5 were controls. No changes in BAERs occurred in controls for 22 days so they were subsequently injected with 250 mg/kg. Two animals died after the fifth high dose and no changes in BAERs were seen. In the other 3 rats peak conduction times increased to 2.55, 2.58 and 2.48 msec from an average baseline of 2.03 msec. As expected, there was a consistent lengthening of latency for all components as stimulus intensity was reduced. The low dose produced no obvious behavioral toxicity before two weeks. The latency of components 3 and 5 exceeded 1.96 SDs of the baseline mean from the 14th through 35th day. There was a significant change in component 1 only at the lowest intensity. These results suggest that the peripheral mechanisms were relatively spared. For all three intensities the .025 probability level for central conduction time was exceeded by the 14th day. Average conduction times increased from a baseline of 2.09 msec to a peak of 2.33 msec. Recovery began soon after injections terminated but were not fully normal after 13 days.

These results indicate that the BAER can be a robust index of neurotoxicity. Clinical utility of the BAER in this context is suggested by our findings (Rebert, Schaeffer and Dahlgren) that a large proportion of industrial workers exposed to heavy metals and solvents have prolonged central conduction times.

677 THE GENERATORS OF THE AUDITORY BRAIN STEM POTENTIALS AS STUDIED BY DEPTH RECORDING IN THE CAT. Foster K. Redding, Richard J. Meltzer*. Dept. Neurol, Wayne State U. Sch. Med. Detroit, MI.

Short latency evoked potentials were first recorded from the intact skull of the cat, using averaging techniques. Subsequently, an amazingly similiar series of positive deflections were recorded following click stimuli in the intact human. Evoked potentials have proved clinically useful in patients with lesions of the brain stem.

Methods: A laminar analysis of the auditory evoked potential waves was made in 19 barbiturate-anesthetized cats. Fine stainless steel wire electrodes were placed stereotaxically at a calculated oblique angle into the superior olivary nucleus(SO), the lateral lemniscus (LL), and the inferior colliculus(IC). Conventional responses were recorded from an electrode at the vertex, all recordings using a reference in the pinna. Clicks were delivered through hollow ear bars. The recording parameters and averaging and read-out routines were the same as those used by other workers.

Results: A series of 4 to 6 positive waves were recorded from the vertex, identical to those reported by others. These ranged up to 6 or 7 ms. in latency, and had amplitudes in the 1 microvolt range.

Evoked potentials recorded directly from the depth in the brain stem were of much greater amplitude, so that they could clearly be seen on the oscilloscope face even without averaging. At each stereotaxic target point, a series of 2 or 3 positive or biphasic waves were recorded. As the electrode was advanced gradually, the waves remained of uniform configuration over a length of 4 or 5 mm. A locus of maximum amplitude could easily be found. This was presumed to be the center of the neural activity.

Latency of the first of the series of waves of each evoked potential, was shortest at SO. The first wave occurred progressively slightly later at LL and at IC. The amplitude of the waves was clearly greatest at SO, and successively somewhat lower at LL and at IC.

The precise latencies of the peaks of the waves recorded from the several brain stem electrodes did not all exactly correlate with each other, nor with the exact latencies of the peaks recorded from the vertex.

These results agree with the preliminary descriptions of Starr and Achor. It is clear that a simplistic "generator" theory of the origin of the vertex-recorded auditory evoked potential is untenable. A more complex analysis, analogous to that of the electrocardiogram recorded from the surface of the body, is needed.

678 PREDICTION OF CLINICAL PSYCHIATRIC CHARACTERISTICS BY MEANS OF CLUSTER ANALYZED EVOKED POTENTIAL MEASURES. Richard A. Roemer and Charles Shagass*. Temple University and Eastern Pennsylvania Institute. Philadelphia, Pa. 19129

This presentation reports the initial results of a rational, stepwise analysis of evoked potential (EP) measures conducted for the purpose of predicting clinical psychological characteristics by electrophysiological methods. Subjects were a diagnostically heterogeneous, consecutively tested group of 145 unmedicated psychiatric inpatients. Somatosensory (SEP), visual (VEP) and auditory (AEP) EPs were recorded in one session, using pseudorandomly presented left (LSEP) and right (RSEP) median nerve shocks, checkerboard pattern flashes and binaural auditory clicks. Recordings were made from one EOG and 14 scalp leads. Clinical criteria were as follows: (a) psychiatric diagnosis--discharge diagnosis independently made by two senior psychiatrists; (b) symptom ratings--16 Brief Psychiatric Rating Scale (BPRS) items rated by a psychiatrist; (c) intelligence--Raven's Progressive Matrices.

Visual detection of EP peaks in key leads provided estimates of the latency of each of 11 or 12 consecutive peaks (depending on the type of stimulus). The estimates were used to automatically determine the amplitude of each peak in all scalp and EOG records.

The first stage of analysis was to reduce the dimensionality of the data by extracting the factors involved in the spatial distribution of each peak. A varimax-rotated factor analysis of the amplitudes for a given peak at all leads usually resulted in the extraction of five factors, one of which often reflected EOG activity. The resulting factor scores for all peaks of a given type of EP for the 145 patients were subjected to hierarchical cluster analysis. Using RSEP factor scores as an example, six distinct clusters of patients were identified, and the results so far obtained indicate that two of these clusters contained a large weighting of depressive patients. Other RSEP clusters were significantly related to the intelligence measure and to ratings of anxiety.

The encouraging results justify further research aimed at classifying psychiatric patients by means of EPs to identify clinically meaningful subgroups that transcend conventional diagnostic categories.

Support (in part) by USPHS Grant MH 12507.

679 CONTRIBUTIONS TO THE SEP BY THE MAJOR ASCENDING SENSORY PATHWAYS. Richard K. Simpson Jr., John G. Blackburn, Henry F. Martin and Sidney Katz. Department of Physiology., Medical University of South Carolina, 171 Ashley Avenue, Charleston, South Carolina. 29403.

The contributions of various spinal cord pathways to the somatosensory evoked potential (SEP), was investigated in monkeys anesthetized with 70% N_2O and 30% O_2. SEPs were recorded in response to stimulation of exposed superficial peroneal nerves. Stimulus intensities were sufficient to excite either large diameter nerve fiber groups or all nerve fiber groups. While applying maximal stimulus intensities, the large diameter nerve fiber groups were blocked using a combination cooling and electrical polarization, (Blackburn, J.G. and Katz, S. 1976., J. Electrophysiol. Tech. 5:14-17.). This procedure allows selective small diameter nerve fiber input to continue. SEPs were recorded in response to stimulating various peripheral nerve fiber groups following either bilateral dorsal or anterolateral transection, left or right hemisection, and central cord lesion or complete cord transection at levels T3-T4. The results indicate that only the dorsal column system, (including the spinocervical tract), contributes to components P1 and N1. Only the anterolateral column systems contribute significantly to components P3 and N3. Both the dorsal and anterolateral column systems contribute to components P2 and N2. It appears that small diameter nerve fibers and the anterolateral columns contribute significantly to the later wave components of the SEP. The observation that both major ascending spinal cord pathways contribute to various components of the SEP enhances the possible utility of the SEP as a method of evaluation and treatment of human spinal cord injury. (Supported by NINDS grant P-5P81-NS-11066).

680 AUDITORY BRAIN STEM EVOKED POTENTIALS IN AUTISM. Barry F. Skoff*, Allan F. Mirsky. Laboratory of Neuropsychology, Boston University Medical Center, Boston, MA 02118.

Current theories of childhood autism suggest that the dysfunction is an organic one, primarily affecting perceptual and language mechanisms. Furthermore, it has been suggested that pathology involving the brain stem could explain many of the symptoms commonly seen in autistic children. The auditory brain stem evoked potential (ABSEP) is a simple, non-invasive method of assessing the integrity of the brain stem areas through which the auditory system courses.

In the present study, ABSEPs were acquired in a group of 20 children who had been diagnosed as autistic, or who exhibited autistic-like behaviors. Click stimuli (10 Hz., 60 dBSL) were presented monaurally to each ear, while the filtered (300-3K Hz.) EEG was recorded. Signal averaging was done off-line with artifact rejection.

Data from 3 children could not be analyzed. Of the remaining 17, 6 (or 35%) had abnormal ABSEPs when compared to a group of normal control subjects. One child had a prolonged latency in the components (I-III) said to reflect transmission from VIII nerve to pons. Four children had prolonged interwave III-V latencies (pons-midbrain) on at least one side, and 2 of these children apparently had no response when the other ear was stimulated. The remaining child had early waves I through III, and no detectable wave V (midbrain/inferior colliculus).

It appears that some form of brain stem pathology exists in at least some children that are diagnosed as autistic or exhibit autistic symptoms. The next step in elucidating the etiology of the syndrome is to determine whether there exists a correlation between brain stem pathology as shown by the ABSEP and specific behaviors or symptoms. The ABSEP may be eventually a simple and painless method of screening for early detection of childhood autism.

681 LUMBOSACRAL REPRESENTATION IN HUMAN CORTEX: SOMATOSENSORY EVOKED POTENTIALS RELATED TO DISCRETE TACTILE SENSATIONS IN THE ANOGENITAL REGION. H. Stowell, ERBP Unit, Central State Hospital, Milledgeville GA, USA.

Cortical representation of the body surface is of intrinsic interest to neurologists. Correlation of easily replicable, recognizable, natural sensations with cerebral electrophysiology is useful for understanding the functional significance of event related brain potentials (ERBP). Marginal mucocutaneous skin of anogenital regions has these advantages over other peripheral sites for recording somatosensory evoked potentials (SEP): (1) Transcutaneous electrical minipulses (0.03-0.08 ms), suitably entrained, elicit only tactile, superficial, and spatiotemporally discrete sensations, without shock overtones, for a wide range of qualities and magnitudes; (2) SEP so elicited are amplitude-focal at vertex, without polarity reversal laterally or evidence of electro-ocular interference; (3) risk of local muscular reflex is low (contrasted to median and other nerve-trunk stimulation); and (4) stimulation and recording sites are distant (compared to lip and orodontal sites, where sensation also tends to radiate).

For formal Informed Consent reasons, this intensive study was confined to two volunteers: an experienced male who self-paced his stimulus time-window, and a relatively naive female who received conventional, regularly repetitive stimulation programmed by the experimenter. Unequivocal results: (1) Anogenital SEP has later cortical processing times (peak latencies, 30-250 ms) than SEP for comparable stimulation, electrical and mechanical, eliciting comparable sensory magnitudes but different qualities, on hand and foot; also higher mean frequency in the intermediate time segment (50-175 ms) than is recordable for stimulation at other extremities; (2) its dipole origin seems not to be oriented normal to the gross medial surfaces of the hemispheres, as expected from the classical neuroanatomy.

It is hoped the above advantages will outweigh possible psychosocial disadvantages. This form of input might be a more sensitive probe than median nerve shock for diagnostic SEP recording in prospective surgical cases.

682 TRANSIENT WAVE ADJUSTMENT: AVERAGING IN THE FREQUENCY DOMAIN. Andrea Lee Thompson* and Donald O. Walter. BRI, UCLA, Los Angeles, CA 90024.

In those situations where one or more components of activity vary in latency, averaging in the time domain underestimates their amplitude and smears their shapes. The Fourier transform separates amplitude and phase information, allowing us to estimate those parameters separately for each record. One use of these parameters is to estimate their average for each frequency. The inverse transform of this function is a latency-adjusted average wave in the time domain with well estimated amplitude and shape.

Applications of transient wave adjustment (TWA) to event-related potentials, and to produce a "typical" page of EEG will be displayed.

683 BRAINSTEM AUDITORY EVOKED POTENTIALS (BAEPs): WHEN IS WAVE-2 A ROSE AND WHEN IS IT A CARNATION ? Peter L. E. van Kan*, Rob McLain*, Gwen Gale*, Al Seacord*, W. Jeffrey Weidner*, and Timothy A. Jones. Department of Animal Physiology,UCD,Davis,CA. 95616

It is often the case that multiple electrode derivations are used to record and identify specific peaks of BAEPs. This usually entails recording from two vertex-mastoid pairs, one from each mastoid side and a common vertex as "G1". In cat both derivations produce a series of positive peaks which can be labeled 1 through 5 with activity in primary afferents producing wave-1 of both records. For the first three peaks slight differences in latencies and amplitudes are commonly seen between the two records even though they are recorded simultaneously. Ordinarily, the generators for each peak have been taken to be the same for both derivations, that is, the generator for wave-2 in the ipsilateral derivation is thought to be the generator for wave-2 in the contralateral perspective. In a series of experiments designed to identify BAEP generators in cat, we have established that this latter point of view may be missleading; that is for example, in the case of wave-2 the brain region generating this component in ipsilateral records may not be the same region which generates wave-2 in the contralateral record. This multiple generator concept is suggested since cooling in two putative generator regions differentially affects the two records, where the contralateral wave-2 can be delayed independently of the ipsilateral wave -2. A similar phenomenon can be demonstrated for waves 3 and 4 suggesting a generalized bilateral representation where the generators of each respective side can be physiologically and anatomically distinguished although the respective far-field potentials may be labeled the same. In the case of wave-2, ipsilateral cooling in caudal pontine regions, as would be expected, slows activation of both generators whereas contralateral cooling affects contralateral wave-2 to a greater extent than the ipsilateral wave-2.

684 BINAURAL INTERACTION IN AUDITORY BRAINSTEM POTENTIALS. Kathy S. Wrege* and Arnold Starr (SPON: C. E. Ribak). Depts. of Psychobiology and Neurology, Univ. of Calif., Irvine, Irvine, CA 92717.

Binaural interaction was examined by recording auditory brainstem responses to clicks from scalp electrodes (vertex-neck) in human subjects. Deviations of the binaural response from the sum of the monaural potentials were observed at the time of occurance of waves V-VII. Both amplitude and latency of the interactions were dependent on click polarity: rarefaction clicks produced interactions of larger magnitude relative to the monaural sums (38.2 ±9.3%) and longer latency (6.26 ±.65 ms.) than did condensation clicks (25.4 ± 4.4%; 5.34±.63 ms.). These latency differences cannot be accounted for by any concurrent latency shifts in the monaural or binaural evoked potentials. The relationship of binaural interaction to stimulus intensity, interaural time and intensity differences, and audiograms were examined.

685 PSEUDORANDOM BINARY SEQUENCE (PRBS) STIMULATION FOR VISUALLY EVOKED POTENTIALS (VEP). Weldon W. Wright, Richard Srebro and Barry A. Sokol*, Department of Ophthalmology, Southwestern Medical School, Dallas, Texas 75235.

PRBS stimulation permits a rapid measurement of the power spectrum of the VEP with an input that approximates bandlimited white noise but which is amenable to signal averaging techniques. We have applied the method to both luminance modulation of a 30^{0} homogeneous red field and to pattern reversal of sinusoidal and square wave gratings. Power spectra were obtained in less than 2 minutes of recording time. These spectra are similar to those obtained using an array of single sinewave frequencies each presented separately but the PRBS technique requires much less recording time and has the additional advantage that separate epochs are not required for each frequency tested. The PRBS consists of a repeating sequence of N equally likely binary states. It simulates a true coin toss experiment in that the number of runs of consecutive identical states of length γ is proportional to (1/2) State changes are allowed only at equally spaced time intervals, Δt, and the sequence has a periodicity of $N\Delta t$. In the frequency domain, the PRBS is represented by a set of discrete equispaced pulsed of constant amplitude in the frequency band from $1/N\Delta t$ to $1/3\Delta t$. The PRBS can be conveniently generated using a shift register with appropriate feedback, An n stage shift register generates a PRBS whose length is $N=2^{n}-1$. Selecting n and Δt, permits adjustment of the frequency resolution and bandpass appropriate to the system being studied. We have generated PRBS stimuli from both an inexpensive hardware shift register and by simulation using a small computer. For luminance modulation the binary states were made to coincide with 2 adjustable luminance levels so that average luminance and % modulation were precisely and independently adjustable. For pattern reversal experiments the position of the grating on an oscilloscope was shifted by 1/2 cycle left or right in accordance with the binary state of the PRBS. The VEPs were recorded both by using a conventional signal averager and were later digitized, or were averaged directly by the lab computer, A Blackman-Harris spectral window was applied to the VEP before taking the Fourier transform.

686 EVOKED POTENTIALS TO SHIFTS IN FREQUENCY OF A CONSTANT TONE Charles D. Yingling. Langley Porter Neuropsychiatric Institute, University of California, San Francisco, CA 94143.

Much recent research in visual evoked potentials has used patterns (such as checkerboards) or pattern transitions (ie., checkerboard reversals) as stimuli rather than simple light flashes. In the pattern reversal EP, there is no change in the total stimulus flux, the effective stimulus being rather the change of pattern in a field of constant average illumination. The EPs thus produced are different in both waveform and scalp distribution from those produced by flashes or even flashed checkerboards, suggesting that a different process is involved in their generation (Allison et al, EEG Journal 42:185-197,1977).

In the auditory modality, the simplest example of such a shift in pattern is a sudden shift in frequency of a tone of constant amplitude. Given the tonotopic mapping of auditory cortical areas, one might predict that a greater shift in pitch would cause a greater shift in the neural population activated by the stimulus and that this would be reflected in the amplitude of the cortical EP. To test this hypothesis, six adult subjects listened to a constant 1250 Hz tone which changed unpredictably by an amount ranging from a barely detectable 20 Hz to a shift of 1050 Hz, nearly an octave higher. Subjects were instructed to count the number of occurrences of the smallest shift. 48 trials at each shift were averaged from Cz referenced to A_1.

All subjects displayed clear EPs to the transitions, with an "N100" component whose latency ranged from 150 msec (20 Hz shift) to 120 msec (1020 Hz shift) and an "N200" component of relatively constant 215 msec latency. The N100-P200 peak to peak amplitude increased almost monotonically as a function of the amount of shift, ranging from 4.58 μV (20 Hz shift) to 13.42 μV (1020 Hz shift). The P300 component, defined as the most positive point between 300 and 500 msec, averaged 5.67 μV to the target shift of 20 Hz, and only 2.94 μV to the nontarget shifts which had however produced larger N100-P200 components. Thus the earlier components depend primarily on the physical parameters of the stimulus (ie., amount of shift) whereas the P300 component is more a function of the cognitive response of the subject (target detection).

In a second experiment, five subjects listened to a narrow range of shifts, from 20 to 120 Hz above the same base tone of 1250 Hz. These shifts were so similar that subjects could not accurately tell them apart, so no detection task was performed. Nevertheless, the N100-P200 amplitude again varied as a function of the amount of shift, being within one point of a monotonic function for three of the five subjects. In this case, the EP was apparently more sensitive at detecting differences among these small shifts than were the subjects themselves.

FEEDING AND DRINKING

687 THE EFFECT OF RESTRICTED FOOD AVAILABILITY SCHEDULES ON CIRCADIAN RHYTHMS. Norman T. Adler and Rodney J. Pelchat. Dept. Psych., Univ. of Penna., Phila., PA.

Much recent work has suggested that food restriction schedules (FR) can entrain or synchronize circadian rhythms. We performed a series of experiments to compare the entraining effects of food availability cycles to the known effects of light cycles on two rhythms - wheel-running activity and feeding as measured by an operant response which led to food delivery. Although some effects seem best explained by entrainment of an oscillator, others clearly do not fit the classic effects of entraining agents.

First, although there is an anticipatory wheel-running response to FR which can persist for two days of total food deprivation, FR does not entrain free-running activity rhythms of either blinded animals or animals in constant light. The free-running rhythm and the food-related activity seem to be independent.

Second, the effect of a shift from FR to ad libitum food while concurrently on a light-dark cycle is different for the feeding and activity rhythms. If food availability were entraining an oscillator, then residual effects of this entrainment might be expected at the old feeding time. Residual effects for the operant feeding response but not for wheel-running were observed.

Third, extra access to food either as an extension of the normal feeding time or as a separate feeding seems to affect the expression of the anticipatory food-related responses of both wheel-running and the food-getting operant.

The results suggest that the food-availability cycles are not acting as classic Zeitgebern and that mechanisms other than entrainment of an oscillator are at work.

688 INSULIN-INDUCED ELEVATION OF HYPOTHALAMIC NE TURNOVER PERSISTS AFTER GLUCORESTORATION UNLESS FEEDING OCCURS. Steven I. Bellin and Sue Ritter. College of Veterinary Medicine, Washington State Univ., Pullman, WA 99164.

Both food intake and norepinephrine (NE) turnover are increased during cerebral glucoprivation. R.C. Ritter, et al. (Am. J. Physiol. 234(6):E617-E621, 1978) have demonstrated that if food is returned to rats 6 hours after regular insulin administration, intake will still be enhanced even though normoglycemia has been restored. In other words, feeding can be temporally dissociated from other signs of glucoprivation. This paradigm, therefore, provides an opportunity to assess the possibility that a glucoprivation-induced increase in brain NE turnover is specifically related to feeding behavior and not to other effects of insulin or glucoprivation. To evaluate these relationships, we measured turnover of NE and dopamine (DA) in selected brain regions immediately and 6 hr after insulin administration in the absence of food. In a second study, catecholamine (CA) turnover was again monitored 6 hr after insulin injection, but food was present during the delay. Sixty-three adult male rats were used in these studies. In the first experiment, rats were treated with saline or regular insulin (3U/kg, s.c.) and α-methyl-p-tyrosine (AMT, 350 mg/kg, s.c.) was given 30 min or 5 1/2 hr later. At 1, 1 1/2 and 2 1/2 hr after insulin, turnover of hypothalamic NE and caudate DA were enhanced compared to saline-AMT controls. Cortical, midbrain and brainstem CA turnover were unaffected. At 6, 6 1/2 and 7 1/2 hr following insulin, however, when blood glucose levels had returned to preinjection baseline values, caudate DA turnover did not differ from control, but NE turnover was still significantly enhanced in the hypothalamus. In the second experiment, rats were given the same dose of insulin but were allowed to eat during the 5 1/2 hr postinsulin period prior to AMT injection. In this study, where food was consumed by insulin-treated rats, the insulin-induced increase in hypothalamic NE turnover was abolished. These results suggest that insulin-induced increases in NE turnover in the hypothalamus may be specifically related to food intake and not to other signs of glucoprivation.

689 OVARIECTOMY (OVX) ALTERS BODY FAT BUT NOT THE LOWERED BODY WEIGHT (BW) 'SET POINT' OF RATS WITH DORSOMEDIAL HYPOTHALAMIC LESIONS. Larry L. Bellinger and Lee L. Bernardis. Dept. Physiol., Baylor Col. Dent., Dallas, TX 75246 and VA Med. Ctr. and Depts, Surg. and Path., SUNY at Buffalo, Buffalo, NY 14215.

Withdrawal of ovarian steroids by OVX results in a temporary increase in food intake with a concomitant increase in BW. Food intake generally returns to control levels when BW reaches a new, higher level. The primary effect of hyperphagia may be to alter the level at which body fat is regulated, i.e., the 'body fat set point.' Recent data shows that rats with DMNL have experienced a lowering of the 'set point' for BW but not for body fat (Bellinger, et al, Neurosceince, in press). The present study was designed to investigate whether OVX would be able to raise the body fat 'set point' in DMNL. Rats received DMNL at the age of 28 days, sham-operated rats served as controls. At the age of 84 days some DMNL and control animals were OVX while others were sham-OVX. BW, food intake and obesity index were monitered and the experiment terminated when the rats were 140 days old. Both OVX and sham-OVX caused precipitous drops in BW that lasted only three days; however, the BW drop was greater in the sham-lesioned than in the DMNL rats. Subsequently, the patterns of BW increase were identical in the DMNL-OVX and sham-lesioned-OVX rats, the curve of the former being merely shifted to a lower absolute BW. The data allows the inference that OVX causes the same degree of BW gain in DMNL and sham-DMNL rats and thus cannot override the BW-lowering effect of DMNL. Deposition of body fat as evidenced by the Lee Index was greater in DMNL-OVX rats than in any of the other three groups of rats. The data suggests that DMNL, although lowering BW on an absolute basis predisposes the rats to the lipogenic consequences of OVX. Similar to BW, the post-operative drop in food intake was smaller in DMNL rats than in sham-lesioned rats when OVX was performed. Subsequently, for six post-operative days DMNL-OVX rats ate more than DMNL-sham-OVX animals, but thereafter food intake normalized. By contrast, sham-lesioned rats responded to OVX by increasing their food intake for 27 days, whereupon they too normalized food intake. The data are analogous to recent findings that DMNL lowers the 'set point' for BW but not for body fat. Furthermore, while DMNL have lowered the BW 'set point,' the neural structures involved in regulating the body fat 'set point' seems intact and more responsive to manipulation, i.e., OVX. Finally, as reported by others OVX may lead to obesity by means other than solely affecting food intake as illustrated in the DMNL-OVX group.

690 TAIL PINCH (TP)-INDUCED HYPERPHAGIA AND MACRONUTRIENT PREFERENCE IN YOUNG-MATURE RATS MADE HYPOPHAGIC BY LESIONS IN THE DORSOMEDIAL HYPOTHALAMIC NUCLEI (DMN). Lee L. Bernardis and Larry L. Bellinger. Veterans Administration Medical Center and Depts. of Surgery and Pathology, SUNY at Buffalo, 14215 and Dept. of Physiology, Baylor Coll. Dent., Dallas TX 75246.

Sprague-Dawley rats received bilateral electrolytic lesions in the DMN at the age of 49 days. Sham-operated rats served as controls (CON). The rats were originally used in various feeding studies. At the age of 153 days they were subjected to TP for five minutes per day for eight days. Three equicaloric diets, complete in all nutrients and accessory food factors, with one macronutrient higher than the other two, were available ad libitum during the TP sessions in color-coded pellet form. They were a high-carbohydrate (HCD), high-fat (HFD) and a high-protein (HPD) diet. In their home cages, the rats received Charles River Rat Mouse Hamster Formula ad libitum. Rats with DMN lesions (DMNL rats) ate significantly more than their sham-operated controls from each of the three diets during TP sessions, but particularly from the HCD and the HFD diets. Nevertheless, in terms of per cent intake, the DMNL rats and the CON rats ate similar amounts of food from each of the three diets. In their home cages, the DMNL rats showed the previously reported profound hypophagia. Indeed, food intake in the home cages showed over time a trend to decrease in the DMNL rats and a trend to increase in the CON. The data show that the mature DMNL rat, as its weanling counterpart, is grossly hypophagic in its home cage but shows stimulus-bound hyperphagia when subjected to TP. Similarly the mature DMNL rat shows preference for a HCD and HFD diet, as does the weanling DMNL rat. The data also show certain similarities to the stimulus-bound hyperphagia in rats with lateral hypothalamic lesions (LHA rats) which have been shown to be capable of increased food intake during the critical post-operative time until recovery, i.e. spontaneous food intake, supervenes. However, DMNL rats never go through stages of aphagia and adipsia. The possibility is entertained that DMNL cause a partial disruption of some inhibitory tracts, possibly part of the noradrenergic bundle, thus disinhibiting it so that on TP the dopaminergic (DA) system is more active in DMNL than in CON rats.

691 METHYSERGIDE STIMULATES RHYTHMIC AND ARRHYTHMIC EMG-RECORDED SUCKING IN 20-DAY-OLD RATS. Stephen C. Brake* and Christina L. Williams. Dept. Psychiat., Montefiore Hosp., Albert Einstein College of Medicine, Bronx, N.Y. 10467 and Institute of Animal Behavior, Rutgers Univ., Newark, N.J. 07102.

The likelihood that a rat pup will attach and remain attached to a dam's nipples declines between 10 and 20 days of age, as the pup begins to eat solid food. Methysergide, a putative serotonin receptor blocker, administered i.p. increases the probability of nipple attachment in pups 20 days of age and older without altering pups' control of milk or solid food intake. In this study we asked: 1) Does sucking behavior of rat pups also decline between 10 and 20 days? and 2) Does methysergide stimulate sucking as it does nipple attachment, or does it have no effect on sucking as if sucking were related to intake control?

We injected 10- and 20-day-old, short (4-6 hr) and long (20-24 hr) deprived pups with methysergide (20 mg/kg) or the saline vehicle (10 ml/kg). Twenty min later we recorded their sucking for 1hr using an EMG recording technique designed to measure the frequency, duration, and intensity of dry sucking (sucking from an anesthetized dam who provides no milk).

It has previously been shown that rats less than 14 days of age suck in 2 different patterns: rhythmically and in arrhythmic bursts. Pups deprived of food, water, and sucking for 20-24 hr show both sucking patterns, while nondeprived pups display only arrhythmic bursts at a lower frequency than deprived pups. The present results indicate that 20-day-old pups, in contrast to 10-day-old pups, spend little of the time they are attached to the nipple actually sucking, and rarely suck rhythmically, even after 24 hr of deprivation. However, methysergide stimulates arrhythmic sucking activity and reinstates the rhythmic sucking pattern characteristic of deprived, 10-day-old pups. This effect was not caused by indirect drug effects on activity, since overall EMG intensity and nipple shifting (both indexes of activity) were not altered by the drug. Methysergide had no effect on sucking duration or intensity in 10-day-old pups.

These data show that: 1) Sucking declines between 10 and 20 days of age and, in fact, rhythmic sucking disappears completely, and 2) Because methysergide has previously been shown not to alter pups' control of milk or solid food intake, it is interesting that in 20-day-old pups this drug induces vigorous and prolonged sucking normally displayed only by pups younger than 14 days of age.

692 ANGIOTENSIN-INDUCED SODIUM APPETITE: EFFECTS OF SODIUM SOLUTION CONCENTRATION, DELAYED ACCESS TO SODIUM, AND DIET. Richard W. Bryant, Steven J. Fluharty*, and Alan N. Epstein. Dept. of Biology, Univ. of Pennsylvania, Philadelphia, PA 19104.

Continuous intracerebroventricular infusion (cICV) of angiotensin II (AII) evokes massive intakes of both 3% NaCl solutions and water (Bryant et al., Fed. Proc. 37:1978; Avrith & Fitzsimons J. Physiol. 282:1978). The salt intake is dose-related, specific for Na^+, not secondary to the large water intake and temporally unrelated to it. The appetite appears with a latency of several hours after initiation of the AII infusion and persists after its termination. When 0.9% is substituted for 3% NaCl massive intakes of both 0.9% NaCl and water occur during cICV of AII (6µg/µl/hr), however, unlike the 3% NaCl and water intakes, more 0.9% than water is drunk (116.8±21.7 water, 147.2±15.4 ml 0.9% NaCl;216.1± 33.5 water, 74.5±14.6 ml 3% NaCl). Total intake is therefore the sum of the preference for dilute salt solutions and the induced appetite for salt. The excess intake does not appear more quickly despite access to a preferred concentration, and intakes of 0.9% NaCl persist after termination of AII infusion.

After establishing that cICV of AII produces Na^+ appetite, it was of interest to determine whether salt ingestion was necessary for its induction. Therefore, after rats had access to water and 3% NaCl for 4 days, the 3% NaCl was removed and 4 days of AII (6µg/µl/hr) were begun, and then when cICV of AII was stopped, either no delay or a 24hr delay was imposed before the 3% NaCl was returned. The long delay was imposed to assure that exogenous AII could not be affecting the salt intake when the 3% NaCl was returned. In addition, other groups of rats were fed normal Purina rat pellets (containing approximately 1% Na^+) or a Na^+-free diet either throughout the experiment or only during infusion.

Rats that had normal diet before and during infusion drank immediately and avidly when given access to 3% NaCl (17.1±2.1 ml, 1st day), and it persisted. Avid acceptance also occurred in rats receiving normal diet for the first 4 days then Na^+-free diet throughout the experiment. The 24hr delay did not alter initial salt intake, but made persistence less likely. Rats given Na^+-free diet for 5-13 days with or without cICV of AII also drank immediately, but persistence occurred only in those receiving cICV during Na^+ deprivation.

Thus, 1) it is not necessary that the animals drink salt solutions during AII infusion in order for the hormone to evoke salt appetite, and 2) salt ingestion, either in solution or in solid food, during chronically elevated AII, produced either by cICV or by Na^+ deprivation, appears to be necessary in order for the excess salt intake to persist. 693 VMH OBESITY REDUCED BUT NOT ABOLISHED BY SCOPOLAMINE METHYL NITRATE. Richard G. Carpenter* and S.P. Grossman. Univ. Of Chicago, Chicago, IL 60637.

A recent review by Powley (Psych.Rev.84:89, 1977) suggests that VMH obesity may be entirely explained by increased vagally mediated insulin secretion. Friedman and Stricker (Psych. Rev. 83:409, 1976) agree but suggest that vagal (or other neural) influences on the liver may also contribute to the obesity. Vagal influences should be abolished by antimuscarinic drugs. Therefore, food intake and body weight were measured daily for controls and rats with ventromedial (VMH) obesity. Chronic treatment with the antimuscarinic drug scopolamine methyl nitrate (ScMN; 0.15mg/Kg 4 times per day) which does not enter the CNS, reduced food intake initially to about 10gm/day in both control and VMH obese group. Intake recovered to normal during the next 5-10 days in the controls; body weight loss was less than 10gm and was recovered in 10 days. VMH rats recovered normal food intake more slowly and lost 35% (80gm) of their obesity in 15 days. Both VMH and control rats doubled their water intake during ScMN treatment, probably to compensate for the absence of saliva. The dose of ScMN was doubled at 20 days, again at 30 days, and again at 35 days. By 40 days food intake was again essentially normal in both groups; the VMH group had lost only 20gm since day 20, the controls had not changed. With the highest dose, gastrointestinal motility was obviously decreased in both groups; the stomach and gut were distended with food. In a second experiment, rats were maintained on the highest dose (1.2mg/Kg 4X/day) for 20 days, then given VMH lesions. Food intake increased greatly in the first days after VMH lesions (day 3: VMH=40gm, control=18gm); body weight increased by 38gm in 10 days. However, food intake returned to normal after 10 days, with no further weight gain, probably because of gross distention of the stomach and gut.

Vagally mediated insulin secretion has been shown by Henderson et al (Acta Endo.83:772, 1976) and Bergman and Miller (AJP 225:481, 1973) to be abolished by low doses of antimuscarinic drugs. Secretory effects of parasympathetic stimulation are more easily blocked than effects on smooth muscle; this differential sensitivity explains why ScMN treatment causes much less weight loss than vagotomy. These results suggest that a substantial fraction of VMH obesity is independent of vagally mediated insulin secretion.

694 THE EFFECTS OF HEPATIC VAGOTOMY ON SALT INTAKE AND BODY WEIGHT IN RATS. Robert J. Contreras. Yale Univ., Dept. Psychol., New Haven, CT. 06520.

The mammalian liver is believed to contain neural receptors that are sensitive to changes in the osmolarity, and ionic and metabolic composition of the blood. These receptors might play a role in maintaining steady state levels of fluid, electrolytes and glucose by activating physiological and behavioral processes that act to correct for deviations from homeostasis. Sensory functions of the liver are believed to be mediated by the hepatic branch of the vagus nerve. The present study was carried out to ascertain the effects of hepatic vagotomy on salt intake, body weight and food intake in rats.

Six rats received hepatic vagotomies and another six rats received sham operations under sodium pentobarbital anesthesia. All animals were examined postoperatively for two months. The two groups of rats were given two-bottle preference tests between water and solutions of NaCl (.03 M, .1 M, .3 M) or glucose (.1 M). Each test solution was presented for two days and 24 hr intakes were measured. Hepatic vagotomized (HV) rats ingested less NaCl solution (.1 M, .3 M) than sham controls (SC) but there were no differences in glucose intake. The animals were given a second drinking test following 9 to 16 days of sodium deprivation. Both groups showed an increased salt appetite and salt intake compared to rats fed a sodium-replete diet. Nevertheless, HV rats tended to consume less NaCl (.1 M, .3 M) solution than SC, although these differences were nonsignificant. The differences in NaCl intake may be attributable to the lessened ability of HV rats to excrete electrolytes in conditions of osmotic stress (Adachi, Niijima and Jacobs, 1976).

HV rats gained weight at a faster rate than SC. These differences in weight gain were modest, yet were apparent soon after the operation and continued for the two month period of examination. The preoperative weight of SC was 4.8 g more than that of HV rats; two months later HV rats weighed 37.4 g more than SC. The relative obesity of HV rats was apparently not due to differences in food intake. For six days daytime (7 am - 7 pm) and night-time food intakes were measured. The two groups of rats did not differ in the amount of food consumed over 24 hr nor in their relative intakes between day and night periods. The differences in average body weight agree with the results reported by Sawchenko and Friedman (personal communication) although they also report that HV rats ingested more food than SC. The relative obesity of HV male rats may be due to disturbances in peripheral metabolic processes rather than due to hyperphagia. (Supported by a NIH Biomedical Research Support Grant 5-507-RR-07015).

696 SEX DIFFERENCES IN RAT OBESITY PRODUCED BY HIGH-FAT DIETS. D.V. Coscina, J.W. Chambers*, and G.H. Anderson*. Sect. Biopsychol. Res., Clarke Inst. Psychiat., and Dept. Nutr. Food Sci., Fac. Med., Univ. Toronto, Toronto, ONT. M5T 1R8

Under fixed environmental conditions, rats closely regulate their bodyweight (BW) by eating constant quantities of energy in response to caloric dilution or concentration of single diets. Therefore, the relative overeating and obesity which can develop on diets high in fat is an interesting model of apparent breakdown in caloric intake metering. However, a confound exists in that such caloric enhancement simultaneously lowers protein concentration. This latter factor is rarely considered despite abundant data demonstrating behavioral and physiological regulation of protein intake in this species. Our experiment addressed this issue by comparing the development of obesity on high-fat (HF) diets in which the concentration of energy in the form of protein was either low or equal to that found in standard maintenance diets. Adult (250-280g) male (n=30) and female (n=30) Wistar rats were housed separately in a temperature (22°C±1°) and light (12 hrs on commencing 0800 hrs) controlled colony. Following 2 wks acclimatization to these conditions and ad lib access to Teklad chow (4% fat) and tap water, rats were randomly assigned to one of three (n=10 each) dietary conditions: (1) stock diet (18% protein energy in the form of casein; 5% fat; 4 kcal/g), (2) HF diet (7.2% protein energy; 43% fat; 6 kcal/g), (3) HF diet (2) + casein, vitamins and minerals at the expense of cornstarch (18.1% protein energy; 43% fat; 5.75 kcal/g). Tap water and diets (in non-spill food cups) were freely available for 9 wks during which BWs and food intakes were recorded every 2-4 days. At the end of this time, all rats were lightly etherized for measurement of naso-anal (NA) length. Clear sex differences in magnitude and expression of obesity were found as a function of HF diet type. Female rats showed equal linear growth on all diets. Both HF diets produced equivalent enhanced BW gain compared to controls (+220%) and equivalent obesity (316 or 318) by the Lee index (cube root of total g BW X 10^4/mm NA length; 300-310 is considered normal). Male rats showed slight but significant linear growth decrement (-2%) on HF but enhanced linear growth (+3%) on supplemented HF. BW gain was significantly enhanced only on supplemented HF (+60%). However, the Lee index showed males to be obese on both HF diets (314 or 316). These data show that (1) the continued linear growth of adult male vs female rats confounds assessment of obesity if only BW is used as an index, and (2) unsupplemented HF diets create nutrient deficiencies which impair growth of lean body mass in male rats.

