Distinct behaviors in Pleurobranchaea are organized into a priority sequence, or behavioral hierarchy, which governs rudimentary choices in this organism (J. Comp. Physiol. 90, 207, 225, 1974). Several legs of the behavioral hierarchy involve unidirectional suppression of one behavior by another; thus, feeding behavior suppresses righting, but righting does not suppress feeding. In contrast, we have found that one leg of the hierarchy, feeding versus withdrawal from tactile stimulation, involves reciprocal rather than unidirectional inhibition. To demonstrate this reciprocal inhibition, 32 specimens were used to analyze quantitatively the interaction between the two behaviors. In each animal, withdrawal was elicited by delivering a controlled, graded tactile stimulus, and monitored visually. The sensory stimuli for the two behaviors were presented separately (control trials) and simultaneously (experimental trials), and each varied in a graded manner over a large range. Analysis of the behavioral data showed that as previously reported (J. Comp. Physiol. A 117, 199, 1977) the withdrawal amplitude declines from control levels during active feeding. Conversely, feeding declines in intensity during withdrawal, and the suppression is graded with the intensity of withdrawal behavior. Thus, the two motor systems are reciprocally inhibitory.

Plots of feeding intensity versus withdrawal stimulus intensity are not linear, but instead show several turning points and inflections. Analog electronic modeling of reciprocally inhibitory neural networks resembled the behavioral data best when: 1) the models employed feedback rather than feedforward inhibition; and 2) when cross excitation was also added. These two features of the models have been largely confirmed by neurophysiological investigations showing 1) an inhibitory connection from a corollary discharge cell in the feeding network onto a command-like cell in the withdrawal network (Science 198, 632, 1977; J. Neurophysiol., in press, 1979) and 2) an excitatory/inhibitory connection from the withdrawal network to the paracerebral cell, a command-like neuron in the feeding network. The study introduces a new integrative variable into considerations of how the nervous system regulates animal behavior, namely reciprocal inhibition between motor systems subserving distinct behavioral acts.

820 TRANSMISSION BETWEEN CRAYFISH GIANT FIBERS AND NON-GIANT MOTONEURONS IS NOT PRIMARILY MONOSYNAPTIC. F.B. Krasne, A.M. Roberts,*† A.P. Kramer,†† Dept. Psychol., UCLA, Los Angeles, CA 90024. J.J. Wine, Dept. Psychol., Stanford, Palo Alto, CA 94305.

The mechanism for generation of the motor patterns that produce giant fiber escape reactions in crayfish is believed to be particularly simple: The medial and lateral giant command neurons (MG/LG) are thought to distribute excitation directly to relevant fast flexor motor neurons via monosynaptic connections in each bodily segment, and these connections are believed to be the sole or paramount cause of motoneurons firing in appropriate extent and sequence. The direct connections of the command neurons to the motoneurons is important for at least two reasons: (1) These connections have been a source for the discovery of principles of neuronal communication such as electrical transmission at MG/LG - motor giant (moG) junctions and amplification by dendritic spikes at MG/LG - nongiant fast flexor motoneuron (FF) junctions. (2) The direct activation of motoneurons by command neurons has been viewed as an unusual form of motor system organization. Prevailing conceptual schemes picture the neuron that triggers or turns on a behavior (ie. the 'command neuron') as activating an independent pattern generating network; it is believed that command neurons may commonly bias motoneurons via monosynaptic connections but not fire them. In this view crayfish escape seems to be anomolous.

We have found that in each hemiganglion, in parallel with the monosynaptic pathway between MG/LG and the FFs, there is a disynaptic pathway in which a neuron we call the segmental driver (SD) is interposed. This disynaptic pathway is absolutely necessary and usually sufficient for driving of the FFs by MG/LG. The monosynaptic connections between MG/LG and FFs are weak and quite incapable of firing the FFs by themselves.

821 INCREASED ELECTROGENICITY OF CRAYFISH NEURONS FOLLOWING AXOTOMY: INVESTIGATIONS OF THE SIGNAL AND MECHANISM. John Y. Kuwada, Grace C. Hagiwara, & Jeffrey J. Wine. Department of Psychology, Stanford University, Stanford, CA 94305.

The peripheral inhibitor (FI) to the fast flexor muscles of the crayfish abdomen has a spiking axon and a nonspiking cell body. Axotomy or partial axotomy induces a transient increase in the electrogenicity of FI somata. Overshooting action potentials can be recorded in the soma from 2 days to 2 weeks following axotomy (Kuwada & Wine, Soc. Neuro. Abs., 4, 1978).

We would like to discover the signal that initiates the increase in excitability and clarify the nature and mechanism of the change. With regard to the signal, we find that (1) axotomy of other crayfish efferents (the phasic extensor motoneurons) also induces soma spikes; (2) axotomy of crayfish interneurons does not induce soma spikes; (3) cutting one branch of an efferent axon induces the same transient increase in soma excitability as cutting the whole axon; (4) after excitability has waned, recutting the stump of a previously cut axon will not reinstate excitability, but (5) cutting another, intact branch of the axon will reinstate excitability. Finally, preliminary evidence suggests that the onset of soma excitability occurs slightly sooner if the axon is cut proximally rather than distally. These results, plus the ability of colchicine to mimic axotomy-induced changes in excitability (Ritman, Tweedle & Cohen, Science, 178, 107 (1972), are consistent with the hypothesis that the signal is a sudden decrease in a factor transported along the axon from muscles to the neuron soma.

With regard to the nature of change in membrane excitability, we find that (1) the axotomy-induced soma spikes are sodium dependent; (2) like many other cells, FI has latent, electrogenic calcium channels that can be unmasked with tetraethylammonium ions; but (3) no changes in calcium conductance are detected following axotomy; and (4) increases in membrane excitability are not confined to the soma but can also be detected in the neuropilar processes of FI.

The mechanism of the change is unknown, but involves a temperature dependent process, in which a 10°C temperature increase shifts time of onset from c. 36 hours to less than 24 hours after axotomy, and offset from c. 21 days to c. 11 days. Systemic injections of cycloheximide, a protein synthesis inhibitor, prevent or retard the increase in excitability if given during the period following axotomy. Cycloheximide did not affect normally spiking neurons.

822 SEROTONIN-INDUCED HYPERPOLARIZATION OF APLYSIA NEURON R15 IS MEDIATED BY CYCLIC AMP. Irwin B. Levitan and Alan H. Drummond*. Friedrich Miescher-Institut, P.O. Box 273, CH-4002 Basel, Switzerland.

Serotonin elicits alterations in the endogenous bursting activity of neuron R15 in the abdominal ganglion of Aplysia californica. Bath perfusion of serotonin at concentrations greater than 0.05 μM enhances the interburst phase of the burst cycle; both the depth and the duration of the interburst hyperpolarization are increased. Higher concentrations of serotonin (10-100 μM) cause complete cessation of bursting and "chemically clamp" the cell to about -70 mV. These effects are mimicked by bath application (1-500 μM) or intracellular injection [Treistman and Levitan, NATURE 261:62-64 (1976)] of cyclic AMP analogs such as 8-parachlorophenylthio-cyclic AMP, and by activation of adenylate cyclase in R15 following intracellular injection of guanylyl-imidodiphosphate [Treistman and Levitan, PNAS 73: 4689-4692 (1976)]. Furthermore the serotonin-induced hyperpolarization is potentiated by phosphodiesterase inhibitors; in the presence of 1 μM RO 20-1724, 0.1 μM serotonin can abolish bursting completely.

Serotonin stimulates adenylate cyclase activity in membranes from abdominal ganglion, or from isolated R15 cell bodies. It also causes cyclic AMP to accumulate in R15 in intact ganglia. A pharmacological analysis indicates that the threshold concentration of serotonin and its analogs, necessary to alter bursting, correlates well with the concentrations necessary to stimulate adenylate cyclase. All the criteria necessary to assign a role for a cyclic nucleotide in a physiological response have been satisfied for this case. Accordingly we conclude that the hyperpolarization induced in R15 by serotonin is mediated by cyclic AMP.

823 DIPHENYLHYDANTOIN DEPRESSES FIRING IN THE APLYSIA GIANT NEURON BY BLOCKING A SLOW INWARD CURRENT. D.V. Lewis*, K.L. Zbicz* and W.A. Wilson. (Spon: P.B. Bennett). Div. of Ped. Neurol., Duke Univ. Med. Ctr., Durham, N.C. 27710 and Epilepsy Ctr., V.A. Hosp. Durham, N.C. 27705.

Injection of constant depolarizing current into the Aplysia giant neuron, R2, produces a train of action potentials with an initial high firing rate followed by a gradual adaptation with slowing of the firing rate. Diphenylhydantoin (DPH)(3.8 to 10.0 x 10^{-5}M) markedly slows the initial firing rate as does lanthanum (La^{+3})(1-3mM). Voltage clamp techniques were used to analyze this effect of DPH on firing rate. When the membrane potential of R2 is held at resting level (-50 to -60 mV) and then depolarized to between -35 and -45 mV for many seconds (sec), a changing current is seen. Initially, current is inward and peak magnitude is attained in 1 sec. This inward current rapidly declines to zero by 3 to 4 sec, after which a slowly and persistantly increasing outward current is seen. On a current voltage graph of one sec. current values, the inward current is reflected by a negative slope resistance region of the curve. Both DPH and La^{+3} block this inward current at concentrations which reduce early firing frequency as described above. Also, after 1 hour in calcium free 10 mM cobalt sea water, the inward current is markedly reduced. The blockade of inward current is reflected in the current voltage curve as disappearance of the negative slope resistance region and increased magnitude of outward current values. The reduction of inward current by DPH may explain the slowing of action potential generation by this drug. The similar effects of La^{+3} and zero calcium with cobalt suggest that calcium may carry a portion of the inward current, and that DPH may be blocking this calcium flux.

824 RESETTING THE CIRCADIAN CAP RHYTHM IN THE APLYSIA EYE BY LL TO DD TRANSITIONS, I: THE EYE AND BRAIN INTERACT. Marvin E. Lickey and Robert G. Prichard* (SPON.: Richard Young). Dept. of Psych., U.of Oregon, Eugene, OR 97403.

Many circadian systems can be reset to a precisely defined phase by switching the system from continuous light (LL) to continuous darkness (DD). The circadian rhythm of compound action potentials (CAP) in the Aplysia eye is no exception. Intact Aplysia were first exposed to LD 12:12 and then, beginning at dawn, switched to LL varying in duration from 1 to 62 h. The eyes were then removed and placed in culture for recording the CAP rhythm in DD for 3 or more cycles. When LL>24 h the phase of the CAP rhythm was always reset by the LL to DD transition (LL/DD) such that the midrise point of the rhythm occurred about 12 h after LL/DD. This fixed phase lag between the CAP rhythm and LL/DD occurred regardless of the initial phase of the CAP rhythm. The reset, or phase shift ($\Delta\phi$) was not caused by the procedure of eye removal or setting up for recording; if LL was continued in vitro for 3 to 12 h, the phase of the rhythm was determined by the time of LL/DD and not by the time of the set up. The optic nerve contains efferent fibers from the cerebral ganglion and we investigated whether these fibers can influence resetting of the eye by LL/DD. The eyes together with the brain were removed and the optic nerve of only one (detached) eye was cut; the other (attached) eye was left free to interact with the brain. When $12 \leq LL \leq 24$ the detached eye was not reset by LL/DD but the attached eye was; i.e. the duration of LL pretreatment required to produce resetting by LL/DD was less in the attached than in the detached eye. The brain, via the intact optic nerve, must participate in resetting the phase of the CAP rhythm when $12 \leq LL \leq 24$. We discount the possibility of hormonal interaction between the eye and brain because the attached and detached eyes were side by side in the recording medium. The critical signals in the optic nerve might represent the output of photoreceptors signalling LL/DD. To test this we reversibly blocked activity in the optic nerve with isotonic sucrose for 3 h beginning just before LL/DD. Resetting was not prevented. Resetting was prevented, however, by a 3 h nerve blockade beginning 3 h after LL/DD. The long delay between LL/DD and the effectiveness of nerve blockage suggests that the critical nerve signals are not from photoreceptors. In summary, following $12 \leq LL \leq 24$ h the eye and brain interact in vitro in DD to cause a phase shift of the CAP rhythm. This interaction is mediated by the optic nerve. The interaction is not continuous and does not occur until several hours after LL/DD. In another abstract we further explore the timing of the critical signals in the optic nerve and suggest that the eye-brain interaction may best be explained by two separate timing mechanisms in the eye-brain system. NSF 28251, NS 12374.

825 CENTRAL PEPTIDE-CONTAINING NEURONS MODULATE GUT ACTIVITY IN TRITONIA. Philip E. Lloyd* (SPON: A.O.D. Willows). Dept. Zool., Univ. Washington, Seattle, WA 98195

The paired buccal ganglia of Tritonia are largely responsible for the neuronal control of feeding. On the dorsal surface of each ganglion, there is a large neuron (100-150 μm diameter) that appears white when epi-illuminated (termed the large dorsal white cells or LDWC). Both electrical stimulation of nerve trunks and back-filling with Co^{++} indicate that each LDWC sends its axon out the ipsilateral gastro-esophageal nerve. These nerves run parallel along the foregut and contribute to a complex plexus on the surface of the stomach.