697 BEHAVIORAL AND NEUROCHEMICAL EFFECTS OF NEONATAL ADMINISTRATION OF MONOSODIUM L-GLUTAMATE IN THE MOUSE. Ralph Dawson, Jr. and Joan F. Lorden. Dept. of Psychology, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

Mice treated during infancy with monosodium L-glutamate (MSG) suffer neuronal degeneration and exhibit both obesity and neuroendocrine abnormalities as adults. The present study evaluated the behavioral, physiological and neurochemical effects of MSG treatment. Albino mice were injected with MSG from days 4-13 postnatally in increasing doses from 2.8 mg/g to 4.8 mg/g. Controls received equivalent volumes of 0.9% saline. MSG-treated mice showed significant increases in body weight and adiposity and significant decreases in nasoanal length. Animals were housed in either individual or group cages. Many characteristics of the MSG syndrome were found to differ under these conditions. When mice were caged individually, body weight declined to control levels; however, at sacrifice the MSG-treated mice were found to have a significantly higher percentage of body fat than controls. Activity levels were significantly lower in group-housed MSG animals than in controls; but no differences were observed in the individually-housed mice. Body temperature was also affected by housing condition. At 22°C the group-housed MSG-treated mice maintained their body temperatures at a significantly lower level than any of the other groups. No differences in mean body temperature were observed between MSG and saline-treated mice housed individually. Measures of food intake indicated that MSG-treated mice were hypophagic in both housing conditions and consumed a significantly larger percentage of their food during the light part of the light-dark cycle than did controls. In addition, 24h food deprivation produced a significantly smaller increase in food intake in the MSG groups than in the controls. A glucoprivic challenge induced by injection of 250 mg/kg of 2-deoxy-D-glucose (2DG) caused a significant suppression of food intake in both MSG and control mice that were caged individually. In group-housed animals, 2DG significantly increased food intake in MSG and saline treated mice; however, the increase was significantly larger in the controls. The data suggest the importance of housing condition as a variable; but the mechanism by which housing alters the MSG syndrome is unknown. It is also apparent that hypophagia and adiposity are relatively enduring aspects of the syndrome.

Assay of hypothalamic norepinephrine (NE) and dopamine (DA) indicated that in the mouse MSG treatment significantly reduced DA but did not alter NE levels. The behavioral effects of MSG cannot as yet be attributed to a loss of DA; however, a change in dopaminergic control of the pituitary may account for some aspects of the syndrome. (Supported by NINCDS Grant 14755-01)

696 WEIGHT LOSS CAUSED BY INTRAVENTRICULAR INFUSION OF SUBSTANCES INVOLVED IN CARBOHYDRATE AND FAT METABOLISM. John D. Davis, Karen Asin, and David Wirtshafter, Dept. Psychol., Univ. of Illinois, Chicago, IL 60680.

Body weight and food and water intake were measured in rats before, during and after continuous intraventricular infusion of a variety of substances which can be metabolized by the brain. Unincumbered infusion was achieved by means of a subcutaneously implanted Alzet osmotic minipump which was connected to a ventricular cannula by a polyethylene tube. The pumps delivered fluid to the ventricular space either at a rate of 1.0 µl hr^{-1} for 7 days or 0.5 µl hr^{-1} for 10 days. The substances infused were glycerol, propylene glycol, glucose, fructose and β-hydroxybutyrate, all at a rate of 0.15 µM hr^{-1}. All solutions infused were adjusted to be isoomolar with cerebrospinal fluid by adding appropriate amounts of NaCl to the solution.

The infusion of all of these substances resulted in a significant reduction in body weight to approximately 90 per cent of the initial weight. The weight loss resulted in part from a hypophagia which occurred principally during the dark phase of the 12:12 light dark cycle. Food intake during the light phase was largely unaffected. Infusion of 0.15 M NaCl resulted in a transient weight loss due probably to trauma associated with pump implantation, but after this brief period of weight loss the rats gained weight at a normal rate during the remainder of the infusion period. Infusion of 0.15 M glycerol into the fourth ventricle had effects similar to those obtained with NaCl in the third ventricle. The amount of weight lost during infusion of the nutrients was correlated with the body weight at the beginning of the infusion period ($r = +.77$, $p < .01$). When the infusions were terminated, all of the animals gained weight rapidly and returned toward their normal body weight. When body weight was reduced by food deprivation prior to the infusion of 0.15 M glycerol no further reduction in body weight was observed during a 10-day infusion period.

Neither the total weight lost during the infusion perior nor the accelerated weight gain after the infusions were terminated could be accounted for solely in terms of the magnitude of changes of food intake. For example, the correlation between weight loss and reduction in food intake during the infusion period was +.30.

These results are interpreted as indicating that a variety of substances involved in carbohydrate and lipid metabolism are also involved in the body weight and food intake control mechanisms of the brain. Brain tissue in the vicinity of the third ventricle may be monitoring the availability of carbohydrates and products of lipid metabolism in its regulation of body weight and food intake. Supported by NSF Grants BMS75-17091 & PCM78-09602.

698 AREA POSTREMA LESIONS CAUSE INCREASED INTAKE OF HIGHLY PALATABLE FOOD. Gaylen Edwards and Robert C. Ritter. Dept. of Veterinary Medicine, Univ. of Idaho, Moscow, ID 83843, and College of Veterinary Medicine, Wash. State Univ., Pullman, WA 99164.

The area postrema (AP) is a circumventricular organ located in the caudal fourth ventricle. This structure, which is a known chemoreceptor for certain drugs and toxins, has been shown to be involved in drug-induced vomition and formation of conditioned taste aversions (McGlone et al., Neuroscience Abst cts, 1979). In addition, the AP is in close anatomical proxim ty to cranial nerve nuclei and integrative centers for gustatic and gastrointestinal function. These anatomic and physiologi al features recommend the AP as an area through which control of feeding behavior might be exerted.

We have made lesions of the AP in adult male rats. After recovery from surgery, AP lesioned rats consumed normal amounts of laboratory chow and water ad libitum. Following 21 hours of food deprivation, AP lesioned rats increased their food intake by amounts which were statistically indistinguishable from sham operated rats and unoperated controls. However, when non-deprived AP lesioned rats were permitted to consume a highly palatable liquid food (vanilla instant breakfast) during a thirty minute test, they consistently ate more than double the amount consumed by sham operated or control rats. For example, in a typical experiment involving 10 lesioned rats and a pooled group of 5 sham operated and 5 control rats, the AP lesioned rats ate 27.5 ± 2.5 mls whereas shams and controls averaged only 12.1 ± 1.0 mls. This increased intake by AP lesioned rats appeared shortly after surgery and persisted for at least 6 months.

Overeating of the highly palatable liquid food was suggestive of a satiety deficit in AP lesioned rats. Therefore, we tested the possibility that AP lesion-induced overeating resulted from reduced sensitivity to the putative satiety hormone cholecystokinin (CCK). Intraperitoneally injected CCK octapeptide (20 or 40 Ivy dog units/kg) produced similar percentage decreases in liquid diet intake by all groups.

Our data suggest that the AP is involved in termination of feeding induced by highly palatable liquid foods. The elevated liquid food intake by AP lesioned rats cannot however be attributed to decreased sensitivity to CCK. Therefore, destruction of the AP may impair satiety by interfering with detection of, or response to, some other satiety signal.

699 ELEMENTAL HYPOTHALAMIC OBESITY AFTER DISCRETE LESIONS OF THE PARAVENTRICULAR NUCLEUS. Ricardo Eng, Richard M. Gold, and Antonio Nunez*. Dept. Psychol., Univ. Mass., Amherst, MA 01003.

The large electrolytic lesions of the ventromedial hypothalamus (VMH) which produce hyperphagia and obesity in the rat typically damage many nuclei and fibers and thus are not useful for the localization of neural substrates mediating satiety. More discrete lesions have shown that the critical area which must be damaged lies rostral to the ventromedial nucleus (Gold, 1973). Using asymmetrical knife cuts Gold et al. (1977) revealed the coronal plane of the paraventricular nuclei (PVN) as the rostralmost terminus of the satiety neurocircuit. The PVN is the most sensitive brain site for norepinephrine-induced eating (Leibowitz, 1978). However, knife cuts of the tractus filiformis, a major noradrenergic tract to the PVN, paradoxically produce a transient reduction in food intake, despite a significant depletion of PVN norepinephrine (Crowley et al. 1978). In the present study we report that discrete lesions of the PVN produce hyperphagia and rapid weight gain in the rat without the several additional deficits traditionally associated with VMH lesions. We thus suggest a specific role for the PVN in satiety.

Bilateral anodal lesions were made in 40 female rats using a platinum electrode (1 MA x 10 sec.). The lesions were aimed in a grid pattern centering on the PVN.

The greatest weight gains (7 g/d) were obtained when the PVN was completely and selectively destroyed. This rate is comparable to that produced by large VMH lesions. Partial damage to the PVN produced a partial effect (3-4 g/d) while lesions sparing the PVN showed weight gains comparable to that of shams (0-2 g/d). Thus no single compact fiber bundle entering or leaving the PVN can be implicated. The normal nocturnality of eating and drinking was not significantly reduced by PVN lesions (70% vs. 80-90% for controls). The PVN lesions also did not produce polydipsia (water to food ratios were normal). Rats showed normal estrous cycling and wheel running activity. In contrast, large obesity-producing VMH lesions or hypothalamic knife cuts usually disrupt all 4 of those measures. We conclude that traditional VMH lesions disrupt PVN afferents and/or efferents.

700 INTRAVENTRICULAR 2-DEOXY-D-GLUCOSE CAUSES FEEDING IN THE ABSENCE OF HYPERGLYCEMIA. Robert M. Engeset* and Robert C. Ritter. College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Previous work from our laboratory demonstrated that feeding in response to 2-deoxy-D-glucose (2 DG) or insulin persists after the sympatho-adrenalmedullary response to glucoprivation has abated (American Journal Physiology 234-236, 1978). This result suggested that the stimulus for 2 DG and insulin induced food intake might persist in the absence of ongoing glucoprivation, i.e., postglucoprivically. In order to determine whether postglucoprivic feeding is mediated by central or peripheral receptors, we investigated feeding induced by intracerebroventricular (ICV) 2 DG infusions. Sequential blood samples for glucose analysis collected after ICV 2 DG doses of 3.5 or 5.0 mg confirmed that 2 DG-induced hyperglycemia had abated by six hours post 2 DG infusion. Feeding tests were performed in which food was withheld until six hours after the ICV 2 DG infusion (delayed feeding test). When food was subsequently returned for two hours, rats infused with ICV 2 DG (3.5 or 5.0 mg) ate 1.2 ± .3 and 1.5 ± .5 grams respectively above control intakes even though the 2 DG-induced hyperglycemia had abated. Since both ICV 2 DG doses were below the peripheral threshold dose for feeding, these results suggest that at least part of the delayed feeding after 2 DG resulted from activation of cerebral receptors.

It is interesting that the magnitude of feeding induced by ICV 2 DG is only 50% of that which is induced by subcutaneous 2 DG. This finding suggests that either part of the feeding response is not mediated by receptors accessible from the cerebral ventricles or that the kinetics of 2 DG presentation to cerebral receptors are less effective via the ICV route than via the subcutaneous route. We are currently pursuing experiments to determine which of these explanations is correct.

701 TAIL-PINCH BOUND FOOD-DIRECTED BEHAVIOR EXHIBITED BY LATERAL HYPOTHALAMIC RATS DEPENDS UPON LESION SIZE. Barry Fass and Jeffrey M. Greenspon*, Psych. Dept., Clark U.,Worcester, MA 01610

Feeding and sensorimotor impairments characteristic of Stage 1 of the lateral hypothalamic (LH) syndrome are hypothesized as resulting from a loss of endogenous tonic-arousal (Levitt & Teitelbaum, 1975; Wolgin & Teitelbaum, 1978). If this hypothesis is correct, then exogenous sensory-stimulation which increases LH rats' arousal should restore feeding behavior (Stricker & Zigmond, 1976). Confirmatory evidence previously was reported; for example, noninjurious tail-pinch (TP) allegedly resulted in "basic feeding behavior" when administered to LH rats presented with dry food (Mufson, Balagura, & Riss, 1976).

We now report contrary evidence; namely, that TP given to LH rats in Stage 1 does not elicit feeding, but rather food-directed behavior (FDB) which easily can be mistaken for feeding upon casual observation. Two groups of 40-day-old male albino rats (N=8 per group) were subjected to 1.0 mA anodal-current passed through LH. Current passage lasted for 10 sec for one group (after Mufson et al., 1976) and 20 sec for the other (after Levitt & Teitelbaum, 1975); coordinates for lesion placement were held constant across groups (after Lytle & Campbell, 1975). Every subject was aphagic and adipsic on the second day after surgery; however, 10-sec rats were noticeably less somnolent and cataleptic than 20-sec rats. Noninjurious TP administered to 10-sec rats for 2 min on the second day after surgery resulted in biting and dropping of dry-food chunks, with little or no chewing and swallowing (mean ingestion=0.15 gm, mean spillage=0.35 gm). In contrast, TP administered to 20-sec rats for 2 min resulted in mouthing of food pellet, with infrequent or no biting (mean ingestion=0.03 gm, mean spillage=0.05 gm). TP-bound behaviors exhibited by 10-sec rats were 1) different from food-deprivation induced behaviors (i.e., normal feeding) exhibited by intact rats (mean ingestion=1.86 gm, mean spillage=0.22 gm), and 2) reminiscent of TP-bound behaviors exhibited by intact rats, albeit less frequent (mean ingestion=0.73 gm, mean spillage=0.98 gm). Histological analysis of lesions confirmed that damage sustained by 10-sec rats was significantly less extensive than damage sustained by 20-sec rats (p=.01).

The present findings are taken as evidence that arousal resulting from noninjurious TP is not sufficient to restore feeding behavior lost after LH damage, regardless of whether the damage is extensive enough to produce sensorimotor impairments. Rather, TP results in FDB superficially similar to feeding in that both involve biting of pellet. FBD differs from feeding, however, in that FDB involves dropping of food-chunks with little or no chewing and swallowing. Funds provided by Clark Univ. and by grant 5 ROl AG00295-03 awarded to D. Stein.

702 SODIUM APPETITE INDUCED BY CONTINUOUS INTRAVENOUS INFUSION OF ANGIOTENSIN II. A.L.R. Findlay* and A.N. Epstein. Dept. Biol. and Inst. Neurol. Sci., Univ. of Pa., Phila., PA 19104.

It has been shown that continuous infusion of angiotensin II (AII) into the anterior cerebral ventricles provokes a large increase in the ingestion of strong NaCl solutions (Avrith and Fitzsimons, J Physiol 282: 40P, 1978; Bryant, Fluharty and Epstein, Fed Proc 37: 323, 1978). If the hormone participates in the arousal of the appetite for sodium that arises during sodium deficiency, then it should induce excess sodium chloride intake when its level is increased in the blood as well as in the cerebral ventricles.

Adult male rats that had been maintained on dry food and both water and a 3% solution of NaCl received continuous infusion of AII through right atrial catheters. AII was delivered in 0.315 ml hr^{-1} of isotonic saline at doses of 15, 30 and 60 ng min^{-1} rat^{-1}. Infusions were maintained (except for brief interruptions once a day) for 3 to 5 days. During the first night of infusion, intakes of salt increased above preinfusion levels in rats infused at 30 and 60 ng min^{-1}. Surprisingly, at the 30 ng min^{-1} dose, water intake did not increase until the second day of infusion. The intake of saline and water remained elevated for so long as the infusion continued. In most rats there was no tendency for persistence of high levels of salt intake after the cessation of AII infusion. The results (mean intakes in ml ± SEM) for the middle dose of AII are shown below:

	Day before infusion (5)	Days after infusion Day 1 (5)	Day 2 (5)
Water	36.6±7.3	44.4±3.9	43.8±2.9
3% NaCl	0.0±0.0	3.8±2.6	1.8±1.8

	AII Infusion Days (30 ng^{-1} min^{-1} rat^{-1}) 1 (5)	2 (5)	3 (5)	4 (3)	5 (2)
Water	36.8±7.3	70.0±7.3	78.2±12.7	77.3±19.6	73.5±24.5
3% NaCl	15.2±4.5	21.0±3.6	20.0± 7.2	22.3±11.9	21.0±20.0

(Numbers in parentheses = number of animals)

Mean daily intakes (ml) at 60 ng hr^{-1} were 103.6±4.1 (water) and 30.4±2.6 (3% NaCl); at 15 ng hr^{-1} were 34.3±6.6 (water) and 4.4±2.1 (3% NaCl). The animals did not gain excess weight and there was no sign of edema at any dose.

Elevated blood-borne levels of AII are clearly capable of inducing appetite for salt, and this can occur without necessarily increasing water intake.

703 EATING AND DRINKING FOLLOWING CENTRAL CHOLINERGIC AND ADRENERGIC STIMULATION OF THE GENETICALLY OBESE RAT. Judith A. Finkelstein and William T. Chance. Depts. Anat. and Pharmacol., N.E. Ohio Univs. Col. Med., Rootstown, Ohio 44272.

The genetically obese Zucker rat represents a possible animal model for the experimental analysis of human obesity. The obesity is transmitted as a Mendelian recessive trait and appears to result primarily from hyperphagia. Although food intake of the fatty rat (fafa) and its lean littermate (Fa-) has been studied with a variety of drug and dietary manipulations, no reports of eating following chemical stimulation of hypothalamic areas have been made. The literature concerning the neuropharmacology of eating has typically focused upon noradrenergic systems as principle mediators of the response. Recent research has indicated that cholinergic stimulation of perifornical hypothalamic areas (PFH) also elicits dose-dependent eating in satiated rats (Chance et al., Physiol. Psych. 5: 440, 1977). In this experiment, we examined eating and drinking following cholinergic and noradrenergic stimulation of the PFH in 6 fatty and 6 lean littermate Zucker rats. The rats were anesthetized (chloral hydrate) and cannulae were implanted into the PFH. After at least one week to recover from surgery, the rats were placed on ground chow and water ad lib. An additional 7 day period of adaption to the new diet was allowed before any intracranial injections. Food and water intake was determined in satiated rats 1 hr. following the initial control injection of normal saline (1 µl) as well as 1 hr. following subsequent administration of carbachol (CARB; 4.0 nmol) or norepinephrine (NE; 24.0 nmol) with intake being expressed as mean differences between these two periods. In the initial experiment CARB was administered daily for 5 consecutive days. Following a 2 day drug-free period, NE was administered for 3 consecutive days. Although there was no difference between groups, NE elicited significant eating which increased from an initial value of 1.8 g to 3.1 g by day 3. Following the injection of CARB, significant drinking was observed in both groups (overall mean = 6.2 g) with no group differences being apparent. Food intake following CARB was dramatically different between the two groups, with the lean littermates consistently showing significant eating across the 5 days (overall mean = 0.9 g). The fatty rats ate more during the control period than following CARB on the first 2 days, however, this pattern changed by day 4 when there was no difference between the obese and lean rats. These data suggest that the adrenergic systems may be similar in fatties and normal rats. Although the physiological significance of eating elicited by cholinergic stimulation is at present unknown, genetically obese rats appear to exhibit an initial refractoriness to this stimulus. 704 DOPAMINERGIC MODULATION OF FEEDING IN HUNGRY RATS. Harriet R. Friedman* and Edgar E. Coons* (Spons: Samuel M. Feldman). Dept. of Psychology, New York University, New York, N. Y., 10003.

Rats intrahypothalamically injected with dopamine (DA) while 22 hrs food deprived and measured on consumption for 1 hr immediately thereafter demonstrated facilitated food intake compared to baseline saline controls not only on that day but on similarly conducted saline injection tests administered thereafter every 6 days. This after-facilitation declined significantly as the temporal interval between drug and subsequent saline test increased. By contrast, no facilitated food intake was observed in rats injected with DA while satiated and then tested. Nor did these rats show facilitated intake if they were retested on their subsequent saline injection tests while 22 hrs food deprived. These data imply that DA-facilitated feeding is strongly linked to the state of the animal at the time of the DA injection and not to the state on subsequent saline retests. Given, but only given, that a reward mechanism is activated, as it is when a rat encounters food while hungry, does it appear that DA can enhance this activation. But once the enhancement occurs this facilitated reinforcement of food intake is reflected on similar saline tests for some time thereafter.

In the preceding experiments the rats tested 22 hrs deprived nevertheless had free access to food between test dates; a further experiment placed severe constraints upon the feeding situation by routinely allowing the rats only 2 hrs daily access to food. After weight and intake stabilized, DA was intrahypothalamically injected prior to the presentation of food. Food intake was not significantly increased. However, intake was not attenuated as has been reported by Heffner, Zigmond and Stricker (J. Pharm. Exp. Ther., 201: 386-99, 1977) after i.p. injections of DA agonists in a similar paradigm. These data suggest that under such temporal restraints the pressure to feed until satiated superceded at all times any expression of DA-facilitated intake. A role of DA in modulating the rewarding consequences of food intake will be discussed further.

705 MEAL PATTERNING IN INTACT AND VAGOTOMIZED ANIMALS. Paula J. Geiselman, James R. Martin, Dennis A. VanderWeele, and Donald Novin. Dept. Psychol. & Brain Res. Instit., UCLA, Los Angeles, CA 90024; Dept. Beh. Sci., Swiss Fed. Instit., Zurich, Switzerland; Dept. Neurol., NYU Sch. Med., New York, N.Y. 10016.

In Experiment 1, meal patterns of intact female rabbits were measured throughout a 12:12 light-dark cycle. Changes in food intake across the cycle were reflected differentially in other variables, depending upon the specific time of the cycle at which the animals were tested. The increase in food intake occurring during the hours immediately following light offset was attributed to increased meal frequency and feeding rate, while that found during the latter hours of darkness was attributed to increased meal duration and meal size. Meal patterning was also nonhomogeneous within the various portions of the light-on period. The differences in meal patterning of intact animals from one period to another would suggest that this source of variation has been problematic in developing an understanding of short-term regulation of food intake.

Experiment 2 was conducted to study the disruption of feeding patterns following vagotomy. This study demonstrated the times of the light-dark cycle when feeding patterns of vagotomized rabbits were different from those of intact rabbits and, further, delineated the relevant variables that were altered by vagotomy. During the first portion of the dark cycle, vagotomized rabbits were distinguished from intact rabbits by slower feeding rate and decreased total food intake. Interestingly, the meal patterning of vagotomized animals was not only significantly different from that of intact animals during the initial portion of the dark cycle but, furthermore, bore a resemblance to the feeding patterns of both intact and vagotomized animals during the latter portion of the dark cycle. During the period immediately following light onset, vagotomized animals were distinguished from intact animals by decreased feeding frequency, increased meal duration, and increased satiety ratio. During the periods immediately preceding either light onset or light offset, the feeding patterns of vagotomized animals could not be distinguished from those of intact animals.

706 BOMBESIN SUPPRESSES SHAM FEEDING IN RATS. J. Gibbs and C.F. Martin*. Dept. Psychiatry, Cornell Univ. Medical College and E.W. Bourne Laboratory, The New York Hospital, White Plains, N.Y.10605.

We have previously reported (Abstr.Soc.Neurosci.4:174,#529, 1978) that the gut-brain peptide bombesin (BBS) suppresses food intake in rats, and have suggested that BBS may play a role as a satiety signal when it is released by food during a meal.

This previous test was performed in intact rats feeding normally, in which BBS had the opportunity to interact with other food-contingent satiety signals. In order to analyze the satiety power of BBS alone in a situation in which other effective food-contingent satiety signals were minimized, we tested its satiety action in a sham feeding paradigm. (In this situation, rats eat almost continuously throughout a 60 min test--thus, no effective satiety signals operate.) Thirteen adult male Sprague Dawley rats were each surgically equipped with a chronic gastric stainless steel cannula; these cannulas could be temporarily opened to provide drainage and complete collection of an ingested liquid food. After recovery from surgery, rats were injected intraperitoneally with different doses (2,4,8,16 or 32 $\mu g kg^{-1}$) of synthetic BBS (the gift of R. de Castiglione, Farmitalia Carlo Erba, Milan) or equivolumetric 0.15M NaCl control just prior to presentation of liquid food (25% EC116, GIBCO) following a 17h overnight food deprivation. Tap water was always available.

BBS had a clear and rapid satiety action during sham feeding:

Percent Suppression of Food Intake 15 min after BBS Injection

	Dose of BBS ($\mu g kg^{-1}$)				
	2	4	8	16	32
cannulas open	-6	6*	14*	15*	25**
cannulas closed	16	22*	25**	23*	47**

*$p < .05$; **$p < .01$, statistical difference from control injections

Throughout the 60 min test, BBS not only reduced the rate of sham feeding, but it also elicited prolonged periods during which rats stopped sham feeding entirely, groomed, and appeared to sleep. The incidence of these periods of behavioral satiety increased as the dose of BBS increased.

Comparisons of percent suppressions produced by each dose of BBS between the closed and open cannula conditions (see table) revealed a consistent tendency for BBS to produce a more pronounced satiety action when cannulas were closed, but this tendency did not usually reach statistical significance.

We conclude:(1) BBS alone is sufficient stimulus for the induction of satiety under these sham feeding conditions; (2) the satiety action of BBS does not depend upon the presence of gastric distention.

707 **HYPOPHAGIA-INDUCING LATERAL HYPOTHALAMIC LESIONS AND KNIFE CUTS: EFFECTS ON MOBILIZATION OF FREE FATTY ACIDS AND BLOOD GLUCOSE.** Carlos V. Grijalva, Donald Novin, and George A. Bray*. Depts. Psychol. and Med., UCLA, Los Angeles, CA 90024.

Ventromedial hypothalamic (VMH) lesions suppress the mobilization of free fatty acids (FFA) but do not affect the rise in blood glucose typically elicited by 2-deoxyglucose (2-DG) (Nishizawa & Bray, J. Clin. Invest. 61: 714, 1978). Because VMH lesions are associated with hyperphagia and obesity, and also with a decrement in sympathetic activity, the present study examined the possibility that hypophagia-inducing lateral hypothalamic (LH) lesions or parasagittal knife cuts (placed lateral to the LH) differentially alter FFA and blood glucose levels.

In the first experiment groups of rats were given bilateral electrolytic LH lesions, knife cuts (KC) or control operations and sacrificed 24 hr postoperatively. The KC group had lower FFA levels than either the LH or control groups, however, the KC and LH groups had higher blood glucose levels than the control group.

In a second experiment 3 groups of rats similarly were given LH lesions, knife cuts, or control operations and allowed 25 days to recover feeding behavior. Two additional groups were pair-fed to the LH and KC groups to maintain equivalent body weight. The results showed that the LH group and the 2 pair-fed control groups had significantly higher FFA and lower triglyceride levels than the KC or control (ad-lib) groups. Because the KC and control group appeared to eat in a similar manner, these differences in lipids probably were related to eating patterns rather than to CNS intervention. The LH group also had lower blood glucose levels than either the KC or control group.

In the third experiment groups of rats were similarly treated as in Expt. 2 except that after 25 days of recovery, all groups were given 2-DG 30 min prior to sacrifice. The results showed that the LH and KC groups were less capable of mobilizing FFA when compared to the pair-fed or ad-lib-fed control groups. Interestingly, the KC group did not show the hyperglycemic response to 2-DG that was seen in the LH group or the control groups.

The present results and previous findings indicate that hypophagia-inducing as well as hyperphagia-inducing hypothalamic damage suppresses the mobilization of FFA, but does not interfere with the hyperglycemic response to 2-DG. However, parasagittal knife cuts placed lateral to the LH additionally block the hyperglycemic response to 2-DG. This unique finding suggests that these knife cuts interfered with the sympathetic activation of the adrenal medulla.

708 LACK OF INGESTIVE COMPENSATION TO DEHYDRATIONAL STIMULI IN DECEREBRATES. H. J. Grill and R. R. Miselis. University of Pennsylvania, Phila. Pa. 19104.

The traditional view of the forebrain, particularly the hypothalamus, as the site of the requisite neural circuitry for regulatory behaviors has been effectively challenged in recent years. Hypothalamically lesioned preparations have demonstrated compensatory responses to a range of regulatory challenges suggesting to some a more general arousal deficit. Furthermore, it has been shown that the chronic decerebrate rat can regulate its intake of an orally presented sugar solution as a function of food deprivation and repletion (Grill and Norgren, '78). We reasoned that a parallel regulatory system for water intake in response to dehydrational stimuli could exist caudal to the forebrain. The present experiments sought to determine whether decerebrate rats which others have shown to have a functioning osmo-ADH system and which would compensate for food deprivation by increasing their ingestion of a sucrose solution would also compensate for deficits in body water by increasing their intake of orally presented water. Decerebrates (n=11) and their controls (n=18) were examined using a simple behavioral test for their ingestion of orally presented water as a function of 3 dehydrational challenges and were allowed extended periods of time to demonstrate their capacity to compensate. Supracollicular decerebration was performed in two stages with a hand-held spatula; a minimum of 10 days was allowed before testing commenced. Decerebrates and their controls were fed exclusively by gavage. To assess their compensatory response each rat was injected intraorally with 50 µl of distilled water every 5 sec. via fistulas until water was actively or passively rejected. The volume ingested of this constant stimulus was examined under two conditions: sated baseline, 1 hr. post gavage; and challenged, 24,30 or 48 hrs. post gavage; 1, 4, 8 and 24 hrs. post sodium adulterated meal and 4, 8, 10 and 24 hrs. post s.c. hypertonic saline. Subsequent to these experiments the volume of 0.03M sucrose ingested was compared in sated and deprived conditions. Unlike controls, decerebrates failed to increase ingestion of water following intracellular dehydration regardless of the means of producing dehydration or the duration of the time permitted for a response. Since the same rats showed increased ingestion of sucrose as a function of deprivation it is unlikely that general debilitation or lack of arousal would account for these data. The lack of increased water intake in response to dehydration favors the existence of at least some aspects of the regulatory circuitry in the forebrain. Relevant sensors and integrative mechanisms may both reside in the forebrain or one or the other could exist within the caudal brainstem. In summary, when physiologically challenged decerebrates demonstrate regulatory responses to orally presented sucrose but not water.

709 ANALYSIS OF NORADRENERGIC PROJECTIONS MEDIATING FEEDING RESPONSE ELICITED THROUGH PARAVENTRICULAR HYPOTHALAMIC DRUG STIMULATION. Ronnie Halperin, Lucy L. Brown, and Sarah F. Leibowitz. Rockefeller Univ., New York, NY 10021; Albert Einstein College of Medicine, Bronx, NY 10461.

Noradrenergic stimulation of the hypothalamic paraventricular nucleus (PVN) causes an increase in feeding behavior in the rat. This response can be observed after injection of the receptor agonist norepinephrine (NE), as well as after injection of tricyclic antidepressants (such as desipramine and amitriptyline) which produce their effect through activation of endogenous NE stores. In the present study, the ascending noradrenergic projections which innervate the PVN and mediate these drug effects on feeding were examined through the combined use of three techniques, involving hindbrain electrolytic lesions, drug-injection cannulas aimed at the PVN, and fluorescence histochemistry. Tests examining drug effects on feeding were conducted before and after lesion. The functional integrity of mediating postsynaptic receptors and efferent fibers was evaluated through injection of the receptor stimulant NE and the functional integrity of afferent noradrenergic projections from the hindbrain was evaluated through injection of the presynaptically-acting drugs desipramine and amitriptyline. Anatomical analysis of catecholamine (CA) fiber damage was conducted using fluorescence histochemistry.

Dorsal midbrain tegmental lesions, which damaged fibers coursing immediately ventrolateral to the central gray, selectively abolished the feeding response elicited by desipramine, while significantly potentiating the feeding response to NE. This change in drug responsiveness, which did not occur with lesions in other midbrain locations, was associated with a small to moderate loss of CA fluorescence in the PVN and with evidence for degeneration of CA fibers that course through the dorsal pontine tegmentum and radiate sharply ventrally along the dorsal surface of the superior cerebellar peduncles. In attempting to identify the specific cell group(s) from which these mediating fibers may originate, somewhat more caudal lesions at the level of the pons were examined in animals tested with amitriptyline and NE. Discrete lesions, which damaged the anterior portion of the locus coeruleus (A6) cell group but left intact posterior A6 and ventral (subcoeruleus) cell bodies as well as fibers radiating dorsal to the superior cerebellar peduncles, have so far been found to have little impact on the animals' responsiveness to PVN adrenergic stimulation. Results obtained from current studies examining the effects of more caudal hindbrain lesions will be discussed.

710 THE EFFECT OF EXOGENOUS INSULIN ON FOOD INTAKE IN THE RABBITS. PART I: THE ROLE OF THE DOSE, DURATION OF ACTION AND THE ROUTE OF ENTRY. V. Havlicek and M. Rezek, Dept. of Physiology, University of Manitoba, Winnipeg, Manitoba, R3E OW3, Canada.

Subcutaneous (SC) administration of 1, 5 and 10 U of Protamine Zinc Insulin (PZI) in free-feeding unrestrained rabbits produced a significant and prolonged elevation of diurnal, nocturnal and total daily food and water intakes. Eating was initiated before drinking and the latencies of both responses were considerably shortened; the maximal consumptions occurred between 3 and 8 hr post-insulin. Feeding and drinking changes were paralleled by a gradually developing and prolonged hypoglycemia which was sustained despite the continuous elevation of food intake; the hypoglycemia was also maximal between 3 and 8 hr postinsulin. The dose of 5 U of PZI was most effective in stimulating food and water intake while 10 U of PZI produced greater hypoglycemia associated with manifestations of behavioral depression as well as the alteration of EEG wave pattern and sleep-waking cycle. Repeated daily administration of 5 U of PZI were equally effective in stimulating food intake as the original administration and resulted in a cumulation of daily caloric excesses which was subsequently reflected in a progressive gain of body weight. The administration of 1, 5 and 10 U of regular insulin via the intraperitoneal (IP) route resulted in a temporary stimulation of food and water intakes which was characterized by an earlier onset, maximal significant increase occurring between 1 and 3 hr postinsulin and a complete caloric compensation by the end of 24 hr. The latencies of both feeding and drinking were significantly shortened but now drinking was initiated before eating. The changes in blood glucose were characterized by an early rapid fall, maximal hypoglycemia between 1 and 3 hr and subsequent faster recovery with baseline levels achieved at 24 hr postinsul in. The dose of 5 U was again most effective in stimulating food and water intake while 10 U was clearly excessive as indicated by lower intakes, marked increase in the shallow slow wave sleep (drowsiness) and abnormalities of the EEG wave pattern. The results of this part of experiment suggest that the expression, duration and intensity of insulin-induced hyperphagia is dependent on the route of insulin entry as well as the dose and duration of insulin action.

711 HYPOTENSION AND THIRST IN RATS AFTER ISOPROTERENOL OR PHENTOLAMINE TREATMENT. Jean A. Hosutt* and Edward M. Stricker. (SPON: David J. Kupfer). Psychobiology Program, Department of Psychology, University of Pittsburgh, Pittsburgh, PA 15260.

Blood pressure and water intake were monitored simultaneously in rats following the administration of hypotensive agents. Arterial pressure was recorded from chronic indwelling aortal catheters for 60 min after injection of isoproterenol (33, 100, or 330 ug/kg, sc) or phentolamine (5 or 10 mg/kg, sc). Most of the drinking to these agents occurred when blood pressure was within the range of 60-90 mm Hg, corresponding to a drop of 25-50 mm Hg. Animals whose blood pressure fell within this range generally drank 3.0 - 9.0 ml. This was true regardless of whether they were intact or nephrectomized. Animals whose blood pressure fell above or below this range usually drank little or nothing in response to these agents. For those animals that did drink, there was no clear relation between blood pressure and water intake, although above 60 mm Hg there was a tendency for larger drops in blood pressure to be associated with higher intakes. In view of the relatively minor effect of β-adrenergic stimulation on venous pressure (Abboud et al., Am. J. Physiol., 209: 383, 1965), the present results are consistent with the suggestion that arterial hypotension alone is sufficient to produce drinking. Removal of the source of renin by nephrectomy did not attenuate drinking during moderate hypotension. Severe hypotension, however, may be so debilitating as to preclude a behavioral response in both intact and nephrectomized animals.

712 LIVING FROM HAND TO MOUTH: EFFECTS OF TRIGEMINAL DEAFFERENTATION UPON FEEDING BEHAVIOR PATTERNS IN RATS. Mark Jacquin* and H.P. Zeigler. Dept. of Psychol., Hunter College, CUNY, New York, N.Y. 10021.

To evaluate the generality of disruptive effects upon food intake seen after trigeminal orosensory deafferentation, rats were trained to obtain food by reaching one paw into the food magazine and scooping out mash. The procedure involves an appetitive response which is easily monitored and linked more directly to eating than an operant lever pressing response, but its sensorimotor control does not directly involve trigeminal mechanisms. Prior to deafferentation rats using this "scooping" response show diurnal feeding patterns similar to those recorded with conventional procedures. Varying degrees of bilateral trigeminal orosensory deafferentation were produced by section of anterior and posterior superior dental, sphenopalatine, inferior alveolar and lingual nerves. Following complete deafferentation "scoopers" exhibited periods of aphagia and hypophagia. Their reduced food intake is mediated by a striking decline in the frequency and duration of "scooping" bouts during the immediate postoperative period. Following partial deafferentations aphagias and hypophagias are reduced or absent. In all deafferented animals, the recovery of feeding is accompanied by a striking reduction in the consummatory efficiency of the "scooping" response as measured both by food spillage and by an increase in the ratio of time spent feeding (bout frequency X bout duration) to food ingested. The reduced efficiency of the deafferented rats reflects a disruption in the organization of the "scooping" response sequences involving either an impairment in the continuity of the hand to mouth sequences or a failure to initiate mouth opening and tongue extension on those occasions when the mash is brought to the mouth. Deafferentation effects upon "scooping" were compared with their effects upon a food-reinforced bar-pressing response and upon species-typical consummatory responses. The results suggest that trigeminal orosensory inputs contribute to both the sensorimotor and motivational control of a variety of response classes related to hunger in the rat.

713 HYPOTHALAMIC OBESITY IN RHESUS MONKEYS: GLUCOREGULATORY AND NEUROCHEMICAL CORRELATES. Joseph W. Kemnitz, Robert W. Goy, and Gary W. Kraemer, Primate Research Center, University of Wisconsin, Madison, WI 53706

Bilateral hypothalamic lesions were produced in three young adult male Macaca mulatta. Two sham-lesioned males served as controls. Histological analysis revealed that the lesions were located in the rostromedial lateral hypothalamus. Analyses of regional catecholamine concentrations indicated that norepinephrine (NE) was depleted in the lesioned animals to 46%, 42%, and 34% of the control mean in dorsal/orbital cortex and to 75%, 10%, and 22% of the control mean in caudate/corpus striatum.

During the year of observation following surgery the lesioned animals became markedly obese. The maximal weights of the lesioned animals were 9.25 kg (104%), 8.75 (93%), and 5.26 (51%) greater than their presurgical weights, while the corresponding values for controls were 1.40 kg (15%) and 2.18 (18%). At autopsy large masses of fat were noted subcutaneously, intraperitoneally, and pericardially; there was fatty infiltration of virtually every organ.

The obesity was largely dependent upon hyperphagia. The lesioned animals were overeating during the time of supranormal weight gain and they lost weight when food was restricted to control levels.

One of the lesioned animals exhibited elevated postprandial serum glucose levels (268 mg/dl vs. 70.5 ± 4.5 for controls) as well as elevated postabsorbtive glucose levels (116 mg/dl vs. 69.0 ± 0.0 for controls) and impaired glucose clearance during an intravenous glucose tolerance test after the obesity was established. There was also a smaller decrease in glucose levels for this animal during an insulin challenge test in this phase of the experiment (8 mg/dl vs. 30.0 ± 11.0 mg/dl for controls and 29.5 ± 9.5 mg/dl for the other lesioned animals). Postprandial and postabsorbtive glucose values were more normal (84 mg/dl and 106 mg/dl, respectively) after a 3-week period of food restriction, but were elevated again after the animal was returned to ad lib feeding (347 mg/dl and 132 mg/dl). The other two lesioned animals and the controls exhibited apparently normal glucoregulation throughout the experiment.

The results are consistent with previous reports of obesity following interruption of ascending NE systems in rodents and primates. They further suggest that glucoregulatory deficits are not an invariable consequence of such lesions and that such deficits, when they occurred, may be described as insulin impedance secondary to obesity.

714 *ABDOMINAL VAGOTOMY DISRUPTS DRINKING ELICITED BY PREGASTRIC FOOD-CONTINGENT STIMULATION IN RATS.* *F. Scott Kraly. Dept. Psychology, Colgate University, Hamilton, NY 13346*

Drinking in rats occurs in close temporal association with eating. Rats with complete bilateral subdiaphragmatic vagotomy (Vgx-C) with hepatic branch intact fail to drink normally after eating a meal of solid or liquid food; vagotomized rats drink later and less than normal rats and Vgx-C rats' drinking is not related to the amount of food eaten (Kraly, Smith & Carty, 1978). While these findings implicate the abdominal vagus as a neurological substrate for food-related drinking in the rat, the nature of the vagally-mediated signals that stimulate food-related drinking has remained unknown. The results reported below show (1) that food-contingent stimulation of pregastric sites (i.e., mouth and esophagus) is a sufficient stimulus for drinking in normal rats and (2) that Vgx-C disrupts drinking behavior elicited by pregastric food-contingent stimulation. These findings were obtained from Vgx-C (n=6) and normal (n=8) rats sham feeding and drinking (with open stainless-steel gastric fistulas) after 24-hr food deprivation.

Normal rats initiated sham feeding quickly upon being offered liquid food (GIBCO 116EC) and began drinking with a median latency of 16.8 min after having begun eating. They sham drank a mean of 1.8 ± 0.4 ml/100 g BW in the first 30 min of the test and exhibited a water:food consumption ratio of .37 ± .08.

Rats with anatomically-verified complete Vgx-C also initiated sham feeding quickly and sham fed amounts that were not significantly different ($p > .10$) from amounts sham fed by normal rats. Vgx-C rats drank with an abnormally long median latency (23.5 min; $p = .00$, normal vs. Vgx-C), however, and they sham drank significantly less ($p < .01$) water than normal rats in temporal association with sham feeding (0.2 ± 0.1 ml/100 g BW) while exhibiting a smaller ($p < .05$) than normal water:food ratio (.10 ± .06). Analysis of covariance showed that sham-feeding-related drinking was significantly ($p < .025$) reduced by Vgx-C separate from any effects of Vgx-C upon sham feeding behavior. These effects of Vgx-C upon latency to drink (p's from .008 to < .06) and amount of water sham drunk (all p's < .05) persisted for six repeated sham-feeding tests. These findings were not due to differential collection of ingesta through the gastric fistulas (all p's > .10). Thus, preabsorptive pregastric food-contingent stimulation is sufficient to elicit drinking in normal rats and the abdominal vagus has a role in mediating this effect.

715 FUNCTIONAL AND ANATOMICAL STUDIES OF NORADRENERGIC SYSTEM OF THE PARAVENTRICULAR HYPOTHALAMUS THAT CONTROLS FEEDING BEHAVIOR. Sarah F. Leibowitz. Rockefeller University, New York, NY 10021.

The paraventricular nucleus (PVN) and periventricular region of the hypothalamus are densely innervated by noradrenergic and adrenergic neurons. This area has been shown to be uniquely sensitive to the feeding stimulatory effect of exogenous norepinephrine (NE) and epinephrine observed in the rat. A series of tests focused on increasing our understanding of the significance of this phenomenon have yielded the following results.

1) When antidepressant drugs (such as protriptyline and amitriptyline) are injected into the PVN, increased feeding can similarly be seen. This response apparently results from drug-induced release of endogenous NE, as it is selectively blocked by α-adrenergic antagonists, and it fails to occur in animals with a local and selective inhibition of NE synthesis.

2) Electrolytic lesions in the area of the PVN and periventricular hypothalamus attenuate or abolish the feeding response to both NE and the antidepressant drugs.

3) Discrete damage to the PVN also causes hyperphagia leading to obesity, in male as well as female rats maintained on standard lab chow or high fat diet.

4) The increased eating observed with PVN injection of NE is attenuated or abolished by surgical (subdiaphragmatic) removal of the vagus nerve. Cholinergic vagal efferents to the viscera may be involved in this effect, since peripheral injections of the anticholinergic drugs atropine and scopolamine, at very low doses, similarly antagonize the eating evoked by NE.

5) Caudal hypothalamic and midbrain lesions or knife cuts, which presumably sever PVN efferents to the medullary vagal complex, have yet to be found to significantly interfere with the NE eating response.

6) Tests using a self-selection feeding paradigm, where dietary protein, carbohydrate, and fat are systematically manipulated in solid and liquid food, yield suggestive evidence that NE-injected rats, in comparison with mildly food-deprived rats, manifest an increased preference specifically for carbohydrate and, in particular, sugar.

716 CRITICAL TISSUES WITHIN THE PERIVENTRICULAR REGION OF THE ANTERO-VENTRAL THIRD VENTRICLE (AV3V) ASSOCIATED WITH SPECIFIC THIRST DEFICITS. H. Lind*, R. W. Lind, E. E. Shrager*, S. L. Bealer, and A. K. Johnson (SPON: I. Gormezano). Dept. of Psychology, University of Iowa, Iowa City, IA 52242.

Lesions of the AV3V produce acute adipsia and upon "recovery", a chronic refractoriness in drinking to angiotensin II (AII) and hypertonic saline (HTS). Smaller lesions within the AV3V may produce deficits to only one of the dipsogens. This finding suggests that different areas within the AV3V are crucial for drinking to AII and HTS.

Thirty rats were tested prelesion and 2 weeks following AV3V ablations for drinking responses to s.c. injections of AII (1.56 µg/kg) and HTS (1 ml 12% NaCl/100 g). Six rats were refractory to AII and 12 to HTS while seven rats responded normally to AII and 12 drank normally to HTS.

At the completion of testing, serial sections (40 µ) were cut through the area of the lesion. Both sagittal reconstructions (see fig. below) and common overlap analyses at three horizontal levels (dotted lines) were employed to identify common regions of destruction. These procedures identified critical areas for AII and HTS thirst which are distinct from each other. Complete destruction of the nuclei preopticus periventricularis and suprachiasmaticus (SCN) (note: not the SCN of the anterior hypothalamus) and the organum vasculosum was seen in all animals which evidenced attenuated responses to either dipsogen. However, these three structures were also ablated in the majority of lesioned animals that drank normally. Extensive damage to the preoptic nucleus medianus was present in both the AII- and HTS-deficit groups. However, animals refractory to HTS suffered greater damage to this nucleus. Lesions in animals with deficits to AII were more caudal. The critical areas for both of the dipsogens were within .4 mm of the midline. Two animals that responded normally to each of the challenges could not be distinguished on histological grounds from deficit animals. These findings support the hypothesis that different but closely associated areas within the dorsal AV3V contain neural substrates necessary for drinking to AII and HTS.

717 ANTEROVENTRAL THIRD VENTRICULAR REGION (AV3V) LESIONS: THIRST DEFICITS TO BETA-ADRENERGIC RECEPTOR AGONIST STIMULATION. R. W. Lind and A. K. Johnson. Department of Psychology and Cardiovascular Center, University of Iowa, Iowa City, IA 52242.

Recent work from this laboratory has demonstrated that lesions of the periventricular tissue surrounding the anteroventral third ventricle (AV3V) produce acute adipsia without a compensatory antidiuresis. Animals that recover ad libitum water intake to normal levels remain hypernatremic and hyperreninemic. They also evidence attenuated drinking responses to central and peripheral injections of angiotensin II (AII) and hypertonic saline (HTS).

The beta-adrenergic agonist, isoproterenol (ISOP), is a potent dipsogen (Lehr, Mallow, & Krukowski, JPET, 158:150-163, 1967). Water intake following administration of this compound has been hypothesized to be mediated via the activation of the renin-angiotensin system (Houpt & Epstein, Physiol. Behav., 7:897-902, 1971). However, this interpretation has recently been challenged (Stricker, JCPP, 91:1220-1231, 1977).

The present experiment investigated the effects of the AV3V lesion on the drinking response to ISOP. Rats were pretested with subcutaneous injections of AII (1.56 µg/kg), HTS (1 ml of 12% NaCl/100 g), and ISOP (100 µg/kg). Following recovery from sham lesioning or ablation of the AV3V, lesioned (n=10) and sham-lesioned (n=9) animals were tested with AII and HTS at the prelesion doses, and 10, 30, 100, 200, and 300 µg/kg of ISOP. Water intakes were measured for 2 hrs following AII and HTS injections and for 3 hrs following ISOP treatment. An analysis of variance yielded a significant difference ($p<.025$) between the drinking responses of lesioned and sham-lesioned rats after ISOP injection. The experimental subjects manifested both an elevation in threshold and a decrease in their maximal response to the beta-adrenergic receptor agonist. The mean responses across doses in AV3V lesioned animals were between 36 and 56% of those in control animals. Responses to the AII dose and 30 µg/kg ISOP (the ED50 in controls) were significantly correlated ($r=.93$, $p<.001$) in lesioned rats. Postlesion drinking responses to HTS did not correlate significantly with water intake following the 30 µg/kg injection of ISOP ($r=.372$, $p>.1$) or AII ($r=.304$, $p>.1$). This lack of relationship corroborates the finding by Lind, Lind, Shrager, Bealer, and Johnson (Neurosci. Abs., 5: 1979) that postlesion response deficits to AII and HTS are associated with destruction of different loci within the AV3V. The high correlation between the residual drinking to AII and ISOP following AV3V lesions supports the interpretation that responses to both of these dipsogens are mediated by common neural substrates.

718 EARLY METABOLIC EFFECTS OF VENTROMEDIAL HYPOTHALAMIC LESIONS. Robert G. MacKenzie*, Lee L. Bernardis and Jack K. Goldman* (SPON: M.B. Kristal). Dept. Med., Sch. Med., SUNY and VA Med. Ctr., Buffalo, NY 14215.

Male weanling rats (75-100 g), under sodium hexabarbital anesthesia, were lesioned (1.5 mA anodal d.c. for 10 s) at ventromedial hypothalamic (VMH) coordinates (AP 5.0, ML 0.5, DV 8.2). Controls were lesioned 1 mm beneath the surface of cortex. The rats were injected IV with 1.75 mCi ^3H_2O either immediately following lesion, 2½ hr or 5½ hr post-op and then killed 1 hr post-injection. Food and H_2O were unavailable during the experiments. ^3H_2O served as a tracer for lipogenesis and glucogenesis. Lipid and glycogen content of liver and carcass as well as plasma glucose concentration (PGC) were determined along with the specific activity (SA) of these substances and the SA of plasma H_2O.

The results demonstrate that within 1 hr post-VMH lesion, PGC is increased 25% ($p<.01$) and glucogenesis by 51% ($p<.05$) while lipogenesis is decreased 17% ($p<.02$). Between 2½-3½ hrs post-VMH lesion PGC approaches control values (+15%, NS) as incorporation of tracer into liver (+70%, $p<.05$) and carcass (+71%, $p<.05$) glycogen and liver lipids (+40%, $p<.05$) is accelerated. At 5-6 hrs post-VMH lesion, PGC continues the tendency to be elevated but does not differ significantly from control levels. Glucogenesis is increased (23.5%, $p<.02$) as are carcass and liver lipogenesis (42.5%, $p<.01$ and 52%, $p<.05$ respectively). Our hypothesis is the VMH lesions cause an immediate and transient sympathetic discharge promoting glycogenolysis and suppressing lipogenesis. This is followed by increased uptake of plasma glucose by tissues until uptake begins to lower PGC. At this stage gluconeogenesis is increased to maintain PGC.

These data indicate that complex metabolic disturbances occur very early after VMH lesions. It remains to be determined whether these processes seen in the weanling rat also occur in the mature VMH-lesioned rat and whether they underlie the hyperphagia exhibited by the latter preparation.

719 MODULATION OF THE CENTRAL EFFECTS OF ANGIOTENSIN II (AII) BY SODIUM. Johannes F. E. Mann*, Ernesto L. Schiffrin*, A. Kim Johnson, Roger Boucher*, Jacques Genest*. Clinical Research Institute of Montreal, Montreal, P.Q. H2W 1R7, Canada.

We investigated whether sodium influences the actions of AII on its receptor in the brain in vivo and in vitro. Rats were maintained on a normal (controls) or low sodium diet for 2 weeks and received demineralized water ad lib. For intracerebroventricular (i.v.t.) tests chronic cannulas were implanted into the lateral cerebral ventricle. (I) Drinking was induced in the rats by i.v.t. injections of AII (400 pmol), carbachol (400 pmol) and hyperosmolar NaCl (1.5%) in a volume of 4 µl. In rats on a low sodium diet water intake (as compared to controls) was reduced following AII (4.8 vs 13.1 ml/30 min, p<.001, n:18), it was enhanced by administration of 1.5% NaCl (2.0 vs 0.7 ml/30 min, p< .01, n:20) and there was no difference following carbachol (9.7 vs 9.2 ml/30 min, n:19). (II) The pressor effects of AII and carbachol were tested in conscious, unrestrained rats with chronic arterial catheters to monitor blood pressure (BP). Drugs were applied i.v.t. in a volume of 3 µl. BP increases following AII were significantly reduced in sodium deprived rats (n:8) as compared to controls (n:8) at doses of 10 pmol (8.1 vs 11.3 mm Hg), 100 pmol (13.3 vs 16.3 mm Hg), 1000 pmol (14.6 vs 19.4 mm Hg), and 3000 pmol (17.3 vs 25.0 mm Hg). Carbachol elicited BP increases were only diminished at a dose of 1000 pmol (21.9 vs 28.4 mm Hg) but not so at 10 and 100 pmol respectively when sodium deficient rats were compared with controls. (III) ^{125}I-AII binding to brain homogenates in vitro in rats on a low sodium diet was consistently reduced by 30-50% as compared to controls (3 experiments). (IV) Addition of 75 mM NaCl to the incubation medium in vitro enhanced ^{125}I-AII binding to brain homogenates by 30-40% (5 experiments). Unspecific binding (i.e. not displaceable by an excess of cold AII) was not modified by sodium. These results show that the dipsogenic and central pressor effects of AII are reduced in sodium deficient rats. This may be due in part to changes in the binding properties of AII to its brain receptor. AII has been implicated in the physiological regulation of water intake. It is evident from the present experiments that the potency of AII to elicit drinking depends on the state of sodium balance. The same applies to its effect on central mechanisms of BP regulation.

720 BETA-ENDORPHIN: HORMONE FOR THE CONSERVATION OF BODILY RESOURCES AND ENERGY IN ANTICIPATION OF FAMINE. David L. Margules. Dept. Psychol., Temple Univ., Phila., Pa. 19122.

Almost all of the diverse actions of beta-endorphin(bE) are consistant with the theory that this hormone produces a widespread series of adaptive reactions that conserve fuel&water & reduce energy expenditures, thus prolonging survival during famine. Many forms of excretion cease & retention occurs of H_2O, ions, fuels,& CO_2. Energy expending activities cease & lethargy, passivity & skeletal muscle relaxation occur. An attenuation occurs of the arousal capacity of the stimuli for the activation of the sympathetic nervous system including pain, cold, asphyxiation, oxygen lack and the emotions of fear and rage.bE lowers energy usage by the reduction of thyrotropin release, the lowering of set point for body temperature & the elevation of set point for CO_2 tension in the blood. Drops in body temperature,respiration rate, cardiovascular output, sympathetic tone, and thyroid hormone release, reduce the energy production and oxygen consumption in almost every tissue in the body. bE acts in conjunction with insulin & glucagon, whose release it stimulates, to conserve,extract & store nutrient, H_2O, & ions in the body. Sphincters for defecation, urination, and bile release are tightly contracted. Propulsive peristalsis ceases & the gastrointestinal contents are stirred & mixed in place. bE stimulates the release of anti-diuretic hormone which acts on the kidney to conserve H_2O. bE also acts to inhibit the release of the gonadotrophic hormones, thus reducing sexual urges. Starving organisms can not afford the energy necessary to pursue sexual activities. The actions of bE are supported by ACTH release, which stimulates the adrenal cortex to release the mineralocorticoids and glucocorticoid hormones. These hormones further conserve Na^+ and carbohydrates and reduce the rate of their utilization. bE stimulates feeding and drinking and encourages the development of a pre-famine obesity. Obese organisms can survive periods of famine up to ten times longer in duration than lean littermates. The widespread and integrated series of bE mediated changes in many organ systems suggests that this hormone & its associated receptors may be important new modulators of autonomic nervous system activity. Hibernation is an extreme example of the adaptive power of the bE system in coping with seasonal food short age. Part of preparation for hibernation involves storing calories either on the body as adipose tissue or in the nest as hoarded food. Moreover, many of the physiological changes during hiber nation are consistant in direction with the above bE mediated influences. In support of this theory, naloxone (5mg/kg,sc), an opioid antagonist, increases markedly the respiratory and cardiac rate of hibernating Turkish hamsters, and causes premature arousal from hibernation. Endogenous naloxone-like peptides may exist for arousal from hibernation by antagonism of the bE system.

721 A TEST OF THE VASOMOTOR HYPOTHESIS FOR DRINKING TO ANGIOTENSIN II. Richard R. Miselis and Steven J. Fluharty*. Animal Biol., Sch. Vet. Med., Inst. Neurol. Sci., and Psychol., Univ. of Pennsylvania, Philadelphia, PA 19104.

The vasomotor hypothesis states that angiotensin II (AII) is dipsogenic because of special sensitivity within the brain to AII's vasoconstrictive action. AII presumably vasoconstricts the vascular bed of the receptive site to AII. This is detected by mechanoreceptors which drive drinking behavior. The hypothesis is based on the inhibitory effects to AII drinking caused by central administration of substances which are vasodilators (Nicolaidis and Fitzsimons, C. R. Acad. Sci. 281, 1975; Kenney and Epstein, JCPP, 92, 1978). In this study we measure the effects of AII on blood pressure and local cerebral blood flow to infer what happens to resistence (i.e. vasoconstriction). Sprague Dawley male rats were used for subjects. The autoradiographic technique developed by Reivich et al., J. Appl. Physiol., 27, 1969 and Sakurada et al., Am. J. Physiol. 234, 1978 was used to measure local cerebral blood flow quantitatively. This method uses an inert freely diffusable ^{14}C isotope of iodoantipyrine as a tracer for blood flow. Rats were prepared under ether anesthesia with two femoral arterial and two venous catheters. Following surgery they were restrained by taping the trunk to a brick and allowed to recover from the anesthesia for 3 to 5 hours. Two rats given a control infusion of isotonic saline were compared to 3 rats given 32 ng AII/rat/min. The infusion of the tracer for the measurement of cerebral blood flow commenced 4 minutes after the onset of the saline or AII infusion and continued for one minute. The rats were decapitated, the brains rapidly removed and quickly frozen. AII raised blood pressure an average of 18 mm of Hg. Cerebral blood flows in control rats (saline) ranged from 74.8 to 108.1 ml blood/100g tissue/min. for the structures observed. Cerebral blood flows measured after AII were increased for the same structures. However, the increases were heterogeneous ranging from 19 to 101%. The increases for the following areas were: organum vasculosum of the lamina terminalis- 78%, medial preoptic area - 41%, nucleus medianus - 67%, supraoptic nuclei - 41% and the subfornical organ (SFO) - 19%. If the reduced increase observed in the SFO represents more resistance to a passive increase in blood flow due to the pressure rise, then the results can tentatively be interpreted as support for the vasomotor hypothesis. However, the magnitude of the changes suggest metabolically stimulated increases in blood flow, as well.

722 CHANGES IN THE EFFECTS OF ESTROGEN ON DIURNAL FEEDING PATTERNS FOLLOWING HYPOTHALAMIC KNIFE CUTS. D.M. Nance and C.P. Phelps, Department of Anatomy, College of Med., Univ. South Florida, Tampa, Florida 33612.

In addition to anorexia and weight loss, estrogen priming of ovariectomized female rats results in a marked alteration in diurnal feeding patterns when animals are maintained on a 12:12 light:dark schedule. The changes in meal patterns include: decreases in a.) the number of meals (NM) during light, b.)intermeal interval (IMI) during dark and c.) average meal size (MS) and meal duration (MD) for both photoperiods; but increases in a.) the NM eaten during dark and b.) the IMI during light (Nance & Gorski, Brain Res. Bull. 3:549, 1978). These estrogen induced changes in meal patterns represent an exaggeration in the diurnal distribution of feeding behavior and include a dark phase increase in "nibbling" behavior (many small meals of short duration separated by short intervals) and a further reduction of already low light phase feeding. The net effect of estrogen on MS and MD is an attenuation of diurnal changes in these variables. The neural pathway(s) mediating part of all of these effects of estrogen on feeding behavior have not been established. In the present experiments, the effects of a single injection of 6µg estradiol benzoate (EB) on food intake (FI) and meal patterns were examined in spayed female rats which had received frontal (FC), frontal lateral (FLC) or sham (S) hypothalamic knife cuts (1.5mm radius) in the retrochiasmatic region. FC and FLC were similar except that FLC extended 2.5mm posteriorly along the lateral edge of the ventromedial nucleus (VMN). In rats that had a FC passing through the suprachiasmatic nucleus (SCN) there was a reduced diurnal distribution of feeding behavior before EB and in contrast to S rats, no change in NM and IMI after steroid treatment. In animals with FC posterior to SCN, but anterior to VMN, diurnal variations in meal patterns were present before EB and were altered in the same directions as S rats after EB (increased NM and decreased IMI in dark; decreased NM and increased IMI in light). However, relative to S rats, FLC attenuated diurnal variations in all meal parameters prior to EB, and after EB, NM and IMI of FLC rats were unaffected by EB treatment. Thus, either a FC passing through the SCN or a FLC produced an attenuation in diurnal feeding behavior and prevented EB effects on NM and IMI. These data suggest an interaction between SCN neurons and anterolateral neural connections of the VMN in the mediation of estrogen-sensitive diurnal feeding behavior. Supported by NIH HD11345.

723 EFFECTS OF TESTOSTERONE ON BODY WEIGHT AND FOOD INTAKE: SITES AND MECHANISMS OF ACTION. Antonio A. Nunez*, Linda I. Siegel*, Janet M. Gray* and George N. Wade*. (SPON: J. Meyer). Univ. Mass., Amherst, MA 01003.

Treatment of castrated male rats with low doses of testosterone propionate (TP; .2 mg/day) increases food intake and body weight gain, but long-term (30 days) treatment with a higher dose of TP (1 mg/day) reduces body weight gain and carcass fat content. Concurrent treatment with androsta-1,4,6-triene-3,17-dione (ATD), which blocks the aromatization of androgens to estrogens, prevents the weight-reducing effects of high doses of TP. Long-term treatment with 1 mg TP/day also depletes cytoplasmic estrogen receptors and reduces lipoprotein lipase activity in epididymal fat pads. Both of these effects are blocked by concurrent treatment with ATD and are observed after treatment with estradiol.

Bilateral implants of TP in the ventromedial hypothalamus (VMH) also reduce the food intake of castrated male rats. Similar implants in the preoptic area or VMH implants of 5∝-dihydrotestosterone propionate do not reduce food intake. The effects of VMH implants of TP are comparable to those observed after diencephalic implants of estradiol in both sexes (JCPP, 72: 328-336, 1970; Bull. Psychon. Soc., 3:273-274, 1974).

The results of these experiments suggest that estrogenic metabolites of TP may act on different sites to reduce food intake and body weight. In addition to a direct effect on the hypothalamus, estrogens may reduce body weight gain by inducing changes in adipose tissue metabolism, including lipoprotein lipase activity. These mechanisms may underlie the reductions in body weight, food intake, and carcass fat content seen in gonadally-intact, sexually-active male rats.

724 ANORECTIC AND NEUROCHEMICAL EFFECTS OF D-AMPHETAMINE IN GENETICALLY OBESE (obob) MICE. Roma Olsauskas and Gary A. Oltmans. Dept. Pharmacol., Chicago Med. Sch., Chicago, IL 60612.

Genetically obese mice (obob mutation) have significantly elevated food intakes and hypothalamic norepinephrine (NE) levels compared to those of lean controls (Oltmans et al., Pharmacol. Biochem. Behav. 5:617, 1976). Food intake and brain catecholamine (CA) levels were studied in obob and lean mice following treatment with d-amphetamine (AMP). Female obob and lean mice (5-6 mos old) were acclimated to a 6 hr food access schedule. Drug injections (3 mg/kg AMP or 0.9% NaCl) were administered ip 30 min prior to food access; food intake was measured 1, 3, and 6 hrs thereafter. After 6-11 days of testing, mice were decapitated either 1.5 or 5 hrs following AMP injection, and the hypothalamus (HT), telencephalon (TEL), and brainstem (BST) were analyzed for CA content.

Food intake during the initial 3 hrs of food access did not differ significantly between saline-treated obob and lean mice (1.49±.34g vs 1.31±.23g). During the second 3 hr period, obob mice ate significantly more food than lean mice (1.46±.44g vs 0.94±.28g). While AMP treatment significantly reduced food intake during the first 3 hr period in both obob (70% of control) and lean mice (74% of control), it did not affect the food intake of either obob (114% of control) or lean mice (106% of control) during the second 3 hr period. Consequently,during this period AMP-treated obob ate significantly more than AMP-treated lean mice (1.55±.25g vs 1.07±.26g).

Saline-treated obob mice had significantly higher HT NE levels (+14%) than saline-treated lean mice. At 1.5 hrs after AMP injection (during the period of anorexia), HT NE levels were significantly reduced in both obob (-16%) and lean mice (-11%). At 5 hrs after AMP injection (when mice had resumed a normal feeding pattern), HT NE levels in both obob and lean mice were not significantly different from those of control mice. HT dopamine (DA) levels in lean mice were not significantly changed at either 1.5 or 5 hrs. HT DA levels in obob mice were initially significantly decreased (-23%) and then significantly increased (+37%) at 5 hrs after the injection. Amphetamine-induced CA changes in other brain areas (TEL and BST) varied between lean and obob mice and, in general, indicated that the CA systems in obob mice respond differently to AMP treatment than those in lean mice.

The results indicate that AMP has a comparable anorectic effect in lean and obob mice in the immediate post-injection period. This anorectic action is paralleled by comparable reductions in HT NE levels in both groups. Subsequent to this period of anorexia normal feeding is restored and obob mice again eat significantly more than lean mice. This period of normal feeding coincides with normal HT NE levels in the AMP-treated obob and lean mice.

725 MORPHOLOGICAL EFFECTS OF INTRAHYPOTHALAMIC KAINIC ACID. Gary M. Peterson and Robert Y. Moore. Dept. Neurosciences, UCSD Sch. Med., La Jolla, CA 92093.

Bilteral injections of kainic acid (KA), a neurotoxic analogue of glutamate, into the lateral hypothalamic area (LH) of rats duplicates the aphagia and adipsia produced by electrolytic lesions in the same region (Stricker et al., Brain Res., 158: 470, 1978). Because KA preferentially destroys cell bodies and spares axons of passage (Coyle et al., J. Comp. Neurol., 180: 301, 1978), the resulting feeding and drinking deficit has been interpreted as evidence that cells in the LH may have a role in the control of ingestive behaviors (Stricker et al., 1978). Since KA may affect a wide area of tissue but does not affect all cell groups equally, a detailed histological analysis of those cell groups actually destroyed is necessary.

The effects of LH injections of KA on hypothalamic and thalamic nuclei and on extrinsic fibers passing through the LH were examined by light microscopy. Brains from three groups were examined: 1) bilateral LH injections resulting in aphagia and adipsia, 2) bilateral LH injections which did not result in these deficits,and 3) unilateral LH injections. Brains from the two bilateral groups were from Stricker et al. (1978) and received approximately twice the volume and concentration of KA as the unilateral group (1.14 µg/.57µl and 0.3µg/0.3µl, respectively).

All cell groups in the medial hypothalamus were intact. The LH showed moderate to heavy cell loss. Several subthalamic nuclei, the zona incerta, subthalamic nucleus and medial portion of the reticular thalamic nucleus, were consistently affected by the KA and commonly showed more complete cell loss than the LH. The substantia nigra was not affected. The unilaterally injected brains showed the same pattern of cell loss except that the cellular degeneration did not spread as far rostrally as with the bilateral injections. The bilaterally injected group which did not show ingestive deficits had needle tracks which passed entirely through the brain tissue and no cellular loss. Examination of brain sections stained with the Bodian method showed no destruction of fibers of passage. The concentration of dopamine (as determined by radioenzymatic assay) in forebrain areas receiving fibers which pass through the LH was not significantly affected by the injections.

The anatomical substrate of the LH syndrome has not been well elucidated even though the syndrome was described more than 20 years ago. Whereas intrahypothalamic KA injections produce deficits in feeding and drinking identical to those produced by electrolytic lesions, the present morphological study suggests that damage to nuclear regions in the lateral hypothalamus and subthalamus is important to production of the behavioral syndrome. (Supported by USPHS Grant MH-32410.)

726 EVIDENCE FOR THE PRIORITY OF A RENAL RELATED MECHANISM MEDIATING THIRST INDUCED BY ISOPROTERENOL TREATMENT. R. Rettig and A. K. Johnson. Dept. Psychology and Cardiovascular Center, Univ. of Iowa, Iowa City, IA 52242.

Isoproterenol (ISOP), a beta-adrenergic receptor agonist, induces drinking in normal rats but fails to do so in nephrectomized animals. The renin-angiotensin system (RAS) has been considered to be responsible for the mediation of thirst after isoproterenol treatment (Houpt & Epstein, Physiol. Behav., 7:897, 1971). The hypothesis that ISOP induced drinking is completely dependent on the RAS, however, has been questioned. The greater reduction in arterial blood pressure (BP) in nephrectomized as compared to intact rats after ISOP injection has been suggested to produce debilitation incompatible with drinking. It has been concluded that the RAS merely plays a permissive role by allowing the animal to maintain a sufficiently high BP, while the main stimulus for the water intake is hypotension, mediated by arterial baroreceptors (Stricker, Fed. Proc., 37:2704, 1978).

Our studies were designed to investigate the relative importance of arterial baroreceptor vs. renal mechanisms. In Experiment 1 male albino rats were implanted with catheters in the right femoral artery for BP measurement and in the right femoral vein for i.v. infusion.

Two experimental groups and 2 control groups were formed. Rats in group 1 and 2 (n=7/group) were subjected to bilateral nephrectomy, while rats in group 3 and 4 (n=8, n=6) received ureteric ligations. Three to 4 hrs after surgery a drinking test was conducted. ISOP (40 µg/ml) was infused (.2 ml/hr) by means of a syringe pump in groups 1 and 3. Groups 2 and 4 served as controls and received isotonic saline at the same rate. Prior to the start of the infusions there were no differences in BP between groups 1 and 3. The ISOP infusion lowered the BP 20.2 ± 1.54 mmHg in group 1 and 8.3 ± .75 mmHg in group 3. There was no change in BP in groups 2 and 4. After 1 hr the water intakes were: Group 1, 1.3 ± .7 ml; group 2, 1.3 ± .8 ml; group 3, 4.2 ± .9 ml; group 4, .7 ± .3 ml. The water intake in the group receiving ISOP and ureteric ligation (group 3) was significantly greater than that of group 1 ($p<.05$), group 2 ($p<.05$), and group 4 ($p<.01$). In Experiment 2 a total sinuaortic baroreceptor denervation was performed in 7 male albino rats. Five animals received a sham denervation. After 30 days of recovery 33 µg/kg ISOP was injected subcutaneously in both groups. No significant differences in water intake were observed within a 3-hr period after injection. Therefore, no evidence could be found for an involvement of the arterial baroreceptors in ISOP-induced dipsogenesis. From the results of these experiments we conclude that a major factor mediating thirst after ISOP treatment is associated with a renal mechanism, probably the RAS.

727 [^{14}C] DEOXYGLUCOSE MAPPING OF BRAIN AREAS ACTIVATED BY HYPOTHALAMIC STIMULATION ELICITING GNAWING, EATING, AND DRINKING IN RATS. Warren W. Roberts. Dept. Psychol., Univ. of Minnesota, Minneapolis, MN 55455.

Rats having 1 or 2 ipsilateral hypothalamic electrodes that elicited gnawing, eating, and drinking received intermittent electrical stimulation for 45 min following i.v. injection of [^{14}C] deoxyglucose, and their brains were processed according to the method of Sokoloff for determining regional differences in glucose metabolism. To maximize detectability of elicited activity, baseline metabolism was reduced by light barbiturate anesthesia. The stimulation produced predominantly ipsilateral increases in glucose consumption in an extended sequence of structures extending anteriorly from the lateral hypothalamus into the diagonal band of Broca and the septal area, and posteriorly into the central grey, zona incerta, ventral tegmental area of Tsai (VTA), medial raphe, a portion of the tegmentum dorsal to the brachium conjunctivum (BC), parabrachial nuclei, and locus coeruleus. Many areas were similarly affected in control rats by hypothalamic stimulation that did not elicit the three behaviors. The largest differences between experimental and control rats were in the lateral VTA, supra-BC tegmentum, and dorsal and ventral parabrachial nuclei. These and possibly a few other marginal structures appear to be the most likely candidates for the destinations and/or pathways of hypothalamic efferents producing gnawing, eating, and drinking.

728 REDUCTION OF VOLUNTARY ALCOHOL CONSUMPTION BY MALE GOLDEN HAMSTERS AFTER MELATONIN ADMINISTRATION. P. K. Rudeen* and S. K. Symmes*. (Spon: C. P. McGraw). Department of Anatomy, Bowman Gray School of Medicine, Winston-Salem, N.C. 27103

Male golden hamsters preferentially consume alcohol solutions (< 10%,w/v) when given a free-choice between water and the alcohol solution. The pineal gland has been implicated as influencing the predilection for the ethanol solution. Male golden hamsters were allowed to consume a 5% ethanol solution for 72 days. Light-deprived, sham-pinealectomized hamsters drank more ethanol solution (38 ml/day) than did light-deprived pinealectomized hamsters (31 ml/day; $p < 0.001$). Sham-pinealectomized hamsters maintained in a long photoperiod consumed more alcohol solution (35 ml/day) than did their pinealectomized counterparts (30 ml/day). Serum alcohol levels were higher in sham-operated animals and lower in pinealectomized animals. In subsequent experiments, melatonin, a pineal hormone, was administered either daily for 11 weeks as a subcutaneous injection (25 µg/animal) or weekly as a subcutaneous beeswax implant (1 mg melatonin/24 mg beeswax) for 5 weeks to hamsters allowed a free-choice between water or a 10% ethanol solution. Food, water and alcohol consumption was measured on a daily basis. Animals treated daily with melatonin consumed slightly less ethanol (16.5 ml/day) than did animals not given melatonin (18.0 ml/day). However, in light-deprived animals given chronic implants of melatonin, alcohol consumption was reduced (27.3 ml/day) when compared to alcohol consumption by light-deprived hamsters not receiving melatonin (34.4 ml/day). Total fluid consumption was also reduced by melatonin treatment (30.7 ml/day) and was greater in hamsters which did not receive the melatonin implants (40.7 ml/day). Melatonin treatment resulted in reducing daily total fluid intake as well as ethanol consumption in light deprived hamsters. The results indicate that the pineal gland may influence fluid consumption in the hamster, but the data suggest that the pineal gland does not alter the propensity to consume alcohol.

729 PREOPERATIVE Na^+ EXPERIENCE AND LATERAL HYPOTHALAMIC LESIONS Jay Schulkin* and Jeff Ruger*. Dept. of Nat. Sci., SUNY-Purchase, Purchase, N.Y.; Dept. of Phil., Univ. of Penn., Philadelphia, PA. 19104. (SPON: Leo M. Hurvich).