Using an in vitro snail heart assay (Lloyd, J. Comp. Physiol. 128: 269, 1978), it was found that these neurons contain large quantities of a cardioactive peptide. This assay is sensitive to as little as 0.005 the contents of a single LDWC. A minimum of 95% of the cardioactivity present in a LDWC is destroyed by incubation with trypsin or Pronase. Furthermore, a survey of other large identified neurons (12 orange, 11 white, under epi-illumination) demonstrates that none contain protease sensitive cardioactivity. The peptide found in LDWCs co-elutes with a small cardioactive peptide found in the brains of Helix and Tritonia when subjected to both molecular sieve and ion exchange chromatography. It has an apparent MW of under 1,000, and an extremely basic isoelectric point (pI of approx. 11.0).

Intracellular recordings from semi-isolated preparations (buccal ganglia-foregut) reveal that in "non-feeding" ganglia, the LDWCs are tonically active, firing as slow beating pacemakers with weak phasic synaptic modulation. However in "feeding" ganglia (feeding-like activity induced by stimulation of nerve roots), the LDWCs fire high frequency bursts at short intervals. These bursts are in phase in both LDWCs, but the two neurons are not synaptically interconnected.

The response of the foregut to electrical stimulation of the LDWCs is biphasic. The initial response to a high frequency burst is a contracture of the gut. This response is highly refractory. A much longer lasting response is the inhibition of the gut's spontaneous activity. Experiments are currently underway to more precisely determine the role of the LDWCs and the peptide during feeding in Tritonia (supported by NSF grant BN575-1359 7A02.

826 IMMUNOHISTOCHEMICAL LOCALIZATION OF A SPECIFIC SECRETORY MEMBRANE GLYCOPROTEIN IN IDENTIFIED *APLYSIA* NERVE CELL BODIES. B.W. Lubit, R.T. Ambron, and J.H. Schwartz. Div. Neurobiol. & Behav., Depts. Anat. & Physiol., Columbia U., New York, N.Y. 10032, U.S.A.

A small number of membrane glycoproteins become rapidly labeled when identified neurons of *Aplysia* are injected with ^{3}H-sugar precursors. Rapid synthesis may imply that these membrane components play an important role in the physiological activity of the cell. In order to relate biochemical information to physiological functioning, we have been studying the localization of individual ^{3}H-glycoproteins to specific organelles within the neuron. We had previously shown in the giant cholinergic neuron R2 that a glycoprotein with a molecular weight of 180,000 daltons (Component-I) is preferentially retained in the cell body, whereas the lower molecular weight membrane glycoproteins are exported into the axon for rapid transport. Using both quantitative electron microscope radioautography and subcellular fractionation, we found that Component-I is a constituent of somatic vesicle membranes. Recent analyses of glycoproteins in other identified cells have suggested that Glycoprotein-I may be a common constituent of *Aplysia* neurons. We have now examined the distribution of this membrane glycoprotein by direct immunofluorescence using a specific antibody raised in rabbits.

Component-I was purified by extraction of neuronal membranes with lithium diiodosalicylate; it was then further purified by SDS polyacrylamide gel electrophoresis and the region of the gel containing Component-I emulsified with complete Freund's adjuvant. Antibody was detected by Ouchterlony immunodiffusion and rocket immunoelectrophoresis using an SDS membrane extract as the test antigen. The antibody was shown to bind selectively to ^{3}H-Component-I isolated from an R2 injected with ^{3}H-N-acetyl-galactosamine. There was no binding to other labeled glycoproteins. The antibody was purified by adsorption with acetone-powders of liver and of *Aplysia* body wall muscle, and was then coupled to fluoroscein isothiocyanate. In cryostat sections of ganglia treated with the antibody, fluorescence was confined to neurons: cytoplasm of nerve cell bodies appeared intensely fluorescent. There was little staining of nuclei and, consistent with biochemical studies, no staining of axons, neuropil or glial cells was observed. Examination of the fluorescence in tissues other than the nervous system indicates that Component-I is a universal constituent of *Aplysia* secretory cells. Thus both the salivary gland and the winding gland stain intensely, whereas there was no staining of muscle or connective tissue. Using the antibody as a specific probe, experiments are now in progress to determine the role of this membrane glycoprotein in neuronal activity.

827 FOOD INCREASES CNS SUPPRESSIVE CONTROL OVER GILL REFLEX BEHAVIORS IN APLYSIA. Ken Lukowiak* (SPON: L.K.Vaughan). Div. Med. Physiol. Fac. of Med., Univ. of Calgary, Calgary, ALTA. T2N 1N4, Canada.

The central (CNS) and peripheral (PNS) nervous systems interact and are parts of an integrated system which mediates adaptive gill reflex behaviors evoked by siphon stimulation. In this system the CNS exerts suppressive and faciltatory control over gill behaviors. I now report that continuous exposure to food significantly increases the CNS's suppressive control which results in a significantly smaller reflex amplitude and a significantly faster rate of gill reflex habituation. The experimental group (n=10) had continuous exposure to food while the control group was fed once a week. The following data were obtained: 1) In controls the amplitude of the reflex evoked by a 1g. siphon stimulus with branchial (Br), ctenidial (Ct), siphon (Sn) nerves and PNS intact was not significantly different than the reflex with only the PNS intact (19.3mm ± 2.6 vs. 20.1mm ± 2.2). The reflex was significantly enhanced if only Br was cut (33.0mm ± 2.4). The rate of habituation with Br, Ct, Sn and PNS intact (-0.55) was not different from that with only PNS intact (-0.56). 2) In the experimental group the reflex amplitude with Br, Ct, Sn and PNS was significantly smaller than with only the PNS intact (3.0mm ± 0.5 vs. 20.3mm ± 4.1). Again the reflex was enhanced following only Br cut (36.5mm ± 6.0). The rate of habituation with Br, Ct, Sn and PNS intact (-1.81) was significantly faster than with just PNS (-0.53). 3) The reflex with Br, Ct, Sn and PNS intact in the experimental group was significantly smaller than the reflex with everything intact in the controls (3.0mm vs. 19.3mm). Yet the reflex amplitudes with only the PNS present were not significantly different nor were the amplitudes with only Br cut. Moreover, the rate of habituation in the experimental group with everything intact was 3x faster than in the controls. But the rates were not different when only the PNS was intact. 4) The neural activity evoked in L7 by the siphon stimulus was less and decremented faster in the experimental group than in controls. 5) In young Aplysia there were no observable differences between control and experimental animals. It is concluded that continuous exposure to food alters the central "state" of the preparation by increasing the CNS's suppressive control over gill behaviors. This CNS control is absent in young Aplysia. Thus, to completely understand the neural mechanisms of habituation, it is necessary to take into consideration CNS suppressive and faciltatory control over gill behaviors. (Supported by the MRC of Canada.)

28 THE NUMBER OF NEURONS IN SEGMENTAL GANGLIA OF THE LEECH. Eduardo R. Macagno. Dept. Biological Sciences Columbia University, New York, N.Y. 10027

The number of neurons was measured in specific segmental ganglia from the nerve cord of four different species of leeches. Quantitative data were obtained by means of computer-aided techniques for the analysis of nerve structure from serially-sectioned or whole-mounted tissue (Macagno et al,1979, Ann. Rev. Biophys. Bioeng. 8). The species studied were Hirudo medicinalis, Macrobdella decora, Haemopis marmorata (family Hirudinidae) and Haementaria ghilianii (family Glossophoniidae).

Two sets of ganglia were studied in each species: middle ganglia (9, 10 and 11) and sex ganglia (5 and 6). The middle ganglia, as well as the rest of the 21 segmental ganglia excepting 5 and 6, are thought to be quite similar. The sex ganglia are associated with the sexual organs and, visually appear to have more neurons.

The data to be presented show that: (a) the number of neurons in a specified ganglion varies by one to two percent from animal to animal of a given species; (b) the middle ganglia of a particular leech have approximately the same number of neurons, with a variation also within one or two percent; (c) the middle ganglia of Hirudo, Macrobdella and Haemopis have three to four hundred more neurons than their middle ganglia, with the exact number varying according to the species, but the sex ganglia in Haementaria have only about 20 more neurons than its middle ganglia.

829 **THE MYOCHORDOTONAL ORGAN IMPOSES THE CONTRACTILE PROPERTIES OF ITS RECEPTOR MUSCLE ONTO THE FLEXOR MUSCLE OF THE MERUS-CARPUS JOINT OF THE CRAYFISH.** **John D. Marrelli*, James L. Larimer. Dept. Zool., U. Texas at Austin , Austin , Texas 78712**

The Myochordotonal Organ (MCO) is a muscle-sensory organ whose distal tendon spans the Merus-Carpus joint (MC) of the crayfish claw. Its sensory cells are in series with the small Accessory Flexor muscle (AFm) and in parallel with the large working Flexor muscle (Fm). Thus the MCO is stretched by AFm contraction and released by Fm contraction. Voluntary flexion of the MC joint is normally produced by co-activation of Fm and AFm. When AFm and Fm contract simultaneously, the resulting stretch of the sensory ending is proportional to the difference between the extent of contraction of AFm and Fm. The rate sensitive MCO cells thus record the differential AFm-Fm contraction velocity. During imposed movements of the MC joint, some MCO cells are extension sensitive. During voluntary flexion, these units gain additional properties: First, they discharge before any detectable movement of the MC joint (10 um resolution). Second, they discharge during flexion , but only during flexion deceleration. Ablation of the AFm motoneurons eliminates these responses leaving only the extension sensitivity. These additional properties are thus emergent properties of the sensory motor loop. Selective electrical stimulation of these sensory units produces one-for-one activation of the working muscle, Fm. The following sequence accompanies voluntary flexion : Co-activation of Fm and AFm; Fm fatigue or inadequate Fm tension causes Fm contraction to slow down relative to AFm contraction; MCO responds in proportion to this differential contraction; Fm receives additional activation and the limb speeds up; MCO output declines as Fm rate of contraction approaches that of AFm.

This system is a negative feedback control system in which the contractile speed of Fm is forced to conform to the contractile speed of AFm. This kind of control of intrinsic working muscle properties is important because Fm growth, injury, fatigue, heterogeneity of muscle fibers, motoneuron recruitment and external loads can alter limb movements arising from a stereotypic motor program. These factors are less likely to influence the contractile properties of the AFm because of its location, homogeneity of muscle fibers,size and simpler motor innervation.

The MCO sensory-motor loop thus acts to reduce the complexity of Fm response to motor input, insuring that successive motor programs produce similar limb movements.

830 Swallowing and Regurgitation in the Isolated Nervous System of Pleurobranchaea: Distinguishing Features and Higher Order Control. Andrew D. McClellan* (SPON: P. Sheafor). Dept. of Anatomy and Dept. of Biomed. Eng., Case Western Reserve University, Cleveland, Ohio 44106

In Pleurobranchaea regurgitation has several features in common with feeding. For example, both behaviors display rhythmic radula movement, a kinematic component commonly thought to be exclusive to feeding. Alternating buccal root activity, which underlies this rhythmic radula movement, is therefore not an adequate criteria for identification of feeding in the isolated nervous system. The motor programs for swallowing and active regurgitation can be selectively elicited in isolated nervous system preparations by extracellular stimulation of various nerves at low and high levels, respectively. Since swallowing is one of the phases of both the feeding and regurgitation responses, it presently can be behaviorally classified only in more intact preparations, where natural stimulation is possible.

In so far as feeding and regurgitation have similar motor programs, the behavioral specificity of some of the putative feeding "command" cells is in question. The metacerebral and paracerebral cells are thought to be command cells specific for feeding. Although these cells are sometimes active during the regurgitation motor pattern, particularly at its termination, they do not elicit the response when stimulated. This result suggests that these cerebral cells may perform a non-command function during regurgitation. Several cells in the buccal ganglia do appear to specifically evoke active regurgitation. One class of cells, some of which are "ventral white cells", elicits the complete motor pattern for regurgitation when stimulated and actively bursts when the same response is evoked by nerve stimulation. A second class of cells is also capable of commanding regurgitation, although the membrane potential of these cells is only modulated during regurgitation elicited by other means.

This study implies that the higher order command cells for swallowing and regurgitation reside in the buccal ganglia, while the higher order cells for consumatory feeding are located in the brain. The results also indicate that rigorous criteria must be developed for identifying feeding in isolated gastropod nervous systems; rhythmic, alternating buccal root activity does not appear sufficiently specific for feeding.

831 HETEROGENEITY OF EXCITATORY INNERVATION ALONG SINGLE MUSCLE FIBERS IN THE LOBSTER. D.E. Meiss and C.K. Govind. Scarborough College, University of Toronto, West Hill, Ontario, Canada M1C 1A4.

Crustacean neuromuscular synapses arising from a single excitor axon are known to be well differentiated between different fibers but little is known about their condition along single fibers. Focal recording techniques were used to examine the quantal transmitter release and facilitation properties of synapses located at opposite ends of single muscle fibers in the singly excitatory innervated distal accessory flexor muscle of the lobster, Homarus americanus. Synapses were reliably differentiated with respect to quantal output such that those located near the tendon end were 1.15-4.12X greater than those at the opposite, exoskeletal end ($p < 0.01$, paired t-test). Similar differences were seen in the amount of facilitation determined from twin pulse experiments. The fine structural basis for these differences were determined by serial section electron microscopy of 10 µm segments at each end to ensure that the area of focal recording was sampled. No quantitative differences were found in the terminals or synapses in the two regions. Instead, the physiological diversity is correlated with number and size of presynaptic dense bars. Thus, the tendon end had a greater number and larger mean surface area of dense bars compared to the exoskeletal end. This heterogeneity of excitatory multiterminal innervation is correlated with the axonal branching pattern. Thus, the main axon and the larger primary axon branches lie in close proximity to the tendon end of the muscle fibers whereas the exoskeletal end is innervated by smaller secondary and tertiary axonal branches. This proximity to the large axonal branches of the larger quantal output synapses at the tendon end may be regulated by some neural influence including a timing of innervation and/or access to greater amounts of metabolites in the larger branches which may be conducive to forming larger transmitter synapses.