Lateral hypothalamic lesions disrupt the rat's ability to respond to a Na^+ deficit by ingesting saline. What we found, however, was that animals given pre-operative experience of Na^+ need and saline ingestion did not show this deficit.

Eighteen lateral hypothalamic lesioned animals were used in this study. The Na^+ appetite was induced by injecting the animals subcutaneously with 10 mg of furosemide (Lasix, Hoechst-Roussel) and 5 mg of deoxycorticosterone acetate (Percorten, CIBA). Nine of the animals underwent this treatment prior to the lesion and 9 did not. Both groups underwent this treatment post-operatively. The animals were given a 3% saline solution and deionized water. The 9 injected animals had access to the saline prior to the lesion and the other 9 did not. After an initial post-operative aphagia and adipsia the animals were once again maintained on normal rat chow. (The coordinates with bregma and lambda at the same horizontal plane were 2.7mm posterior to bregma, 1.5 mm lateral to the longitudinal suture and 9.1 below the skull surface at bregma. Anodal dc was administered with .5 mm exposed at the tip for .5 mA for 20 sec.)

The table shows the mean increase of Na^+ and HoH for the 2 days following the treatment from the 2 days baseline prior to the treatment. T test revealed a significant difference between the two groups for the Na^+ scores ($p = < .01$) but not for the HoH scores.

	No Experience	Experience
Na	1.57	8.89
HoH	14.11	12.56

This research, and earlier studies, are an attempt to demonstrate the relevant stimuli that an animal requires prior to the brain lesion in reducing the behavioral deficit. "The Na^+ appetite paradigm" is a screening system for determining which stimuli are most relevant to which anatomical locus in reducing this behavioral deficit.

730 EFFECTS OF ATROPINE AND VAGOTOMY ON APPETITE IN HYPOTHALAMIC HYPERPHAGIC RATS. Anthony Sclafani, Paul Aravich*, Martin Landman*, and Steven Xenakis*. Dept. Psychology, Brooklyn College, Brooklyn, N.Y. 11210.

Bilateral parasagittal knife cuts in the medial hypothalamus of adult female rats produced overeating and obesity. The Cut rats also drank more of a 20% sucrose solution than did sham controls during 30 min/day tests. Pretreating the rats with atropine methylnitrate (5 or 10 mg/kg) did not reduce their sucrose intake, and the Cut rats continued to drink more sucrose than did the controls. Atropine reduced 24 hr chow intake, although the Cut rats still ate more than did control subjects. The results suggest that cholinergically-mediated visceral responses are not essential for knife cut induced sucrose overconsumption. In a second experiment subdiaphragmatic vagotomy (Vag) or sham vagotomy (Sham) were performed in knife cut (Cut) and control (Con) female rats. Vagotomy reversed the hyperphagia and obesity of the Cut rats, and also blocked their overconsumption of 20% sucrose solution during 1 hr and 24 hr/day tests. The atropine results of Exp 1 suggest that the vagotomy effect on sucrose consumption may be due to the disruption of vagal afferent activity, or atropine-resistent vagal efferent activity. In a third experiment the subjects of Exp 2 were given ad libitum access to palatable foods (high fat diet, sweetened milk, chocolate-chip cookies) in addition to chow for 40 days. At the start of the experiment the Cut-Vag and Con-Vag groups weighed less than did the Con-Sham group, which weighed considerably less than did the Cut-Sham group. All rats gained weight on the palatable foods, but the Cut-Vag group gained the most (260 g), while the Con-Vag group gained the least (85 g). The Cut-Sham group gained more than did the Con-Sham group (195 vs 145 g). Interestingly, both the Cut-Vag and Con-Vag groups consumed significantly less of the sweetened milk diet than did the Cut-Sham and Con-Sham groups, which is consistent with the suppressive effect of vagotomy on sucrose solution intake observed in Exp 2. When returned to the chow only diet all groups lost weight, but the Cut-Vag group lost the most (190 g/40 days). These results demonstrate that while vagotomy reverses the overeating of chow and sucrose diets induced by hypothalamic knife cuts, it does not block the hyperphagia and enhanced weight gain displayed by knife cut rats offered an assortment of palatable foods.

731 DRINKING TO CAVAL LIGATION FOLLOWING ABLATION OF PERIVENTRICULAR TISSUE SURROUNDING THE ANTEROVENTRAL THIRD VENTRICLE (AV3V) IS SPECIFICALLY CORRELATED WITH THE POSTLESION RESPONSE TO ANGIOTENSIN II. E. E. Shrager* and A. K. Johnson (SPON: J. A. Harvey). Dept. of Psychology, University of Iowa, Iowa City, IA 52242.

Lesions of AV3V periventricular tissue produce acute, primary adipsia; animals which subsequently regain ad lib water intake demonstrate deficits in the drinking responses to exogenously administered angiotensin II (AII) and hypertonic saline (HYP). These animals also sustain persistent elevations in serum sodium and osmolality (Buggy & Johnson, Am. J. Physiol., 5:177, 1977). In a previous report from this laboratory it was shown that AV3V lesions attenuated or abolished the drinking response to caval ligation. This response failure did not appear to reflect an inability to release renin in response to the surgical manipulation; in fact, lesioned rats demonstrated chronic elevations in basal plasma renin concentration (PRC)(Shrager & Johnson, Neurosci. Abs., 4:180, 1978).

The present studies further explored the contributions of the AV3V region to the control of drinking in response to both exogenously administered and endogenously generated, peripheral AII. Rats were tested to a range of subcutaneously (s.c.) administered doses of AII (0.5,1.0,2.0,4.0,6.0 mg/kg) and of HYP (1-16 cc/kg of 10% NaCl w/w) prior to placement of anodal lesions in the AV3V or sham lesioning procedures. The dose-response curve for AII had an ED50 at 1.0 mg/kg and a maximal response of 7.2 ml (in a 1-hr test) at the 4.0 mg/kg dose. One month postsurgery, dose-response testing was repeated. Half of the lesioned and sham lesioned rats then underwent ligation of the inferior vena cava and were observed for their water intakes over the next 4 hr. The remaining animals were bilaterally nephrectomized and 24 hr later, the water intake to 2.0 mg/kg AII was tested. The drinking response over the 4 hr postligation was positively and significantly correlated with the postlesion response to AII ($r = .686$, $p<.01$). Thus, rats which failed to drink to s.c. AII postlesion also failed to respond to caval ligation. The postlesion response to HYP was not significantly correlated with either the response to AII or to that following caval ligation. The chronic elevation in PRC cannot account for the failure to drink to s.c. AII postlesion as nephrectomy did not reverse the deficit.

These data support the hypothesis that caval ligation acts to induce drinking via those systems mediating the response to s.c. AII, and further, that the lesion produced disruptions of drinking to both the endogenous and exogenous challenges are independent of accompanying alterations of the peripheral renin angiotensin system. Histological analysis for an area of critical damage within the AV3V region, which produced AII response deficits, implicated a portion of the median preoptic nucleus.

732 EFFECTS OF LIMBIC LESIONS ON CIRCADIAN DRINKING RHYTHMS IN THE RAT. Cheryl L. Sisk and Friedrich K. Stephan. Dept. Psychology, Florida State University, Tallahassee, FL 32306.

Large bilateral lesions of the amygdala and ablation of the dorsal hippocampus, including the fornix, significantly enhanced nocturnal drinking and resulted in a tendency toward accelerated re-entrainment following a 12-hr phase shift of the light-dark (LD) cycle. None of the rats were in permanent estrus or anestrus. Knife cuts of the fornix resulted in highly irregular transients after the phase shift of the LD cycle and significantly increased the number of days required to re-entrain drinking rhythms. Since drinking rhythms appeared to free run normally in constant light, the impairment in phase shifting is probably not a deficit in the circadian regulation of drinking. Furthermore, since ablation of the fornix did not produce this deficit, it appears that some other structure damaged by the knife cuts is responsible. All rats in the fornix and hippocampal lesion groups displayed a change in the pattern of drinking bouts for the duration of the experiment but average daily water intake was not affected. It was concluded that the major extrahypothalamic limbic structures may play a modulatory role in the drinking of rats but are not essential to the generation or entrainment of the circadian rhythm in water intake. (Supported by NSF Grant BNS 78 2497 and NIH Grant MH 11218.)

733 FEEDING IN RESPONSE TO SYSTEMIC AND INTRAVENTRICULAR 5-THIOGLUCOSE. Peter G. Slusser* and Robert C. Ritter (SPON: M.E. DeSantis). College of Veterinary Medicine, Wash. State Univ., Pullman, WA 99164

Systemic or intracerebroventricular injection of 2-deoxy-D-glucose (2DG) causes sympothoadrenally mediated hyperglycemia and increased food intake in most mammals. Both of these physiological responses to 2DG are thought to be mediated in part or in total by brain glucoreceptors which detect decreased glucose utilization, glucoprivation. Unfortunately, the feeding and hyperglycemic response to glucoprivation have not been studied in animals treated with other potent antimetabolic glucose analogues. Accordingly, we have been studying the effects of several hitherto unexamined glucose analogues upon food intake and hyperglycemia in rats. We have devoted particular attention to 5-thio-D-glucose (5TG), a glucose analogue in which the glucopyranose ring oxygen has been substituted with sulfur.

5TG is a potent inhibitor of phosphoglucomutase and glucose-6-phosphate dehydrogenase, two enzymes which are not strongly inhibited by 2DG. We have found that intracardiac infusion of 5TG produced marked dose dependent increases in food intake and blood glucose concentrations. In fact, at 0.30 and 0.61 mmols/kg 5TG produced significant elevations of food intake ($N=10$, $p<0.01$) above control values (1.5 ± 0.3 g and 2.6 ± 0.3 g respectively) while equimolar 2DG doses produced no statistically significant changes from control intake ($N=13$, $p>0.1$). Food intake in response to 5TG increased linearly with dose up to 1.22 mmols/kg. However, 2DG induced intake was not dose dependent. At 1.22 mmols/kg, 5TG increased food intake by 5.5 ± 0.7 g and 2DG increased intake by 6.2 ± 0.9 g. These were the maximal responses for both analogues. 5TG also produced 3.0 to 4.6 times greater plasma glucose elevations than did 2DG and appeared to be a more potent inhibitor of insulin release in the presence of food than is 2DG. Work in progress is investigating the comparative potencies of 5TG and 2DG for elicitation of feeding when infused intracerebroventricularly.

The known biochemical actions of 5TG differ markedly from those of 2DG. Therefore, the greater efficacy of 5TG for elicitation of feeding suggests that the metabolic events inhibited by 5TG deserve closer scrutiny with regard to control of food intake.

734 SELECTIVE GASTRIC VAGOTOMY DECREASES THE SATIETY EFFECT OF CHOLECYSTOKININ IN RATS. G.P. Smith, C. Jerome*, R. Eterno* and B. Cushin*. Dept. Psychiatry, Cornell Univ. Med. College and E.W. Bourne Behavioral Research Lab., The New York Hospital, White Plains, N.Y. 10605.

Bilateral abdominal vagotomy markedly decreases or abolishes the satiety effect of the C-terminal octapeptide of cholecystokinin (CCK-8) in rats (Lorenz and Goldman, 1978; Smith and Cushin, 1978). Resection of the hepatic branch is not necessary for this effect (Smith and Cushin, 1978). In an attempt to localize the specific abdominal vagal terminal field that mediates the satiety effect of CCK-8, we performed selective resections of the coeliac (n=8) or gastric (n=9) branches of the abdominal vagus. After recovery from surgery, rats were adapted to overnight (17 hr) food deprivation and offered their maintenance diet of sweet milk. When intakes stabilized, rats were injected i.p. with CCK-8 (1-16 mcg/kg) or with saline 15 min before food was offered. Gastric vagotomy decreased the satiety effect of CCK-8, but coeliac vagotomy had no effect. The dose for 50% inhibition of food intake in gastric vagotomy rats was about 16 mcg/kg compared to about 2 mcg/kg in sham operated rats. The results suggest that (1) the stomach is the major site of action for the satiety effect of CCK 8; and (2) vagal afferents relay the satiety signal to the brain.

735 ANTICIPATION OF 24 HR FEEDING SCHEDULES IN RATS WITH LESIONS OF THE SUPRACHIASMATIC NUCLEI AND HYPOPHYSECTOMY. Jennifer M. Swann* and Friedrich K. Stephan. Dept. of Psychology, Florida State University, Tallahassee, FL 32306.

We have shown previously that rats with lesions of the suprachiasmatic nuclei (SCN) anticipate restricted access to food by an increase in wheel running as readily as intact rats and presented evidence that this behavior shows some of the basic properties of a circadian rhythm, despite the absence of circadian rhythms in activity and drinking in ad lib. conditions. Anticipatory activity was not prevented by adrenalectomy (Stephan, Swann and Sisk, Behavioral and Neural Biology, 1979, in press). To elucidate the possible role of the pituitary gland in anticipatory activity, hypophysectomized rats and controls were maintained in constant light with ad lib. access to food and water for 10 days, followed by a restricted feeding schedule (one or two daily access periods) at 24 hr intervals for 20 consecutive days. Under ad lib. conditions, both groups showed free running activity rhythms with a period of approximately 25 hr. Under restricted access conditions, the dominant period of activity became exactly 24 hr in both groups, although a weaker activity component with a period longer than 24 hr persisted in some animals. However, while controls showed distinct anticipatory activity within 2-5 days after initiation of the restricted feeding schedule, hypophysectomized rats required 10 days or longer before anticipatory activity appeared. Furthermore, the amount of anticipatory activity was significantly reduced compared to controls. Preliminary data on hypophysectomized rats with SCN lesions indicate that these rats are still capable of anticipating restricted feeding schedules. While some rats no longer showed anticipatory wheel running, simultaneously collected event records of drinking indicated the presence of anticipatory licking. These results show that restricted access to food at 24 hr intervals synchronizes activity of hypophysectomized rats and that anticipatory activity is reduced, but not prevented, by hypophysectomy. Furthermore, SCN lesions in hypophysectomized rats may abolish anticipatory wheel running but not anticipatory drinking. Thus, the locus of control for anticipatory behavior remains to be determined.

737 INSULIN AND SATIETY IN OBESE AND NORMAL-WEIGHT RATS. Dennis A. VanderWeele, Edward Haraczkiewicz* and Theodore B. Van Itallie*. Dept. Neurol., Sch. Med., NYU, New York, NY, 10016 and Obesity Res. Cent., Dept. Med., Columbia Univ., New York, NY, 10025.

The role of insulin was evaluated in normal-weight, male rats using the osmotic minipump to elevate endogenous insulin levels. Normal-weight animals reduced food consumption by lowering meal sizes without any change in meal frequency when 1.92 U regular insulin was delivered via minipump. Meal sizes averaged 21% smaller with 1.92 U insulin compared to isotonic saline delivered via the pump. Body weight gain was significantly decreased in animals receiving 1.92 U but not in subjects receiving 0.96, 4.0, and 6.0 U insulin per 24 hr, when compared to animals receiving saline. Thus, normal-weight animals, with induced elevation of insulin levels, may increase satiability and limit weight gain by clearing the blood of nutrients more efficiently.

The above findings indicate a sustained modest elevation of insulin is associated with reduced food intake. Obese animals with attendant hyperinsulinemia have been shown to reduce food intake when the manipulation inducing the obesity is terminated and, therefore, it was hypothesized that impairment of insulin release would attenuate the hypophagic response. To test this proposal, insulin release was severely impaired with injections of streptozotocin at 45 mg/kg body weight, based on the weight of the lightest subject. Obese, diabetic animals consumed 17% less food daily than nonobese, diabetics; obese, nondiabetics consumed 16% less food daily than nonobese, nondiabetics; and mild diabetics which were also obese (<2% glycosuric) consumed 21% less food daily than did nonobese, nondiabetics. These differences are all significant at the 0.05 level. A dietary snack-food paradigm had been used to induce obesity in the rats, but food intake comparisons post-streptozotocin were made with regular Purina chow only. Thus, the hypophagic behavior of dietary obese rats shifted to less palatable diets does not appear to depend upon obesity-induced insulin excess. Insulin-enhanced satiety in normal-weight animals may not be inconsistent with the obese animal effects due to increased insulin resistance which would develop in the obese animals.

736 INHIBITION OF ADH SECRETION AND SATIETY FOLLOWING WATER INGESTION IN WATER-DEPRIVED DOGS. T.N. Thrasher*, J.F. Nistal Herrera*, L.C. Keil*, C.J. Brown* and D.J. Ramsay. Dept. of Physiol., UCSF, San Francisco, CA 94143 and Ames Res. Cent. Moffett Field, CA 94035.

It is well known that some species, such as dogs, sheep and goats, are able to repair a water deficit due to deprivation within the first few min. of access to water. Since, in dogs, drinking is complete long before ingested water alters plasma tonicity or volume, the mechanism which matches water intake to deficit must rely on other afferent information. Stimuli which elicit thirst usually also elicit ADH secretion. Therefore, we questioned if ADH secretion was reduced before restoration of plasma tonicity in water-deprived dogs. A preliminary experiment on four dogs, dehydrated for 24-hours, indicated that plasma ADH fell before a detectable change in plasma sodium or osmolality occurred. The two most likely stimuli which could account for this phenomenon are drinking-induced oro-pharyngeal stimulation or gastric distention. In order to test between these two stimuli, a second population of dogs was prepared with permanent gastric fistulae, thus allowing either immediate removal of ingested water, or loading of water directly into the stomach. Blood was sampled before dehydration, after 24-hours of dehydration, and at 3, 6, 9, 12, 15, 30 and 60 min. after allowing access to water. Three experiments were carried out: (1) oral rehydration with water available to satiation; (2) oral rehydration coupled with simultaneous removal, via the fistula, of the ingested water; and (3) gastric loading of water, via the fistula, the amount being determined from (1) above. Dogs allowed to drink ad lib were satiated within six min. and showed a significant reduction in plasma ADH before a detectable change in plasma sodium or osmolality occurred. When offered water 60-min. later, it was ignored suggesting complete satiation. Dogs which drank but lost the water via the fistula also were satiated within six min. Plasma ADH was significantly reduced at 3, 6, 9 and 12 min. after drinking but rapidly increased to pre-drinking levels. No changes in plasma sodium or osmolality were detected at any time. When offered water 60 min. later, they drank approximately the same volume that was consumed in (1) above. Gastric administration of a water load equivalent to that drunk in the first experiment produced a simultaneous reduction in plasma ADH, sodium and osmolality. When offered water 60 min. later, they drank 20% of the volume consumed in (1) above. Since plasma sodium and osmolality had returned to predehydration levels, this drinking suggests that oro-pharyngeal stimulation is required for complete satiety. These data indicate that oro-pharyngeal influences, but not gastric distension, acts to suppress ADH secretion in water-deprived dogs. Supported by NIH Grant AM 06704.

738 ONTOGENY OF CHOLECYSTOKININ-INDUCED SATIETY IN RATS. C.H. Wang* and S. Hsiao*. (SPON: M. Wetzl) Dept Psych, U Arizona, Tucson

Three hundred and fifty-eight neonatal rats selected from 44 litters of different ages were used in four experiments to investigate the development of behavioral response to a satiety hormone cholecystokinin (CCK). The CCK-induced satiety was first seen in 9 day-old rat pups followed by a disappearance of the effect at day 10 through 12 and then permanently reappeared at day 13. This phenomenon was replicated at the critical ages of day 9 through day 13. Thyroxine injections during the first postnatal week facilitated the onset of CCK-induced satiety whereas hypothyroidism induced by treating the nursing mothers with n-Propylthiouracial (PTU) during their late pregnancy retarded the onset of CCK-induced satiety. These alterations of behavioral response by manipulating the thyroid hormones were parallel to the alterations of morphological growth rate such as teeth eruption, ears and eyes openings.

739 CIRCADIAN DRINKING RHYTHMS AND MODULATION BY EXOGENOUS LIGHT. Andrea L. Wesley. Dept. Psy., Univ. Sou. Miss., Hattiesburg, Ms 39401.

Physiological and behavioral studies have shown that the light-dark cycle exerts a pronounced exogenous influence upon endogenous eating and drinking rhythms. The exogenous stimulus of light was used to investigate its effects upon the rhythmic pattern of water intake as well as the total daily consumption. Low, medium, and high intensity light levels (1 log difference) were used in a series of three experiments to study the interaction of exogenous and endogenous mechanisms in three strains of rats, Wistar (WS), Long-Evans (LE), and Charles River (CH). In experiment 1 with constant light of the three intensity levels, WS and CH rats reduced daily water intake significantly ($p < .01$). LE rats, however, did not exhibit a significant decrease in water intake, even at high light intensities. Nocturnality of drinking (%dark/total daily intake) was reduced in both CH ($p < .01$) and WS ($p < .02$) after exposure to a light-dark cycle with low intensity light periods in experiment 2. With high intensity light periods nocturnality increased in these two strains ($p < .01$). Again, LE rats did not exhibit a significant modification of drinking in response to light intensity manipulations in the light periods. In experiment 3 the superior accessory (SAOT) and primary optic (POT) tracts were lesioned to evaluate the possible influence of the accessory optic system; this lesion resulted in disinhibition of the inferior accessory optic system (IAOT). When compared with non-lesioned controls for each respective strain, LE rats reduced daily water intake at medium ($p < .001$) and high ($p < .05$) intensity levels of constant light. These reductions were comparable to those exhibited by WS and CH rats ($p < .02$). The results suggest that in the LE rats, the SAOT is able to compensate for the effects of light intensity on water, preserving the homeostasis of fluid balance as well as nocturnal drinking patterns. In summary these experiments demonstrate the interaction of exogenous factors with the rhythmic controls of drinking in the rat.

740 AV3V DESTRUCTION IN INFANT RATS AND THE DEVELOPMENT OF DRINKING BEHAVIORS AND BODY WATER REGULATION. Robert L. Wyatt* and C. Robert Almli. (SPON: C. Spirito). Dept. Psychol., Ohio Univ. Athens, Ohio 45701.

Infant albino rats (males and females) sustained electrolytic lesions of the periventricular tissue surrounding the anteroventral third ventricle (AV3V) at 10 days of age. Following weaning at 25 days of age, and throughout development, drinking behaviors were measured daily. Also measured were drinking behaviors following specific dipsogenic treatments, as well as various blood and urine variables.

Daily ad lib water intakes of AV3V rats were elevated over control intakes from the first measurement period and thereafter. Female AV3V rats were reliably hyperdipsic by 25-30 days of age, and males were reliably hyperdipsic by 45-50 days of age. The daily ad lib hyperdipsia was maintained through 200-250 days of age for both sexes, and reached 216% of control intakes. When the rats were tested for drinking behaviors following specific manipulations, the AV3V rats (of both sexes) were hyperdipsic in response to hypovolemia produced by polyethylene glycol injections, they were hyperdipsic during 24 hour food deprivation, and they were hyperdipsic following 24 hour water deprivation. More noteworthy, because of the contrast with rats sustaining AV3V lesions as adults, the rats sustaining AV3V lesions at 10 days of age were also hyperdipsic in response to cellular dehydration produced by injection of hypertonic NaCl solution. Latency to initiate drinking following hypertonic NaCl solution injection did not differ between AV3V and control rats. Water intakes of AV3V and control rats did not differ following injection of isoproterenol, and AV3V rats displayed a normal sodium appetite following formalin injection.

Under ad lib conditions, urine output:water intake ratios of AV3V rats were elevated over controls, and their urine was more dilute than controls. However, the AV3V rats were hyperdipsic, and even with an elevated urine output, these rats were retaining more body water than controls. This water retention was associated with serum hyponatremia for AV3V rats under ad lib conditions. These results suggested a possible disruption of water savings mechanisms; thus, the rats were water deprived for 24 hours. The AV3V rats displayed ability to reduce urine volume (AV3V = 64-74%, control = 26-51%) and to increase urine concentration (AV3V = 200-300%, control = 100-200%) during 24 hour water deprivation. Thus, the hyperdipsia of the present AV3V rats seemed primary, and the etiology of the hyperdipsia is under study. Supported by: NICHHD (HD-08504) and OURC (OU-520).

741 NEUROPHYSIOLOGICAL CORRELATES OF GUSTATORY AND VISCERAL SENSATION OF ALCOHOL AND OTHER NUTRIENTS IN THE RAT. Warren G. Young* and J. Anthony Deutsch* (SPON: R.B. Livingston). Dept. Neurosciences and Psychology, UCSD, San Diego, CA 92093.

The nucleus of the solitary tract receives gustatory and visceral afferents arising from the facial (VII), glossopharyngeal (IX), and vagus (X) nerves. Extracellular neuronal recordings have been carried out in this nucleus only as a function of sapid, thermal, and tactile stimulation of the tongue.

Gustatory information is essential for the neural mechanism of taste aversions and for modulating hunger-satiety levels. We know that rats have an extraordinarily well-developed mechanism of bait shyness. Our experiments have consistently shown that naive rats will avoid alcohol ingestion. However, forced intubation will yield a chronically dependent rat.

We are investigating this disparity by recording extracellular single unit activity from the nucleus of the solitary tract. Correlations are being made between the naive and the chronic rat and their respective neuronal response patterns. Furthermore, there is an integration of gustatory neural coding with visceral neural coding arising from vagal afferents synapsing on the nucleus. We have found evidence substantiating differential gastric sensibility (J.A. Deutsch, W.G. Young, and T.J. Kalogeris, Science 201, 165 (1978)). We are continuing investigations into this total quality coding of alcohol and dietary nutrients by recording unit activity correlated with gustatory and visceral parametric manipulations. Full results will be presented at the meeting. (This work is being supported by grant AA 07129-04 to J.A. Deutsch).

742 WATER INTAKE AFTER VOLUME DEPLETION IN SHEEP: EFFECTS OF CRUSHING THE LEFT ATRIAL APPENDAGE. Mark B. Zimmerman*, Edward M. Stricker and Edward H. Blaine*. Merck Institute for Therapeutic Research, West Point, PA 19486, and Dept. of Psychology, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Reduction of the intravascular fluid volume has been shown to induce water ingestion in a variety of mammalian species. The present experiments provide the first direct evidence that cardiovascular baroreceptors play an important role in mediating this response. In one group of adult female sheep (I; 7 experiments on 5 animals), removal of 2460-3208 ml of protein-free, isoosmotic fluid was accomplished using a Gambro dialyzer and an extracorporeal blood pumping system. Filtration occurred over a 5-hr period in conscious food- and fluid-deprived animals, followed immediately by access to food and water for 2 hr. In a second group of sheep (II; 5 experiments on 4 animals), the appendage of the left atrium of the heart was crushed 15-20 days prior to filtration. A similar procedure has been shown to abolish the increases in urine flow and heart rate that normally occur following distention of the atrial appendages in dogs (Kappagoda et al., J. Physiol. 227: 233, 1972). The results are tabulated below (mean ± SEM; B = value before filtration, A = value after filtration):

		ABP mm Hg	PP g%	PRA ng/ml/hr	P_{Na} mEq/L	GFR ml/min	RPF ml/min	△INTAKE ml/2 hr
I	B	90±2	6.0±0.2	1.2±0.2	142±1	62±3	454±44	
	A	59±6	7.8±0.3	27.6±6.4	142±1	9±4	91±43	1238±265
II	B	83±2	7.0±0.3	3.0±0.3	145±1	64±7	535±74	
	A	57±4	9.0±0.4	49.6±7.5	147±1	7±3	106±29	163±106

In both groups of animals, the filtration procedure raised plasma protein concentration (PP) and plasma renin activity (PRA) while it reduced arterial blood pressure (ABP), renal plasma flow (RPF), and glomerular filtration rate (GFR); plasma sodium concentrations (P_{Na}) remained unchanged. The major finding of this study is that hypovolemic intact sheep ingested considerably more water than usual, whereas sheep with crushed appendages did not. (△INTAKE was the volume of water consumed after filtration minus the mean water intake averaged from comparable testing periods of the previous 5 days.) Control experiments showed that neither ad libitum water intake nor the drinking response to intracarotid infusion of 4 M NaCl solution was affected by the crushing. These data suggest that volume receptors located in the area of the left atrium may play a role in mediating thirst during hypovolemia.

HYPOTHALAMUS

743 INDIVIDUAL BEHAVIORAL RESPONSES TO HYPOTHALAMIC STIMULATION PERSIST DESPITE DESTRUCTION OF TISSUE SURROUNDING ELECTRODE TIP. Susan E. Bachus* and Elliot S. Valenstein. Dept. Psychobiology, Univ. Michigan, Ann Arbor, Michigan 48109.

Striking individual differences in the behavior evoked by electrical stimulation of the lateral hypothalamus (ESLH) have been noted in animals, even with indistinguishable electrode placements and identical testing procedures (Cox & Valenstein, Brain Behav. Evol. 2:359, 1969). It has been argued that individual differences in response to ESLH may be due to variability in localization of critical neural substrates, but responses have been reported not to change after incremental movements of the electrode (Wise, Physiol. Behav. 6:569, 1971). In the latter experiment, however, the possible roles of current spread or stimulation experience were not considered. We investigated whether the same behavior would be elicited by stimulation of different substrates in individual rats by retesting after producing lesions around the tips of the electrodes, in rats with either extensive or minimal stimulation experience prior to the lesions.

Sprague-Dawley and Long Evans rats were implanted with bipolar electrodes, and screened for elicitation of drinking by ESLH. Some S's received daily tests until current thresholds for eliciting drinking had stabilized. Other S's were given "minimal stimulation" experience (as few as 2 stimulus trains) to establish the presence of elicited-drinking. Electrolytic lesions were then administered through the stimulating electrodes. One group of S's received a series of progressively larger lesions, each succeeding extensive daily testing. In another group, single stage large lesions were produced in S's which had minimal stimulation experience. In all cases, drinking was elicited by ESLH after extensive lesions, usually at greatly elevated thresholds. Histological examination revealed that drinking was evoked after lesions in which damage spread over 3 mm along an anterior-posterior axis through the medial forebrain bundle, with a maximum diameter of over 1 mm.

When the low stimulating current levels (as low as 1.0uA, 60 Hz sine wave) that were initially sufficient to evoke drinking are considered along with the large area of destruction around the electrode tips, we infer that the neuronal elements that were directly activated by the stimulation during screening were completely destroyed, or at least, the circuitry radically altered; yet the initial response persisted. These results suggest that individual differences in response to ESLH cannot be attributed solely to variation in the neuroanatomical locus of stimulation. Moreover, this persistence does not reflect changes induced by a long regimen of stimulation or experience. We conclude that some animals are predisposed to drink in response to stimulation within a relatively large hypothalamic area.

744 A NEUROPHYSIOLOGICAL DETERMINATION OF LATERAL HYPOTHALAMIC AND LATERAL PREOPTIC AREA INTERCONNECTIONS. F. C. Barone, M. J. Wayner, W. H. Tsai* and F. E. Barash*. Brain Research Lab, Syracuse Univ, Syracuse, NY 13210.

Single unit recordings were made from central neurons in anesthetized male hooded rats. In some animals the effects of lateral hypothalamic stimulation on lateral preoptic area-medial forebrain bundle (LPA-MFB) unit activity were determined. In other animals the effects of LPA stimulation on lateral hypothalamic-medial forebrain bundle (LH-MFB) neural activity were determined. Recordings were made ipsalateral to the stimulating electrode. A stable baseline discharge frequency was established and single pulses, 0.5 msec in duration, and/or trains of pulses were applied to the stimulation site through a concentric bipolar electrode. Both frequency, usually 0 to 20 Hz, and voltage, 0 to 10 volts, were varied in a random manner. The reliability of effects was established by repeated testing. The results of single pulse stimulation on neural activity were examined on a storage oscilloscope and photographed. The results of trains of pulses on neural activity were illustrated graphically by means of a strip chart recorder. Frequency and voltage response relationships were established. Both excitatory and inhibitory effects were observed. Analysis of single pulse stimulation indicated that the effects were mono and polysynaptic. The effects occurred with relatively short latencies and low voltages indicating that interconnections between the LPA and LH exist. Data obtained from repetitive stimulation confirmed the results of single pulse effects. These results together with neuroanatomical data unequivocally demonstrate a significant degree of interconnectivity along the extent of the LPA-LH-MFB neuropil.

745 AFFERENT PROJECTIONS TO THE MEDIAL PREOPTIC AREA AND MEDIAL HYPOTHALAMIC REGIONS OF THE RAT. Mitchell L. Berk* and Judith A. Finkelstein. Dept. Anat., N.E. Ohio Univs. Col. Med., Rootstown, Ohio 44272.

Many neuronal pathways to the medial preoptic area (MPOA) and hypothalamus of the rat have been determined by the use of a variety of neuroanatomical techniques. However, in order to obtain a complete overview of the afferent projection to this region, the horseradish peroxidase (HRP) technique was utilized. Iontophoretic injections of HRP were placed in the MPOA-anterior hypothalamic area and the regions of the paraventricular, dorsomedial (DMH) and ventromedial hypothalamic (VMH) nuclei using standard stereotaxic procedures. Survival times were usually 24 hrs. Sections were processed by the tetramethylbenzidine (TMB) procedure which produces a blue reaction product.

The following description of labeled cells pertains to all injection sites, unless stated otherwise. In the telencephalon, HRP granules were localized ipsilaterally in the perikarya of the ventral subiculum, medial amygdala, and the lateral septal nucleus. The basolateral nucleus of the amygdala was labeled only with VMH injections. Labeled cells in the bed nucleus of the stria terminalis were found in VMH and DMH injections. At midbrain levels, labeled cells were located in the ventromedial part of the periaqueductal gray and the dorsal and median raphe. Injections in the VMH region resulted in intensely stained cells bilaterally (ipsilateral> contralateral) in the peripeduncular nucleus. With all other injection sites only ipsilateral peripeduncular cells were labeled; the intensity of the staining was less than with the VMH region injections.

At pontine levels, labeled cells were located bilaterally (ipsilateral> contralateral) in the lateral parabrachial nucleus and the locus coeruleus. The dorsolateral tegmental nucleus, as well as cells medial and ventral to the dorsal tegmental nucleus, were labeled. Also, DMH-VMH injections resulted in labeled perikarya in the dorsal and ventral tegmental nuclei.

In the medulla, labeled perikarya were located bilaterally (ipsilateral> contralateral) in the nucleus of the solitary tract and lateral reticular nucleus (possibly the A2 and A1 catecholaminergic cell groups respectively). Labeled cells of the lateral reticular nucleus were more intensely stained on the ipsilateral than on the contralateral side. Labeled medullary reticular cells were found bilaterally in the area bordering the medial longitudinal fasciculus, lying ventral to nucleus prepositus hypoglossi. These results indicate that a multiplicity of areas send their input to cells in the medial hypothalamus where they may modulate homeostatic mechanisms. Supported by NIH Grant 5 R01 NS14344 and NSF Grant BNS 77-19302.

746 HYPERPHAGIA AND OBESITY FOLLOWING LESIONS OF THE MEDIAL HYPOTHALAMUS IN MAN. Gastone G. Celesia, Carol R. Archer* and Hyung D. Chung*. Veterans Administration Medical Center and St. Louis Univeristy, St. Louis, MO 63104.

Food intake is regulated by the hypothalamus. Bilateral destruction of the ventromedial nucleus (VM) in animals induces abrupt onset of voracious eating while bilateral destruction of the lateral hypothalamus at the level of VM causes cessation of eating. Similarly in man, lesions of the lateral hypothalamus causes anorexia and emaciation; in contrast the effects of VM lesions are more controversial.

A 28-year-old man developed progressive left hemiparesis followed three weeks later by face and trunk cutaneous vasodilatation and hyperphagia. He began eating five to six meals per day and constantly felt hungry, he gained thirty-five pounds in sixty days. Computerized tomography with coronal and sagittal reconstruction revealed a neoplastic lesion involving the right lenticular nucleus, the right internal capsule, crossing the midline via the hypothalamus and reaching the contralateral lenticular nucleus. Endocrine studies including HTSH, growth hormone, prolactin and cortisol serum levels were normal. Hyperphagia and consequent obesity was caused by bilateral destruction of VM, cutaneous vasodilatation was related to involvement of preoptic area.

It is suggested that in man a medial hypothalamic syndrome is characterized by hyperphagia, obesity and cutaneous vasodilatation. Additional signs may be hyperthermia and diabetes insipidus.

747 ULTRASTRUCTURE OF NEURONS OF THE VENTROMEDIAL NUCLEUS OF OVARIECTOMIZED AND ESTROGEN-TREATED FEMALE RATS. Rochelle S. Cohen* and Donald W. Pfaff, The University of Illinois at the Medical Center, Chicago, Il. and The Rockefeller University, N.Y., N.Y.

Cells in the ventrolateral area of the ventromedial nucleus in the hypothalamus have a high affinity for estradiol. We are studying the cellular architecture of these cells to see what differences exist between such cells and other neurons, and to look for estrogen effects.

Estradiol benzoate was injected daily subcutaneously in one group of ovariectomized rats. The control group was injected subcutaneously with the vehicle, sesame oil. After 20 days, exposure to estrogen, the experimental rats showed a strong lordosis reflex response and at this time the rats were sacrificed by anesthetizing with nembutal and perfused with fixative according to standard electron microscopy procedures (Peters, 1970). Three regions of the brain were dissected from each rat: the ventrolateral and dorsomedial subdivisions of the ventromedial nucleus of the hypothalamus and, as a control, the ventrobasal thalamus. These areas were embedded and thin-sectioned for viewing with the electron microscope.

The overall morphology of the ventromedial nucleus consists mainly of neurons and a few interspersed glial cells. The neurons contain large oval nuclei, the nuclear membrane of which is often invaginated; the nucleoplasm is finely granular with a densely granular nucleolus. The assemblage of organelles present include rough endoplasmic reticulum (RER), a Golgi complex with coated and uncoated vesicles attached or in the vicinity, small (~125nm) dense-cored vesicles, lysosome-like bodies, dense, granular, non-membrane bound structures referred to as inclusion bodies, multivesicular bodies, and occasionally, myelin figures are present.

Two trends seen as differences in the ventrolateral subdivisions of the two groups include a greater stacking of RER and a greater number of dense-cored vesicles in estrogen-treated rats compared to the control group. King et al. (1973) also found changes in the organization of the RER and dense-cored vesicles, among other changes, in arcuate neurons of the rat during the estrus cycle.

748 AUTORADIOGRAPHIC ANALYSIS OF HYPOTHALAMIC AREA CONTROLLING CARDIOVASCULAR RESPONSE TO EMOTION. J. DeVito, O. Smith, J. Stein and K. Walsh*, Reg. Primate Res. Ctr., Univ. Wash., Seattle, WA 98195

The cardiovascular (CV) responses to an acute emotional situation in unanesthetized chair restrained baboons include elevations in heart rate, blood pressure, and terminal aortic flow and a complex biphasic reduction in renal flow. The same CV responses can be produced by stimulating an area in the hypothalamus. Furthermore, bilateral ablation of the hypothalamic area eliminates CV responses to the emotional behavior while responses to exercise, free feed and sleep remain unaltered. Efferent projections of the hypothalamic site were traced by means of autoradiography.

Prior to the isotope injection baboons were fitted with recording devices for heart rate, blood pressure and renal flow. They were anesthetized and stereotaxic coordinates determined by ventriculography. An electrode was lowered through a guide cannula into the hypothalamus until stimulation produced the appropriate CV responses. The electrode was then removed, a ul syringe needle was inserted through the cannula to the predetermined site, and 0.15-0.25 ul of a 20-uCi/ul mixture of ^{3}H-isotopes was slowly injected. After a 3-day survival, the brain was processed for autoradiography.

From the injection site, fibers ascended to the nucleus of the stria terminalis and the lateral septal nucleus. There was widespread label in the preoptic area and fibers spread laterally from this region over the optic tract (OT) to the substantia innominata and amygdala. A band of fibers remained above the OT until passing medially into the midbrain. The rostral hypothalamus was widely labeled and fibers ascended at this level into the midline thalamic nuclei. Further caudally there were small projections to densocellularis part of dorsomedial nucleus and to pretectum ventral to habenular nuclei. In the posterior hypothalamus, only the medial and lateral mamillary nuclei were free of label. As fibers passed out of the hypothalamus, they coursed in central grey (CG), zona incerta (ZI) and dorsal to substantia nigra (SN). In midbrain, fibers from ZI were joined by the band descending above OT and passed medially to a dense terminal area in the dorsal tegmentum (DT) medial to medial lemniscus. The fibers paralleling SN appeared to terminate in central tegmentum. Fibers in midbrain CG spread laterally to join medially coursing fibers in DT and appeared to terminate lateral to CG. At this level in the midbrain, an area in lateral CG also gave the appearance of terminal rosettes. There were light projections to the pedunculopontine and lateral parabrachial nuclei. Moderately heavy label was present in dorsal and lateral CG throughout the midbrain.

749 SUPERIOR COLLICULUS AND RETINAL PROJECTIONS TO THE HYPOTHALAMUS James H. Fallon and Robert Y. Moore. Dept. Anatomy, UCI and Dept. Neurosci., UCSD; Irvine, and La Jolla, CA

Recent Golgi and electron microscopic evidence has revealed that dendrites of hypothalamic origin extend into the optic and supraoptic tracts (Riley et al., '79). In a series of anatomical studies with anterograde tracing methods, we now report that these dendrites receive both superior collicular and retinal inputs in the rabbit. Injections of (^{3}H) proline were made into the intermediate or deep layers of the superior colliculus and silver grains could be traced over the supraoptic and optic tracts to the midline. The number of silver grains diminished at the midline with the remaining crossing fibers projecting to the contralateral thalamus and tegmentum. However, the fate of the "disappearing" superior collicular axons in the hypothalamic region of the optic and supraoptic tracts could not be ascertained with certainty. In order to determine if the fibers terminate within the optic and supraoptic tracts, we injected horseradish peroxidase (HRP) into the superior colliculus of three rabbits and demonstrated, electron microscopically, the termination of superior colliculus axons containing HRP reaction product onto dendrites extending into these tracts. In order to determine the cell bodies of origin of these dendrites, (^{3}H) adenosine was injected into the superior colliculus in four rabbits. Anterograde transneuronal transport of (^{3}H) adenosine resulted in autoradiographic labeling of cell bodies in the diffuse supraoptic nucleus, retrochiasmatic area and ventral sectors of the lateral and anterior hypothalamic areas. This projection is predominantly ipsilateral. In separate experiments, the pattern of anterograde labeling of retinal axons in the hypothalamus was studied. With (^{3}H) proline injections into the vitreous of the eye of three rabbits, projections to the hypothalamus included the suprachiasmatic nucleus and a few scattered labeled axons dorsal to the lateral wing of the supraoptic nucleus. With (^{3}H) adenosine injections into the vitreous of the eye of three rabbits, cellular labeling was found not only in the suprachiasmatic nucleus but also in the contralateral lateral hypothalamic area, retrochiasmatic area and supraoptic nucleus. In spite of the potential problems with axonal "leakage" of adenosine or its metabolites, these results provide some evidence that in the rabbit, as in the rat (Riley et al., '79), the retina projects to several hypothalamic nuclei outside the well-known retino-suprachiasmatic projection system. These results also show that separate and overlapping visual and multimodal inputs from the superior colliculus, and visual input from the retina may directly influence cells in a broad expanse of this ventral tier of the hypothalamus. Interestingly, many of these projections are to dendrites located within the sensory lemniscus.

Supported by USPHS Grant NS-05187 and a grant from the University of California, Irvine.

750 RECOVERY OF FUNCTION FOLLOWING TWO-STAGE POSTERIOR HYPOTHALAMIC LESIONS IN RATS. Michael Gruenthal* and Stanley Finger. Dept. Psychol., Wash. Univ., St. Louis, MO 63130.

The "serial lesion effect" (Finger et al., Brain Res., 1973) refers to the observation that under some conditions bilateral brain lesions made in 2 discrete stages are less incapacitating than those produced in a single operation. While this phenomenon has been intensively studied with learning and perceptual tasks following cortical damage, less research has been conducted on staged lesions of the brainstem, and these results have not always been consistent. We therefore investigated the effects of 1- and 2-stage posterior hypothalamic lesions on swimming ability (Robinson et al., Canad. J. Psychol., 1974) and open-field activity to determine if 2-stage lesions would result in greater recovery.

42 male rats received 1-stage or serial (30 days between sides) lesions of the posterior hypothalamus and were tested 1, 3 and 5 weeks after surgery. Subjects with 2-stage lesions swam significantly better than animals with 1-stage lesions across all testing periods. With respect to open-field activity, however, subjects with serial lesions did not demonstrate significantly enhanced recovery until the 3rd postoperative week. These data suggest that serial lesions of the posterior hypothalamus can enhance recovery although the time-course for such recovery may vary with the specific deficit being evaluated.

751 SEROTONERGIC INNERVATION OF THE LATERAL HYPOTHALAMUS: EVIDENCE FROM SYNAPTOSOMAL UPTAKE STUDIES. J. Heym* and W. E. Gladfelter. Dept. of Physiology and Biophysics, West Virginia University Medical Center, Morgantown, WV 26506.

In rats the lateral hypothalamus (LH) has been shown to contain relatively high concentrations of serotonin (5HT) and tryptophan hydroxylase, the rate limiting enzyme for serotonin biosynthesis. Anatomical findings have suggested that ascending 5HT fibers turn off from the medial forebrain bundle and synapse within the LH. The present study has explored further the possibility of a serotonergic terminal field within the LH. ^{3}H-5HT uptake was examined in crude synaptosomal preparations of rat lateral hypothalami. Aliquots (0.2 ml) of the synaptosomal suspension were preincubated at 37°C for 5 minutes in a modified Krebs-Ringer phosphate buffer (pH = 7.4) after which radiolabelled 5HT was added and the incubation was continued for an additional 4 or 5 minutes. When the concentration of ^{3}H-5HT present in the incubation media was varied from 2 X 10^{-8} M to 5 X 10^{-6} M, transport of 5HT by LH synaptosomes occurred by two distinct processes, one which was linearly related to 5HT concentration and the other which was saturable at 5HT concentrations greater than 10^{-7} M. Kinetic constants for the high affinity uptake of 5HT were calculated from a Lineweaver-Burk plot of the saturable component of total uptake at 37°C. The derived constants were: affinity constant (Km) = 4.03 X 10^{-8} M and maximum uptake velocity (Vmax) = 21.6 picomoles/mg protein/5 minutes, which are consistent with values reported for other brain regions.

The relationship between log concentration and % of 5HT uptake inhibition for three differentially selective uptake blocking drugs revealed that fluoxetine, a specific inhibitor of uptake by 5HT neurons, was the most potent inhibitor of 5HT uptake by LH synaptosomes. Fluoxetine was 23 times more potent than desipramine, a selective uptake blocker for noradrenergic neurons, and 437 times more potent than benztropine, a selective uptake blocker for dopaminergic neurons.

Disruption of ascending serotonergic projections at points caudal to the LH significantly reduced ^{3}H-5HT uptake by crude synaptosomal preparations of LH. Electrolytic lesions of either the median raphe nucleus or the dorsal raphe nucleus decreased this uptake by 45% and 63% respectively. Bilateral intracerebral infusions of 5, 7 dihydroxytryptamine into ascending serotonergic pathways also reduced this uptake by as much as 78%.

Collectively, these data support the contention that serotonergic terminals are present within the LH. The majority of these terminals are provided by ascending projections from neurons situated in the midbrain raphe nuclei.

752 COMMISSURAL FIBERS OF THE SUPRACHIASMATIC NUCLEUS. Stephen K. Itaya. Dept. Anat., Univ. Iowa, Iowa City IA 52242.

The paired suprachiasmatic nuclei (SCN) are thought to regulate timing for a variety of biological rhythms, e.g., feeding, drinking, and sleeping, making the study of the SCN both intriguing and important. If the neuroanatomical connections of the SCN were understood, in terms of intrinsic wiring and extrinsic inputs and outputs, a foundation would be available for physiological and biochemical studies. At the present time, little is known about how information is processed within the SCN. To gain further insight of SCN anatomy, the gold-toning Golgi method (Fairen et al., J. Neurocytol. 6:311, 1977) was used on adult rat brains. Neurons located along the ventromedial SCN border were observed which have unmyelinated projections in two main directions: medially, through the infundibular tract to the contralateral SCN, and laterally, as short fibers within the SCN of origin. Terminals appear to be situated within the two SCN, thus suggesting that one function of these neurons is to provide a communicating link between the two SCN. By electron microscopy, there are no features which distinguish these neurons from others in the SCN. From previous work, all SCN neurons have small cell bodies (approximately 8-10 microns diam.), often with a small rim of cytoplasm surrounding an indented nucleus; organelles commonly observed include large dense core vesicles (90-140 nm), ribosomes, lysosomes, mitochondria, some granular ER, and cilia.

The SCN are thus interconnected by commissural fibers from typical SCN neurons. Further studies are underway to ascertain the synaptic connections of these and other possible interneurons in the SCN.

753 CONNECTIONS OF MEDIAL PREOPTIC NEURONS WITH MEDIAN EMINENCE AND AMYGDALA : AN ELECTROPHYSIOLOGICAL STUDY IN THE RAT. B.S.Layton* and L.P. Renaud, Division of Neurology, Montreal General Hospital and McGill University, Montreal, Canada, H3G 1A4

Neurons in the amygdala have direct reciprocal connections with neurons in the mediobasal hypothalamus; these connections are particularly prominent on neurons within the ventromedial nucleus (VMH). Furthermore, some of these VMH neurons have been identified as tuberoinfundibular cells, based on electrophysiological evidence of their projection to the median eminence (J. Physiol.260: 237-252,1976). The amygdala is also known to project to the medial preoptic area (MPOA), a region also shown to contain neurons with median eminence projections. The aim of the present study was two-fold : to further examine the connections between MPOA neurons and the median eminence, and to compare the responses of both MPOA and VMH neurons to electrical stimulation in the amygdala. Experiments were performed on pentobarbital anaesthetized male Sprague-Dawley rats implanted with bipolar stimulation electrodes in various nuclei of the amygdala. Following a transpharyngeal exposure of the hypothalamus, a concentric bipolar electrode was positioned on the surface of the median eminence to activate the terminals of tuberoinfundibular neurons. Extracellular records obtained from more than 400 MPOA neurons during 1 Hz single stimulation of the median eminence indicated evidence of antidromic activation i.e. tuberoinfundibular neurons (25% of cells), orthodromic excitation (13% of cells) or inhibition (2% of cells); the remaining cells were unresponsive. Relatively few spontaneously active MPOA tuberoinfundibular neurons displayed excitability patterns that suggest a possible recurrent inhibitory pathway. Single amygdala stimuli evoked a predominantly negative field potential within MPOA; this potential was seldom as prominent as that evoked within the VMH of the same animal. Recordings from 265 cells indicated evidence of antidromic activation (2% of cells), orthodromic excitation (45% of cells) or inhibition (20% of cells); the remaining neurons were unresponsive. Studies on MPOA tuberoinfundibular neurons indicated that only 22% of tuberoinfundibular neurons displayed evidence of orthodromic activation (18%) or inhibition (4%) from amygdala. On the other hand, comparative studies indicated that the majority (90%) of VMH tuberoinfundibular neurons displayed orthodromic excitation (80% of cells) or inhibition (10% of cells) following amygdala stimulation. These data suggest that the amygdala influences adenohypophyseal function predominantly through tuberoinfundibular neurons in VMH rather than MPOA. We have yet to determine the nature of other MPOA neurons that receive the majority of amygdalo-preoptic actions. Supported by the Canadian MRC.

754 THE TUBEROINFUNDIBULAR SYSTEM OF THE RAT AS DEMONSTRATED BY HORSERADISH PEROXIDASE RETROGRADE TRANSPORT FOLLOWING MICROIONTOPHORETIC INJECTION. R.M. Lechan*, S. Jacobson, J. Nestler*, S. Reichlin, Endocrine Division, Dept. of Medicine, Tufts New England Medical Center Hospital and Dept. of Anatomy, Tufts University School of Medicine, Boston, MA 02111

In order to identify the neuronal perikarya of the tuberoinfundibular tract, retrograde transport of horseradish eroxidase (HRP) was determined following minute microiontophoretic injections into the median eminence of the rat. Under stereotactic control, 20% aqueous HRP was applied directly to the median eminence of fifty-eight 250-300gm, female, CD, albino rats. Using currents of 2.5-3.5 microampers for ten minute intervals, and glass pipettes with tip diameter of fifteen microns, satisfactory local injections of HRP, limited to the median eminence with little or no diffusion into the basal arcuate nucleus, was achieved in six animals. Visualization of HRP-reaction product was accomplished by fixation in Karnovsky's aldehyde solution by cardiac perfusion and incubation of forty micron, coronal, serial sections with tetramethylbenzadine (TMB).

HRP was distributed throughout the median eminence even after strictly localized lateral injections and perikarya were rather symetrically labled indicating diffusion through the substance of the median eminence. HRP-containing beaded neuronal processes resembling axons, were seen to take a ventromedial arching path from the median eminence into the arcuate nucleus, to course for long distances in a subependemal location in the periventricular region, and to lie within the hypothalamic-hypophyseal tract. Based on distribution HRP-containing perykarya, we conclude that the following nuclear regions project to the median eminence: arcuate nucleus (predominantly dorsal and rostral portions); periventricular nucleus, in a diffuse perykaryal system as far anterior as the preoptic region; and the medial division of the paraventricular nucleus. Lesser numbers of cells arise from the medial preoptic, supraoptic, and lateral divisions of the paraventricular nuclei and rare cells from the ventramedial nucleus. The following regions do not appear to project to the median eminence and therefore are presumably not the source of the tuberoinfundibular neuron system: dorsomdeial, suprachiasmatic, anterior, mamillary and the vast majority of the ventromedial nucleus. Failure to find labeling in the septum and in the region of the organum vasculosum of the lamina terminalis (OVLT), supports the view that the neuronal system of this region and that of the median eminence are relatively independent.

755 AN HRP STUDY OF THE AFFERENT CONNECTIONS OF THE VENTROMEDIAL HYPOTHALAMIC NUCLEUS (VMN) IN THE HAMSTER. C.W. Malsbury, V.S. Harris*, D. Weisberg* and J. Daood*. Depts. Psychiatry & Psychology & the Neuropsychobiology Training Program, Western Psychiatric Institute & Clinic, Univ. Pgh. Sch. Med., Pittsburgh, PA 15261.

Horseradish peroxidase (HRP) was applied iontophoretically to sites in the medio-basal hypothalamus in female golden hamsters. After approximately 24 hrs, animals were sacrificed and the brains processed according to the histochemical procedure described by Mesulam (1978) using tetramethyl benzidene as a chromogen.

When injections were centered in the VMN, labelled neurons were found in five extrahypothalamic cell groups: 1) bed nucleus of the stria terminalis (restricted parts), 2) the rostral pole of the medial amygdaloid nucleus, 3) the amygdalo-hippocampal area (area B3), 4) the peripeduncular nucleus of the midbrain, and 5) the nucleus of the lateral lemniscus (NLL). When injections were restricted to the VMN, septal neurons were not labelled. A relatively small number of labelled cells were also seen in the rostral pole of the central amygdaloid nucleus, the ventral subiculum, and the dorsal and median raphé. Within the hypothalamus and preoptic area labelled neurons were found in: the most medio-ventral part of the preoptic area in the region of the lamina terminalis; the medial preoptic area at the level of the anterior commissure; the medial anterior hypothalamus; and the supraoptic, paraventricular and suprachiasmatic nuclei.

VMN lesions and sagittal-plane hypothalamic knife cuts disrupt sexual receptivity (Malsbury & Daood, 1978). We proposed that sagittal cuts produce this effect by cutting efferent connections of the VMN which travel in the supraoptic commissures (SOC). However we now present evidence that such cuts may also interrupt afferent connections of the VMN. Following a knife cut which severed the SOC, HRP was injected into the region of the ipsilateral NLL. When the tissue was reacted and examined, a pile-up of reaction product was seen lateral to the cut in axons of the SOC as they entered the hypothalamus. This appears to be a result of anterograde transport of HRP within axons of VMN afferent neurons whose perikarya are located in the NLL. Thus cutting the SOC may disrupt sexual receptivity by cutting VMN efferent and/or afferent connections.

756 SUPRACHIASMATIC NUCLEUS AFFERENTS IN THE RAT: AN HRP-RETROGRADE TRANSPORT STUDY. R.Y. Moore, E.R. Marchand and J.N. Riley. Dept. Neurosciences, Univ. Calif., La Jolla, CA. 92093.

Localized injections of horseradish peroxidase (HRP) were placed in the suprachiasmatic nucleus (SCN) of rats by iontophoresis. Sections of aldehyde-fixed brain were prepared by the benzidine dihydrochloride method for demonstration of HRP and examined microscopically. Neurons showing retrograde labelling with HRP were observed in brainstem and diencephalon following injections completely localized to the SCN.

Labelling of brainstem neurons was observed in the nucleus centralis superior and in the lateral part of the dorsal tegmental nucleus. Labelled neurons were observed only occasionally in raphe dorsalis. In the hypothalamus numerous neurons were labelled in the medial preoptic area, the anterior hypothalamic area (particularly in the region adjacent to the SCN), the ventromedial nucleus and the periventricular hypothalamic nucleus from its rostral to caudal extent. Scattered arcuate nucleus neurons were labelled. In the thalamus labelled neurons were present in the paraventricular nucleus, nucleus reunions and the ventral nucleus of the lateral geniculate body.

The material also provided evidence for a projection from one SCN to that on the contralateral side. Even in cases of very small injections totally confined to the limits of the SCN, labelled neurons were evident in the contralateral SCN and anterograde labelling of axons was evident with the axons crossing the midline beneath the third ventricle and entering the contralateral SCN.

These observations confirm previous reports of projections to the SCN. They further extend information on the innervation of the SCN by demonstrating previously undescribed projections from brainstem, thalamus and hypothalamus and a projection interconnecting the nuclei on each side. Supported by USPHS Grant NS-12267.

757 ON THE SOURCE OF A NEW PATHWAY FOR VISUAL INPUTS TO THE RAT HYPOTHALAMUS. Daniel A. Pasquier and Juan H. Tramezzani*. Instituto de Neurobiología, Serrano 665, 1414 Buenos Aires, Argentina.

Horseradish peroxidase (HRP) axonal transport was used for tracing afferent fibers to the nuclei of the mediobasal hypothalamus. Iontophoretic delivery of HRP or injections of 0.02-0.03 microliters of a 30 % HRP saline solution through microsyringe were made. Highly specific labeling of the target nuclei was obtained and, from this material, the afferents to the retrochiasmatic area (RCA) are reported herein.

Following HRP deposit in the RCA consistent neuronal labeling was found in the ventromedial hypothalamic nuclei, the lateral part of the substantia nigra and the parabigeminal nucleus along the lateral midbrain-pontine tegmentum. This pattern appeared different from that shown after HRP labeling of other areas of the mediobasal hypothalamus.

HRP studies were also done of the afferents to the superior colliculus and lateral geniculate nucleus for two reasons: a) to see whether the parabigeminal nucleus also projects to the visual centers in the rat, and b) because many of the fibers from the parabigeminal nucleus going to the superior colliculus and lateral geniculate nucleus pass by the supraoptic commissures. HRP injections in the superior colliculus gave rise to neuronal labeling in the parabigeminal nucleus, most of which appeared contralateral and primarily in its ventral part. However, even large HRP injections in the lateral geniculate nucleus failed to show labeled neurons in the parabigeminal nucleus.

These results are the first demonstration of the afferents to the rat retrochiasmatic area and they suggest that those fibers originating in the parabigeminal nucleus might carry visual information towards the hypothalamus.

758 COMBINED EFFECTS OF FRONTAL HYPOTHALAMIC CUTS AND PREOPTIC (POA) STIMULATION ON ANTERIOR PITUITARY HORMONE RELEASE. C.P. Phelps and J.A. Colombo, Dept. of Anatomy, College of Medicine, Univ. of South Florida, Tampa, Florida, 33612.

The present set of experiments continues our investigation of the general problem of segregation of functions within the POA-hypothalamic complex related to the control of LH, prolactin (Prol.) and TSH release by the anterior pituitary. Recently we have examined the effects of chronic (90d) frontal retrochiasmatic cuts (FC) on LH, Prol. and TSH release after electrical stimulation of the POA. We found that when compared with sham surgery (S) values, that POA stimulation 90d after FC resulted in a plasma LH increase (ΔLH) of 166±27ng/ml vs. 233±59ng/ml for S rats 30 min poststimulation and a plasma Prol. increase (ΔProl) of 68±24ng/ml (FC) vs. 182±29ng/ml (S) at the same poststimulation interval. Increases in plasma TSH (ΔTSH) in the same animals, however, were enhanced by FC at 30 min (275±79ng/ml) when compared with those of S (ΔTSH-57±12ng/ml). In subsequent experiments, adult male rats were subjected to retrochiasmatic hypothalamic FC or S placement with a retractable Halasz knife of 1.5mm radius. One and one-half weeks later, under pentobarbital anesthesia, sequential 30 min blood samples were withdrawn before and after bilateral electrical stimulation of the POA. Stimulation was effected through bipolar stainless steel electrodes using monophasic 0.5 msec width pulses, 200μA, in 30 sec on/off trains for 30 min at a pulse rate of 50 Hz. LH, Prol. and TSH were measured by RIA. In rats that were subsequently found to have histologically complete FC, LH levels were approximately doubled by POA stimulation (0 time-50±8ng/ml; 30 min-112±27ng/ml) and this ΔLH was similar to those of S animals (0 time-63±27ng/ml; 30 min-139±38ng/ml) after POA stimulation. The ΔProl. in the same (FC and S) plasma samples showed equal 3-fold increases. Comparisons of ΔTSH in the latter plasma samples revealed no significant change from 0 time baseline levels in S rats (153±4ng/ml) across the 90 min sampling period, however, FC rats showed an approximate doubling at 60 min poststimulation (232±67ng/ml) when compared with their 0 time TSH concentrations (124±14ng/ml). The results of these experiments indicate that effects of frontal hypothalamic cuts on POA electrically stimulated release of LH and Prol. are not demonstrable between 8 and 12 days after surgery. Pituitary release of TSH after POA stimulation is, however, potentiated by FC done 8-12 days earlier. Thus, the differential effects of FC on POA-stimulated anterior pituitary hormone release appears to vary with the time interval between POA stimulation and FC. Investigation of a possible mechanism(s) for these effects are currently under way. Supported by NIH HD11345.

759 OPIATES SELECTIVELY DEPRESS SPONTANEOUS ACTIVITY IN THE HYPOTHALAMIC SLICE PREPARATION. Quentin J. Pittman, James D. Hatton* and Floyd E. Bloom. A.V. Davis Ctr. for Behav. Neurobiol., Salk Inst., La Jolla, CA 92037.

Opiates and opiate peptides administered intracranially and systemically modify neurohypophysial secretion. To investigate a possible mechanism for this effect we have applied opiates by perfusion to hypothalamic slices in vitro while monitoring extracellular unit activity in the paraventricular nucleus (PVN). This nucleus contains cell bodies of vasopressin- oxytocin- and other peptide-containing (e.g., enkephalin) neurons which project to the neurohypophysis.

Brains were quickly removed from 200 g, male Sprague-Dawley rats with or without prior transcardial perfusion of the animal with oxygenated Hank's BSS (4°C) and coronal sections (500 μ) of the diencephalon were cut on a tissue chopper. The slices were placed in a chamber where they were perfused over both surfaces at 1.5 ml/min with a heated (35°C), oxygenated medium (composition in mM: NaCl, 138; $NaHCO_3$ 4.2; $Na_2HPO_4 \cdot 7H_2O$, 0.3; KCl, 8.03; KH_2PO_4 0.4; $CaCl_2$ 0.75; $MgCl_2$ $6H_2O$ 0.5; $MgSO_4 \cdot 7H_2O$ 0.4, glucose 11; phenol red 0.03). Recordings were pursued in the anatomical area of the PVN localized with the aid of a dissecting microscope. 71 probable PVN neurons in 13 slice preparations displayed spontaneous activity (1-5 Hz) which was influenced by Ca^{++} and K^+ levels in the perfusate. 7 neurons displayed bursting activity and another 4 neurons displayed phasic activity similar to that associated with vasopressin neurons. Low intensity electrical stimulation delivered from bipolar metal electrodes placed on the neurohypophysial tract elicited antidromic action potentials in 6 PVN neurons.

Responses to opiate application were investigated in 27 PVN neurons. On 15 of these neurons, including 4 phasic cells, neither the level of spontaneous activity nor the pattern of activity were affected by addition of morphine, naloxone or enkephalin to the perfusate (all at 10^{-6}M). On 12 tonically firing neurons, 10^{-6}M morphine caused a decrease in spontaneous activity which, on 7 neurons, was reversed by naloxone (10^{-6}M). These results demonstrate a direct depressant action of opiates on certain cells in the PVN; however, opiate effects on neurohypophysial secretion in vivo may be indirect and dependent on preservation of appropriate neural circuitry.

760 SUPRAOPTIC PHASIC NEUROSECRETORY NEURONS : RESPONSE TO STIMULATION OF AMYGDALA AND DORSAL HIPPOCAMPUS, AND SENSITIVITY TO MICROIONTOPHORESIS OF AMINO ACIDS AND NORADRENALINE. L.P.Renaud and E.Arnauld*, Division of Neurology, Montreal General Hospital and McGill University, Montreal, Canada, H3G 1A4

It was recently demonstrated by electrophysiological techniques that supraoptic (and paraventricular) neurosecretory (NSO) neurons could be functionally differentiated as oxytocin or vasopressin neurons dependent upon the presence of 'continuous' or 'phasic' activity patterns respectively (Proc.Roy.Soc.Lond.B, 196: 367-384, 1977). The present communication presents our preliminary observations on the responses of 'phasic' NSO neurons (a) during stimulation in the ipsilateral amygdala and dorsal hippocampus and (b) during microiontophoresis of amino acids (glutamate, aspartate, GABA) and norepinephrine. Experiments were performed on pentobarbital anaesthetized male Sprague-Dawley rats previously implanted with bipolar stimulation electrodes in the ipsilateral amygdala and dorsal hippocampus. The hypothalamus was exposed by a ventral approach and a bipolar electrode was inserted into the posterior pituitary in order to identify NSO neurons by antidromic activation. For synaptic studies, evidence of afferent connections were derived from short latency stimulus induced excitability changes determined from poststimulus histograms. Data from 22 phasic NSO neurons indicated that fewer than 10% of cells displayed short latency inhibitory responses following amygdala or dorsal hippocampus stimulation. Microiontophoretic applications of glutamate and aspartate both enhanced the activity of phasic neurons; NSO neurons tended to tolerate aspartate much better than glutamate. These agents appeared capable of initiating and prolonging bursts of activity. GABA depressed most NSO phasic neurons; when GABA was applied in the middle of a burst, phasic cells tended to resume activity following termination of the application. During norepinephrine microiontophoresis most phasic cells tended to increase their excitability : this was usually manifested as a gradual increase in the intraburst firing frequency, but on occasion norepinephrine appeared to initiate a burst of activity or to prolong an ongoing burst of activity. Norepinephrine was seen to depress the activity of a few phasic neurons. On the premise that vasopressin release is correlated with action potential frequency, these results suggest that it's release may be diminished by GABA and promoted by aspartate, glutamate and (?) norepinephrine. Pathways that may be involved in vasopressin release are under investigation.

761 AFFERENT PROJECTIONS TO THE SUPRAOPTIC NUCLEUS OF THE RAT R.C. Rogers, K. Talbot, D. Novin and L.L. Butcher. Brain Res. Inst. & Dept. Psychology, UCLA, Los Angeles, CA 90024.

The afferent projections to the supraoptic nuclei (SON) have been studied with a variety of techniques in several species. Thus far, no anatomical evidence exists for relatively direct projections from the viscero-gustatory relay nuclei (solitary nucleus, parabrachial nucleus and ventrobasal thalamus) and the SON though clearly, viscero-gustatory receptor inputs alter ADH release. Recently investigators have explained viscero-gustatory activation of ADH release on the basis of pathways leading from the solitary nucleus to the paraventricular nucleus, which also releases ADH (Ricardo & Koh; Brain Res., 153:1, 1978).

We sought to demonstrate the afferent connections of the SON by iontophoretically injecting minute quantities of horseradish peroxidase (HRP) into the SON and by processing the tissue with the new and sensitive de Olmos modification of the HRP histochemical method (Exp. Brain Res., 29:541, 1978). Using this technique, we find that both the solitary and parabrachial nuclei (but not the ventrobasal thalamus) project to the SON. Projections from other brainstem and limbic structures to the SON were also demonstrated. They included the lateral septum; nucleus of the diagonal band; paratenial nucleus; periventricular, medial and lateral preoptic nuclei; the bed nucleus of the stria terminalis; subfornical organ; the anterior, lateral, perifornical, circular, premammillary, posterior and supramammillary hypothalamic nuclei; the medial amygdala; subiculum; CA1 and CA3 fields of the hippocampus; central grey; dorsal tegmental nuclei; ventral tegmental area; locus coeruleus; dorsal raphe nucleus; nucleus centralis superior; raphe pontis; nucleus reticularis tegmenti pontis; and the nucleus reticularis parvocellularis.

Placements of HRP into the immediately overlying anterolateral hypothalamus revealed a different afferent projection pattern; it was essentially the reciprocal of efferents to this area described by Saper et al. (J. comp. Neurol., 183:689, 1979).

These results indicate that the lower order viscero-gustatory nuclei project directly to the SON as do many other brainstem and limbic structures involved with autonomic, homeostatic processes.

In addition to these results, some fortuitous HRP injections revealed the efferent projections of the SON alone. Axons leaving the SON ascend vertically for about 1 mm into the anterior hypothalamus before turning sharply in the opposite direction. Upon contact with the medial accessory SON, the fibers turn ventromedially toward the infundibulum.

762 UPTAKE OF HORSERADISH PEROXIDASE (HRP) FROM FRONTAL HYPOTHALAMIC KNIFE CUTS IN RATS. S. Saporta and C. P. Phelps, Department of Anatomy, College of Medicine, University of South Florida, Tampa, Florida 33612.

Frontal retrochiasmatic cuts made in the rat hypothalamus with a Halasz knife result in anterograde fiber degeneration in the periventricular and ventromedial nuclei of the hypothalamus, the optic chiasm, supraoptic commissures, optic tracts, medial forebrain bundle, stria medullaris, stria terminalis, the fimbra and fornix (C. P. Phelps and D. M. Nance, Endo. 102:164A, 1978). In order to better describe which neurons are interrupted in the course of hypothalamic surgery in rats, we have designed a retractable Halasz type knife which can deliver HRP during hypothalamic knife cuts. The knife retracted within a cannula was lowered 5.5 mm and then extruded in the median sagittal plane. A frontal cut (FC) (radius 1.5 mm) was made, unilaterally, by rotating the blade 90° during which time 15 - 25 μl of 15% HRP was delivered. Sham surgery consisted of merely extruding the blade in the midline and delivering 15 μl of HRP. Animals were sacrificed 4, 18 and 23 hrs after surgery and the brains processed for HRP. Damaged neurons, filled with homogeneous HRP reaction product, were visible along the course of the cut at all survival times. With the longer survival times, HRP positive neurons were identified in the lateral habenular nuclei; dorsal medial, reticular, parataenial, and intralaminar nuclei of the thalamus; and in the locus coeruleus, periaqueductal grey and midline raphe nuclei. Within the hypothalamus HRP positive somata were found in the paraventricular, dorsal medial, periventricular, ventromedial, arcuate and supraoptic nuclei. In addition, all but the last structure had HRP filled fibers running through their neuropil. These results indicate that a wide variety of hypothalamic afferents are interrupted after FC, as well as a number of efferents, and that the structures involved are not necessarily reciprocally connected. Supported by NIH HD11345.

763 NEURAL PATHWAYS NECESSARY FOR A BEHAVIORAL RESPONSE TO ANDROGEN. Charles W. Scouten*, Linda Burrell* & Craig F. Cegavske. Dept. of Psychology, State University of New York, Binghamton,NY 13901

Knife cuts were placed in the sagittal plane between the medial forebrain bundle and the medial preoptic-anterior hypothalamic region in male rats. Copulatory behavior, body weight and deposition of urine on a threaded rod were observed in weekly test sessions conducted for the next 20 weeks. Urine deposition is an androgen supported behavior, and declines to about 50% of normal following castration (Price, Hormones and Behavior 6: 393-397, 1975).

In males in which the cuts separated at least the anterior 50% of the anterior hypothalamus and all of the medial preoptic area from the medial forebrain bundle, no copulation was observed even after 20 weeks postsurgery. Subcutaneous implants of silastic capsules of testosterone effectively restored copulatory behavior to castrates, but not to the knife cut males. These animals also deposited 50% less urine on the threaded rods (thus resembling castrated males) than did sham operated males. The testosterone implants did not produce any increase in urine marking in these knife cut males, although intact (sham operated) or castrated males sharply increased urine deposition after implant. Cuts placed anteriorly or posteriorly so as to spare as little as 25% of the area lateral to the medial preoptic area or anterior anterior hypothalamus allowed a nearly normal increase in urine deposition following androgen implant. The cuts appear to selectively block the influence of androgen on urine marking. Since the cuts caused only a decline to the level of castrates, no influence other than that of androgen was removed, and the medial preoptic area is not an integrative area for urine marking.

In contrast, the cuts did not block an androgen induced weight increase.

764 EFFERENTS FROM THE MEDIAL ANTERIOR HYPOTHALAMIC AREA IN THE GUINEA PIG: AN AUTORADIOGRAPHIC STUDY. Ching Liang Shen and Conwell H. Anderson. Dept. Anat., U. Illinois Med. Ctr., Chicago, IL 60612.

Efferent projections from the medial anterior hypothalamus (MAHA) were studied using tritiated amino acid autoradiography in guinea pigs. 48-56 hours after injecting tritiated proline the animals were perfused with 10% formalin and processed through a paraffin technique for autoradiography. Axonal projections from MAHA projected not only to local areas, such as suprachiasmatic n, retrochiasmatic area, paraventricular n and bed nucleus of stria terminalis, but also to other structures in the brain. Labelled axons and diffuse grains could be seen in POA and OVLT, and in the diagonal band of Broca and its horizontal and vertical nuclei. Some of these labelled fibers passed through the diagonal band of Broca and ascended to the septum. Medial, lateral and triangular septal nuclei also received projections which ascended directly from the medial anterior hypothalamus through POA. Dorsally, through the stria terminalis the labelled fibers could be followed to the amygdala. Through the stria medullaris, anterior hypothalamic axons reached the lateral habenula and the central gray of the midbrain. Following the periventricular fiber system, the axonal projections from MAHA terminated in the periventricular and other midline nuclei of the thalamus, and also distributed to the central gray of the midbrain. Laterally, it projected to the lateral hypothalamus, supraoptic n, substantia innominata and the anterior and medial amygdaloid nuclei. Lateral hypothalamus including medial forebrain bundle (MFB) were labelled heavily. The medial part of MFB was labelled heavier than the lateral part. Posteriorly, MAHA projected directly into the medial basal hypothalamus including ventromedial, dorsomedial and arcuate nuclei. The arcuate nucleus was only slightly labelled. The median eminence was labelled in both internal and external zones. Some axons also distributed to the ventral and dorsal premammillary and supramammillary nuclei, and to the posterior hypothalamus. MAHA fibers travelled via the capsule of the mammillary nucleus and reached the ventral tegmental area of Tsai or ascended caudodorsally merging with the periventricular fiber system and distributed to the central gray of the midbrain. Diffuse central gray label could be followed to the rostral pons. A few labelled fibers in the MFB projected to the tegmental area of the midbrain and pons. Contralateral medial POA, MAHA, paraventricular n, and posterior hypothalamus were labelled, and the heaviest contralateral label was in the retrochiasmatic area and ventral and dorsal premammillary nuclei. (Supported in part by NICHHD grant HD 5865)

765 LATERAL HYPOTHALAMIC STIMULATION IN HEMIFOREBRAIN ABLATED RATS: REWARD EFFECTS. James R. Stellar, Judy Illes*, and Linda E. Mills*. Dept. Psych. & Soc. Rel., Harvard Univ., Cambridge, MA 02138.