832 EXPERIMENTAL ARREST OF CLAW MUSCLE TRANSFORMATION AND ASYMMETRY REVERSAL IN ALPHEID SHRIMP. DeF. Mellon and P.J. Stephens*. Dept. of Biol., Univ. of Virginia, Charlottesville 22903.
In alpheid shrimp the first chelipeds are asymmetrical and consist of a small pincer claw and an enlarged snapper claw on opposite sides of the animal. Reversal of claw asymmetry follows loss of the snapper (Wilson, E.B., Biol. Bull., 4 (1903) 197-210) in which the pincer claw is transformed to a snapper. Transformation also occurs in response to damage to the nerve supply of an otherwise intact snapper (Mellon, DeF., Stephens, P.J., Nature, 272 (1978) 246-248). The transformation process entails profound functional as well as morphological changes in the original limb and requires as many as eight consecutive moult cycles to complete (Stephens, P.J., Mellon, DeF., J. Comp. Physiol. (1979) In Press). The mass of the claw musculature increases by as much as ten-fold and is brought about solely by an increase in the diameter and length of existing muscle fibers. Sarcomere length in fibers of the major closer muscle increases by as much as five-fold, apparently by a process of gradual myofibrillar reorganization. In addition, the properties of synaptic release at the neuromuscular junctions undergo modification during claw transformation. Amplitudes of individual ejp's increase from 1-5 mV in the original pincer to as much as 20 mV in the transformed snapper. Facilitation index during the same period is doubled. Pincer transformation does not occur if its nerve supply is interrupted (Wilson, E.B., op. cit.) and, we now find, can also be arrested by specific experimental procedures that prevent the genesis of maximal contractile tension in the closer muscle of the pincer claw. Tenotomy of the major closer muscle of the pincer in many cases prevented transformation of the pincer following snapper amputation. Tenotomy of the pincer opener muscle, an operation which restricts normal length increases of the closer muscle, also resulted in cases in which pincer transformation was arrested. Finally, banding the pincer claw in the fully closed position following snapper amputation prevented claw transformation in most cases. None of these procedures was effective in initiating transformation when they were performed on snapper claws. These results support the hypothesis that transformation of the pincer closer muscle requires a sustained increase in contractile tension, possibly initiated and maintained directly by changes in the functional properties of its motor neurons. The loss of muscle tension in the snapper claw, however, is apparently not implicated in the triggering of transformation.

833 SPATIAL DISTRIBUTION OF SYNAPSES ONTO A SINGLE IDENTIFIED MOTONEURON: AN ULTRASTRUCTURAL STUDY. Thea Mendelson* (Spon: E. L. Gasteiger) Section of Neurobiology and Behavior, Langmuir Laboratory, Cornell University, Ithaca, NY 14850.
The fast flexor motoneurons control tail flexion in the escape response of crayfish. The neural circuitry for this response and the electrophysiology of individual neurons in the circuit have been well studied (Zucker, J. Neurophys. 35, 1972). The structure of the motoneurons has been elucidated by means of single-cell staining with cobalt (Mittenthal and Wine, J. Comp. Neur. 177, 1978). A single one of the fast flexor motoneurons in the 1st abdominal ganglion exits anteriorly in isolation from the other motoneurons. Therefore, this preparation is particularly suitable for studying the role of a single cell in the escape response. Since many inputs converge on each motoneuron, an ultrastructural study was undertaken to provide the morphological basis for the electrical activity of this individual neuron.
Horseradish peroxidase was used to backfill the soma, dendritic arborization and proximal axon of the motoneuron. Subsequent treatment with dianisidine produced deposits of electron-dense benzidine reaction product throughout the neuron. Thus the fine dendritic processes could be identified in sections cut through the ganglionic neuropil.
The pattern of dendritic branching and the form of the fine secondary dendrites were compared in whole mounts and in reconstructions from serial sections. The ultrastructure of the electrotonic junctions formed by both medial and lateral giant interneurons on this particular motoneuron was determined with electron microscopy. The ultrastructure of these synapses was compared with that of electrically rectifying synapses between the lateral and motor giant neurons and with that of the septal electrotonic junctions within the lateral giant interneurons.
Chemical synapses were also found on the dendrites of the motoneuron. Their spatial distribution in relation to the electrotonic synapses and to the configuration of individual dendrites is described.

834 MUSCARINIC CHOLINERGIC BINDING SITES IN TERMINAL GANGLION OF THE CRICKET CNS. M.R. Meyer, J.S. Edwards, and R.E. Morrissey*. Dept. Zoology, Univ. Washington, Seattle, WA. 98195.
Cholinergic binding sites have been reported to be present in the insect CNS and, in most cases are thought to be either nicotinic or mixed nicotinic-muscarinic in nature. Recently, muscarinic sites have been detected in homogenates of whole Drosophila heads (J.Neurochem.,1978,32:543). Although electrophysiological studies indicate that acetylcholine may serve as a neurotransmitter at specific synapses in the terminal ganglion of some insects, little is known of the characteristics of the receptor sites in this area of the CNS. We now report evidence for the presence of sites in the terminal ganglion (TG) of the cricket Acheta domesticus that specifically bind the potent muscarinic antagonist 3-quinuclidinyl benzilate (QNB).
Using a modified [^{3}H]-QNB filter-binding assay, homogenates of isolated TG were shown to specifically bind the ligand with high affinity. [^{3}H]-QNB binding was displaced 70-90% by 10^{-6} M scopolamine, while 10^{-5}M scopolamine or prior heat treatment of the tissue reduced binding to near background levels. Incubation of TG in 10^{-5} tubocurarine and 10^{-4}M oxotremorine reduced binding by 40 % and 86% respectively. Binding was shown to increase linearly with increasing concentrations of TG in the assay mixture. When increasing concentrations of labeled ligand were employed in the assays binding was observed to saturate at ca. 6 nM [^{3}H]-QNB. Scatchard analysis of binding curve data yielded an apparent dissociation constant (K_d) of 5.4 x 10^{-9}M. The maximum number of binding sites (B_{max}) was calculated to be ca. 480 fmol mg^{-1} protein (96 fmol mg^{-1}wet weight tissue). Hill plot data gave a Hill coefficient (n_H) of 0.93, indicating essentially non-cooperative binding. The K_d calculated from the Hill plot data was 5.1 x 10^{-9}M.
Although, at this time, cholinergic binding sites in the cricket TG have not been localized by autoradiography, physiological data generally support the notion that cholinergic transmission occurs in certain neuronal pathways in the ganglion neuropile. Our findings demonstrate a rather high density of binding sites in the cricket CNS that fulfill at least some of the prerequisite requirements for a muscarinic receptor candidate (e.g. high affinity, saturability, specificity). Additional studies are now in progress to further characterize the pharmacology, physiology, and localization of these binding sites.

835 A REFLEX PATHWAY FOR EVALUATING CENTRAL NERVOUS REGENERATION IN A SNAIL. Stacia Moffett. Dept. Zool. WSU, Pullman, WA 99164
Anatomical evidence for regeneration of central nervous connections has been reported for the pulmonate snail Melampus bidentatus by Price (Cell Tiss. Res. 180, 529-36, 1977). In the primitively unfused nervous system of this snail, it is easy to sever the cerebral commissure or the cerebro-pleural or cerebro-pedal connectives. Small diameter nerve connections form in a matter of days to weeks and progressively shorten and thicken to an approximation of their normal condition. The appropriateness of the connections that are formed is evaluated by testing reflex responses to tactile stimulation in a small cerebral nerve, labial nerve 2. This nerve was chosen because it has two large efferent units that are easily recognized in extracellular recordings by their relative spike heights and response patterns. These units in the right or left labial 2 nerve receive tactile information from both sides of the posterior and medial foot and mantle regions primarily through the ipsilateral connectives, with connections through the contralateral connectives and the cerebral commissure making a small contribution to the reflex in normal animals. The cerebral commissure is the pathway through which tactile information from one side of the anterior foot and head region elicits activity in the contralateral labial nerve units.
In snails with regenerated connectives, normal responses to tactile stimulation of the posterior foot and mantle region are present after the contralateral connective pathway has been eliminated. Electrical stimulation of the regenerated connectives also elicits the reflex response. In instances in which no obvious regenerated connective is present, the nerve fibers appear to have wandered extensively; no reflex response could be detected in these animals.
Cerebral commissure transections are more readily repaired than connective transections and both electrical stimulation of the regenerated commissure and tactile stimulation of contralateral head regions elicit the reflex response. Preliminary evidence indicates that an auxillary pathway between the cerebral ganglia via the connectives and ring ganglia is formed or enhanced in some snails as a result of cerebral commissure transection. In these snails stimulation of one side of the head elicits a small reflex response in the contralateral nerve after the regenerated commissure has been cut.

836 FREQUENCY DEPENDENT RESPONSE PROPERTIES OF AN IDENTIFIED AUDITORY INTERNEURON IN THE CRICKET TELEOGRYLLUS OCEANICUS. Andrew Moiseff and Ronald R. Hoy. Section of Neurobiology and Behavior, Cornell University, Ithaca, New York 14853.

The response properties of an identified auditory interneuron (Interneuron-1)[1] were measured over a broad range of stimulus carrier frequencies (3kHz to 100kHz) for male and female T. oceanicus. Interneuron-1 was tonically excited by tones at carrier frequencies of 10-100kHz. The minimum threshold intensity occurred at 25kHz (61.0 dB SPL; n=10, standard deviation= 9.7).

Between stimulus presentations, interneuron-1 is spontaneously active. At frequencies of 3-6kHz this spontaneous activity is suppressed (or inhibited). Suppression was most accurately measured through two-tone suppression experiments. A standard excitatory stimulus was delivered simultaneously with a test tone. The intensity of the test tone (3-6kHz) was varied until the number of spikes recorded in response to this two-tone stimulus was one-half of the number recorded in response to the standard excitatory tone alone. Using this criterion of 50% suppression, it was determined that the peak sensitivity of the "inhibitory response" is at 5kHz (50% criterion met at 62.5 dB SPL; n=11, standard deviation= 5.7).

A single ear was demonstrated to mediate the excitatory and inhibitory responses in the ipsilateral interneuron-1 (n=6), and inhibitory responses alone in the contralateral interneuron-1 (n=3).

We believe that the function of this interneuron is the detection and lateralization of ultrasonic sound signals produced by predators (e.g. insectivorous bats).[2]

837 INTRACELLULAR pH REGULATION IN CRAYFISH NEURONS STUDIED WITH ION-SENSITIVE MICROELECTRODES. William Moody. University of Bristol, Bristol, BS8 1TD,England.

The intracellular pH (pH_i) of crayfish motoneurons was measured using recessed-tip pH microelectrodes. Experiments were performed on both the motor giant and flexor inhibitor neurons of abdominal ganglia; no differences were noted between the two cells. The resting pH_i of the cells in nominally CO_2-free Ringer (pH 7.4) was 7.05 - 7.2. Since the resting membrane potential was -65 to -80 mV, intracellular H^+ activity is maintained well below its equilibrium value. Upon application of 5% CO_2 - 40 mM HCO_3^- Ringer at constant external pH, pH_i decreased rapidly by 0.2 - 0.4 units. This lower pH_i was not maintained, however, and within 1-2 minutes pH_i began increasing back toward its pre-CO_2 level with an approximately exponential time course. The maximum rate of recovery of pH_i ranged in different cells from.05 - .13 units/min. Since the electrochemical gradients for H^+ and HCO_3^- favor further acidification during prolonged CO_2 application, the recovery of pH_i presumably represents active H^+ efflux and/or HCO_3^- influx. When 5% CO_2 was applied in Na-free (Li or BDAC replacement) Ringer, the rate of recovery of pH_i was reduced by 80-100%. In some experiments, pH_i was lowered by removal of NH_4Cl after a brief exposure. Virtually no recovery from this acid load was seen in Na-free HCO_3^--free Ringer. Relatively rapid recovery of pH_i was stimulated when Na was replaced, even in nominally HCO_3^--free Ringer; external HCO_3^- further increased the rate of pH_i recovery. Experiments are presently in progress to attempt to detect Na entry during pH_i recovery using intracellular Na-sensitive microelectrodes, and to assess the degree of coupling between the movements of various ions involved in pH_i regulation.

838 ADAPTATION OF THE TOBACCO HORNWORM (MANDUCA SEXTA) CENTRAL NERVOUS SYSTEM TO NICOTINE. Catherine E. Morris * (SPON: D.L. Gilbert). NIH, Bethesda, MD 20205.