Electrical stimulation of the medial forebrain bundle (MFB) at the level of the lateral hypothalamus (LH) will support vigorous operant self-stimulation behavior in rats and is therefore judged to be rewarding. These rewarding effects can be quantitatively characterized (Gallistel, J. Comp. & Physio. Psych. 92, 1978), but due to the widespread connections of MFB to brainstem and forebrain, anatomical inferences are difficult. In a dramatic report, Huston and Borbely (Physio. & Behav. 12, 1974) demonstrated that rats with complete forebrain ablations, having the thalamus and hypothalamus as the most rostral structures in the brain, would self-stimulate via tail elevation to LH stimulation. However, the basic behavioral impairments prevented a more refined, quantitative analysis of these reward effects in this preparation.

As a first approximation to the bilateral preparation of Huston and Borbely, adult male rats were given unilateral forebrain ablations by surgical aspiration. After recovery these animals fed and cared for themselves under standard laboratory conditions. They were then implanted with a bilateral array of LH stimulating electrodes, and were trained to lever press for LH stimulation on the forebrain-ablated side. Subsequently, they were trained to run a runway for LH stimulation reward according to the techniques of Gallistel.

Alterations in the current or number of pulses of reward stimulation were shown to lead to systematic variations in running speed. These variations occurred over the first 3-5 trials after the reward was changed. Alterations in the pretrial or priming stimulation level were also shown to lead to systematic variations in running speed but these variations occurred, in full, on the very next trial. These results are in good agreement with previous findings in intact rats (Gallistel, Stellar, & Bubis, J. Comp. & Physio. Psych. 87, 1974) and suggest that connections between the MFB and its ipsilateral forebrain targets are not necessary for what appears to be normal LH self-stimulation reward.

766 AFFERENT PROJECTIONS FROM THE PERIAQUEDUCTAL AND PERIVENTRICULAR GRAY TO THE MIDBRAIN RETICULAR CORE. M. Steriade and A. Parent., Lab. Neurophysiol. and Lab. Neurobiol., Fac. Med., Laval Univ., Québec, Canada.

A descending input from the midline diencephalic areas to the mesencephalic reticular formation has been envisaged to underly a tonic, reinforcing control of the waking brain. In order to substantiate morphologically this hypothesis and to precise the exact source of this descending input, unilateral injections (0.04-0.06 µl) of 50% horseradish peroxidase (HRP) were made and confined to the nucleus cuneiformis and the adjacent central tegmental field of cat. The animals were allowed to survive 48 hours and the sections were treated according to either the diamino-benzidine, or the tetrametyl-benzidine, or the benzidine-dihydrochloride procedure, the latter with a counterstaining by means of neutral red to distinguish the limits of nuclear groups. Positive cells, with HRP granules in the soma and processes, were consistently found ipsilaterally (and very few contralaterally) at 0.2 to 0.8 mm from the wall of the aqueduct and the third ventricle. Thus labeled neurons were seen in the midbrain periqueductal gray (mostly in its medio-dorsal aspect), in the periventricular gray medially to the retroflex bundle (contrasting with complete lack of positive cells in the adjacent parafascicular-centromedian thalamic complex), in the periventricular posterior hypothalamic area, and continuing up to the periventricular anterior hypothalamus. These results demonstrate that, in addition to a previously described subthalamic input to the midbrain reticular formation (Soc. Neurosci. Abstr., vol. 4, p.49, 1978), a midline system extending from the mesencephalon to the anterior hypothalamus provide afferent fibers to the upper brainstem reticular core. The nature of this descending projection is now being investigated electrophysiologically. Supported by MRC grants MT-3689 and MT-5781.

767 IMMUNOHISTOCHEMICAL EVIDENCE FOR BIDIRECTIONAL PATHWAYS BETWEEN THE PARAVENTRICULAR NUCLEUS, LOCUS COERULEUS AND DORSAL VAGAL COMPLEX. L.W. Swanson and B.K. Hartman. Depts. of Anat. & Neurobiol., and Psychiatry, Wash.Univ.Sch.Med., St. Louis, MO 63110.

The results of two groups of experiments suggest that the locus coeruleus (LC) and the adrenergic cell group centered in the dorsal motor nucleus of the vagus and adjacent parts of the nucleus of the solitary tract (the dorsal medullary group[1]) project in part to the paraventricular nucleus of the hypothalamus (PVH) in the rat. First, electrolytic lesions were placed in the dorsal vagal complex, or knife cuts were made just rostral to it in 12 animals. After 1-4 wks, the hypothalamus was processed by Hartman's method for the immunohistochemical localization of dopamine-β-hydroxylase, and damage in the brainstem was assessed in thionin-stained frozen sections. In those experiments with lesions involving the dorsal medullary group, and in animals with deep knife cuts, the density of adrenergic varicosities in the caudal half of the ipsilateral PVH was reduced by about one-third. Second, 10-40 nl of HRP (33%) was injected stereotaxically into the PVH and adjacent regions of 10 rats. After 24-48 h survival times, 30 µm frozen sections of the hypothalamus and brainstem were processed with TMB histochemistry. In each experiment, retrogradely-filled cells were identified in the nucleus of the solitary tract[2] and dorsal motor nucleus of the vagus, and in the LC. This evidence, when considered together with the results of the lesion studies, suggests that adrenergic neurons in the LC and dorsal vagal complex project to the PVH. Previous autoradiographic studies have shown that the LC[3] and nucleus of the solitary tract[2] project to the PVH, although the neurotransmitter involved in the latter pathway could not be identified.

In earlier immunohistochemical studies[4], we showed that oxytocin-stained fibers from the PVH innervate the LC and dorsal vagal complex. These anatomical results are discussed in light of physiological data which support the hypothesis that the PVH, LC and dorsal medullary group together are involved in neural circuitry that regulates peripheral homeostatic mechanisms, as well as similar functions within the CNS itself.

768 HORSERADISH PEROXIDASE ANALYSIS OF HYPOTHALAMIC AREA CONTROLLING CARDIOVASCULAR RESPONSES TO EMOTION. K. Walsh*, J. DeVito, O. Smith, C. Astley*, Reg. Primate Res. Ctr., Univ. Washington, Seattle, WA 98195.

The cardiovascular (CV) responses to an acute emotional situation in unanesthetized chair-restrained baboons include elevations in blood pressure, heart rate, terminal aortic blood flow and a complex biphasic reduction in renal flow. Electrical stimulation of an area of the hypothalamus produces the same CV responses and when this area is destroyed bilaterally the CV responses accompanying the emotional behavior are eliminated. The neural structures providing afferents to this hypothalamic area were studied with the HRP method in three baboons.

Flow probes were aseptically implanted on the renal artery. Two weeks later the animal was anesthetized with chloralase (90 mg/g) and an arterial cannula was placed in the femoral artery from which arterial pressure and heart rate were recorded. Using a ventriculographic stereotaxic procedure, the appropriate location in the hypothalamus was identified by lowering a stimulating electrode through a guide cannula and recording the CV responses to electrical stimulation (100 Hz, 0.5 ma, 0.2 ms). When the response mimicking the emotional response was obtained the electrode was withdrawn and replaced at that identical location with an injection cannula. A volume of 0.15-0.25 ul of 30-40% HRP (Worthington) was injected into the site. In one animal a control injection was placed in n. ventralis anterior. After 3 days the animals were sacrificed, perfused with 1% paraformaldehyde and 1.5% glutaraldehyde. The next day the brains were cut on a freezing microtome and sections reacted with tetramethyl benzidine (TMB).

The experimental animals showed substantial retrograde labeling of cells in the subiculum, amygdala (medial, cortical and basal nuclei), lateral septal nucleus, organum vasculosum lamina terminalis, subcallosal gyrus, supraoptic nucleus, periventricular system, arcuate nucleus, tuberomammillary nuclei, paraventricularis thalami, interpeduncular and centralis superior, parabrachial nuclei, periacqueductal grey, dorsal raphe and very heavy labeling of the locus ceruleus. Lighter labeling of only a few cells was found in the lateral hypothalamic area, subfornical organ, lateral reticular formation, lateral pre-optic and nucleus solitarius. Contralateral labeling was found in locus ceruleus, periacqueductal gray, lateral parabrachial and solitarius. Of special note was bilateral heavy labeling in and around the dorsal motor nucleus of the vagus and nucleus ambiguus as well as scattered cells forming a connection between these structures. At least some of these cells could be identified as pigmented. Supported by NIH grants RR00166 and HL16910

769 GOLGI STAINING IN THE HYPOTHALAMUS: CELL GROUPS IMPREGNATED FOLLOWING INTRAVENTRICULAR INJECTIONS OF PUROMYCIN. Steven Warach, William E. Armstrong, and Glenn I. Hatton. Neuroscience Program and Psychology Dept., Michigan State Univ., E. Lansing, MI 48824

It has been established (Switzer, Neurosci. Lett. 2:301, 1976) that intracranially administered puromycin induces neural argyrophilia which results in a Golgi staining upon treatment of the tissue with the cupric-silver technique (DeOlmos, Brain Res. 33: 523, 1971). This staining compares favorably to the results of conventional Golgi procedures. Furthermore, the impregnation of neurons is of sufficiently high quality to serve as the basis for distinguishing morphological cell types in at least one nucleus (Armstrong et al., Soc. Neurosci. Abst. 4:329, 1978). Our interest in the hypothalamic neurosecretory nuclei led us to administer puromycin to the hypothalamus via the ventricular system. The widespread hypothalamic impregnation which consistently resulted warrants this report on the extent and quality of the staining. Injections of 5 µl of puromycin dihydrochloride (0.1M or 0.2M) were delivered into the right lateral ventricle near the foramen of Monroe of rats under pentobarbital anesthesia. The animals were allowed to survive from 6 to 48 hr after which the tissue was fixed, gelatin embedded, and processed as 60 µm sections. Survival times of 12 and 18 hr proved best.

The highest concentration of well-impregnated cells were found in the bed nucleus of stria terminalis, the anterior hypothalamic area (especially a ventrolateral group lying dorsomedial to the supraoptic nucleus), and the ventromedial nucleus. Adequate staining was also observed in the lateral preoptic area, the anterior commissural nucleus, the paraventricular nucleus (especially the posterior subnucleus), the dorsomedial nucleus, and the entire rostro-caudal extent of the periventricular zone (usually excluding the 100 µm nearest to the third ventricle). Although often absent or incomplete, staining occasionally occurred in the medial preoptic area, the lateral hypothalamic area, the perifornical region, and the supramammillary and medial mammillary nuclei. Notable exceptions to the puromycin-induced argyrophilia were the suprachiasmatic, supraoptic, and arcuate nuclei.

Lateral regions stained better than medial ones rostrally, while the reverse was true caudally. In general, the concentration and adequacy of staining decreased along a rostro-caudal gradient. The results suggest that too great as well as too little an amount of puromycin made available to specific regions leads to inferior impregnations.

770 POST-LESION HYPERPHAGIA, HYPERKINESIA AND STOMACH ULCERATION INDUCED BY ANODAL AND CATHODAL HYPOTHALAMIC LESIONS IN RATS. N. I. Wiener* & J. N. Nobrega* (SPON: W. A. Mackay), York Univ., Downsview, Ontario, M3J 1P3, Canada.

Lesions of the medial hypothalamus have been known to produce a number of effects in the early post-operative period, including hyperactivity, voracious eating, and stomach ulcers. It has been suggested that some of these effects may result from stimulation by metal ions deposited by anodal current rather than tissue destruction. However, since anodal current tends to produce larger lesions than cathodal current of the same intensity and duration, the effects of current directionality and lesion size may often be confounded. In the present study the effects of small and large ion-depositing anodal and deposit-free cathodal lesions were tested on four types of responses in the 24 hr post-operative period. Epoxylite-insulated #00 stainless steel electrodes were used to produce bilateral VMH lesions in male Wistar rats. Animals were divided into five groups: Group SA received small anodal lesions (.5 mA/10 sec); Group LA received large anodal lesions (1 mA/20 sec); Group SC received small cathodal lesions (1 mA/20 sec); Group LC received large cathodal lesions (2 mA/40 sec); control rats received anesthetic only. Half of the animals in each group were placed in activity boxes after surgery and had their stomachs examined 24 hr later; the others were given food and saline for 24 hr. ANOVAs were used to test the effects of lesion type and size on activity counts, food and fluid intake at 6 and 24 hr and three measures of stomach pathology. Of the nine response variables a significant effect of type of lesion (current) obtained only for the total amount of activity at 6 hr and saline consumption at 6 and 24 hr. Single comparisons indicated that LA lesions produced higher activity counts than any other in the first 6 hr post-lesion; in the next 18 hr, however, LC rats had higher activity counts, and as a result at 24 hr LA and LC groups had equally high activity counts. Large anode rats drank more than all other groups, again mostly in the first 6 hr after the lesion. The only factor which proved significant for all nine variables was size of lesion. Small-lesion groups behaved indistinguishably from controls on all measures, regardless of type of lesion received. These results indicate that large cathodal lesions can produce as much stomach pathology, eating (but not drinking), and motor activity as anodal lesions of comparable size, although the two types of lesions may produce their effects at different rates.

771 WHAT VENTROMEDIAL HYPOTHALAMIC LESIONS DO TO BRAIN METABOLIC ACTIVITY AS MEASURED WITH THE ^{14}C-2-DEOXY-D-GLUCOSE METHOD.

John S. Yeomans, Neil I. Wiener* and Jose Nobrega*. Dept. Psych. University of Toronto and York University, Toronto, Ont. M5S 1A1.

Anodal (2mA for 20 sec) or cathodal (2mA for 40 sec) electrolytic lesions were made with monopolar stainless steel electrodes aimed at the ventromedial hypothalamus of rats. Both unilateral and bilateral lesions were performed. Behaviorally these anodal lesions produce hyperactivity within two hrs after the lesion, accompanied by voracious eating or stomach ulcers (Wiener, Nobrega, Ossenkopp, in preparation). Cathodal lesions produce only ulcers.

Three and one-half hrs after the lesion, the animals were injected with 30 µCi of ^{14}C-2-deoxy-D-glucose. The procedures of Sokoloff were used to obtain auto-radiographs of brain sections from these rats.

Anodal lesions produce profound decreases in labelling in a sphere around the lesion site almost 2mm in diameter. Furthermore there is usually an intense increase in labelling in some specific ipsilateral regions away from the lesion site including, for example, zona incerta, lateral hypothalamus, globus pallidus, and substantia nigra, zona reticulata. The cathodal lesions, although longer in duration, produce a much smaller region of decreased labelling around the lesion site. These radiographic results were compared with the anatomical changes in these sites observed with conventional histology.

The dynamic three-dimensional changes in local brain activity produced by lesions over time can be observed with this method. This promises to help us understand the neural basis of the behavioral syndromes produced by lesions.

INVERTEBRATE NEUROBIOLOGY

772 SOMA SPIKE OF NEUROENDOCRINE BAG CELLS OF APLYSIA CALIFORNICA. Juan Acosta-Urquidi and F. Edward Dudek. Dept. Zool. and Erindale College, Univ. of Toronto, Mississauga, Ont. L5L 1C6.

Repetitive firing of bag cells in Aplysia leads to egg laying in vivo and secretion of a peptidergic egg-laying hormone (ELH) in vitro. Extracellular recordings from bag cell neurites have characterized the propagation of spikes during afterdischarge. Variations in amplitude and/or duration of spikes during repetitive firing and the ionic basis of the action potentials were examined in soma spikes elicited by intracellular current injection. Spikes in artificial sea water (ASW) were either graded with increasing cathodal current pulses, or had a well-defined threshold. The latter typically had faster rise times, larger overshoots and more fully-developed hyperpolarizing afterpotentials. Repetitive stimulation led to frequency potentiation (FP), which was expressed as an increase in overshoot amplitude with a concommitant increase in duration of successive spikes in a train. FP was usually detectable at 0.5 Hz, and fully expressed between 0.8 - 4 Hz. Accommodation occurred rapidly at ≥5 Hz. The increase in spike duration during FP resulted from a progressive enhancement of an inflection on the falling phase. The expression of this inflection was dependent on membrane potential; depolarization enhanced it, hyperpolarization reduced it. A short conditioning train of strong hyperpolarizing pulses caused inactivation of spike electrogenesis, which lasted a few seconds. Experiments with 0-Na^+ ASW (Tris-substituted) and/or 0-Ca^{++} (1mM EGTA) ASW perfusion revealed mixed Na^+/Ca^{++} spikes with variable degrees of Na^+ versus Ca^{++} dominance. Na^+-dominant spikes showed less FP. Similar to 0-Ca^{++} ASW, solutions containing Cd^{++}, Co^{++} and Mn^{++} reversibly abolished the inflection on the falling phase; the spike was severely attenuated at higher concentrations. FP was generally abolished only if the spike was severely attenuated. The inflection was augmented in 3-aminopyridine (4mM), thus increasing spike duration. Ba^{++} (substituted for Ca^{++}) attenuated spikes and in some cases increased the duration. Results with tetrodotoxin (10^{-5}-10^{-4}M) in normal ASW were equivocal. These experiments generally support the hypothesis that soma action potentials of bag cells have both Na^+ and Ca^{++} components. It is proposed that FP results primarily from potassium-inactivation which then unmasks a calcium current. FP may play a significant role in augmenting ELH release.

773 KINETICS OF THE SLOW CURRENTS DURING NORMAL BURSTING IN APLYSIA CELL R15. William B. Adams and Irwin B. Levitan. Friedrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.

Bursting activity in cell R15 in the abdominal ganglion of Aplysia is mediated by voltage- and ion-dependent conductances having slow kinetics. During a burst the cell is depolarized by a flow of inward current. Using voltage-clamp techniques, we have found a transient increase in the inward current flow following each action potential. The increase amounts to 1 to 2 nA, lasts from 1 to 3 seconds, displays temporal summation when action potentials are sufficiently close together, and tends to maintain the burst. In addition, each action potential elicits a smaller but longer-lasting increase in outward current. The increments in outward current are only a small fraction of a nanoampere, but they persist for tens of seconds and summate throughout the burst. Because of the different kinetics of the two current components, the outward current plays a more important role as the burst progresses. Eventually the net current is outward and the burst is terminated. Thus, the pattern of burst activity appears to depend on the amplitudes and recovery kinetics of these two current components. The normal burst pattern can be altered by dopamine, serotonin, vasopressin and modifiers of cyclic nucleotide metabolism. Attempts to elucidate the effects of these agents on the parameters of the individual current components are in progress.

774 TWO-DIMENSIONAL GEL ELECTROPHORESIS OF NEUROSECRETORY POLYPEPTIDES IN THE CRUSTACEA. R.D. Andrew * (SPON: H. Kwan). Biology Dept., York University, Toronto, Ontario, Canada M3J 1P3.

Two-dimensional polyacrylamide gel electrophoresis is capable of resolving hundreds of proteins from microgram amounts of complex biological material. Proteins are focused according to charge in the first dimension and then, at right angles, according to size in the second dimension. Determining the precise location of neurosecretory cell bodies is prerequisite for studying the synthesis and processing of neurosecretory polypeptides stored in axon terminals comprising the sinus gland of the crustacean eye stalk. Structural data establishes that the crayfish X organ represents 90 - 95% of the cell bodies actively synthesizing neurosecretory vesicles stored in the neurohemal sinus gland. These cell bodies rarely accumulate neurosecretory vesicles as judged by light and electron microscopy suggesting that neurohormone precursors, but not processed products, might be found there. Two-dimensional electrophoresis of sinus gland and X organ homogenates support this hypothesis. In crayfish, lobster and blue crab, stained two-dimensional gels display a number of sinus gland-specific polypeptides whose high concentrations and low molecular weights are consistent with stored neurosecretory material. These neuropeptides are not detected in X organ homogenates or in non-neurosecretory neural tissue with Coomassie Blue staining. By decreasing the porosity of the second dimension, the two-dimensional gel technique has proven useful in determining the molecular weights of a variety of neurosecretory polypeptides (MW 4-20K) stored in the sinus gland. The crayfish and lobster store several polypeptides weighing ~ 7 K daltons. The blue crab stores two 7 K, two 13 K and three 20 K sinus gland polypeptides detected in stained gels.

Following a 4 hr incubation in ^3H-labelled amino acids, predominantly labelled 19 - 21 K molecular weight polypeptides are detected in crayfish X organ homogenates with 2-D gel autoradiography. Concomitantly, three labelled polypeptides (MW 4 - 10 K), which are not stored in enough quantity to be detectable with staining, appear in the sinus gland. Their rapid synthesis but low storage level suggest that they are quickly released. This study is the first to examine neurosecretory precursors (19-21 K) and their putative cleavage products (~ 7 K) in the Crustacea.

775 BAG CELL DEGENERATION FOLLOWING SURGICAL TRANSECTION OF A PLEUROABDOMINAL CONNECTIVE. S. Arch and G. Thayer*. Biological Laboratories, Reed College, Portland, OR 97202.

Two clusters of neuroendocrine cells (the bag cells) associated with the parietovisceral (abdominal) ganglion of Aplysia californica are known to be responsible for the synthesis and secretion of a peptide hormone that causes egg laying. Because the cell clusters are morphologically set apart from the ganglion proper and are structurally, chemically, and electrically homogeneous, they represent an accessible and analytically tractable preparation. Since it has been shown that deafferentation of these neurons results in cessation of spontaneous egg laying (Pinsker and Dudek, 1977, Science 197:490), we were interested to determine if the neurons undergo changes correlated with the elimination of afference. Animals were anesthetized, a small incision was made in the dorsal body wall, and one or the other of the two nerves known to carry bag cell afferents was transected. Most of the animals survived this operation and resumed apparently normal behavior. At various post-operative intervals animals were sacrificed and their parietovisceral ganglia were fixed, embedded, and sectioned for light microscopic analysis. For the first few weeks following transection there was little change evident in the bag cell clusters. However, there was marked hypertrophy of glial and connective tissue in the bag cell organ ipsilateral to the transection. By the sixth post-operative week, extensive degeneration of the ipsilateral bag cells was evident. Surprisingly, the bag cell cluster contralateral to the transection also showed marked degenerative change. Since this cluster was still innervated normally, we had assumed that it would serve as an internal control. The level at which the transections were made (1-2 cm rostral to the cell cluster) were chosen to minimize the likelihood that bag cell neurites would be cut. Studies of axoplasmic transport of radiolabeled egg-laying hormone have shown no indication of hormone movement beyond 1 cm rostral to the cell cluster. Similarly, we have been unable to backfill bag cells with horse-radish peroxidase in preparations having connective nerves longer than about 1 cm. Thus, while neurite transection may have occurred, only a very small proportion of the bag cells could have been involved. It seems unlikely that retrograde degeneration of the entire ipsilateral cluster would ensue as a consequence of the neurite transection that may have occurred. In any case, loss of the contralateral cluster must also be explained. Our present hypothesis is that unilateral transection of the connective nerve has removed afference to the bag cells and that the functional integrity of this afference is crucial to the maintenance of the differentiated state in these neuroendocrine cells.

776 TWO NEUROHORMONES PARTICIPATE IN THE CONTROL OF CIRCADIAN NEURONAL ACTIVITY IN THE CRAYFISH. Hugo Aréchiga, Alberto Huberman*and Irene González* Dept. Fisiol. Ctr. Estud. Avanzados, I.P.N., and Inst. Nac. Nutrición, México, D.F.

It has been postulated that a hormonal channel modulates the excitability of the nervous system of decapod crustaceans along the 24-hour cycle (Aréchiga, H., Fed. Proc. 36:2036, 1977), and a neuropeptide (Neurodepressing Hormone) has been identified in the nervous system and blood of the crayfish, exerting a depressant action on the excitability of an ample variety of neuronal elements (Aréchiga, H., Cabrera-Peralta, C. and Huberman, A., J. Neurobiol., 1979, In Press.) The concentration of this peptide varies along the 24-hour cycle, being highest at day-time.

In experiments measuring the activity of Neurodepressing Hormone (NDH) at different times, it became evident that another substance was present in the nervous system, capable of increasing the spontaneous activity of motoneurons in isolated ganglia. By successive steps of Sephadex G-25 and G-15 chromatography, it has been possible to separate this neuroactive substance, which appears to be a peptide of low molecular weight, eluted in fractions neighbour to those containing NDH in G-15. The greatest amount of this substance is contained in the eyestalk, but lesser quantities are found in the supraoesophageal ganglion and thoracic ganglia. Its excitatory effect does not show noticeable desensitization. The concentration of this peptide in the eyestalk varies along the 24-hour cycle, attaining a high level at night and decreasing during the day. This rhythm persists in constant darkness and is opposite in phase to that of NDH. The rhythm of secretion of both peptides can be phase-shifted by entraining animals to different light:darkness regimes.

From these evidences, it appears that the level of excitability of the crayfish nervous system is modulated in a circadian manner by two peptides with opposite effects.

777 **COMPLEX RECEPTOR NEURONS IN TRITONIA: NEURONAL CORRELATES OF A CHANGE IN BEHAVIORAL RESPONSIVENESS.** **Gerald Audesirk and Teresa Audesirk. Friday Harbor Labs, Univ. of Washington, Friday Harbor, WA 98250.**

When contacted by the tube feet of certain predatory sea stars, the nudibranch Tritonia diomedea performs an escape maneuver composed of an initial swim (Willows, 1967) followed by an "escape run" consisting of rapid crawling locomotion. Although the usual response of a crawling Tritonia to food presentation is to stop locomotion and begin to feed, during the escape run the animal will not feed, and in fact behaves as if it cannot tell that food is being presented.

The CNS of Tritonia contains a population of complex receptor neurons which are both primary mechanoreceptors and secondary mechano- and chemoreceptors receiving sensory input from the oral veil and anterior foot. These receptors normally respond strongly when the oral veil is touched with a sea whip, Tritonia's normal food. After a swim, during the time of the escape run, these receptors are much less responsive (50%) to food stimuli, although their input from the periphery is not qualitatively different.

During the swim, the receptors are synaptically driven to produce bursts of spikes, in phase with ventral flexions. Three hypotheses can be advanced to account for the change in responsiveness of the receptors: (1) aftereffects of swim spiking reduce excitability; (2) aftereffects of swim synaptic activity reduce excitability; (3) synaptic inputs during the escape run inhibit spiking. These hypotheses were tested by hyperpolarizing a receptor neuron during a swim to prevent spiking and by driving an "artificial swim" by current injection. It was found that if spikes were prevented during a swim, nearly all of the responsiveness change was abolished. Second, an almost normal responsiveness change could be induced by an artificial swim of similar frequency and temporal patterning to a natural swim. These excitability changes occurred whether assayed by natural food stimulation of the oral veil or by direct intracellular current injection. Similar changes still occurred when interneuronal firing was reduced by high calcium solutions. These results support the first hypothesis, but minor effects due to the second and third hypotheses cannot be ruled out.

We propose that the responsiveness change is intrinsic to the complex receptors, and is elicited by spiking during a swim. This change in receptor excitability is a possible mechanism by which Tritonia behavior is modified by immediate past experience, contributing to behavioral flexibility.

778 **PROPERTIES OF COMPLEX RECEPTORS IN TRITONIA DIOMEDEA.** **Teresa Audesirk and Gerald Audesirk. Friday Harbor Labs, Univ. of Washington, Friday Harbor, WA 98250.**

The lateral cerebral ganglia of Tritonia diomedea contain a group of approximately 10 neurons ranging in size from 50 to 100 microns. These usually send out three axons, one each in cerebral nerves 2 and 3 innervating the oral veil, and one in pedal nerve 1 to the anterior foot. Ipsilateral cells are electrically coupled to one another. Application of a variety of chemical stimuli to the oral veil produces a burst of synaptically driven spikes in these cells, with food extracts being most effective. Mechanical stimuli delivered to the oral veil and anterior foot also result in synaptic activity and spiking.

When a brain - oral veil preparation is bathed in high Mg^{++}, low Ca^{++} SW to block chemical synaptic activity, the chemoresponsiveness of these cells is eliminated. Responsiveness to mechanical stimuli is retained as blocked afferent spikes, indicating that these are primary mechanoreceptors. Mapping studies reveal that most of these receptors have multiple receptive fields for tactile stimuli in the ipsilateral oral veil and anterior foot. Responses evoked by stimuli delivered to the contralateral oral veil or foot were never observed. When the brain is placed in high Mg^{++}, low Ca^{++} SW and the oral veil is in normal seawater, blocked afferent spikes are recorded in response to food extract as well as mechanical stimuli. This indicates that some peripherally located chemoresponsive cells make chemical synapses on these receptors. When the oral veil is placed in high Mg^{++}, low Ca^{++} SW and the brain is in normal seawater, synaptic activity and spikes are present in response to mechanical stimuli, but no activity is elicited by chemical stimuli. Therefore all chemoreceptive input must pass through peripheral synapses. Some is communicated by way of both peripheral and central synapses to account for the synaptic activity observed in response to food extract when the entire preparation is bathed in normal seawater.

The result of this organization is a neuron responsive to chemical and tactile stimuli, and which responds most energetically when the two are combined. It is hypothesized that Tritonia uses these receptors to determine contact with an object and on which side of the body, and whether or not the object is food.

779 NEURONAL ORGANIZATION OF THE SALIVARY NEUROEFFECTOR SYSTEM OF HELISOMA: REDUNDANCY OF BILATERAL COORDINATING MECHANISMS. Fred Bahls, Stanley B. Kater and Ronald W. Joyner*. Depts. of Physiol. & Biophys. and Zool., Univ. of Iowa, Iowa City, IA 52242.

The salivary neuroeffector system of Helisoma consists of the paired salivary glands and two identified buccal ganglion neurons, 4R and 4L. In contrast to most gastropod neuroeffector systems, both the central and peripheral components of this system are readily accessible to intracellular analyses. Previous work has shown that two different mechanisms can exist to ensure coordinated activation of the salivary glands. First, the two neurons 4 can receive identical synaptic input from higher order buccal ganglion neurons. Second, the two neurons 4 are electrically coupled, with a mean coupling coefficient of .42 (N=28, S.D.= .16). Activity within each salivary gland is coordinated by extensive electrical coupling. However, bilateral coordination of activity between the two salivary glands requires neural control, because there is no communication between the two glands.

We now provide morphological and electrophysiological evidence for a third mechanism for bilateral coordination: innervation of each salivary gland by axons from both neurons 4. Intracellular injection of the fluorescent dye Lucifer Yellow has shown that both neurons 4 can send an axon to both salivary glands. Electrophysiological evidence for dual innervation was obtained in the following manner. When one neuron 4 is stimulated at frequencies $\geq$ 2 Hz., a delay occurs between the spikes in the two neurons 4. Owing to the electrotonic interaction associated with this delay, the waveform of the spike in the stimulated 4 becomes a sensitive monitor of activity in the follower 4. Thus, we monitored the activity of both neurons 4 while recording from only one neuron 4 and a salivary gland cell, and were able to demonstrate in 6 out of 8 preparations in which this stimulus paradigm was used, that at least one of the two salivary glands received innervation from both neurons 4.

Thus, there can be at least three levels of interaction which maintain bilateral synchrony of activity in the salivary glands, indicating a high level of redundancy in this gastropod neuroeffector system. Data from other, less easily studied systems, indicate that redundancy may be a general feature of the organization of gastropod neuroeffector systems.

780 THE ACTIVE ZONE AT APLYSIA SYNAPSES: ORGANIZATION OF PRESYNAPTIC DENSE PROJECTIONS. C.H. Bailey*, P. Kandel*, and M. Chen*(SPON: J. Koester) Div. of Neurobiol. and Beh., Dept. Physiology, Columbia Univ. College of P & S, New York, N.Y. 10032

We have recently developed criteria for recognizing active zones at Aplysia synapses. To obtain independent evidence for these sites and to study their characteristics we have applied to the Aplysia neuropil two special staining techniques - 1) ethanolic phosphotungstic acid (E-PTA) (Bloom and Aghajanian, 1968)and 2) bismuth-iodine impregnation followed by uranyl acetate and lead staining (BIUL) (Pfenniger et al., 1969).

As is the case with active zones at vertebrate synapses, Aplysia ganglia treated with E-PTA or BIUL reveal a series of presynaptic dense projections arising from, or connected by, a thin band of electron-dense material attached to the cytoplasmic leaflet of the presynaptic membrane. Analysis of sections cut perpendicular to the presynaptic membrane suggest some variability of the shape and size of individual dense profiles. A common configuration is that of a flattened or slightly rounded pyramid (mean height=29nm ± 0.8nm S.E.M., N=87 mean base diameter = 46 nm ± 1.4 nm S.E.M., N=87). Additional configurations include small, irregular swellings with smooth borders and larger more complex bodies with short spine-like extensions. Viewed in sections taken perpendicular to the membrane these projections can appear either isolated, or interconnected at their bases by strands of electron-dense material. The center-to-center spacing of presynaptic projections varies from 45 nm to over 100 nm with a mean value of 69nm ± 2.5 nm S.E.M., N=52. Preliminary analysis of sections cut parallel to the synaptic cleft suggest that at least some of these presynaptic densities are discrete projections (as opposed to bar-type densities, Wood et al., 1977), although the precise geometric nature of the presynaptic region is not yet clear.

Postsynaptic specializations occur as a narrow, uniform electron-dense sheet (mean width = 8nm ± 0.5 nm S.E.M., N=11) attached along the length of the postsynaptic membrane or as an interconnected series of irregular expansions (mean width=17nm ± 1.1nm S.E.M. N=14). The periodicity of these postsynaptic tufts is variable although some appear to occur more frequently between opposing presynaptic projections than directly opposite a dense projection.

These techniques confirm the existence of specialized active zones in Aplysia and should prove useful for the quantitative study of changes in synaptic function with experience or age.

781 NEUROTRANSMITTER SYNTHESIS IN THE VISUAL SYSTEM OF LIMULUS B.A. BATTELLE* (SPON: H.B. Pollard) LVR, National Eye Institute, NIH, Bethesda, MD.

The synthesis of putative neurotransmitters in the ventral and lateral eyes of Limulus was studied using a modification of the procedure of Hildebrand et al. (J. Neurobiol. 2, 231-246, 1971). Results are summarized in the table below. Ventral eye preparations were dissected into a photoreceptor rich (p-fraction) and a nerve fraction (n-fraction) before extraction and electrophoresis.

^{3}H labelled precursor	Neuro-transmitter	Ventral Eye P	Ventral Eye N	Lateral Eye	Lateral Eye Nerve
Choline	Ach	-	+	-	+
Glutamate	GABA	+	++	+	++
Tryptophane	5-HT	-	-	-	-
Tyrosine	NE	-	-	-	-
	DA	-	-	-	-
	Oct	+	+	+	+
Tyramine	Oct	++	+	++	+

Several interesting observations emerge. 1. The types of putative neurotransmitters synthesized, and the distribution of synthetic activity between cell-rich and nerve fractions are similar in the lateral and ventral eye preparations. 2. Although serotonin has a number of important pharmacological effects on cells in the lateral eye, no serotonin synthesis is detected. 3. Incubations with tyramine show clearly a selctive synthesis and accumulation of octopamine by cell-rich fractions of both ventral and lateral eye preparations, thus octopamine becomes of interest as a possible neurotransmitter or neurohormone in these preparations. Further support to this idea comes from observations that both ventral and lateral eyes contain significant levels of endogenous octopamine (6.02 and 32.8 p moles octopamine per mg tissue wet weight respectively) and that the photoreceptor cells of the ventral eye stain with neutral red.

Incubations of ventral and lateral eye preparations with tyramine yield two other major radioactive products in addition to octopamine. The nature of these products is unknown, however one is a mixture of octopamine and tyramine metabolites. There is no detectable accumulation of octopamine metabolite when tyrosine is used as the precursor.

782 THE SALIVARY SYSTEM PROVIDES SENSORY INPUTS TO FEEDING NEURONS IN LIMAX. Barbara Beltz and Alan Gelperin. Dept. Biology, Princeton University, Princeton, New Jersey 08544.

The central nervous system of the terrestrial slug Limax maximus provides a convenient system in which to study the interactions between the salivary and feeding systems. Feeding and salivary neurons were monitored extracellularly via their axons in buccal roots while the salivary duct musculature was stretched by microliter injections of saline into the cannulated salivary duct. These injections expanded the duct less than the spontaneous duct expansion measured in vivo.

The feeding motor program (FMP) can be activated by two types of stretch stimuli. When the duct is held inflated for a minute or more, FMP is often initiated when the stretch is released. A series of short inflations of the duct can also result in FMP activation. FMP is detected by monitoring the phasing of motoneuron activity as recorded from the salivary nerves and buccal roots (Gelperin et al, J. Neurobiol. 9(4):285-300, 1978).

Post-synaptic potentials elicited by duct stretch can be recorded intrasomatically from presumptive feeding neurons. Both hyperpolarizing and depolarizing inputs onto these buccal neurons, caused by duct stretch, have been demonstrated.

The salivary bursters (SBs), which are coactivated with feeding, are bilateral buccal neurons each of which sends a process into its ipsilateral salivary nerve. The activity of these autoactive, bursting neurons is also modulated by duct stretch.

This modulation of SB activity can be caused by a chemically mediated inhibitory input to the SBs, evoked in response to stretch of the ipsilateral salivary duct. The SB rebounds from the inhibition with a burst of higher frequency activity than was recorded before duct stimulation.

There is also evidence that the SBs, which are motoneurons to the salivary duct musculature, are also primary sensory neurons activated by duct stretch (Beltz and Gelperin, Neuroscience Abstracts, Volume IV, 1978).

These reflex phenomena are examples of regulation of centrally generated output by peripheral feedback. SB modulation by duct stretch may represent a mechanism to coordinate the processes of salivary secretion and transport during non-feeding periods. FMP initiation caused by salivary duct stretch indicates that mechanosensory input from the salivary network may also contribute to the activation of feeding activity in vivo. 783 SALINITY INDUCED CHANGES IN THE ELECTRICAL PROPERTIES OF MOLLUSCAN NEURONS. Linda S. Beres* and Sidney K. Pierce* (Spon: H. Levitan). Dept. Zoology, Univ. of Maryland, College Park, MD 20742.

Many marine invertebrates are subjected to large fluctuations in environmental salinity. Further, in osmoconforming species, the blood ionic composition undergoes changes which reflect those occurring in the external medium. Since many aspects of neuronal physiology are dependent upon the ionic composition of the extraneuronal medium, exposure to low salinity may have pronounced effects on the properties of the nervous system in these animals. This possibility was examined using conventional intracellular electrophysiological techniques to record from single neurons in isolated visceral ganglia of the clam Mya arenaria, which is an osmoconformer inhabiting salinities as low as 10% of the salt content of normal seawater. Recordings obtained from animals maintained in normal (≈100%) seawater reveal resting membrane potentials of -40 to -80 mV; overshooting action potentials could be elicited by intracellular current injection. Exposure of these neurons to 75% seawater resulted in an immediate hyperpolarization (15 to 30 mV) of the membrane potential. This hyperpolarization was transient, lasting 2 to 10 mins, and was followed by a secondary depolarization of 30 to 60 mV. Further, the changes in membrane potential were accompanied by an increase in apparent input resistance. Despite this increase in input resistance, the excitability of the cells was reduced. Higher current intensities were required to elicit action potentials; in some cases, no action potential could be produced even with a three-fold increase in stimulating current. Action potentials, when present, were reduced in amplitude following the salinity change. Occasionally, spontaneous synaptic potentials were observed in some cells; when they occurred, invariably their frequency was increased by reductions in salinity. Recordings over longer periods of time (2-3 hrs from the salinity change) showed that the membrane potential slowly returns to normal. Preliminary investigations suggest that the excitability also returns. In addition, neurons from animals acclimated for 3-4 weeks to lowered salinity exhibit electrophysiological properties similar to those found in animals maintained in 100% seawater. These results indicate that, following exposure to low salinity, the neurons of Mya arenaria undergo changes in both the membrane properties and excitability. After a period of time, however, the neurons appear to adapt to the change in salinity, as evidenced by a return of the electrical properties to normal levels.

784 CIRCADIAN RHYTHM IN THE EYE OF APLYSIA RECORDED IN VIVO. G. D. Block, Department of Biology, University of Virginia, Charlottesville, Virginia 22903.

The eye of Aplysia expresses a circadian rhythm (CR) in the frequency of compound action potentials (CAPs) when recorded in vitro (Jacklet, Science 164:562-563, 1969). Aplysia also exhibit a circadian periodicity in locomotor activity. Although extraocular photoreceptors and oscillators are involved in controlling the locomotor rhythm, changes in locomotor patterning following eye removal suggest that the eye also contributes to locomotor control as a circadian oscillator (Strumwasser, Physiologist 16:9-42, 1973; Lickey et al., J. Comp. Physiol. 118:121-143, 1977). Unfortunately, the expression and waveform of an ocular CR in vivo cannot be confidently inferred from in vitro CRs, since the optic nerve contains efferent fibers which, when active, modify the patterning and frequency of CAPs (Eskin, Z. vgl. Physiol. 74:353-371, 1971). Thus to further define the role of the ocular CR in controlling locomotor activity it is necessary to: (1) confirm that a CR in CAP activity is expressed in vivo and (2) evaluate the in vivo phase relationship between the ocular and locomotor CR's.

In situ optic nerve activity was recorded by means of .003" teflon coated Pt-Ir hook electrode. Continuous recordings were made for up to 90 hr from Aplysia maintained in 20 l glass aquariums. CAPs recorded in this manner displayed amplitudes ranging from 20-100 μV and in most cases showed irregular burst patterning, suggesting effective efferent modulation.

The results indicate the presence of an ocular CR in vivo. When Aplysia were maintained in constant darkness CAP frequency peaks (200-400/hr) occurred at projected dawn with near peak levels persisting for 6-10 hr. The overall waveform of the ocular CR was similar to CR's obtained in vitro with the cerebral ganglion left attached. When Aplysia were placed on light cycles (LD 12:12), CAP frequencies remained near peak levels for the entire photoperiod, dropping to low levels at dusk (5-10/hr) and remaining at this baseline until 2-3 hr before dawn. Simultaneous recording of locomotor activity by time-lapse cinematography indicated that locomotor onsets closely followed the predawn increase in CAP activity.

785 NUMBERS AND SIZES OF CELLS IN MOLLUSCAN GANGLIA. M. B. Boyle*, L. B. Cohen and E. R. Macagno. Dept. Physiology, Yale Univ. Sch. Med., New Haven, CT 06510; Dept. Biol. Sci., Columbia Univ., New York, NY 10027

One criterion that might be used in the selection of a preparation for studying the neuronal basis of behavior is the number and size of neurons in the central ganglia. Ganglia from three gastropod molluscs were dissected out, pinned out in Sylgard dishes, stained in methylene blue overnight, fixed in 4% formaldehyde in sea water, dehydrated in acetone, cleared in methyl salicylate and mounted between cover slips. Cell counts were performed with the aid of a computer-interfaced light microscope (Macagno et al, Ann. Rev. Biophys. Bioeng. 8,1979). Considering the cells as approximate prolate ellipsoids, the smaller diameter of each cell was entered into the computer. Objects smaller than 4μm were not counted or measured. The measured diameters were multiplied by 1.4 to account for shrinkage during preparation and by 1.16 to give the mean diamter of each cell. We think the cell counts do not differ from the actual number by more than a factor of two.

Species	Ganglion	No. of Cells	Mean Diam.(μm)
Navanax inermis	cerebral	600	24
"	pedal	700	34
"	pleural	200	45
"	supraintestinal	160	46
"	visceral	350	52
"	buccal	240	35
Aplysia californica	buccal	800	28
Hermissenda crassicornis	cerebral	600	14
"	pedal	500	23

Some differences were found. The cell bodies in Hermissenda were only half as large as those in Navanax, and the buccal ganglia of Aplysia had about three times as many neurons as the corresponding Navanax ganglia. Although counts were made on only one example of each ganglion, inspection of additional preparations suggested that these differences between species are not due to variation from individual to individual. There seem to be substantial species differences in cell number and size. The total number of neurons in the Navanax central nervous system was about 4500. We plan to measure ganglia from additional species searching for a preparation with relatively few and relatively large neurons.

786 VASCULARIZATION OF THE ABDOMINAL CENTRAL NERVOUS SYSTEM OF THE CRAYFISH: CONSEQUENCES FOR PHYSIOLOGY. Stephen K. Brown*, Dyane N. Sherwood, and Jeffrey J. Wine. (SPON: Angela C. DiBerardino). Dept. of Psych., Stanford U., Stanford, CA 94305.

The importance of an intact circulatory system to the normal function of the crayfish's nervous system was investigated. This is of interest, for decapod crustaceans lack a blood-brain barrier as it is known in vertebrates while possessing barriers to the diffusion of chemicals into the nervous system from the surrounding open return system (Lane & Abbott, Cell Tiss. Res. 156, 173, 1975). The anatomy of the vascularization of the ventral nerve cord was examined; a technique by which the nerve cord could be perfused via the circulatory system was developed; and neurophysiological experiments were performed to determine whether the perfusion technique provides results different from those obtained with conventional methods.

Injections of ink into the heart revealed extensive vascularization within the ventral nerve cord. Within the ganglia, which received many more major arterial inputs than did the connectives, the greatest vascularization was associated with the nerve cell bodies. The vascularization of the neuropil was also relatively heavy and consisted of numerous fine arterioles which assumed a variety of orientations. The vascularization of the connectives consisted primarily of four or five arterioles of a relatively large diameter running parallel to each other and longitudinally in the central area of each hemiconnective. The roots were the most lightly and variably vascularized.

In order to discover whether arterial solutions have access to central synapses, the arteria descendens was cannulated through the bulbus arteriosis with Silastic tubing, and various solutions were perfused through the system at rates of 50 ml/hr. To test synaptic transmission during perfusion, responses of the lateral giant neurons to both direct and root stimuli were monitored. Root stimuli activate well-known pathways that contain both chemical and electrical synapses and converge onto the lateral giant neurons (Zucker, Kennedy & Selverston, Sci. 173, 645, 1971). Although bathing the nerve cord with high Mg^{+2}/low Ca^{+2}saline for up to one hour did not affect synaptic transmission, arterial perfusion with high Mg^{+2}/low Ca^{+2} saline rapidly blocked chemical but not electrical synapses. These results show that cannulation of the artery provides a means of delivering to the nervous system solutions that do not penetrate the ganglionic neuropil when delivered via the bathing medium.

787 A COMPARISON OF THE NEURAL CIRCUITS FOR INKING BEHAVIOR AND GILL-WITHDRAWAL IN APLYSIA CALIFORNICA. John H. Byrne. Department of Physiology, School of Medicine, University of Pittsburgh.

As our understanding of the neural control of simple behaviors progresses, it becomes of interest to examine to what extent different behaviors utilize different neural substrates. Defensive inking behavior and gill-withdrawal in Aplysia offer simple test systems in which these questions can be examined. While a good deal is known regarding the neural circuit for gill-withdrawal (Kandel,1979), little is known about the neural circuit for inking other than it is mediated by 3 identified motoneurons (L14A,B,C) in the abdominal ganglion (Carew & Kandel,1977). I have begun to identify the sensory- and inter-neurons which mediate inking behavior in order to compare these two defensive reflexes at the cellular level.

The ink motor cells are activated by strong tactile stimulation of the mantle region. At least part of the sensory input is mediated by previously identified LE and RE cluster sensory neurons (Byrne et al., 1974) as well as newly identified RF cluster sensory neurons. The RE and LE cells innervate the mantle shelf and siphon skin while the RF cells overlap these regions and also innervate the gill. Some sensory neurons make direct monosynaptic connections to ink motoneurons, others have mono- and polysynaptic components, while others have only polysynaptic components. There are at least 2 types of polysynaptic excitatory pathways. Sensory neurons make monosynaptic connections onto interneurons, such as cell R17, which in turn make monosynaptic increased conductance EPSPs to ink and gill motoneurons. Tactile stimulation of the skin also excites a cluster of at least 3 interneurons one of which has been identified as L31. L31 makes a slow decreased conductance EPSP to L14 but makes no connections to gill motoneurons. In addition to the excitatory input to L14 there is a pronounced slow inhibitory input from a cluster of at least 4 cells, one of which has been identified as L32. In contrast to the slow inhibition of ink motoneurons, L32 produces fast EPSPs in gill motoneurons. Tactile stimulation inhibits L32 and at least part of the inhibition is mediated by the previously identified (Castellucci et al., in prep.) interneuron L16. L16 is weakly electrically coupled to L14 but not to gill motoneurons. All of the interneurons, as well as the RF cluster neurons send axons in the pleuroabdominal connectives. It is unknown whether these axons are input routes or outputs to drive other neurons such as the opaline motoneurons (Tritt & Byrne, 1978) in the pleural ganglion.

The two circuits utilize a large number of common sensory- and interneurons and are mediated by both mono-and poly-synaptic pathways. However some neurons (L32) have different synaptic actions, others (L31) are used for one circuit and not the other, while one neuron (L16) is coupled to L14 but not the gill motoneurons. In addition the ink motoneurons are coupled while the gill motoneurons are not (Carew & Kandel, 1977). Thus while some general features of organization of these reflexes are common, specific differences have developed which contribute to differences in the expression of the two behaviors (Carew & Kandel, 1977, Shapiro et al., in press). Supported by NIH grants NS13511 & NS00200.

IDENTIFIED MOTORNEURONS INNERVATE IDENTIFIED PHARYNGEAL MUSCLE BANDS AND REGIONS IN NAVANAX, AN OPISTHOBRANCH MOLLUSC. M.S. Cappell, D.H. Hall*, A.J. Susswein, D.C. Spray and M.V.L. Bennett. Div. Cell. Neurobiol., Dept. Neurosci., Einstein Col. Med., Bx,NY

Previous work has identified two populations of neurons in the buccal ganglia that control pharyngeal musculature: expansion neurons innervate radial fibers, causing pharyngeal expansion and circumferential neurons innervate circumferential fibers, causing pharyngeal constriction. The present work provides additional evidence that both neuronal types make monosynaptic connections onto muscle and shows that identified cells innervate specific regions of the pharynx. Longitudinal fascia divide the pharynx into two dorsolateral thirds and a ventral third. A dorsal and a ventral nerve on each side provide motor innervation to dorsolateral and ventral pharynx respectively with insignificant overlap as determined by EMG recordings. Circumferential musculature is composed of distinct bands which are remarkably constant in number over a 15-fold range of pharyngeal weights for both dorsolateral and ventral regions. (Dorsolateral bands: M=31.6, S.D.=1.2, N=52. Ventral bands: M=24.3, S.D.=0.5, N=15) Subpopulations of the bands differ morphologically and are also quite constant in number. Evidence that particular neurons end monosynaptically on the muscle includes: short and constant latency of EMGs, unchanged latencies of EMGs with elevated divalent ion concentrations and appropriate antidromic latencies with peripheral electrical stimulation. EMGs were recorded from a grid work of up to 40 pin electrodes passed through the pharyngeal wall at specific bands to determine motorneuron (MN) fields. Identified circumferential cells appear to innervate single subpopulations of bands. The anterior sphincter is formed from overlapping bands which comprise a distinct subgroup. Four MNs innervate this sphincter: one on each side activates it bilaterally, another on each side activates it only ipsilaterally. Several additional MNs innervate more posterior bands. Expansion MNs innervate particular areas of radial muscle via specific combinations of the dorsal and ventral pharyngeal nerve. Both giant (G) cells innervate the entire pharynx via all four nerves as indicated by EMG recordings, dye injection, and serial section reconstruction. It is not yet determined whether each G cell innervates every radial fiber. The left ventral medium sized (M) cell innervates the anterior dorsal pharynx from circumferential #25 to 31 via the dorsal pharyngeal nerves. Another smaller left ventral cell innervates the posterior area of the ipsilateral pharynx via ipsilateral dorsal and ventral pharyngeal nerves. Several other cells with various motor fields have been observed but not adequately characterized with respect to identifiability and uniformity. This work is providing a framework for studying the contribution of individual MNs to generation of feeding behavior. Supported (in part) by NIH grant 5T 32GM7288.

HORMONAL MODULATION OF EGG-LAYING BEHAVIORS IN APLYSIA BRASILIANA. Jerald Cobbs and Harold Pinsker. Marine Biomedical Institute, UTMB, Galveston, TX 77550.

Egg laying in Aplysia is a sequence of fixed acts which follows natural firing of the neuroendocrine bag cells or injection of bag cell hormone (BCH). BCH has been implicated in the release of mature eggs from the ovotestis and in the prolonged modulation of electrical activity of identified central neurons. However, it is unknown whether behaviors associated with egg laying are released directly by BCH or are secondarily triggered reflexes. Furthermore, the sequence of behavioral events that surround a natural bag cell discharge are unknown.

We simultaneously monitored bag cell activity via chronically implanted cuff electrodes on the pleurovisceral connectives and ongoing behavior via time-lapse video recording. A sequence of behavioral events could precede a spontaneous bag cell discharge by as much as 10-15 mins. One component of egg-laying behavior, head undulations (a rhythmic dorso-ventral flexion of the head) began to increase in frequency on the average 5 mins before a bag cell discharge. There was also a predischarge tendency toward decreased locomotion and the mounting of a vertical surface where eggs are subsequently laid. Head weaving (a side-to-side movement of the head used in the dispersion of eggs about the substrate) began 15 min after discharge onset. The appearance of eggs and tamping behavior followed discharge onset by 32 min.

To determine the role of egg movement in releasing the sequence of behaviors following BCH injection, the oviduct was ligated at one of several points along the passageway from ovotestis to periphery. It was found that movement of eggs through the oviduct was required for a complete sequence of egg-laying behaviors. Two components of egg-laying behavior, head undulation and head weaving, were dependent on egg movements in hormone injected animals. A transient inhibition of feeding seemed to be directly initiated by BCH, however egg movement was required to maintain this inhibition. We are attempting to mimic egg movement by cannulating the small hermaphroditic duct near the ovotestis in hormone and non-hormone treated animals. Removal of both abdominal and genital ganglia does not appear to change either the quantity or quality of egg-laying behavior following hormone injection.

These findings suggest BCH triggers a chained reflex. The initial event is release of eggs from the ovotestis whereas egg movement along the oviduct triggers and maintains subsequent behaviors.

789 THE NEUROPEPTIDE, EGG LAYING HORMONE OF APLYSIA: PURIFICATION, AMINO ACID SEQUENCE AND ANTIBODIES. A. Y. Chiu*, M. Hunkapiller* and F. Strumwasser (SPON: M. M. Nass). Division of Biology, California Institute of Technology, Pasadena, CA 91125.

When the bag cell (BC) neurons of A. californica are electrically stimulated to produce an afterdischarge, they release a number of peptides one of which causes egg laying and related behavior. We have purified this egg laying hormone (ELH) by a two step procedure to yield a homogeneous product with biological activity. Direct microsequence analysis of ELH revealed a single amino acid sequence of 36 residues with a calculated m.w. of 4385 and a calculated pI of 9.7. These results are compatible with previous reports on the size of ELH from SDS gels and gel filtration studies and on the apparent pI of the molecule on isoelectric focusing gels. The amino acid composition of ELH after acid hydrolysis shows good agreement with the sequence data and we report that the amino acid sequence of ELH is: N-Ile-Ser-Ile-Asn-Gln-Asp-Leu-Lys-Ala-Ile-Thr-Asp-Met-Leu-Leu-Thr-Glu-Gln-Ile-Arg-Glu-Arg-Glu-Arg-Tyr-Leu-Ala-Asp-Leu-Arg-Gln-Arg-Leu-Leu-Glu-Lys-OH.

In the purification procedure, the supernatant of a homogenate of BC clusters is subjected to cation exchange chromatography on Sephadex SP C25 followed by gel filtration on Bio-Gel P-6. This results in a 100-fold enrichment of ELH from BC homogenates and a 36% recovery of purified, radiolabeled marker ELH. We calculate, therefore, that a sexually mature animal contains 19-40 µg of ELH in a pair of BC clusters.

The egg laying behavior triggered by ELH includes suppression of feeding and locomotion, head weaving movements, and extrusion and deposition of the egg strand. It is known that neuronal targets respond to the in vitro application of ELH and it is likely that there are also nonneuronal targets. Testing of specific ELH fragments is in progress to locate the active site(s) on the molecule (work in collaboration with R. E. Miller of Monsanto Co.). We have also generated antibodies specifically directed against ELH coupled to Thyroglobulin. This will enable us to localize, by immunohistochemistry, sites of hormone storage within cell bodies and processes of the BC clusters and abdominal ganglion. [This work was supported by a graduate fellowship from the L. A. Hanson Foundation and a Li Ming Scholarship to A.Y.C. and NIH grant NS 15183 to F.S.]

791 DEVELOPMENT OF INDIRECT FLIGHT MUSCULATURE IN A FLIGHTLESS MUTANT OF DROSOPHILA MELANOGASTER. Walter J. Costello. Dept. of Biology, Yale Univ., New Haven, Conn. 06520

Genetic mutations affecting the development of neuromuscular systems can be used as tools to elucidate the parameters important in the development of such systems. A mutation which disrupts the normal development of indirect flight muscle in Drosophila is currently being investigated. Flight in Drosophila is powered by two opposing sets of muscle, the dorsal longitudinal muscles (DLM) and the dorso-ventral muscles (DVM). Both sets are fibrillar type with no known histochemical differences. A mutant allele stripe (Sr) is highly specific in its expression, affecting only the DLM. An adult fly homozygous for stripe contains both sets of flight muscle. However, the size of the DLM is greatly reduced, especially at the anterior insertion; motor neuron connections are present but the organism cannot fly (1973, Levine & Wyman, PNAS 70: 1050).

If a fly homozygous for stripe is crossed with one heterozygous for a deletion at the stripe allele locus (Df(3)Sr), some of the F_1 will possess genotypes with only one copy of the allele: Sr/Df(3)Sr. In most cases these flies contain no DLMs whatsoever (1977,Coggshall,Neurosci. Abstr. 3:173). The adjacent DVMs are always present. In those few cases (~10%) in which some muscle tissue is present where the DLM should be, the tissue is clumped into one mass, extends less than one-half the length of the thorax, and can be asymmetrical (i.e. only one side contains muscle tissue, the other lacking it entirely).

The development of the muscle in Sr/Df(3)Sr flies during pupation has been investigated. In normal and Sr/Sr pupae, adult myocytes congregate around three larval longitudinal muscles during early pupation (<20 hrs). By the 24th hr, each larval muscle is being split in two by the myocytes producing the progenitors of the six DLMs on each side (cf 1956,Shatoury,J. embryol. exp. morph. 4:228). In Sr/Df(3)Sr pupae, these early processes are exactly alike.

By the 40th hr, in normal and Sr/Sr pupae the DLM progenitors have been completely split apart to become separate fibers, though sarcomeres are not yet formed. However, in Sr/Df(3)Sr pupae of the same age the DLM tissue on each side has become clumped; the splitting begun earlier remains incomplete. The muscle is highly vacuolated and during subsequent hours degenerates. The development of innervation in the DLM tissue in normal and Sr/Df(3)Sr pupae is presently being investigated. 792 LABORATORY REARING REDUCES BEHAVIORAL VARIABILITY IN HERMISSENDA. T. Crow and J. Harrigan*. Sec. on Neur. Systems, Lab. of Biophys. NINCDS, NIH, MBL, Woods Hole, MA 02543.

Laboratory-reared animals may show reduced variability in behavioral and electrophysiological studies. Recently, laboratory specimens of the nudibranch mollusk Hermissenda crassicornis were cultured from fertilized eggs of field-collected animals. We now describe sources of variability that are reduced by using laboratory-reared Hermissenda in our behavioral studies.

Hermissenda exhibit photopositive behavior when maintained on a 6.5 hour light: 17.5 hour dark or 12 hour light: 12 hour dark schedule and tested during the light phase of the schedule. Response to light was assessed by measuring latencies of individual Hermissenda to enter an illuminated area. After entering the light field Hermissenda remain in the illuminated area a significantly greater percentage of time during the observation periods as compared with animals tested in darkness ($p<.01$). Response latencies to move into the light area are faster when animals are tested in the light as compared with the same animals or different groups tested in the dark. Response latencies of animals from the F1 and F2 generations (n=15) and F3 generation (n=17) were compared with two samples of field-collected animals. We found that the variability in the response to light of laboratory reared Hermissenda was significantly less than that of field-collected animals maintained under identical laboratory conditions ($p<.01$). The response latencies of the laboratory-reared animals entering the light field were significantly shorter than those of field-collected animals maintained under the same laboratory conditions three weeks before testing ($p<.005$). The latencies for the first movement toward the light were positively correlated with the response latencies to enter the light field ($r=.97$).

We next examined the response to light of laboratory-reared animals following three training days of light paired with rotation (n=15) and random light and rotation (n=12). As was previously shown for field-collected Hermissenda, response latencies to enter light are significantly longer following training for groups receiving light paired with rotation as compared with random controls ($p<.05$). Animals from the F1 and F2 generations had a smaller range of response latencies to enter light following training for both paired and random groups as compared with the greater range for animals from the F3 generation and field-collected animals. A post-training dissection of our F1 and F2 generations revealed that all animals had statocysts that contained one statoconium. Dissection of animals from the F3 generation revealed variation in the number of statoconia per statocyst. This morphological difference may help elucidate the role of the statocyst in the behavioral modification and the reduced behavioral variability of laboratory-reared Hermissenda following training.

793 BEHAVIORAL AND PHYSIOLOGICAL LOCALIZATION OF WIND STIMULI IN FIRST INSTAR COCKROACHES. Daniel Dagan* and Susan Volman*. (SPON: J. A. Paton). Dept. of Behav. Biol., Technion, Haifa 32000, Israel, and Section of Neurobiol. and Behav., Cornell, Ithaca, N.Y. 14853.

Adult cockroaches (Periplaneta americana) are known to respond to wind puffs by turning away from the source of wind and running (Camhi and Tom, J. Comp. Physiol. 128, 193-201, 1978). The wind excites filiform receptor hairs located on two abdominal appendages called cerci. In the adult, each cercus has about 220 hairs arranged in 15 columns of like directional response. There is a single receptor cell at the base of each hair. In any column all the receptors depolarize most strongly when the hairs are deflected in their common "best" direction, and hyperpolarize for deflections in the opposite direction (Dagan and Camhi, J. Comp. Physiol., in press).

First instar nymphal cockroaches have only two hairs on each cercus. Extracellular recordings with tungsten electrodes at the base of a cercus were used to determine the directionality of the response to wind for these hairs. Mechanical deflection of each hair shaft indicated which of the two was being recorded in a given experiment. For the two hairs of each cercus, the most strongly depolarizing directions of deflection were roughly orthogonal to each other. The combined responses of all four hairs are sufficient to discriminate many different directions of wind.

The directionality of behavioral responses to wind was tested in free ranging 1st instar nymphs. They were stimulated with a wind puff of standard intensity (280 mm/sec); the responses were filmed at 64 frames per second and analyzed frame by frame. As with the adults, the turns were highly significantly correlated with the angle of wind — despite the fact they have only 4 as compared to 440 hairs. After cercal sensory input was eliminated by covering or removing all four filiform hairs, the animals were unresponsive to standard wind puffs. In a semi-restrained animal, a single hair was adequate to detect wind and elicit a running response. When one or more hairs were removed from free ranging nymphs, the directionality of the behavior was predictable from the known physiological properties of the remaining hairs.

794 I-V CHANGES IN RESPONSE TO CYCLIC NUCLEOTIDE AGENTS IN APLYSIA NEURONS. Peter F. Drake* and Steven N. Treistman, Department of Biology, Bryn Mawr College, Bryn Mawr, PA 19010.

The bursting cells R15 in Aplysia and F-1 in Helix are subject to synaptic and hormonal alteration which persists for long periods and may be mediated by cyclic nucleotides (Treistman and Levitan, Nature,1976; PNAS,1976). We have shown (Brain Research, 1979) that agents which affect cyclic nucleotide levels (e.g., phosphodiesterase inhibitors, cAMP derivatives, and adenylate cyclase activators) elicit response in many Aplysia neurons other than R15, and these responses include the induction of bursting in silent neurons. Current clamp analysis of the I-V characteristics in one such cell, the metacerebral cell (MCC), which bursts after incubation with the phosphodiesterase inhibitor IBMX, shows the induction of anomalous rectification and hysteresis in response to triangular ramp current injection.

Steady state I-V plots under voltage clamp indicate that the MCC usually exhibits a negative slope resistance region (NSR) which increases with bath perfusion of IBMX and benzylthio-cAMP derivative. Similar increases in NSR occur in the bursting left upper quadrant cells treated with cyclic nucleotide agents. When slow triangular ramp techniques were used in voltage clamped MCCs, where voltage is measured on the horizontal axis and current on the vertical scale, IBMX and the cAMP derivative increase the hysteresis and induce or enhance a downward deflection in the curve at a level more hyperpolarized than holding (resting) potential. In addition, the apparent fast transient inward current in the MCC is shown to decrease markedly after perfusion with IBMX. We are presently investigating whether this is an actual decrease in the inward current, or is the result of a concurrent increased fast outward current.

The importance of Ca^{++} in the burst cycle of R15 has recently received attention (Gorman and Thomas, J. Phys.,1978; Eckert, Science,1978) and we have examined the possible involvement of a transmembrane Ca^{++} current and/or an intracellular shift of Ca^{++} from intracellular stores in response to IBMX. Two techniques have been used to inhibit the IBMX-induced bursting: 1) intracellular injection of EGTA and 2) extracellular perfusion with a solution of 30 mM cobalt hypertonically added to stock ASW. These results imply an induced transmembrane Ca^{++} current, and intracellular accumulation of Ca^{++}. Application of cobalt-ASW extracellularly and of EGTA intracellularly both result in a reduction of anomalous rectification present in MCC. Subsequent extracellular perfusion with IBMX and the cAMP derivative restore and enhance the anomalous rectification.

Intracellular injection of cyclic nucleotide agents under voltage clamp as well as clamp results of injected EGTA solutions will also be discussed. (Work supported by NSF grant # BNS 77-01548.)

795 PHASE RESPONSE CURVES AND ENTRAINMENT OF THE INTERNEURON II OSCILLATOR IN INTACT BEHAVING APLYSIA. I. Eberly, M. Lasseter* and H. Pinsker. Marine Biomedical Institute, Depts. Physiol. & Biophys. and Psychiat. & Behav. Sci., UTMB, Galveston, TX 77550.

Spontaneous contractions of the gill, siphon and parapodia occur at frequent but often irregular intervals in Aplysia californica. These contractions are stereotyped and quite conspicuous in the unstimulated animal. The behavior is mediated by a network of interneurons in the abdominal ganglion called Interneuron II (INT II), composed of pacemaker and premotor neurons that function as an endogenous neuronal oscillator (Byrne and Koester, 1978). A similar patterned behavior can also be triggered by a tactile stimulus to the siphon (Kanz et al., 1979), in addition to the monosynaptic component of the reflex (Kupfermann et al., 1974).

Spontaneous INT II activity produces a specific pattern of either excitation or inhibition in motoneurons innervating the mantle organs. This pattern can be monitored in the siphon nerve by extracellular cuff electrodes implanted in freely-behaving animals. INT II activity triggered by external stimulation can also be followed using chronic recordings.

We measured phase-response curves by presenting siphon stimuli at various parts of the cycle. Stimuli presented late in the cycle can phase advance the INT II oscillator by triggering a short-latency INT II burst. However, if presented early (up to 15 sec after a spontaneous burst), the stimulus does not trigger an INT II burst. We also examined entrainment of the INT II oscillator by varying the interstimulus interval (ISI). The probability of triggering INT II bursts is dependent on ISI within a particular range which is close to the free run period. Entrainment tends to break down at lower ISIs.

The behavioral significance of the INT II burst can be demonstrated by video analysis of gill contractions in restrained animals. Under these conditions even very weak stimuli often trigger an INT II burst. When present, the INT II burst significantly increases the amplitude of gill contractions. Thus the INT II burst contributes a stereotyped amplitude component to reflex withdrawal which tends to produce a maximum contraction. The oscillatory and phase response characteristics of the INT II network therefore predict a variety of behavioral outcomes to a stimulus series depending on ISI and free run period. (This research was supported by NSF grants BNS 76-18480 and 77-25584 to H.P.).

796 ANOMALOUS CONNECTIONS BETWEEN IDENTIFIED NEURONS FOLLOWING MICROLESION IN THE LARVAL PRAWN MACROBRACHIUM ROSENBERGII. David R. Friedlander* and Cyrus Levinthal. Dept. of Biological Sciences, Columbia University, New York, NY 10027.

The specificity in the formation of synapses between identified neurons was investigated by following the anatomical effects of killing the cell body of a giant motorneuron (GMN) in the developing giant fiber system responsible for the escape response in Decapod crustaceans. Analysis was done by observation of complete serial thick (1 μm) and thin (0.1 μm) sections of 80 ganglia, fixed from 1 to 56 days after being irradiated in the first larval stage. The giant fiber system in the adult prawn consists of two pairs of bilaterally symmetric giant interneurons (GIs) and the GMNs, a pair of fused neurons, whose central process splits in two axons that leave the CNS through the motor roots, separately innervating left and right flexor muscles. Each GI synapses exclusively with the ipsilateral GMN axon in the motor root region by means of a short colateral. (Holmes, W., Philos. Trans. B 231:293-311, 1942; Macagno, E. and Friedlander, D.R., Soc. Neurosci. Abst. 2:174, 1976). The adult GMN syncytium is the result of the fusion of individual larval neurons, with axons contralateral to their somata. Connections between the GIs and the GMNs are already established at the time of lesion, the first day after hatching.

Microlesions are produced by focusing a beam of light which has a significant percentage of its energy in the ultraviolet, on a region of the ganglion containing the GMN, immediately above the thin ventral carapace. Within a day, the GMN soma cannot be recognized. Signs of axonal degeneration have been observed two days post-lesion; complete disappearance of the axon takes about 10 days. This indicates that the remarkable ability of some invertebrate neurons to survive without a soma (Hoy, R.R., J. Exp. Zool. 172:219-232, 1969) is not present in early larval stages of the prawn.

The most common result of the removal of the GMN axon is the resorption of the colaterals of the GIs deprived of their target GMN axon. More interestingly, in 30% of the ganglia analyzed 21 or more days after irradiation, one or more anomalous connections were found, usually involving a GI deprived of its normal target, with the contralateral GMN which remains intact. This synaptic plasticity supports the notion of a hierarchical order in the rules governing the formation of neuronal connections, where neuron type ranks higher than laterality.

797 SYNAPTOGENESIS IN THE FLY'S VISUAL SYSTEM. A. Fröhlich* and I.A. Meinertzhagen, Life Sciences Centre, Dalhousie University, Halifax, N.S. Canada.

The formation and selection of synapses during development is the last step in a chain of cellular control mechanisms by which neurons interconnect with great specificity. To study the nature of the rules which control this step we have examined anatomically populations of synapses in the first optic neuropile, or lamina, of the fly Musca in the adult and in various immature stages. Synapses have been scored from limited series of up to 50 consecutive micrographs prepared from material fixed and processed conventionally for electron microscopy. Synapses are segregated in classes according to the identity of the presynaptic element and for each representative the identity of up to four postsynaptic processes established. Studying populations of synapses from serial sections provides not only a direct count of synapse frequency but also some measure of the variability with which different postsynaptic elements associate at a given synapse class, addressing the question of the specificity with which synapse formation occurs. Analysis of different developmental ages provides evidence on how this specificity is attained and may be correlated with the acquisition of adult synaptic ultrastructure.

We have found that synapses form with great specificity. In the adult, the first-order synapse is an elongate tetrad with dyadic symmetry. > 97% of all examples are consistent with L1 and L2 occupying the lateral dyadic positions as previously described (Burkhardt and Braitenberg: Cell and Tiss. Res. 173, 287) while there is variability in the occupants of the polar dyadic positions. The orientation of synapse long axis is also nonrandom. The formation of these synapses occurs relatively late in development (50-80% of pupal life) after the neural elements are represented in their final positions, but before the surrounding glial cell processes have ensheathed the elements. The synapses are less elongate in immature stages but by 80% of pupal life have already attained the same frequency as that found in the adult (approx. 7-9 synapses/μm. receptor terminal segment) and are invariably associated with 4 postsynaptic elements each of which has a postsynaptic density not found in the adult. Some characteristic features of synaptic ultrastructure are however acquired between 80%-100% of pupal life. These include the platform component of a conspicuous T-shaped presynaptic density, a subsynaptic cisterna in each of two (L1 and L2) postsynaptic elements, the full complement of synaptic vesicles and the presence of nearby glial invaginations (capitate projections).

798 THE "PHASE RESPONSE" CURVE OF THE LOCOMOTOR CIRCADIAN RHYTHM IN THE CRAYFISH. Beatriz Fuentes-Pardo, Angélica Alucema-Molina* and José Viccon-Pale*. Departamento de Fisiología, Facultad de Medicina, U.N.A.M., Apdo. Postal 70250, México 20, D.F., México.

The locomotor circadian activity was investigated in the intact crayfish under conditions of complete darkness and constant temperature. In order to obtain information about the sensitivity of the circadian system, among several possible experimental designs we chosed one that involves once only administration of a light stimulus to the organism under "free running" conditions. The light application was done along the twenty-four hours in different "circadian time". The results of such a series of experiments are phase advances or delays which have been summarized in the so-called "phase-response curve".

We observed that one complete oscillation of the phase response curve occurred during each circadian oscillation and that there is only one position of the circle during which the stimulus produces phase advances and another single one during which phase delay results. This unimodal phase response curve which exhibit different oscillators is essential for adaptive capability of "biological clocks" to periodical environmental changes.

799 DYE COUPLING INDICATES THE STRUCTURE OF ELECTROTONICALLY COUPLED NETWORKS IN SENSORY NEUROPIL OF THE CRAYFISH BRAIN. Raymon M. Glantz, Mark Kirk, and Howard Wood. Dept. Biol., Rice University, Houston, TX 77001.

Interneurons which arise in the visual and antennal neuropil of the crayfish brain descend to the more caudal ganglia via the circumesophageal connectives. These neurons are excited by stimuli to the sensory organs of the head and control or modify the activity of lower motor centers in thoracic and abdominal ganglia. Recent studies have shown that within each neuropil there is extensive reciprocal interaction between neurons with similar trigger features and receptive field (Glantz, R.M., J. Neurophysiol, 41:1297-1313, 1314-1327, 1978). Several lines of evidence indicate that many of the ensemble synapses are electrotonic: a) The synaptic delay is 0.1 ms or less; b) The synaptic potentials follow presynaptic spike trains at rates of up to 200 Hz without attenuation; c) The synapses transmit both depolarizing and hyperpolarizing injected currents. Morphological analysis of the ensemble interactions has been carried out with the flourescent dye Lucifer Yellow CH supplied by W.W. Stewart of the N.I.H. Stewart (Cell, 14:741-759, 1978) has summarized evidence that dye coupling is diagnostic for electrotonic coupling. Injection of single antennal interneurons has resulted in the dye spreading up to three additional cells. Transynaptic dye migration is observed in about 60% of the injected preparations. The soma of dye coupled cells may be adjacent to each other or separated by the width of the brain. The axons of the coupled cells frequently exit in each of the two circumesophageal connectives. Individual cells can possess up to three distinct dentritic zones spreading across the entire width and/or length of the brain. The dendrites are punctuated with multiple varicosities suggestive of chemical presynaptic endings. Central neurites of up to 28 μ in diameter are frequently observed.

The reciprocal coupling promotes strong synchronization in the discharge of the parallel descending axons. Since the individual EPSPs are generally subthreshold, the impulse synchronization of a given pair of neurons depends upon the coactivation of other elements in the network. Different stimulus conditions coactivate different subpopulations of cells. The stimulus thus specifies both the activated subpopulation and the spatial pattern of coordination within the active subpopulation (Wood, H. Ph.D. thesis, Rice Univ., 1978).

800 TRANSFER OF HABITUATION FROM ONE PATHWAY TO ANOTHER IN APLYSIA. J. Goldberg* and K. Lukowiak* (SPON: W. L. Veale). Div. Med. Physiol., Fac. of Med., Univ. of Calgary, Calgary, ALTA T2N 1N4

The gill withdrawal reflex and its subsequent habituation in Aplysia can be evoked by repeated stimulation of two distinct sites. Tactile stimulation of either the gill or the siphon evokes these gill behaviors. It has been suggested that the neural pathway which mediates these gill behaviors evoked by siphon stimulation is physiologically independent from the neural pathway which mediates the reflex behavior evoked by gill stimulation. We found that habituation of the reflex evoked in one pathway generalizes or is transferred to the evoked reflex in the other pathway. Thus, our results indicate that an interaction does exist between the two pathways. This supports the idea that the neural circuitry mediating gill withdrawal behaviors involves an integrated system. The following experiments were done: 1) Tactile stimuli (1g) were presented to the gill once every 20 minutes and the reflex did not habituate. 2) If the siphon was stimulated (1g) 10 times (ISI=30s) (which resulted in habituation of the reflex) just before a stimulus was presented to the gill, it was found that the amplitude of the reflex evoked by the gill stimulus was significantly smaller than the control. 3) It was further found that the rate of habituation evoked by repeated gill stimulation was faster following the interposition of the siphon stimuli than in control habituation sessions. 4) Transfer of habituation was also apparent at the neuronal level. The number of action potentials evoked in gill motor neuron L7 by a single tactile stimulation of the gill was reduced following a siphon stimulation habituation run. 5) Similar results were obtained when the gill stimuli and siphon stimuli were reversed. 6) The central nervous system (abdominal ganglion) is not necessary for the transfer of habituation to occur, since similar results were obtained in experiments where the abdominal ganglion was removed. These data show that there are at least 2 sites where the transfer of habituation can occur; centrally at the sensory-gill motor neuron synapse, and peripherally in the gill.