Manduca sexta caterpillars, when feeding on tobacco, chronically tolerate haemolymph levels of 2.3 X 10^{-5}M nicotine (Self et al.,1964,J Ins Phys 10:907), a concentration several orders of magnitude greater than that required to alter synaptic function in some insects. This implies either that the Manduca CNS is intrinsically insensitive to nicotine or that a blood-brain barrier system operates against the toxin. In vitro electrophysiological studies (comparing Manduca to Periplaneta americana) established that Manduca CNS is susceptible to nicotine, but, 2 orders of magnitude less sensitive (indicated by drug-evoked discharge monitored in connectives and ganglionic polarisation measurements) than Periplaneta. During 5 min exposures, desheathed Manduca nerve cords have a threshold for response at 5 X 10^{-5}M, whereas that for intact cords is between 1 and 2 X 10^{-3}M nicotine. The cholinergic agonists muscarine, lobelline and ACh are all effective at 10^{-5}M or less. Studies with radioactive nicotine show: a) the blood-brain interface is not efficient in excluding nicotine passively from the CNS, since uptake ratios are the same in Manduca and the cockroach for incubations of 2-30 min b) nicotione is rapidly metabolised by Manduca's CNS to water-soluble compounds that are almost certainly conjugates of the hydrolysis product(s) of nicotine c) nicotine uptake has a saturable component which may reflect an alkaloid transporting system capable of removing nicotine from extracellular spaces and d) nicotine and its CNS metabolites wash out of the Manduca CNS according to 2 exponentials, whereas 3 exponentials are found in Periplaneta, suggesting that a "nicotine space" (viz. a deep extracellular compartment) is missing in Manduca. Conjugate formation from nicotine would require a mixed-function oxidase system plus conjugating enzymes - these are largely associated with smooth ER, an ultrastructural feature abundant in the perineurium and glia of Manduca. Also relevant to a barrier system is the configuration of the perineurium; in Manduca larvae, individual cells of the innermost layer extend over such a large area of ganglion that a very few cells (forming lateral tight junctions) would encapsulate the ganglion. Consequently, intercellular diffusion of nicotine at the blood-brain interface must be severely restricted so that transcellular permeation probably accounts for the observed nicotine entry, allowing nontoxic conjugates to be formed intracellularly before nicotine can diffuse through to the extracellular spaces. The fact that a limited amount of metabolism occurs in the cockroach CNS indicates that the rate of detoxification relative to influx is the critical factor in conferring protection on Manduca. (Study carried out in Dept. Zool., Univ. of Cambridge, U.K.)

839 ACTION OF ETHANOL ON IDENTIFIED NEURONS IN THE CNS OF ACHETA DOMESTICUS. R. E. Morrisey* and J. S. Edwards. Dept. Zool., Univ. Washington, Seattle, WA 98195.

Giant fiber activity elicited by mechanoreceptor input to identified interneurons of the abdominal nerve cord in the house cricket Acheta domesticus was used as an assay for the action of ethanol on electrophysiological function of an insect sensory system.

Giant fiber activity is affected by perfusion with ethanol. Concentrations above 0.20% caused a 2-4 fold increase in number of giant fiber spikes in response to cercal stimulation within 30 seconds of perfusing the body cavity. The site of action was localized by means of vaseline barriers which isolated specified regions of the CNS. Only perfusion of the terminal ganglion caused an increased spike number comparable to that of wholly perfused nervous systems. Extracellular records from the afferent neurons in the cercal sensory nerve during stimulation were unaffected by alcohol treatment. Similarly perfusion of anterior connectives and segmental ganglia did not cause a significant increase of giant fiber responses to cercal stimulation. The principal site of action of ethanol appears to be in the neuropile of the terminal ganglion, and probably at the sites of cercal nerve input to the giant fiber arborizations.

Spatial localization of point sound stimuli as manifested in giant fiber spike number has been quantitated and can be used as an assay for neural function. Perfusions of ethanol at concentrations of up to 2% induces increased spike number but does not affect directional response. At higher perfusion concentrations directional responses are skewed and distorted. The circuitry of this system is not fully elucidated but the results point to an alteration in relative excitation/inhibition of the giant interneurons. This work was supported by a grant from the Alcohol and Drug Abuse Institute, Univ. of Wash.

840 IDENTIFIED NEURONS OF THE STOMATOGASTRIC GANGLION HAVE DIFFERENT, CHARACTERISTIC MEMBRANE TIME CONSTANTS. Brian Mulloney, Kate Skinner, and Donald H. Edwards, Jr.* Zoology, University of California at Davis, Davis, CA 95616.

The gastric system of the stomatogastric ganglion includes ten motor neurons and one interneuron which interact to generate a characteristic motor pattern. These neurons are identifiable in terms of the muscles they innervate, the nerves their axons travel, and the synapses they make within the ganglion (Mulloney and Selverston, 1974). As part of an effort to simulate the pattern-generating mechanism, we have measured the time-constants (τ_m) of the membranes of some of these neurons using Jack and Redman's (1971) brief current-pulse method, and discovered that these neurons differ characteristically in this parameter. The data on hand for these neurons are:

neuron	τ_m (msec)	R_{in} (Mohm)	R_m (Mohm cm^2)
DGN	140	21	.140
AMN	20	2	.020
LGN	---	7	---
MGN	---	10	---
LPGN	120	15	.120
GM	35	7	.035
Interneuron 1	14	--	.014

τ_m lets us calculate the specific membrane resistivity (R_m) of these neurons, since $\tau_m = R_m C_m$ and $C_m = 1\ \mu F/cm^2$. These neurons differ up to ten-fold in their specific membrane resistivities, and therefore in the density of ionic channels.

The input resistances of these neurons were also measured, in most cases in the same experiment with the same microelectrodes, by injecting long pulses of constant current and measuring the change in membrane potential. Many measurements were made using an active bridge circuit, but some were made with two microelectrodes. The values of R_{in} are given in the Table; R_{in} is not a simple function of R_m.

Chemical synaptic transmission onto these neurons should change both τ_m and R_{in}, since it will cause local changes in the membrane's conductance which our methods will integrate into resistance of the entire cell. When we measure τ_m in x5 Mg^{++} saline, its value increases about 50% in cells suspected to receive continuous synaptic input (Graubard, 1978; Mulloney, unpublished). We think the highest measured values of τ_m most closely approximate the true values.

841 THE DEVELOPMENT OF DISTINCT SYNAPTIC TERMINAL ARBORIZATIONS IN THE CRICKET NERVOUS SYSTEM IS CORRELATED WITH BIRTHDAY AND POSITION IN A RECEPTOR ARRAY. R.K. Murphey. Dept. Biol., SUNY Albany, NY 12222.

An array of sensilla known as clavate hairs are located near the base of the cercus of the cricket (Acheta domesticus). These sensilla are equilibrium receptors which excite a small subset of interneurons which can be recorded in the ventral nerve cord. There are two groups of clavate sensilla, one located ventro-medially and one located dorso-medially on the cercus. Only the ventro-medial group will be discussed here.

The sensilla are arranged in rows running parallel to the long axis of the cercus. In general, a hair is added at the base of each row each time the animal molts. Thus, proximo-distal position within a row correlates roughly with birthday.

A method for staining the sensory neurons associated with individual hairs was then developed. We found that cutting the tip of a hair off and placing a bubble of cobalt over the hair would lead to staining of a single neuron. A similar method has been used by Anderson and Bacon (Dev. Biol. In Press).

First we examined the terminal arborizations of sensory neurons of different ages within a single row. We found that the oldest cells had the most profuse ramifications within the terminal abdominal ganglion, while younger neurons ramified in more restricted areas of neuropile nearer the cercal nerve. We conclude that the position of a hair along the proximo-distal axis has a correlate in position of its synaptic terminal in the ganglion - the most proximal receptors have arborizations which are the most distal (nearest the cercal nerve) in the neuropile.

If birthday were the only variable determining the differentiation of synaptic terminal arborizations then receptors with the same birthday should be virtually identical. In fact within a birthday group, each sensory neuron has a unique terminal synaptic arborization. Since the only variable which appears to distinguish these sensilla is position in the array, we conclude that positional values are assigned to the sensilla and these influence the growth of the terminal arborization.

We conclude that position and birthday of these sensory neurons are correlated with the morphology of the terminal arborization and its position in the ganglion. We intend to delete small numbers of sensilla in order to determine whether there are neighbor-neighbor interactions involved in growth of these terminal arborizations. We will also examine postsynaptic neuron responses in a search for physiological correlates of these distinctive synaptic arborizations.

842 THE EFFECT OF DOPAMINE, ACETYLCHOLINE AND THE NEUROPEPTIDE FMRFamide ON A MOLLUSCAN MUSCLE. G.T. Nagle, D.A. Price and M.J. Greenberg. Dept. of Biological Sciences, Florida State University, Tallahassee, FL 32306.

The excitatory actions of the neurotransmitters, dopamine (DA) and acetylcholine (ACh) have been compared with those of the molluscan cardioexcitatory neuropeptide, FMRFamide, on the isolated radula protractor of Busycon contrarium. The effects of various blocking agents on the mechanical responses to these three agonists were also tested.

The single phasic contraction of the radula protractor muscle elicited by DA is in sharp contrast to the sustained contractures caused by ACh and FMRFamide. Norepinephrine (NE) and epinephrine (E) produce responses similar to those of DA, but the threshold doses are higher. The muscle can be desensitized to DA by repeated treatment with high concentrations. Such tachyphylactic muscles no longer respond to NE or E, suggesting that the three catecholamines may be acting at a common receptor. The effects of FMRFamide and ACh on the radula protractor are undiminished by DA desensitization.

Ergometrine ($3x10^{-4}M$) blocked the response to DA ($3x10^{-5}M$) and to FMRFamide ($10^{-8}M = ED_{50}$), but not to ACh. In addition, d-tubocurarine (dTc; $4x10^{-4}M$) blocked the response to DA ($3x10^{-5}M$) and ACh ($10^{-6}M$); but higher concentrations also antagonized the actions of low doses ($2\text{-}3x10^{-9}M$) of FMRFamide. As inhibitors of the responses of Aplysia neurons, the ergot alkaloids are relatively specific antagonists of DA (Ascher, J. Physiol. 225:173,1972), but dTc appears to block the ionic channels common to a class of receptor-activated Na^+ and Cl^- responses (Carpenter et al., J.Neurobiol. 8:119,1977).

We conclude that DA, ACh and FMRFamide are all acting at different receptors in the radula protractor muscle. (Supported by NIH grant HL-09283 to M. J. G.)

843 HORIZONTAL EYE MOVEMENTS GENERATED BY PROPRIOCEPTION IN THE CRAYFISH, PROCAMBARUS. Richard F. Olivo and Martha M. Jazak*. Dept. Biol. Sci., Smith College, Northampton MA 01063.

Animals with movable eyes stabilize their eyes by using sensory input from vision (the optokinetic response), gravity/motion detectors (the statocysts of crustaceans), and proprioceptors. In crayfish, it is known that stabilization during horizontal turns of the body (yaw) is driven only by vision and proprioception, and thus crayfish offer a good system in which to characterize the role of proprioception in stabilizing the eyes. The proprioceptors involved are in the legs, but their actual identity is not yet known.

Crayfish (Procambarus clarkii) were prepared for experiments by gluing a plastic post to the carapace and attaching a fine silver wire to the left eyestalk. The antennae were cut short and in most cases the left cheliped was autotomized. A capacitative transducer (Sandeman 1968) was mounted on the carapace post to record movements of the left eye, and the same post was clamped to a vertical rod to suspend the animal in space. To stimulate proprioceptors, a turntable with fine gravel glued to it was placed beneath the legs; to stimulate the optokinetic response, a striped drum was placed on a second, concentric turntable. The turntables were oscillated sinusoidally, either in the same direction (in phase) or in opposite directions (out of phase).

Eye movements in response to visual and proprioceptive stimuli were measured at 6 frequencies between 3.5 and 20 cycles/min (0.06 to 0.33 Hz), for several excursion amplitudes between 10^0 and 34^0. With a stationary platform beneath the legs and with the striped pattern covered (control), stimulation elicited no eye movements; with the stripes covered ("legs only") or with the platform placed beneath the legs ("eyes only"), stimulation elicited eye movements with a mean gain between 0.1 and 0.5. The optokinetic response was stronger at low frequencies and the proprioceptive response was stronger at high frequencies. With both stimuli presented in phase, a larger response was elicited that was approximately the sum of the responses to separate visual and proprioceptive stimulation at each frequency. Thus, the optomotor system appears to sum algebraically the visual and proprioceptive inputs. This conclusion is supported by experiments in which the stimuli were presented out of phase; in such experiments the responses were very small. Similarly, in experiments in which the two stimuli had different frequencies, the eye movements were again approximately an algebraic sum of the visual and proprioceptive stimuli.

844 INSTRUMENTAL CONDITIONING IN CRAYFISH: LEVER PULLING FOR FOOD. Gene C. Olson and Robert Strandberg. Dept. of Psych., UCLA, Los Angeles, CA 90024.

Crayfish are relatively adept at manipulating objects with their claws. It would be interesting to determine if they can learn manipulative tasks. Previous studies of learning in crayfish have concentrated on locomotion tasks, e.g. mazes or shuttle box paradigms. This study demonstrates that crayfish can be trained to pull a lever to obtain a food reward.