Supported by the MRC (Canada).

801 CARDIOREGULATORY NERVES IN A SPIDER. F. Gonzalez-Fernandez* and R. G. Sherman. Dept. Biol., Clark Univ., Worcester, MA 01610 and Dept. Zool., Miami Univ., Oxford, OH 45056.

The heartbeat in spiders is initiated and coordinated by a thread-like cardiac ganglion situated along the dorsal mid-line of the heart. The ganglion generates bursts of impulses which are conducted throughout the myocardium to initiate the heartbeat via neuromuscular synapses. There is considerable evidence that the heart receives input from the central nervous system, but no one has yet demonstrated conclusively that cardioregulatory nerves exist in spiders.

Careful dissection of the anterior region of the abdomen of a tarantula (Eurypelma marxi Simon) and subsequent staining with methylene blue revealed the presence of a branch of abdominal nerve VIIIb extending to the cardiac ganglion just anterior to the first pair of ostia. Nerve VIII is paired; each member of the pair arises from opposite sides of the main abdominal ventral nerve and gives rise to three branches one of which is VIIIb. Nerve VIIIb further branches and one such bundle is the cardioregulatory nerve. Consequently, there is a pair of cardioregulatory nerves, each innervating the cardiac ganglion at about the same level, but from opposite sides.

Conclusive demonstration that VIIIb contains cardioregulatory neurons was obtained by stimulating it electrically while simultaneously recording the activity of the cardiac ganglion and the contractions of the heart. Both increases and decreases in the rate and amplitude of the beat could be evoked under appropriate stimulation conditions. The frequency of the cardiac bursts and their duration were altered accordingly. Therefore, both cardioinhibition and cardioacceleration can be achieved by activity in these nerves.

There appears to be only one excitatory and one inhibitory axon in each cardioregulatory nerve. Only one voltage dependent response of each type could be found. Therefore, our tentative conclusion is that there are two excitatory and two inhibitory neurons that arise in the CNS to modulate heartbeat activity.

The cardioinhibitory effect becomes evident at frequencies above 10 Hz; the effect is maximal at about 25-30 Hz and it does not increase appreciably above these frequencies. The excitatory effect first appears at 10 Hz; it becomes maximal at about 40-50 Hz. The cardioinhibitor predominates when the inhibitor and excitor are stimulated simultaneously at the same frequency.

802 DOPAMINERGIC INHIBITION OF BURST FIRING IN CELL R 15 OF APLYSIA CALIFORNICA: ESTABLISHMENT OF A DOSE-RESPONSE RELATIONSHIP. Sidney M. Gospe, Jr., and W. A. Wilson. Dept. Pharmacol., Duke Univ. Med. Ctr., Durham, N. C. 27710, and Epilepsy Center, V.A. Hospital, Durham, N. C. 27705.

Studies of the physiology of the bursting process of cells L2 - L6 and R15 of Aplysia californica have shown that the oscillatory currents responsible for burst firing are endogenous to the cell, but that synaptic input can modify the bursting pattern. Recently, it was demonstrated that the inhibition of bursting by acetylcholine in L2 - L6 and by dopamine (DA) in R15 was due to the abolition of the negative resistance region in the current-voltage (I-V) relationship of the cell (W. A. Wilson and H. Wachtel, Science 202:772, 1978).

Since the effect of DA on cell R15 is stable over long time periods and reversible with washing, it was possible to bath apply the neurotransmitter to the ganglion and determine the dose-response relationship.

Abdominal ganglia were constantly perfused with artificial sea water. Double the normal Mg^{++} concentration was used in order to eliminate naturally occurring IPSPs that also affect negative resistance. Different concentrations of DA and other pharmacologic agents were selectively added to the perfusate. The I-V relationship of cell R15 was determined under voltage clamp conditions using the single micro-electrode technique.

The threshold DA dose for an effect on the I-V relationship is 10^{-4} M. With increasing doses, the negative resistance region of the curve is progressively reduced. Doses of 6×10^{-4} M DA tend to linearize the curve and effectively abolish bursting activity. Washing the ganglion with sea water restores the I-V relationship to the control conditions. Addition of imipramine or pargyline to the perfusate in doses shown to affect DA metabolism in molluscan systems does not change the characteristics of the dose-response relationship. Experiments using putative dopaminergic agonists and antagonists to characterize the receptor mediating this response will be discussed.

803 AXONAL SPROUTING IN AN IDENTIFIABLE LARVAL LOBSTER MOTONEURON. C.K.Govind and Joanne Pearce*. Scarborough Coll., Univ. of Toronto, West Hill, Ontario, M1C 1A4, Canada.

Axonal sprouting is a well known but poorly understood phenomenon of the nervous system which should ideally be examined in a single identifiable neuron. The excitor motoneuron to the limb receptor muscle in lobster, Homarus americanus, provides this opportunity when examined in a larval stage. The distal accessory flexor muscle is innervated by an excitatory and an inhibitory axon which are recognizable in electron micrographs by the shape of their synaptic vesicles. The former are more spherical than the latter. This permits identification of the excitatory motoneuron in the 1st larval stage when it sprouts vigorously to innervate the rapidly growing muscle. Consequently almost two thirds (60μm) of the entire length of the motoneuron was examined by serial section electron microscopy. In the 1st larval stage there is little or no inhibitory innervation.

The excitor axon however traverses the width of the muscle and sprouts branches toward the tendon and exoskeleton ends. This primary sprouting occurs in regions of the axon which differentiate into terminals by contacting muscle granular sarcoplasm and accumulating agranular synaptic vesicles. The terminals possess presynaptic dense bars which are regarded as active sites of transmitter release, either by themselves or as part of fully formed synapses. The newly formed sprout is in contact with muscle sarcoplasm, is filled with synaptic vesicles and has synapses; in effect it is a terminal. The primary sprout gives rise to secondary sprouts which have similar characteristics. Thus sprouting in an identifiable larval motoneuron occurs only when it is in contact with muscle sarcoplasm. This suggests that the target tissue (muscle) may induce sprouting which would be a mechanism for regulating the innervation of the muscle during development and growth.

804 COMPARISON OF SEROTONERGIC CEREBRAL CELLS OF HELISOMA TRIVOLVIS WITH THE METACEREBRAL CELLS OF SOME OTHER GASTROPODS. Bonnie Granzow, Stanley B. Kater, Dept. Zool., University of Iowa, Iowa City, IA 52242, and C.H. Fraser Rowell. Dept. Zool., University of California, Berkeley, CA 94720.

As previously demonstrated, a bilaterally symmetrical pair of serotonergic neurons in the cerebral ganglia of Helisoma trivolvis have an excitatory influence over the feeding motor program of the buccal ganglia. This excitation is manifested in the cells' ability to initiate and maintain patterned bursting in buccal ganglia motoneurons (Granzow and Kater, Neuroscience 2:1049-1063, 1977).

These cerebral neurons of Helisoma have characteristics in common with the Metacerebral Cells of other gastropods including their content of serotonin, their axonal distribution with branches extending into buccal ganglia nerve trunks, and their ability to influence buccal ganglia neurons. These commonalities indicate that the cerebral cells of Helisoma might be homologous to the Metacerebral Cells. However, we have found certain physiological properties of Helisoma cerebral cells which differ from those of the Metacerebral Cells of Helix and Aplysia. These properties include, among others, a high spontaneous firing rate (approx. 2 spikes/sec), a predominance of tonic inhibitory synaptic potentials, and a linear I-V relationship, i.e., no anomalous rectification of the membrane. The behavioral significance of these differences has not yet been determined. However, the cerebral cells of Helisoma strongly effect the pattern of the buccal ganglia feeding motor output, whereas the effect of activity in the Metacerebral Cells of Aplysia is most apparent as a potentiation of intensity of motoneuron activity. Since the serotonergic cerebral cells may have somewhat different roles in various gastropods, it is not surprising to find differences related to the integration processes of these cells.

805 DIURNAL CHANGES IN LYSOSOME-RELATED BODIES IN THE CRAYFISH PHOTORECEPTOR CELLS. G.S. Hafner, G. Hammond-Soltis* and T. Tokarski*. School of Optometry, Indiana University, Bloomington, IN 47405.

The effect of illumination on the degradation of microvillar membrane in the invertebrate photoreceptor cell has been correlated with the appearance in the cytoplasm of certain structurally distinct lysosome-related bodies. Three types of bodies can be clearly distinguished in the retinula cell cytoplasm of the crayfish using the electron microscope, large (4.2-1.5 microns) and small (1.4-0.3 microns) multivesicular bodies (MVB), combination bodies (CB) and lamellar bodies (LB). The structural details of these bodies have been previously described in both crustaceans and insects by Eguchi and Waterman (1967) and White (1967). To determine the relationship between diurnal lighting and the appearance of these bodies in the cell, the numbers of each type of inclusion were determined at various times during a 12:12 lighting cycle.

Under the diurnal lighting conditions significant temporal differences were found in the appearance of all lysosome-related bodies. Small MVB increase rapidly after the onset of light and peak within 30 minutes. Thereafter they decline rapidly to a constant level during the remaining light phase. During the dark phase of the cycle they again increase reaching high levels by 6 hours. The large MVB begin to increase at 30 minutes and reach a peak 4 hours after the onset of light. Thereafter they decline in numbers to near zero by 12 hours. Combination bodies and LB do not begin to increase until 1 hour after light onset but then rise rapidly to reach maximum values at 6 hours. Both CB and LB decline rapidly to near zero by 8 hours. This low level persists throughout the remaining time in the light and no increases are seen during the dark phase of the cycle. Control animals maintained in the dark during the normal light phase show a slight increase in small MVB through 10 hours. These levels reached values near the basal values for small MVB seen in the light. The combined peak production of all three lysosome-related bodies occurs between 4 and 6 hours in the light. This peak corresponds with the minimum rhabdome diameter which also occurs between 4 and 6 hours. The maximum rhabdome diameter occurs during the dark phase of the cycle.

These data support the hypothesis that light produces microvillar membrane breakdown resulting in the initial production of MVB which undergo degradation to form CB and finally LB. This process appears to be completed within the first 6-8 hours after the onset of light.

806 MORPHOPHYSIOLOGY OF AN IDENTIFIED AXON BUNDLE IN THE BUCCAL GANGLION OF NAVANAX INERMIS. D.H. Hall*, D.C. Spray, M.S. Cappell and M.V.L. Bennett. Dept. Neurosci., Albert Einstein College of Medicine, Bronx, NY 10461.

Serial reconstruction of 3μ sections through the buccal ganglia of Navanax inermis has revealed a group of large axons (10-50μ diameter) in a bundle which runs mediolaterally through both ganglia in a linear fashion and crosses the midline commissure. Most or all of these large axons belong to physiologically identified motoneurons innervating radial musculature, which are responsible for pharyngeal expansion. Some of this group of motoneurons were not previously recognized as motoneurons physiologically. However, their morphological similarities to known motoneurons prompted further studies which confirm that they do cause local expansions of the buccal mass. Presently, there appear to be six to eight identifiable expansion motoneurons in each buccal ganglion innervating partially overlapping or discrete regions of the buccal mass. These motoneurons can be identified morphologically in the reconstructed series by comparison to a catalogue of physiologically identified expansion motoneurons that had been injected with the dye Lucifer Yellow CH. The morphological criteria for identification include the size, shape and position of the soma and the number, size and distribution of the neurites, e.g. do axons exit only ipsilaterally or both ipsilaterally and contralaterally.

The expansion motoneurons are known to be electrotonically coupled to one another by way of the largest members, the G (giant) cells. This coupling can be blocked by synaptic input from a population of inhibitory neurons at least some of which are sensory. The coupling and uncoupling synapses may be localized within or very near the bundle of large axons. Intracellular recordings show stronger electrotonic coupling from soma to postsynaptic axon than from soma to postsynaptic soma. Also, IPSPs in the G cell are larger with faster rise times in the axon than in the soma. Examination of the axon bundle in thin section reveals a heavy glial sheath which prevents contact between axons. There are however nearby specializations between primary branches of the axons which resemble gap junctions in some respects and extracellular lanthanum treatment is being used to further characterize these appositions. Chemical synapses are also found on the axons and their primary branches in this region. These synapses may mediate uncoupling of expansion motoneurons.

807 Saxitoxin Binding to Sodium Channels from Wild-Type and Mutant *Drosophila melanogaster*. Linda M. Hall, Jane Gitschier* and Gary R. Strichartz*. Dept. Biol., 16-713, MIT, Cambridge, MA 02139 and Dept. Physiol. Biophys., SUNY, Stony Brook, NY 11794.

The voltage-sensitive sodium channel in *Drosophila melanogaster* has been studied using two neurotoxins, tetrodotoxin and saxitoxin, which are known to bind specifically to sodium channels and block the action potential. These toxins are identical in their ability to block nerve conduction in *Drosophila* larval motor nerves; 200 nM tetrodotoxin blocks conduction within 20 minutes. [^{3}H]-saxitoxin binds specifically to *Drosophila* head extracts. The high-affinity interaction (K_D=1.9 nM) between the toxin and extract is reversible, noncooperative, and inhibited by tetrodotoxin. The number of saturable saxitoxin binding sites in *Drosophila* is 6.4 fmol per mg wet weight head. A comparison between the physiological and biochemical studies in *Drosophila* and other organisms suggests that the *Drosophila* saxitoxin receptor is part of the voltage-sensitive sodium channel. Binding and electrophysiological studies were done on a mutant, ttx^s, which is abnormally sensitive to dietary tetrodotoxin. The ttx^s mutation does not appear to affect the density or structure of sodium channels since there is no difference between mutant and wild-type with regard to physiological sensitivity to tetrodotoxin and [^{3}H]saxitoxin binding parameters. These studies provide techniques which can be used to identify mutants with defects in the sodium channel.

808 ADDITIONS TO THE PHYSIOLOGY OF THE STOMATOGASTRIC GANGLION (STG) OF THE SPINY LOBSTER, Panulirus interruptus. - D.K. Hartline, D.V.Gassie*, C.D. Sirchia*, Békésy Lab., U. Hawaii, Honolulu, HI.

We present additional properties and connections of specific cells in isolated STG to aid understanding pattern generation by a simple network (some results confirmed or extended in collaboration with D. Russell ("*") or K. Graubard and J. Raper ("†")).

AB Neuron compared to PDs (intrasomatic records): a) often has twice as many spikes due to firing twice on each summed PD electrical EPSP; b) receives a smaller IPSP from LP; c) often has a smaller excursion of interburst pacemaker potential relative to driver-potential amplitude.

LP Neuron has a rectifying electrotonic connection to PLs.†

PY Neurons are of two types, PEs ("early") and PLs ("late"): a) after strong stomatogastric nerve (Stn) stimulation, PEs fire at early phase, often overlapping with LP; PLs fire later, rarely overlapping; b) PEs but not PLs get EPSPs from HD; c) PLs but not PEs put strong IPSPs on LP and IC; d) PEs primarily innervate the posterior pyloric muscles (p10, p12); PLs anterior (p2, p8); e) PE somata are often smaller than PL*; f) PLs are electrically interconnected*†; g) axon counts show 4-6 PEs; 2-4 PLs. Variability in individual PYs may reflect a spectrum of types.

VD Neuron appears to receive major inhibition from AB and little from PD. With AB bursting weakly, VD activity can increase during PD burst and terminate during PD repolarization, likely due to its electrical coupling to PD. Addition of AB inhibition can lead to a gap in VD pattern, with two VD bursts per cycle. Transmitter release from PD/AB via electrotonic paths may explain weak delayed VD IPSPs on LP, PL, and IC, blocked by hyperpolarizing PD.

LG Neurons: These gastric motoneurons send axon branches in the internal pyloric nerve and appear to innervate pyloric muscle p6.

HD Axon: Hepatopancreas-duct nerve stimulation gives: a) antifacilitating unitary EPSPs in AB, PD, PE; b) higher pyloric cycling rates; c) intense PE firing. EPSPs in PEs show post-tetanic potentiation*. The axon may arise from a multi-polar cell (sensory?). It travels in the lateral ventricular nerve, synapses in STG, and exits via Stn and superior oesophageal nerves.

Delaying conductance: In PY, PD, and GM* cells, a hyperpolarizing conditioning pulse followed by a suprathreshold step depolarization produces an unusually long delay in recovery to beginning of repetitive firing as compared to other cells (LP, VD, CP). In PYs this is associated with a rapidly developing slowly decaying conductance increase and a membrane potential trajectory with a characteristic rapid hyperpolarizing "hook" followed by a slow depolarizing ramp. These properties appear similar to those of the Connor-Stevens "A-conductance". This mechanism may be activated by inhibitory inputs (e.g. PD/AB) producing a phase-delay of activity in a burst cycle. Support: NIH NS13138; NSF GJ 43177.

809 ACTIVITY OF CLAW OPENER MOTOR NEURONS DURING HABITUATION AND DISHABITUATION OF THE CRAYFISH DEFENSE RESPONSE. R.D. Hawkins and J. Bruner. CNRS, Gif-sur-Yvette and Université de Picardie, Amiens, France.

A neural mechanism which has been proposed for behavioral habituation is an increase in the activity of inhibitory neurons. We have investigated this hypothesis for habituation of the crayfish (Astacus) defensive claw opening response. Claw opening is caused by contraction of the abductor of the dactylopodite, which is innervated by only two motor neurons: one excitor and one inhibitor. In partially restrained animals we recorded simultaneously the activity of these two neurons, the electromyogram of the opener and closer muscles, and movement of the claw. Tactile stimulation of the thorax produces phasic activity in both the excitor and inhibitor motor neurons, and opening of the claw. If this stimulation is repeated at 30 second or 1 minute intervals, the claw opening response becomes progressively smaller. This habituation is due to a progressive decrease in the evoked excitor activity, while the activity of the inhibitor remains unchanged.

The habituated claw opening response can be dishabituated by tactile stimulation of the claw or head, or by visual stimulation. Dishabituation was found to be due to (1) an increase in the evoked excitor activity, (2) a decrease in the evoked inhibitor activity, and (3) PTP at the excitor neuromuscular junction. PTP was demonstrated in isolated claw preparations using physiological parameters of stimulation, and shown to be of sufficient magnitude and duration to contribute to dishabituation.

Thus, at the level of the motor neurons, habituation of this response is due to a decrease in evoked excitor activity while the inhibitor activity remains unchanged. Dishabituation, on the other hand, involves both an increase in excitor activity and a decrease in inhibitor activity, as well as PTP at the excitor neuromuscular junction.

810 AFTERDISCHARGE IN BAG CELL NEURONS IS INITIATED BY PEPTIDES FROM THE ATRIAL GLAND OF APLYSIA. E. Heller*, L. K. Kaczmarek, M. Hunkapiller* and F. Strumwasser. (SPON: W. R. Adey). Division of Biology, California Institute of Technology, Pasadena, CA 91125.

The neuropeptidergic bag cells in the abdominal ganglion of Aplysia are able to initiate egg laying and its associated behavior by secreting egg laying hormone (ELH) during a long lasting afterdischarge. This afterdischarge may be triggered by electric stimulation of a presumed afferent pathway from the head ganglia. Copulation may be a natural stimulus for egg laying and it has been shown that the atrial gland in the reproductive tract of Aplysia contains a factor that is able to induce egg laying behavior when injected into recipient Aplysia (Arch et al., J. Comp. Physiol., 1978). We have now found that extracellular application of crude extracts or of purified peptides from the atrial gland produces long lasting afterdischarges in the bag cells. This effect is also observed with isolated pleuroabdominal nerve preparations which contain asomatic bag cell neurites. Two preliminary lines of evidence suggest that these peptides may act by activating the afferent input from the head ganglia. i) No effects were observed on isolated bag cells in primary cell culture, ii) In experiments with the entire intact nervous system, in which the abdominal ganglion and the head ganglia were maintained in separate chambers, application of these factors to the head ganglia alone could induce bag cell afterdischarge.

We have purified two peptides, A and B, that are able to induce both egg laying behavior in recipient animals and bag cell afterdischarges. These peptides were isolated from homogenates of the atrial gland by a combination of ammonium sulfate precipitation, agarose gel filtration and cation exchange chromatography. Each peptide has 32 amino acid residues. Microsequencing revealed the following sequence for peptide A: H-Ala-Val-Lys-Leu-Ser-Ser-Asp-Gly-Asn-Tyr-Pro-Phe-Asp-Leu-Ser-Lys-Glu-Asp-Gly-Ala-Gln-Pro-Tyr-Phe-Met-Thr-Pro-Arg-Leu-Arg-Phe-Tyr-OH. Peptide B differs from A in only four positions. The first nine residues of B are: Ala-Val-Lys-Ser-Ser-Ser-Tyr-Glu-Lys- while residues 10-32 of B are identical to those of A. Neither sequence resembles that of ELH. The calculated Mw of A is 3714 and that of B is 3822. The pI of A is about 8 and that of B is 9. Gel filtration of atrial gland homogenates on agarose in the presence of urea reveals material that can induce egg laying in the excluded volume in addition to those fractions containing peptides A and B. We are currently determining the relative potencies of these differing fractions. [Supported by NIH grant (NS 15183) to F.S.]

811 NEURONAL NETWORK OF THE EYE OF APLYSIA: INTRACELLULAR AND DYE MARKING ANALYSIS. Jon W. Jacklet. Dept. Biology, SUNYA, Albany, NY 12222.

A circadian clock resides in the isolated eye of Aplysia. In culture medium and complete darkness endogenous compound action potential (CAP) activity from the optic nerve waxes and wanes rhythmically with a periodicity of about 26 hours. The circadian aspects of the eye activity have been studied extensively (i.e. Jacklet, Science 198, 69, 1977).

Intracellular recording with KCl electrodes of 60-70 MΩ and injection of Lucifer yellow with similiar electrodes filled with the dye has allowed a better understanding of the eye neuronal network. Three basic neuronal response types were obtained. One, R, had resting potentials of 70 mV and gave a graded depolarizing receptor potential to illumination. Light adaptation reduced this response from the maximum of 70 mV in the dark adapted state. Some had depolarizing and others hyperpolarizing afterpotentials. These cells were usually silent during endogenous optic nerve CAP activity but sometimes biphasic electrotonic potentials followed the CAP. Injection of Lucifer yellow revealed this cell situated in the pigmented retina, with a distal photoreceptive apparatus and an axon contributing to the optic nerve. Thus, the R type appears to be a primary receptor making weak electrical connections with neurons that produce the endogenous CAP. A second response type is H. This had resting potentials of 30-45 mV and always actively spiked (up to 90 mV) when impaled. Illumination caused initial depolarization and spiking followed by prolonged hyperpolarization. Spikes in this cell appear in optic nerve but do not contribute to the CAP. Dye injection shows it in the retina near the R type. A third type is D. These cells have 30-40 mV resting potentials and attenuated spikes of 5-20 mV. They spike in synchrony with the endogenous and evoked CAP. Several spike potentials of different amplitudes are often observed in these neurons suggesting that neighboring D neurons are electrically coupled. Apparently the spike initiation zone and site of coupling are near the origins of the optic nerve some distance from the soma. Lucifer yellow injection shows this neuron type has a large axon in the optic nerve and a non-receptor soma. There is extensive but weak electrical coupling among the D neurons which accounts for the synchronous optic nerve CAP. These results provide evidence for three basic types of neurons in the retina even though the total number of neurons is about 5000. Continued analysis should yield the complete network of a neuronal circadian clock.

812 STRUCTURES AND CHARACTERISTIC PROPERTIES OF SWIMMERET COMMAND FIBERS IN CRAYFISH. G.A. Jacobs and B. Mulloney. Dept. Zoology University of California Davis, Davis, CA 95616

Rhythmic swimmeret beating in crayfish can be driven by stimulating any one of five pairs of command interneurons (Hughes and Wiersma, 1961; Ikeda and Wiersma, 1964). We have further distinguished these pairs of fibers by using both physiological and structural criteria.

We investigated the effects of proprioceptive feedback on the period of the motor pattern by interfering with the movements of individual swimmerets. Experiments were performed on Procambarus clarkii (Girard) and Pasifasticus leniusculus. The abdomen was separated from the body and pinned in a Sylgard lined dish which allowed the swimmerets to move freely. Activity of the motor neurons was monitored with extracellular pin electrodes. Bundles of axons containing command fibers were stripped from the ventral nerve cord anterior to the second ganglion and stimulated with suction electrodes. When a command fiber was located and a regular motor pattern produced, we interfered with one swimmeret's movement with a pin held in its path. The swimmeret was held in the fully retracted position which occurs at the end of a power stroke for several bursts then allowed to move freely. We observed four different kinds of results. Either the period decreased, did not change, increased, or bursting was inhibited. We think these differences reflect the individual command fiber isolated for stimulation.

Swimmeret motor neurons abruptly stop bursting when stimulation of some command fibers stops. However when stimulation of others stops, motor neurons burst for several more cycles.

Bundles of axons each containing a command fiber, were filled with Co^{++} to discover the fibers' structure. The most obvious structure seen when bundles containing command fibers are filled is a large diameter axon (20-30μ) which has one or two branches which ramify ipsilaterally in swimmeret neuropil; medial command fibers project laterally and lateral fibers project medially. The axon narrows as it enters the ganglion, branches and flares again in the posterior connective. The structure of a fiber is similar in successive ganglia. No contralateral projections have been observed.

813 PROTEIN PHOSPHORYLATION DURING AFTERDISCHARGE OF THE NEUROENDOCRINE BAG CELLS IN APLYSIA. K. R. Jennings,*, L. K. Kaczmarek and F. Strumwasser. (SPON: C.A.G. Wiersma) Biology Div., Caltech, Pasadena, CA 91125.

The neuroendocrine bag cells in the abdominal ganglion of Aplysia generate a long-lasting afterdischarge upon brief electrical stimulation of a pleurovisceral connective nerve. Evidence has been presented that activation of adenylate cyclase may be involved in the genesis of afterdischarge (Kaczmarek, Jennings and Strumwasser, P.N.A.S. 75: 5200, 1978). Experiments were therefore conducted to determine whether the actions of cAMP might be mediated by a protein kinase. Intact abdominal ganglia were incubated at 14°C in the presence of $Na_2H^{32}PO_4$ overnight (Levitan and Barondes, P.N.A.S. 71: 1145, 1974). Experimental ganglia were either electrically stimulated to afterdischarge or incubated for 15 minutes in the presence of 8-benzylthio cAMP. These treatments resulted in 51% (N=9) greater ^{32}P incorporation into TCA-insoluble material from the bag cell somata and surrounding connective tissue, which contains many bag cell neurites. Increased phosphorylation into one protein band was observed with either electrical stimulation or treatment with cAMP analogue when compared with controls. Microdensitometric analysis of the gel autoradiograms showed a 45% (N=10) increase in phosphorylation of this protein. The m.w. of this phosphoprotein was estimated to be 22,000 daltons by its migration on SDS polyacrylamide gels. The phosphorylation of the 22,000 m.w. protein in the bag cell region occurs within 2 minutes of the onset of afterdischarge. We have also observed phosphorylation of two high m.w. (approx. 120,000 and 125,000 dalton) proteins in the bag cell region. The long time course of the excitability changes observed in the bag cells (30 minutes) may allow correlation of the time course of protein phosphorylation with the onset and termination of the afterdischarge. (K.R.J. is a Gordon Ross Medical Research foundation fellow.)

814 CYCLIC AMP ANALOG GENERATES AFTERDISCHARGE IN APLYSIA BAG CELL NEURONS. L. K. Kaczmarek, K. R. Jennings* and F. Strumwasser. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

A long lasting afterdischarge can be generated in the neuropeptidergic bag cells of the abdominal ganglion of Aplysia following brief electrical stimulation of a pleuroabdominal connective. The afterdischarge can also be elicited by the extracellular application of the cAMP analog, 8 benzylthio cAMP (8BT-cAMP). We have now shown that 8BT-cAMP is able to induce afterdischarge in dissociated bag cells in primary cell culture. Normally, cultured bag cells will fire repetitively in response to depolarizing current pulses but do not discharge spontaneously. The extracellular addition of 8BT-cAMP (0.5 mM), however, induces the cells to discharge after a delay of 8-55 min. This "afterdischarge" may continue for 2-4 hr and is correlated with an increased membrane resistance (1.5- to 3-fold), spike broadening and, occasionally, a regenerative hyperpolarizing response that can be blocked by 12 mM Cs^+. These effects are consistent with the hypothesis that cAMP induces a decrease in the membrane conductance to K^+ ions.

The mean duration (MD) of an electrically stimulated bag cell afterdischarge in a freshly dissected (Day 1) intact abdominal ganglion is 29.6 min (N=11) after which the cells remain refractory to further electrical stimulation for several hours. After 16-24 hr (Day 2) full recovery takes place (MD=32.0 min, N=11). If, however, the ganglion is incubated continuously with the protein synthesis inhibitor anisomycin (3×10^{-6} M) during the first afterdischarge and its recovery period, full recovery fails to occur (MD for Day 1 = 54.8 min, N=5; MD for Day 2 = 4.0 min, N=5). Previous work has shown that bag cell neurites in the connective tissue of the pleuroabdominal connectives retain the ability to afterdischarge after they have been surgically isolated from their somata. Full recovery of afterdischarge in response to electrical stimulation also fails to occur in these asomatic neurite preparations (MD for Day 1 = 30.2 min, N=16; MD for Day 2 = 4.6 min, N=10). For both the pharmacological and surgical treatments, control experiments showed that full length afterdischarges occur on Day 2 if no stimulation is given on Day 1. Furthermore, when after either treatment, electrical stimulation failed to produce any afterdischarge, vigorous afterdischarges could still be obtained in response to 8BT-cAMP (0.5 mM). This data suggests a role for de novo protein synthesis in the control of bag cell excitability, possibly in the synthesis of proteins regulating cAMP levels. (K.R.J. is a Gordon Ross Medical Research Foundation Fellow. This work was supported by grants to F.S. from the NIH [NS 13896, NS 15183].)

815 INNERVATION OF THE DIRECT FLIGHT MUSCLES IN DROSOPHILA. David G. King. School of Medicine, Southern Illinois University, Carbondale, IL 62901.

In insects such as flies whose wing-beat is powered by large indirect fibrillar muscles, the orientation of the wing during flight is controlled by several smaller muscles attached to the wing base, the direct flight muscles. The abbreviations for these muscles used here will be those of Zalokar (1947, Revue Suisse de Zoologie 54:17-33) who described the thoracic musculature of Drosophila melanogaster, followed in parentheses by those of Heide (1971, Zool. Jb. Physiol. 76:87-137) who described the functions of these muscles in Calliphora. Nerve abbreviations follow Power (1948, J. Comp. Neurol. 88:347-409). The direct flight muscles are innervated by the ADMN and the MAN. These nerves both cross a notch in the pleural apophysis so that at this point they form a single nerve with axons running in opposite directions. Individual axons were traced with light microscope through serial thin sections (½μm) from the thoracic ganglion to specific muscles. Axons from the ADMN innervate muscles pa1 (I1), pa3 (b2), pa4 (b1), pa5 (b3), pp1 (hg1), pp5 (I2) and the anterior portion of pp4 (III3,4?). Axons from the MAN innervate muscles pa2 (III1), pp2 (hg2,3), pp3 (hg4), the posterior portion of pp4 (III2?) and sp1 (ps1); the latter muscle receives two axons.

The 10-15μm diameter of the ADMN axon to muscle pa4 (b1) makes this axon one of the largest in Drosophila, comparable only to the cervical giant fibers and the motor axon to the tergotrochanteral muscle. The large diameter of this axon suggests a function that requires rapid impulse conduction. Such rapid conduction would be important if this axon were to participate in an escape response, such as the initiation of flight. Since in Calliphora muscle pa4 (b1) begins firing before the start of spontaneous wing-beat and since this muscle functions to abduct the wing, this muscle may serve to extend the wing in preparation for flight. In Drosophila a giant fiber pathway (King, in preparation; Tanouye, in preparation) activates the tergotrochanteral muscle and the dorsal longitudinal flight muscle; both of these actions contribute to the initiation of flight in response to sudden visual stimulation. Thus, since the large axon to pa4 (b1) appears to participate in rapid activation of another aspect of flight initiation, this axon may also be part of the same giant fiber pathway. Synapses of the pa4 (b1) motor neuron with the cervical giant fibers are now being sought.

816 CHARACTERISTICS OF AND INTERACTIONS BETWEEN SEPARATE BRANCH SPIKES FOUND IN CRAYFISH SENSORY INTERNEURONS. Mark Kirk and Raymon Glantz. Dept. Biol., Rice University, Houston, TX 77001.

Intracellular recording from neuropilar processes of the crayfish brain and abdominal ganglia reveal action potentials which can be distinguished as spikes originating from separate branches of the same cell. Each branch spike is usually seen to have a distinct threshold to injected currents. They may occur in a variety of temporal sequences with respect to each other. Often EPSPs precede either event when they occur separately or alternatively one branch spike may lead into the other. In special cases, such as during a step of depolarizing current, one spike is seen to entrain the other's discharge. The branch spikes may have overlapping or completely separate sensory receptive fields, and in the extreme case may subtend different sensory modalities. During recordings from neurons of the supraesophageal ganglion, in which the branch spike corresponding to the cell's descending "main" axon discharge can be uniquely identified, it can be seen that summation of the "dendritic" spike with other depolarizing events (injected outward current, PSPs) is required for the main axon to each threshold. In some instances the occurrence of the axon spike is invariably associated with the sequential activation of the "dendritic" spike on the descending phase of the axon spike. Conversely, several observations have been made of neurons in which the "dendritic" spike and main axon spike were completely independent. The latter observation suggests that the "dendritic" spikes may have a role in communication or integration that does not involve the axonal process at all.

817 A MAGNESIUM- AND BARBITURATE-SENSITIVE INHIBITORY SYNAPTIC POTENTIAL IN LEECH GANGLION. Anna L. Kleinhaus and Scott Brand*. Dept. Neurology and Section of Neuroanatomy, Yale Med. Sch., New Haven, CT 06510.

Stimulation of the leech mechanoreceptive cells sensitive to pressure (P cells) evoked hyperpolarizing postsynaptic potentials in a neuron of unknown function located near the annulus erector motor neurons on the ventral surface of the ganglion. This potential had an amplitude of 3-5 mV at resting membrane potential and a stable onset latency of 5 msec measured from the peak of the presynaptic action potential. Its reversal potential was -71.8 +- 1.4 mV (n = 20) and was unaffected by removal of 90% of the Cl from the bath. Changing external K from 10 mM to 1 mM shifted the reversal potential about 35 mV in the hyperpolarizing direction. At rates of stimulation above 0.5 Hz the amplitude of the postsynaptic potential was depressed by about 80%. At lower rates amplitude was stable and there were no failures of transmission. Magnesium 20 mM reversibly blocked the synaptic response.

Electron micrographs made after injection of horseradish peroxidase into the pre- and postsynaptic neurons showed that they were in direct contact; the regions of contact had the morphological characteristics of synapses described in leech neurons by other workers.

The amplitude of the hyperpolarizing potential was greatly decreased by 0.5 mM Na phenobarbital, a concentration which had no effect on the pre- or postsynaptic action potentials. Thus, at least one inhibitory postsynaptic potential in leech ganglion is depressed by a barbiturate, in contrast to other preparations in which such potentials have been reported to be unaffected or enhanced by this class of drugs.

818 METABOLIC CONSEQUENCES OF CHRONIC DEAFFERENTATION IN THE CRICKET CNS. T.E. Knox*, M.R. Meyer, and J.S. Edwards. Dept. Zoology, Univ. Washington, Seattle, WA. 98195.(SPON: R. Haschke)

Chronic removal of the cercal appendages of the cricket Acheta domesticus throughout postembryonic development results in loss of known afferent input to identifiable giant interneurons (GI) in the CNS of the terminal ganglion (TG) (Proc. R. Soc. Lond. B.,1974,185:105). Such prolonged deafferentation retards the growth of GI dendritic processes (J.Comp.Neur.,1975,159:407) which depends on presence, rather than activity of intact presynaptic input (Soc. Neurosci. Abstr.,1977,7:186). These findings suggest the likelihood that growth of the GI's may be trophically dependent upon presynaptic sources.

To assess what effects deafferentation might have on metabolism in the TG, we compared incorporation of [^{3}H]-leucine into TG between normally reared (control) crickets and those receiving bilateral deafferentation throughout development and changes in amount of TG protein content after removal from adults. Chronic deafferentation resulted in statistically significant reduction (>30%) in TG protein content when compared to control TG's. Such decreases were in accord with marked reduction in neuropile volume observed in histological sections of deafferented TG. However, when adult crickets were subjected to short-term deafferentation following development through instar 9, only a slight (<8%) decrease in total TG protein was noted, probably ascribable to degeneration and loss of cercal sensory axons, terminals, and glial elements.

We then compared in vitro incorporation of [^{3}H]-leucine into TCA insoluble protein between control and chronically deafferented TG, which resulted in a marked (60%) decrease in incorporation in the deafferented TG's. When data was normalized for decreased protein content of deafferented TG's, TCA insoluble activity was still significantly lower (>40%) in the experimentally treated TG's. In contrast, TG taken from crickets receiving a short-term deafferentation regimen showed no decreases in incorporation. These data indicate that chronic removal of presynaptic input to the TG does depress protein metabolism within the CNS. We cannot say which elements of the CNS are principally affected. A generalized injury response to deafferentation, however, seems unlikely.

In an attempt to determine whether loss of input directly affects metabolism of known target GI's, autoradiographic analysis is being performed on serially sectioned, unilaterally deafferented TG. Qualitative results show decreased grain density over the somata and dendritic processes of deafferented GI's.