For testing the crayfish were loosely restrained in front of the response lever. A food delivery tube was positioned near the subjects mouth area. Each pull of the lever delivered .005 cc of ground brine shrimp through the food tube. The crayfish would often chew on the end of the food tube as they held the tube with one claw and pulled the lever with the other claw. To control for non-specific effects the trained animals were compared to yoked control animals that received the same amount of food in an identical apparatus, but with an inoperative lever (non contingent food) Four matched pairs of crayfish received 9 training sessions. Training sessions lasted 30 minutes and were separated by 24 to 72 hours. Over all 9 sessions the food contingent animals performed an average of 51.1 lever pulls per session, compared to 19.1 pulls per session for the yoked control animals ($p<.02$, two-tailed t test).

After this initial training the groups were reversed: the former control animals now received contingent food and vice versa. In the following 9 sessions the newly trained animals averaged 62.4 pulls per session, the new control animals (formerly food contingent) declined to 19.9 responses per session ($p<.02$, two tailed t test).

It should be noted that the trained animals had no consistent improvement after the second session; individual subjects showed marked variability in daily performance. One possible explanation of this variability may be variance in the level of motivation. Further refinements will be necessary to determine the true performance capabilities of crayfish.

These data provide evidence that crayfish can learn a manipulative task for a food reward. This paradigm may be useful in the study of learning in simple systems.

845 IN TANDEM PHYSIOLOGICAL AND CHEMICAL STUDIES: USE IN IDENTIFICATION OF NEW HISTAMINERGIC NEURONS IN APLYSIA. Joyce K. Ono and Richard E. McCaman, City of Hope Nat. Med. Ctr., Duarte, CA 91010

We have modified a freeze-substitution technique used for isolating individual neurons for chemical assay to permit chemical measurements of physiologically characterized neurons. In a previous study, identified cholinergic, serotonergic, and histaminergic neurons from Aplysia californica were assayed for their respective transmitters after intracellular recording and staining (Ono & McCaman, Brain Res. 165:156). The histaminergic neurons (RC2 and LC2) proved to be particularly sensitive and adversely affected by the freeze substitution procedure used for their isolation. This freeze-substitution procedure utilized ethylene glycol (Giller & Schwartz, J. Neurophysiol. 34:93) and greatly facilitated isolation of "clean" individual somata. In the present study, substitution of propylene glycol for ethylene glycol in the freeze-substitution procedure permits excellent recovery of histamine (Hm) from C-2 neurons subjected to intracellular recording and staining.

Additional Hm-containing neurons have been discovered in the CNS of Aplysia using this new freeze-substitution procedure. These neurons are generally difficult to distinguish as individuals on the basis of visual inspection. Application of in tandem physiological and chemical techniques has resulted in the unequivocal identification of additional histaminergic neurons. The new histaminergic neurons, designated RC3 and LC3: (a) are located bilaterally on the ventral surface of the cerebral ganglion; (b) contain a concentration of Hm comparable to the previously identified C-2 neurons; (c) make monosynaptic connections with some of the same follower cells of the C-2 neurons; and (d) evoke the same types of postsynaptic responses as does C-2 in these followers.

Use of the propylene glycol medium also markedly improves the recovery of dopamine (DA) from Neutral Red-stained anterior ganglionic roots from the leech, Macrobdella decora. Previous studies with the ethylene glycol medium indicated a significant loss of DA from the rootlets during freeze substitution. It is anticipated that the use of the propylene glycol procedure will now make it possible to isolate and assay the single Neutral Red-stained neuron in these rootlets for DA.

In tandem physiological and chemical studies of individual neurons are essential for characterizing small, visually nondescript neurons and for examining the possible effects of physiological perturbations on endogenous transmitter levels. The use of the propylene glycol freeze-substitution technique promises to greatly facilitate such studies. [Supported by USPHS (NS05343) to J.K.O. and USPHS (NS9339) and NSF (76-06053) to R.E.M.]

846 MOTOR TERMINALS AND MUSCLES IN LIMB BUDS OF THE REGENERATING CUTTER AND CRUSHER CLAWS OF THE ADULT LOBSTER. Natalie G. Pascoe. Boston University Marine Program, Marine Biological Laboratory, Woods Hole, MA 02543.

The lobster has dimorphic claws. The cutter claw is adapted for speed; the crusher claw for power. If these claws are lost due to injury, the animal has the ability to regenerate them. The claws regrow in the form of soft buds enclosed in a chitinous capsule. At the next molt, the capsule is shed with the carapace, and a small but functional claw appears. The system has potential for experimentation relevant to neurotrophic influence on muscle development.

Opener and closer muscles of the lobster differentiate early in the development of the bud and then increase in size. Electron microscopy shows that innvervation occurs early in the growth of the buds. Motor terminals appear active: they have dense bodies and well defined synaptic clefts. They are already well equipped with mitochondria and large numbers of vesicles, dense cored as well as clear.

Muscle fibers are at first contiguous. As the bud grows they come to lie further apart with spaces between them. Individual fibers increase in diameter, and there is apparent infolding of the surface leading to fiber splitting. Cross sections of paired buds show that the opener and closer muscles of the cutter are smaller than the corresponding muscles of the crusher. The tendons are similarly unequal. In addition, the closer muscle in each bud has histochemical and ultrastructural characteristics that identify the type of claw from which it originates.

Crustacean muscle can be typed on the basis of histochemical differences in respect to oxidative capacity by NADH-diaphorase, and "fastness" by myofibrillar ATP-ase pH 9.4 (Ogonowski and Lang 1978). The closer of the cutter bud, but not the closer of the crusher bud, contains fibers with high activity for ATPase at pH 9.4. However, very early cutter buds will not stain darkly for ATPase at pH 9.4, which may qualify the closers as slow muscles at that stage. On the basis of the two enzymes surveyed, closer fibers in the crusher bud are slow fibers of high oxidative capacity.

The sarcomeres of the "fast" fibers of the cutter bud are shorter and differ from those in slow areas by having thinner, less dense Z-lines, clear H-bands and lower filament ratios of actin : myosin.

847 THE MORPHOLOGY OF GIANT INTERNEURONS: A STUDY USING COBALT BACKFILLING IN THE COCKROACH, P. AMERICANA. S.P. Pazdziorko* (SPON: R.A. Bernard). Anatomy and Biophysics Departments, Michigan State University, East Lansing, Mich., 48824.

The ventral nerve cord of the cockroach contains seven bilateral pairs of giant fiber interneurons (GFs), which are arranged into dorsal and ventral groups consisting of three and four pairs respectively. Anatomical experiments were done to determine the distance traversed and to examine the branching patterns of the GFs anterior to and including the third thoracic ganglion. Cobalt (introduced in one of the connectives between the fifth and sixth (last) abdominal ganglia) revealed at least seven axons entering the supraesophogeal ganglion (brain). The absence of supporting cell bodies, aside from the ones in the sixth abdominal ganglion, indicates that these axons are the GFs and that they are continuous throughout the length of the ventral nerve cord.

Extensive branching of the GFs was seen in all the ganglia examined. Branching in all three thoracic ganglia was similar, occurring primarily (but not solely) ipsilaterally and in both dorsal and ventral regions of the neuropile. Close examination of branching in this region revealed serially homologous branching patterns (identical branching in the same axon in two or more ganglia). This phenomenon appears to be a characteristic common to most, if not all, of the GFs as well as several other axons that extend through this region. At present, three GFs and two non-GFs have been mapped and found to exhibit this characteristic. Branching of the GFs in the subesophogeal and supraesophogeal are solely ipsilateral. Processes in the subesophogeal extend into both dorsal and ventral regions of the neuropile, whereas in the supraesophogeal ganglion they are confined to the dorsal region.

Since previous work has shown the existence of almost identical large neuronal cell bodies in the three thoracic ganglia, it is hypothesized that the serially homologous branching patterns observed in the GFs may transmit similar information to all three ganglia.

848 PHYSIOLOGICAL CORRELATES OF PHONOTAXIS IN FLYING CRICKETS. Gerald S. Pollack and Ronald R. Hoy. Section of Neurobiology and Behavior, Cornell University, Ithaca, New York 14853.

Tethered, flying crickets (Teleogryllus oceanicus) perform steering movements in response to electronically synthesized models of calling song played from loudspeakers located to the right or left. They attempt to turn toward song models with carrier frequencies similar to those found in cricket songs, but away from song models in which the carrier frequency approximates that of bat echolocation cries (Moiseff, Pollack and Hoy, Proc. Natl. Acad. Sci. U.S. 75, 4052-4056, 1978). We have studied steering behavior both by visual observations and by recording the electrophysiological activity of relevant nerve roots and muscles.

Steering maneuvers include lateral movements of the antennae, legs and abdomen, rotation of the head, and changes in the pronation of the forewings. The movements are rhythmic and reflect the temporal structure of the song stimulus. Discrete pairs of sound pulses in the song stimulus are followed by discrete steering movements. The temporal structure of the song is evident in the firing patterns of motor neurons and muscles as well. Electrophysiological recordings show that, in some motor neurons, the song pattern is superimposed on the regular flight rhythm.

The auditory receptors which mediate sound-activated steering are located on the front legs and project to the prothoracic ganglion. Motor neurons which accomplish many components of the behavior (e.g. wing adjustments, leg and abdomen movements) are located in the thoracic and abdominal ganglia. Section of both cervical connectives eliminates sound-activated steering, even though it does not disrupt any direct connections that might exist between the auditory and motor centers mentioned above. It is therefore possible that the neurons which provide phasic sound-related information to steering motor neurons originate in the head ganglia. Alternatively, steering motor neurons may be driven in a phasic, sound-related manner by neurons from the prothoracic ganglion, and the effectiveness of this pathway might be modulated by information descending from the head ganglia.

849 FINE STRUCTURAL AND AUTORADIOGRAPHIC STUDIES OF IDENTIFIED NEURONS R3-R14 OF APLYSIA. C.H. Price and D.J. McAdoo, Univ. Texas, Marine Biomedical Inst., Galveston, TX 77550.

We have traced the axons of R3-R14 to their peripheral terminals, using light and electron microscopy and autoradiography. The R3-R14 cell bodies in the parietovisceral ganglion are white, large (100-750 μm dia.), and contain dense core vesicles (1800 A dia.). Their axons can be traced in vivo by their white color and in fixed material by their large size (up to 40 μm dia.), extensive glial infolding, dense core vesicles, and specific labeling by ^{3}H-glycine. The terminals (several hundred/cell) are of two distinct types: (1) varicose, neurosecretory endings on hemolymph spaces; and (2) neuromuscular endings on or near vascular smooth muscle (in the walls of arteries, of the pericardial chamber, and of the gill vein). Terminals are free of glia, packed with dense core and larger clear vesicles, and have a rapid and specific uptake system for ^{3}H-glycine, as previously described for the R3-R14 cell bodies. Large en passant varicosities (up to 100 μm dia.) are formed by R3-R14 axons within and alongside the branchial nerve near the osphradial and branchial ganglia; these appear to be vesicle storage and processing sites.

Previous studies on these cells suggested that they are peptidergic neuroendocrine cells. Recent neurochemical and physiological evidence suggests that they may be glycinergic. Axonally transported ^{3}H-glycine in R3-R14 axons is in the free form and preliminary EM autoradiographic evidence indicates that the ^{3}H-glycine is localized to the dense core vesicles. The present morphological work supports a bifunctional role for R3-R14 since they possess endings in neurohemal release areas for secreting a long range messenger (possibly a peptide hormone) and neuromuscular junctions at which a short range messenger (possibly glycine) acts on vascular muscle. 850 RESETTING THE CIRCADIAN CAP RHYTHM IN THE APLYSIA EYE BY LL TO DD TRANSITIONS, II: EVIDENCE FOR TWO TIMING MECHANISMS. Robert G. Prichard* and Marvin E. Lickey. Univ. of Ore., Eugene, OR 97403.

In another abstract we reported that activity in the optic nerve can participate in causing a phase shift (Δφ) in the circadian rhythm of compound action potentials (CAP)in the Aplysia eye. We now report that (i) the timing of this nerve activity is determined by one photic cue while the magnitude of Δφ is determined by another and (ii)the critical photoreceptors for determining the magnitude of Δφ are in the eye itself. Aplysia were first exposed to LD 12:12 and then,beginning at dawn, switched to LL for 18, 21 or 24 h. The eyes and brain were then removed to a recording chamber, the optic nerve of one (detached) eye was cut and the entire preparation put into DD (LL/DD). After 1 to 14 h in DD the optic nerve of the other (attached) eye was also cut. On the following 2 or 3 cycles the CAP rhythm of the attached but not the detached eye showed a Δφ of the predicted size provided that the nerve remained intact for a sufficient time. If the nerve was cut too soon the Δφ did not occur at all; there were no partial Δφ 's. Thus activity in the optic nerve has an all or none effect on the attached eye. The minimum required duration of attachment (Dm) following LL/DD decreased linearly as the duration of LL increased. The duration of LL plus Dm always equaled 28±1 h;i.e.the critical nerve activity always occurred at a fixed interval following the last dawn seen by the intact Aplysia. The nerve activity, therefore, must be timed by a mechanism that is initiated or reset by dawns. Its timing is unaffected by LL/DD. As described in the previous paper, the magnitude of Δφ caused by the nerve activity establishes a 12 h phase lag between LL/DD and the midrise point of the CAP rhythm. This requires a second timing mechanism that, unlike the first, is initiated or reset by LL/DD. It is difficult to resist the hypothesis that these two mechanisms are two separate circadian oscillators, one reset by dawn, perhaps the CAP rhythm itself, and the other reset by LL/DD. In a second experiment we exposed Aplysia to several cycles of LD 12:12 terminated with LL = 18 h. The brain and eyes (one attached, one detached) were then removed to a special recording chamber in which the eyes and brain could be separately illuminated. LL was continued for another 6 h in vitro for either the eyes or the brain but not both. During the in vitro LL optic nerve activity was blocked with isotonic sucrose to prevent transfer of photoreceptor information between the eye and brain. The magnitude of Δφ in the attached eye was determined by the LL/DD applied to the eye and not that applied to the brain. Thus, dominant photoreceptors for the second timing mechanism, and probably the mechanism itself, are in the eye. The question of how the optic efferents contribute remains unanswered.Perhaps they facilitate coupling between two ocular oscillators. NSF 28251, NS 12374.

851 Role of the Pneumostome Motor System in Water Balance and Respiratory Function in the Terrestrial Slug, Limax maximus. David J. Prior, School of Biological Sciences, University of Kentucky, Lexington,KY.40506

A major problem faced by air breathing animals is the threat of dehydration due to evaporative water loss across respiratory surfaces. Many behavioral responses to dehydration result in reduction of the area of exposed respiratory surface. This however leads to a physiological dilemma; responses which reduce water loss likewise reduce oxygen uptake. Therefore such behaviors must be balanced responses to both dehydration and oxygen demand. Using the terrestrial slug, Limax maximus, we have begun a study of the neural control of the behavioral responses to dehydration and oxygen demand. In a hydrated Limax, the pneumostome is continually open. Following a specific level of dehydration(10% loss of body weight) the pneumostome begins to open and close rhythmically, an activity that can reduce both water loss and oxygen uptake. In that the onset of the pneumostome rhythm corresponds with a specific level of hydration the possibility exists that the sensory cue initiating the activity is increased hemolymph osmolality. To test this hypothesis the osmolality of hemolymph from slugs at varying levels of hydration was measured. Dehydration results in an increase in hemolymph osmolality that is essentially linear. Hence this variable could be involved in the onset of the pneumostome rhythm. This hypothesis is being further tested using a brain-pneumostome preparation that allows intracellular recordings to be made from abdominal ganglion neurons whose activity is correlated with the opening phase of the pneumostome rhythm. Their activity patterns are affected by varying the osmolality of the perfusion medium. An attempt is being made to study the responsiveness of these and other neurons to saline osmolalities in the range that corresponds to the initiation of the pneumostome rhythm. Supported by NSF #BNS 74-15217-A01 and an Alfred P. Sloan Fellowship.

852 MORPHOLOGICAL PARAMETERS OF THE SQUID GIANT SYNAPSE: RELATIONSHIP OF ACTIVE ZONE PARTICLES TO IONIC CONDUCTANCE. D. W. Pumplin, R. Llinás and T. S. Reese. Dept. Anat., Univ. of Md. Med. Sch., Dept. Physiol. Biophys., NYU Sch. Med. and Lab. Neuropath. Neuroanat. Sci., NINCDS, NIH, Bethesda, MD 20205.

Previous studies of the giant synapse of the squid Loligo peali (Pumplin and Reese, Neurosci. 3,685) showed this synapse to consist of a number of active zones (AZ) defined by: 1) parallel appositions between membranes of the pre- and postsynaptic giant axons, 2) electron-dense fuzz subjacent to both membranes and within the synaptic cleft, and 3) clusters of vesicles within the presynaptic cytoplasm. Freeze-fracture revealed patches of large, relatively-homogeneous, intramembranous particles in the cytoplasmic leaflet of the presynaptic membrane and in the external leaflet of the postsynaptic membrane. These patches were coextensive with each other and with AZ seen in thin sections. From the freeze-fracture data, the concentration of particles at the presynaptic AZ was $1.5\pm.3 \times 10^3$ (N=17) particles/μ^2. In addition, ultra-thin sections were taken at 50μ intervals through an entire giant synapse. The length of AZ appearing in a section at each interval was plotted vs. the distance along the synapse (total distance=900μ); the curve was relatively smooth, tapering off slowly toward the distal end of the presynaptic axon. The total area of AZ (area under the curve) was $1.3 \times 10^4 \mu^2$. By plotting the distribution of lengths of individual AZ in thin sections, and assuming that these lengths were sections through circular active zones whose diameters had a normal distribution, we estimated the average AZ area as $1.25\pm.4\mu^2$. From these figures, the entire synapse contained 2.0×10^7 presynaptic particles in 1.1×10^4 active zones with 1.8×10^3 particles each. Assuming that each presynaptic particle is, or contains, a voltage-sensitive channel for Ca^{2+}, the conductance of such channels may be calculated from the total synaptic conductance. The resulting estimates are 8.5 Ca^{2+}/spike/particle with a Ca^{2+} conductance of 0.2 picosiemens/particle. These estimates agree with values for the Ca^{2+} conductance of individual channels derived from noise analysis studies on molluscan neurones (Brown, Akaike, and Lee, Ann. N.Y. Acad. Sci.,1978). In addition, the number of postsynaptic particles is about equal to the number of presynaptic particles. From the total postsynaptic current, the calculated conductance is 1-10 picosiemens/particle, again in agreement with results of noise analysis on Na^+ channels. The agreement between these sets of data suggests that equating presynaptic active-zone particles with Ca^{2+} channels, and postsynaptic particles with channels carrying postsynaptic current, is quantitatively reasonable.

853 IDENTIFIED CELLS R2 AND P1 CONTROL MUCUS RELEASE IN *APLYSIA:* A MODEL SYSTEM FOR STUDYING THE DEVELOPMENT OF BEHAVIOR ON THE CELLULAR LEVEL. Stephen Rayport and Eric R. Kandel. Division of Neurobiology & Behavior, Depts. Physiology & Psychiatry, Columbia University, P & S, New York, N.Y. 10032

The cholinergic cells R2 and P1 are among the largest and the best studied identified cells in *Aplysia*. Despite this, their behavioral function has not been known. The cells send axons into all the pedal and parapodial nerves and receive sensory input from all surfaces of the body (Hughes, J Exp Biol 46:169, 1967). Although each cell sends axons bilaterally, ipsilateral input is more effective in stimulating each cell. The cells are output cells since they make no known central chemical synapses, and *in vivo* recording in the adult shows that all action potentials flow towards the periphery (Cobbs & Pinsker, J Neurobiol 9:121, 1978).

With this background, we considered two possible behavioral roles involving the body wall: control of motor output and control of mucus release. We ruled out a motor role by stimulation of R2 alone or in conjunction with a foot or parapodial motor neuron and saw no interaction of any sort. By contrast, tests for mucus release were positive. We severed the cerebral commisure so that each cell was only connected to its ipsilateral axons and compared one side of the animal against the other over time. We modified CM Lent's carmine red assay (Science 179:693, 1973) for use on *Aplysia* and saw a significant difference between stimulated and control sides with as few as a few hundred spikes in the stimulated cell.

In the adult, graded mucus release is primarily a defensive behavior that may serve a specific role in the hierarchy of defensive responses intermediate between withdrawal, mediated by low threshold, spontaneously active motor neurons which are not coupled electrically; and inking controlled by high threshold motor cells that are well coupled electrically, and silent except when they fire all-or-none bursts. R2 and P1 are typically silent, but readily activated by synaptic input, and functionally uncoupled electrically in the adult.

Recording from R2 is feasible at least from the time of metamorphosis and perhaps earlier. One can therefore use this cell and the afferent input to it to examine on the cellular level how a behavior and its capabilities for being modified (Kandel & Tauc, J Physiol 181:1, 1965) develop.

854 NEURONAL PATHWAYS INVOLVED IN TRANSFER OF INFORMATION RELATED TO LEG POSITION LEARNING IN THE COCKROACH, P. AMERICANA . Roger L. Reep and E.M. Eisenstein, Zoology and Biophysics Departments and Neuroscience Program, Michigan State University E. Lansing, Mi. 48824

Behavioral experiments have shown that transfer of information related to leg position learning occurs via the interganglionic connectives. Anatomical and electrophysiological experiments were done to identify specific pathways by which information transfers from the prothoracic to the mesothoracic ganglion. Phase and electron microscopy were used to map the projections of sensory fibers which carry shock information from the leg to the CNS. These fibers were found to terminate ipsilaterally and ventrally in the neuropile of the ganglion with which the leg was associated. Cobalt staining of leg motorneurons showed that their CNS branches are wholly contained within the ipsilateral portion of the ganglion from which their axon exits peripherally. Since neither sensory nor motor neurons have branches that project interganglionically, all transfer must be via interneurons in the connectives. Groups of interneurons were stained and found to have ipsilateral and contralateral branches in both the prothoracic and mesothoracic ganglion.

Suction electrode recordings of connective interneurons showed that some large fibers carry corollary discharges of leg motorneuron activity. There is a one-to-one copy of spikes in corollary units of flexor motorneurons and an approximate copy of spikes in corollary units of extensor motorneurons. Corollary units were found in ipsilateral and contralateral descending connective fibers for prothoracic flexor and extensor motorneurons and in ipsilateral and contralateral ascending connective fibers for mesothoracic flexor and extensor motorneurons.

We hypothesize that sensory information related to prothoracic leg shock and motor information related to prothoracic leg position are independently transferred (by interneurons) down each prothoracic-mesothoracic connective to the mesothoracic ganglion, where they are associated and lead to the observed behavior change in mesothoracic legs.

855 FEEDING MODULATION IN LIMAX: BEHAVIOR AND PHYSIOLOGY. Stephen C. Reingold & Alan Gelperin, Dept. Biology, Princeton University, Princeton, N. J. 08544.

A central neuronal pattern generator underlies movements of buccal musculature used in feeding by the terrestrial mollusk Limax maximus. The activity of the pattern generator is independent of sensory feedback. However, feeding activity in intact animals and feeding motor program (FMP) in isolated nervous system preparations can be modulated by changes in food-related sensory stimuli. We examined the effects of load on buccal muscles, concentration of food substances, and gut feedback, on feeding in intact animals and FMP in isolated preparations.

To monitor feeding movements in intact animals, pellets of prepared food in an agar matrix were attached to the arm of a movement transducer. Sequences of individual "bites" were recorded and data analysed in terms of instantaneous bite frequency throughout a meal, and meal duration. By varying the amount of agar and amount of food extract in a pellet, hardness and chemostimulative quality of food were varied, and the effects on feeding determined.

Isolated preparations consisted of buccal and cerebral ganglia with attached chemoreceptive lips. Delivery of food extract to lips triggered bouts of FMP, recorded by extracellular electrodes. Innervated buccal muscles or esophagous and crop were included in some preparations. Effects on FMP of load on buccal muscles, concentration of food extract, or degree of esophagous/crop inflation were examined.

LOAD. Increasing hardness of a food pellet increased load on feeding apparatus in intact animals. Individual animals fed on a hard pellet (15% agar base) showed a lower instantaneous bite frequency than when fed on a soft pellet (3% agar base). Weights attached to buccal musculature in isolated preparations provided analogous load increase during FMP. Instantaneous FMP frequency was lower with muscles loaded than unloaded.

FOOD CONCENTRATION. In intact animals, increases in concentration of attractive food substance in a food pellet increased both number of animals which fed and duration of a meal once feeding had begun. Instantaneous bite frequency was unchanged. In isolated preparations, duration of FMP was similarly increased in response to more concentrated food substances, but instantaneous FMP frequency was constant.

GUT FEEDBACK. Intact slugs use satiety signals from gut distention to terminate feeding activity: an animal will eat the same amount of food (weight) on successive days, independent of the type of food consumed. In isolated preparations with esophagous and crop attached, inflation of the crop with saline injections served to terminate FMP as well as to reduce peak FMP frequency. 856 EFFECT OF PAIRED STIMULATION OF GIANT INTERNEURONS IN THE COCKROACH PERIPLANETA AMERICANA. Roy E. Ritzmann Dept. Biol., CWRU, Cleveland, OH 44106

Recent evidence indicates that the 14 giant interneurons (GIs) of the cockroach Periplaneta americana can excite motor neurons which direct movements of the metathoracic (T3) legs (Ritzmann and Camhi, J. comp. Physiol. 125:305-316, 1978). Each of the GIs is excited by a specific set of wind directions (Westin et al., J. comp. Physiol. 121:307-324, 1977). The specificity of the wind input and the motor output of each GI suggests that they may play an important role in directing the wind mediated escape behavior (Camhi and Tom, J. comp. Physiol. 128:193-201, 1978). However, a wind stimulus from any direction will excite 8-12 GIs simultaneously. Therefore, in order to understand how the GIs function in response to natural stimuli, we must know how the output of these cells combine when more than one GI is excited.

With this in mind, I have investigated the motor response to intracellular stimulation of pairs of GIs. The GIs were impaled with microelectrodes filled with 4% Procion yellow as in previous experiments (Ritzmann and Camhi, 1978). They could then be stimulated with high frequency trains of current pulses while motor activity was monitored with extracellular electrodes on nerve branches 5r1 (containing primarily depressor axons) and 6Br4 (containing primarily levator axons) in one of the metathoracic legs. Subsequent to the recording session Procion yellow was iontophoresed into the GIs for histological identification. A paired T-test was used to compare the motor response to stimulation of each GI individually and the response to stimulation of both GIs together.

When two dorsal GIs were stimulated, the motor activity was summed. For example, GI-5 excites primarily depressor motor neurons, while GI-7 excites both levators and depressors. When GIs 5 and 7 were both stimulated the resulting depressor activity was greater than that from either GI alone. Moreover, when the GIs were paired, less activity in either GI was required to elicit a motor response than when they were stimulated individually. A similar situation occurred when two ventral GIs were stimulated. GI-2 enchanced the output of GI-1 when these cells were paired. However, when ventral and dorsal GIs were paired, the result was not as expected. GI-1 and GI-5 both excite primarily depressor motor neurons. Nevertheless, in the paired situation the depressor output was less than that from GI-5 alone. The ventral GI appeared to inhibit the output of the dorsal GI. This suggests that the dorsal and ventral GIs are not designed to operate together. Rather, they may represent two distinctly separate pathways.

858 EFFERENT NEURONS TO THE RETINA OF OCTOPUS: ANATOMY AND PHYSIOLOGY. William M. Saidel* (SPON: T.H. Bullock). Dept. of Neurosci., Sch. Med., UCSD, La Jolla, CA 92093

The eye of Octopus bimaculoides is connected to the ipsilateral optic lobe by about 150 small retinal nerves. Each nerve contains both centripetal and centrifugal fibers. Using the proximal stump of a cut nerve as a wick for cobalt staining, the relationship within the optic lobe between photoreceptor axon terminations and optic lobe cells stained through a given nerve has been determined and confirmed by HRP eye injections. Photoreceptor terminations from a single nerve are found predominantly in an area of the optic lobe plexiform layer restricted along the anteroposterior axis. Most efferent cells whose axons travel in the same nerve are found within the inner granule layer directly below the area of photoreceptor terminals. A few other cells are found deeper within medullary cell islands. Efferent cells may be uni-, bi- or multipolar. A striking characteristic of many cells is the axon collateral projecting into the same plexiform level at which the type II photoreceptors end.

Physiological activity of these cells in restrained animals has been recorded with suction electrodes from intact and cut retinal nerves. Activity from these cells can be distinguished from that of photoreceptors by their shorter (1.5 vs. 5 ms) spike duration. Efferent cells show responses to visual, tactile or statocyst stimulation. Steps of increasing light cause a delayed, transient spike frequency increase followed by a steady state whose frequency depends on the amplitude of the step. Reverse steps cause a frequency decrease whose size is proportional to the amplitude of the step and also prior activity. Hysteresis occurs, depending upon prior retinal adaptation.

A water stream or stroking the mantle or web produce two kinds of responses: a transient burst or suppression of background activity. Suppression also spontaneously followed a mantle movement resembling swimming or escape movements seen in the wild. Bursts of spikes were induced by vibrating the experimental chamber and by angular rotation of the preparation presumably via disturbance of the statocysts.

Golgi material indicates that these cells terminate at or near photoreceptor inner segments. The anatomy and physiology of these cells suggest a local feedback loop from a portion of the retina to a restricted portion of the optic lobe and back to the retina.

857 PURIFIED BAG CELL PEPTIDE MIMICKS SOME BUT NOT ALL RESPONSES OF CENTRAL NEURONS TO BAG CELL STIMULATION IN APLYSIA. B.S. Rothman, P. Brownell* and E. Mayeri, Department of Physiology, UCSF, San Francisco, CA 94143.

An electrically stimulated discharge of bag cells produces a variety of distinct effects, each lasting several hours, in other neurons of the isolated abdominal ganglion. Certain left upper quadrant (LUQ) cells (L2,3,4,6) are inhibited; left lower quadrant (LLQ) cells of the LB and LC clusters show a marked increase in tonic activity; and in cell R15, bursting pacemaker activity is augmented (Mayeri et al., 1979). Egg laying hormone (ELH), a peptide isolated from bag cells, is the putative mediator of the effect on R15, since application of ELH to the cell's soma mimicks the effect of bag cell discharge (Branton et al., 1978).

To further investigate the mediation of bag cell effects, we isolated a basic peptide from bag cells by extraction in formic acid, fractionation on G-50 Sephadex and elution from CM-25 Sephadex, a cation exchange resin. The peptide has an apparent molecular weight of 4200 on SDS-polyacrylamide gels and is 84% pure based on an amino acid analysis. In preliminary experiments (N= 2, F.E. Dudek, personal communication) at 0.1 μM it released eggs from isolated fragments of Aplysia ovotestis.

In desheathed ganglia, somatic application of the peptide not only augments burst activity in R15, but also increases tonic activity in LLQ cells. The threshold for both responses is about 1 μM, with increasing intensities of response at higher concentrations. At the highest concentration used (300 μM) no inhibition of LUQ cells occurred, even though at this dose the intensity of the R15 response was greater than normally seen after bag cell discharge. Injection of the peptide (0.1 to 300 μM) into the caudal artery of the ganglion, with sheath intact, produced almost identical results as those obtained by somatic application. The lack of LUQ response is not explained by inaccessibility of perfusates to critical target sites since 1) arterial application of peptide did produce responses in R15 and LLQ cells, and 2) arterial application of acetylcholine (100 μM) produced its expected inhibitory effect on LUQ cells.

These data suggest that ELH mediates two distinct excitatory responses in target neurons, although at present we cannot rule out the possibility of more than one active factor in our purified material. These data also suggest that the peptide(s) causing the excitatory responses does not directly produce the LUQ inhibition. Supported by NIH postdoctoral fellowships: NSO 7067 and NSO 5931 and NSF grant BNS 76-20978.

859 OPTICAL SPIKES FROM A SALIVARY GLAND.

B.M. Salzberg and D.M. Senseman*. Dept. of Physiology and Pharmacology, School of Dental Medicine, University of Pennsylvania and Monell Chemical Senses Center, Philadelphia, PA 19104.

The mechanism(s) underlying excitation-secretion coupling in gland cells is not presently understood. The small size of many of these cells has limited the utility of conventional intracellular microelectrode recording. Since optical measurement of membrane potential has proven possible in giant axons, invertebrate central neurons, and vertebrate skeletal and cardiac muscle, as well as a number of other preparations, we hoped that these techniques could be used to study electrical phenomena in glandular tissue. In an effort to establish the feasibility of this approach for endocrine as well as exocrine glands, we attempted first to use optical probes to follow electrical activity in an exocrine gland which is also amenable to microelectrode methods. The salivary gland of the snail Helisoma trivolvis has been shown to produce overshooting action potentials and, in the experiments to be reported here, the Merocyanine-oxazolone dye NK 2367 was used to record extrinsic voltage dependent absorption changes from extended regions of this gland while electrical activity in a single ascinar cell was monitored simultaneously with a microelectrode. Optical signals easily visible in a single oscilloscope sweep could be obtained whether the gland was superfused or perfused through the lumen with a Ringer's solution containing the dye. The wavelength dependence of the optical signal differed significantly from that exhibited by this dye when applied to voltage clamped squid giant axons or barnacle supraesophageal ganglion cells, but was similar to that found with a close Merocyanine-rhodanine analogue (Dye XVII) in cardiac muscle. The largest signal:noise ratio was measured at 676 nm, where there was an increase in absorption by the stained gland. Decreases in absorption were recorded at 540 nm and 720 nm. In squid giant axons, a depolarization resulted in a decrease in absorption at all wavelengths measured.

We attributed some observed variability in the amplitude of the optical signal to differential invasion of the gland, and, in order to study this phenomenon further, electrical activity in the salivary gland was monitored optically for 50 seconds at a time while intracellular microelectrode recordings were made from the primary neuroeffector cells in the buccal ganglion. Compared with its bilateral homologue, activity in the contralateral effector neuron seemed to evoke electrical changes in the gland which were accompanied by smaller optical signals.

Supported in part by NSF grant BNS 7705025, NIDR grant DE-05271 and BRS grant RR-05337-17.

860 TRIMETHADIONE HAS DIFFERENTIAL EFFECTS ON NORMAL AND PROLONGED ACTION POTENTIALS IN NEURON R2 OF APLYSIA. O. Sartor*, W.M. King* and N.R. Kreisman (SPON: A. Epstein). Dept. of Physiology, Tulane U. Sch. Med., New Orleans, LA 70112.

Effects of trimethadione (TMO), the prototypical drug for treatment of petit mal epilepsy, were studied on somatic action potentials in neuron R2 of the abdominal ganglion of Aplysia californica. Intracellular stimulation and recording was accomplished by inserting two 3M KCl filled glass micropipettes into R2.

In artificial seawater (ASW), TMO (10 mM) increased the action potential repolarization time (RT) (Horn and Miller, J. Neurobiol. 8:399-415, 1977) by 37-60% in four experiments. This prolongation of RT occurred without any change in action potential amplitude. In 0 Ca^{++} ASW, 10 mM TMO produced a maximum increase in RT of only 10%.

The addition of 50 mM tetraethylammonium (TEA) bromide or chloride to ASW resulted in prolonged action potentials with RT's of usually 50-200 msec in different experiments compared to RT's of 1.6-2.6 msec in ASW. The RT of action potentials in all experiments was noticeably dependent upon the stimulus rate and the resting membrane potential value. TMO (10 mM) caused a 33-41% reduction in the RT of action potentials in ASW + TEA.

In addition to effects on action potential RT, 10 mM TMO also increased threshold for spike generation by 250-300% in ASW. Threshold was determined by measuring the magnitude of a 100-1000 msec constant currect pulse just sufficient to elicit a soma spike. All effects of TMO were reversible upon flushing with 20 times the chamber volume.

The effects of TMO on spikes elicited in ASW can be interpreted as an increase in gCa^{++} (see Klein and Kandel, PNAS 75:3512-3516, 1978). Our experiments in 0 Ca^{++} ASW tend to support this suggestion. The effect of TMO on the TEA spikes, however, would conventionally be taken to indicate that TMO decreases gCa^{++}. Possible explanations for this apparent discrepancy are that TMO enhances the Ca^{++} dependent increase in K^+ conductance (Meech, Comp. Biochem. Physiol. 42A:492-499, 1972) and/or enhances the Ca^{++} dependent inactivation of gCa^{++} (Tillotson, PNAS 76:1497-1500, 1979).

861 PRESYNAPTIC INHIBITION AND THE CONTROL OF TRANSMITTER RELEASE BY PRESYNAPTIC MEMBRANE POTENTIAL: IONIC MECHANISMS FOR SYNAPTIC MODULATION IN APLYSIA. E. Shapiro*, V. Castellucci, and E.R. Kandel. Div. of Neurobiol. & Behav., Depts. Physiol. & Psychiat. Columbia University, P&S, New York, N.Y. 10032

We have examined the relationships between transmitter release and specific ionic currents of the presynaptic cholinergic double action neuron L10 by simultaneously voltage clamping the presynaptic cell body and assaying transmitter release with intracellular recording from the postsynaptic cell under various pharmacological conditions.

When, in the presence of TTX, cell L10 is voltage-clamped from a holding potential of -60mV graded transmitter release can be evoked by graded depolarizing command pulses in the range of membrane voltage (-35mV to +10mV) in which the Ca^{++} current is also increasing. Depolarizing the holding potential of L10 results in increased transmitter output (Shimahara & Peretz, 1978; Nicholls & Wallace, 1978). Two ionic mechanisms contribute to this form of plasticity. First, depolarization inactivates some K^+ channels so that command pulses recruit a smaller K^+ current. In unclamped cells the decreased K^+ conductance causes spike-broadening and increased influx of Ca^{++} during each spike (see Klein and Kandel, 1978). Second, small depolarization around resting potential (-55mV to -35mV) activates a steady-state Ca^{++} current which also may contribute to the modulation of transmitter release, since even with most presynaptic K^+ currents blocked (using Ba^{++} substitution for Ca^{++}, TEA^+, and 4-AP) varying holding potential still affects transmitter release (see also Nicholls & Wallace, 1978). In contrast, under these conditions, the transient inward Ca^{++} current evoked by depolarizing clamp steps is relatively unchanged from various holding potentials.

The output of cell L10 undergoes presynaptic inhibition in response to connective stimulation. Since depolarization (postulated for primary afferent fibers in vertebrates) cannot be responsible for this effect (see also Mudge and Fishbach, 1978), we examined changes in presynaptic currents during presynaptic inhibition in L10. The inhibition could still be obtained with pharmacological blockage of K^+ currents. Reduction in transmitter release is correlated with decreases in transient and steady-state presynaptic Ca^{++} current.

Our results show that these two forms of synaptic plasticity are due to modulation of the Ca^{++} current which contributes to transmitter release. This current can be controlled in at least 3 ways: 1) By membrane potential control of available K^+ channels which can broaden or narrow spikes and indirectly modulate Ca^{++} inflow. 2) By direct steady-state activation of Ca^{++} channels at more depolarized membrane potentials. And, 3) by transmitter-mediated decrease of Ca^{++} current.

862 ORDERLY SEQUENCE OF POLYSYNAPTIC SENSORY INPUTS TO CRAYFISH TAILFLIP MOTONEURONS. Dyane N. Sherwood and Jeffrey J. Wine. Dept. Psych., Stanford U., Stanford, CA. 94305

The only tailflip command neurons that are excited by sensory stimulation in the isolated crayfish abdomen are the lateral giants (LGs) (Wine & Krasne, 1972, J. exp. Biol.56:1). Following an LG command, all of the efferents to the fast flexor muscles receive synaptic inputs: the motor giants (MoGs) are directly excited by the LGs and inhibited via polysynaptic pathways (Furshpan & Potter, 1959, J. Physiol. 145:289); the nongiant motoneurons (FFs) are excited by electrically-mediated PSPs (Zucker, 1972, J. Neurophysiol. 35,638); and the peripheral inhibitors (FIs) are excited with a delay (Wine & Mistick, 1977, J. Neurophysiol. 40:904).

It had been thought that sensory stimulation plays only a triggering role, with motor organization left to the central command. However, we have now demonstrated a set of polysynaptic pathways that are excited by nearfield stimuli and excite or inhibit all three classes of flexor efferents. A notable feature of the sensory pathways is that the order in which their effects are delivered to the flexor efferents matches the order of firing imposed by the LG command cells. Specifically, the effects of these pathways are (1) inhibition of MoGs, (2) subthreshold excitation of FFs via chemical synapses, and (3) sub- and suprathreshold excitation of FIs. Sensory-derived PSPs can summate in the efferents with giant-evoked PSPs. Further, sensory stimuli can facilitate indirect pathways from the LGs to the flexor efferents.

Sensory inputs to each class of cell must arrive via at least partially independent pathways, in order to explain the selective timing. Further details of the pathways were obtained by simultaneous recordings from FIs and motoneurons in different ganglia. PSPs in different FIs are always correlated 1:1, whereas PSPs in different MoGs often are not. We interpret this to mean that FIs receive direct inputs from interganglionic interneurons, whereas local (segmental) interneurons may be in the pathways to the MoGs.

For giant-mediated tailflips, the decision to move is made at the command cell level, and its outputs dictate the appropriate sequence of activity in the flexor efferents; whether the additional sensory-motoneuron pathways play a role beyond reinforcing the giant commands is not yet known. However, many tailflips are mediated by so-called nongiant pathways (Wine & Krasne, 1972). For these behaviors, the locus of decision may shift to the motoneurons, and the sensory pathways may then play an important role in insuring the orderly sequence of efferent activity.

863 NON-SPIKING INTERNEURONS AND CONTROL OF POSTURE IN LOCUSTS. Melody V.S. Siegler* (SPON: P. D. Evans) Dept. Zoology, University of Cambridge, Cambridge, CB2 3EJ, U. K.

The metathoracic ganglion of the locust Schistocerca americana gregaria (Dirsh) contains local non-spiking neurons which can effect graded changes in the membrane potential of identified motor neurons of the hind legs (1,2,3). This study examines the relationship between imposed changes in the posture of a hind leg and tonic changes in the effectiveness of non-spiking neurons in producing changes in the membrane potential of motor neurons.

Simultaneous intracellular recordings were made from non-spiking neurons and motor neurons (2). The coxa and femur of the hind leg ipsilateral to the penetrated motor neuron were fixed. Imposed movements of the tibia set the femur-tibial angle (FTA) at either 0^o (flexed), 90^o, or 140^o (extended). The following results were obtained when the set position of the tibia was altered at 15-30s intervals. (a) In some non-spiking neurons that affect tarsal motor neurons, the tonic change in membrane potential was 8-10 mV, but in others that affect tibial motor neurons, the change was only 1-2 mV. (b) Different interneurons were maximally sensitive to different ranges of tibial movement; e.g., some showed the greatest tonic changes when the FTA was reset between 90^o and 140^o, others when the FTA was reset between 90^o and 0^o. (c) Most interneurons showed hysteresis in their tonic response to changes in FTA. The tonic membrane potential at 90^o was different when this position was approached from 0^o than if approached from 140^o. (d) Tonic changes in membrane potential could be of opposite polarity to phasic changes which occurred as the tibia was moved. (e) The effectiveness of non-spiking neurons in producing changes in the membrane potential of motor neurons was dependent upon the position of the tibia; the curve relating presynaptic current to postsynaptic change in voltage was shifted by changing the FTA. This change appeared in part to be due to a tonic change in the membrane potential of the non-spiking neuron, and could not be explained by tonic changes in the membrane potential of the motor neuron.

It is hypothesized that tonic changes in the membrane potential of non-spiking neurons are important in maintaining posture. In addition, the effectiveness of other synaptic inputs to an interneuron could be modified or "gated" by changes in the posture of the animal.

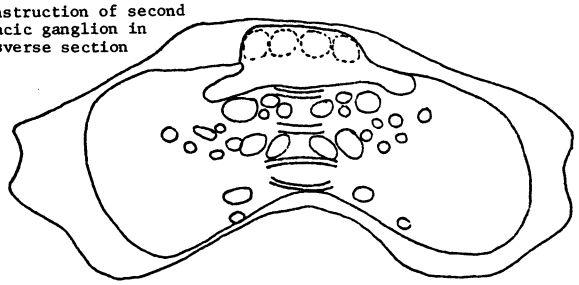
864 THE ANATOMICAL ORGANIZATION OF CRAYFISH SEGMENTAL GANGLIA. Kate Skinner. Dept. Zool., UCD, Davis, CA 95616.

The structural organization of crustacean ventral cord has been investigated using cobalt backfills and serial sections, silver-stained by the method of Rowell, of Procambarus clarkii thoracic and abdominal ganglia. The basic pattern of longitudinal tracts, cross-ganglion commissures and vertical tracts is being mapped. The major groups of cell bodies and the central projections of the peripheral nerves will be localized in terms of these landmark pathways.

The segmental ganglia are built on a sandwich plan of alternating longitudinal and commissural bundles of axons which form tracts through the ganglia. The most dorsal longitudinal tract contains the giant fibers and has the largest cross-sectional area. The most ventral longitudinal tract layer is the smallest in cross-sectional area. There are seven major commissures which cross the midline of the ganglion in four broad bands or layers. Between commissural layers three and four, in the ventral part of the ganglion, lies a dumbbell-shaped mass of very finely textured neuropil which may be homologous with the "ventral association center" of insect segmental ganglia (Pipa et al., 1959; Gregory, 1974; Tyrer, pers. com.). It is not yet known whether the layers carry comparable numbers of fibers or whether the neuropilar masses can be assigned behavioral or physiological functions.

Reconstruction of second thoracic ganglion in transverse section



The histological maps will make it possible to localize identified neurons more precisely within the ganglion (Stretton and Kravitz, 1973), to quantify the constancy and variability of individual neurons relative to stable "addresses" within the neuropil, to test ideas about the functional layering of invertebrate ganglia, and to propose homologies between related taxa.

865 THE EQUILIBRIUM SYSTEM OF A BURROWING COCKROACH: AFFERENT TO INTERNEURON CONNECTIVITY. Randall R. Stewart and H. Bernard Hartman. Dept. of Biol. Sci. Texas Tech Univ., Lubbock, TX. 79409.

In the equilibrium system of the cockroach Arenivaga, each of four interneurons are excited primarily by one of four rows of tricholiths. Tricholiths are spheroid-shaped sensilla, each about 15 μ in diameter, located in rows on the ventrobasal surface of the cerci. Two rows, a medial and a lateral, are found on each cercus. Extracellular recordings made from the connectives show that the interneurons signal the animal's spatial position. The larger interneuron, termed Positional Interneuron Ipsilateral or PII, receives its input from tricholiths on the medial row of the ipsilateral cercus; the smaller interneuron, called Postional interneuron Contralateral or PIC, is driven by tricholiths in the lateral row of the contralateral cercus.

Does a singular association exist between one row of tricholiths and one interneuron, or do the sensilla of a row contribute input whether excitatory or inhibitory to the other three interneurons? Three types of experiment were performed to answer this question. In the first, termed a cercal reflection experiment, recordings were made from both connectives of the ventral nerve cord during controlled changes in the animal's spatial position while the left cercus was moved anteriorly and posteriorly to alter the output of the PII's and PIC's driven by that cercus. Would changes in the output from the left cercus alter the response pattern of interneurons driven by the right cercus? The positional interneuron responses were graphed as a polar plot. No significant changes in the control cercus polar plot as a result of manipulation of the opposite cercus were observed indicating that a singular association does exist. In the second experiment, single rows of tricholiths were removed, and the effect of the removal on the responses of the remaining three position interneurons determined. Upon removal of either a medial or lateral row, the position interneuron response driven by the remaining row on that cercus increased. Thus, intracercal inhibition is suggested. No changes in output of interneurons driven by the opposite cercus could be detected. In the third experiment, with the animal tilted to a particular orientation, two or three tricholiths in a row were moved with a piezoelectric driven probe, and the output of all four interneurons observed. Medial row tricholiths on one cercus evoked consistent activity in the PIC driven by the other cercus suggesting intercercal interaction. No evidence could be found for intracercal inhibition with this method. Because of the conflicting results, improved manipulative methods are being employed to resolve the question posed.

866 A CINEMATOGRAPHIC ANALYSIS OF FEEDING IN THE OPISTHOBRANCH MOLLUSC, NAVANAX. A.J. Susswein, M.S. Cappell, D.C. Spray and M.V.L. Bennett. Dept. Neurosci., Albert Einstein College of Medicine, Bronx, NY 10461

Motoneurons to feeding musculature in Navanax have been extensively characterized; however, the firing pattern of these motoneurons during feeding has not been studied. To understand the neural generation of feeding behavior, it is first necessary to describe the behavior. To this end, we have filmed feeding in Navanax. We have addressed ourselves to three questions: 1) What is the sequence of events in feeding? 2) Is the sequence a fixed action pattern, or can components of feeding occur without the entire sequence? 3) Is the sequence sufficiently unaffected by dissection that a feeding preparation is suitable for electrophysiological study?

Feeding begins with slow protraction of the pharynx, followed by expansion of the anterior pharynx and flaring of the lips around the prey. Removing prey during protraction or flaring stops feeding. Prey engulfment begins with a fast, lunging protraction, followed by lip closure that seals prey in the anterior pharynx. Engulfment continued with pharyngeal expansion and retraction. Removal of prey during sealing alters this sequence; retraction occurs without expansion. Expansion produces negative pressure, pulling prey into the pharynx. Holding the prey in place at the anterior pharynx does not eliminate posterior expansion; however, a second expansion superimposed upon the first may occur. Expansion is followed by contraction of circumferential musculature. There are both inward- and outward-directed waves of circumferential contraction around prey, as well as more localized movements. Motoneurons producing movements reminiscent of those observed in specific phases of feeding have been identified.

Essentially identical sequences of movement have been observed in animals in which progressively larger segments of body wall were removed for better visualization of the pharynx and CNS. Successful prey engulfment occurs even in radically dissected preparations. This insensitivity to operative procedures allows for recording from muscles and nerves in normally feeding preparations, which should confirm the functional role of specific motoneurons.

867 LOCALIZATION OF DOPAMINE IN THE GILL OF APLYSIA: SOME PHYSIOLOGICAL IMPLICATIONS. John W. Swann, Martha G. Pierson*, and Annica Dahlström*. Neurobiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014 and Institute of Neurobiology, University of Göteborg, Göteborg, Sweden.

The gill of Aplysia contains 3 ug of dopamine (DA) per gram of tissue. Physiological experiments utilizing the semi-intact gill preparation led one of us (JWS) to hypothesize that DA acts as a neurotransmitter for both motor and modulatory neurons thought to innervate the gill musculature (Swann et al., Br. Res. 157: 167, 1978). Additional experiments have suggested that L_9 neurons of the abdominal ganglion are dopaminergic gill motor neurons (Swann et al., Neurosci. Letters 10: 275, 1978). In experiments reported here, the distribution of DA within the gill is examined anatomically using fluorescence histochemistry for catecholamines. The Hillarp Falck technique was used.

Green fluorescing nerve fibers, with the same emission spectrum as that of DA, are distributed on muscle fibers throughout the gill with the notable exception of the bundles of longitudinal muscle fibers of the efferent vessel. Green varicosities, indicative of DA nerve terminals, cover muscle fibers in four areas of the gill: the afferent vessel, the pinnules, the efferent vessel trunklets and the circular muscles of the efferent vessel. These four areas of the gill contract when small quantities of dopamine are added to a gill perfusate and, with the exception of the circular muscles of the efferent vessel, all of them contract upon activation of L_9 cells. These observations support the contention that DA is a neuromuscular neurotransmitter in the gill and that L_9 cells are dopaminergic.

Contractions of the longitudinal muscle fibers of the efferent vessel are initiated by firing motor neuron LDG_1. These contractions are greatly enhanced by perfusing the gill with DA. Since these muscle fibers are not innervated by DA-containing nerve fibers, dopaminergic modulation of LDG_1 contractions cannot be mediated physiologically by dopaminergic modulatory neurons as originally proposed. Instead, DA modulation of LDG_1 contractions may be humoral in origin. We have found that a major portion of the DA content of the gill is located in highly fluorescent structures which are in close association with the microvasculature of the gill. The cellular origin of this potentially humoral source of DA will be discussed.

868 IDENTIFICATION AND MORPHOLOGICAL VARIABILITY OF A PEPTIDERGIC NEURON IN THE HAWKMOTH. P.H. Taghert* and J.W. Truman (Spon: M.D. Binder). Dept. of Zoology, UW, Seattle, WA. 98195.

We are investigating the control over the release of a specific peptide hormone by studying the individual neurons responsible for its production in the tobacco hawkmoth, Manduca sexta. The hormone - bursicon - functions to trigger the sclerotization of the wing vein cuticle following adult emergence. In response to combined hormonal and neural inputs, the peptide is released from specific segmental nerves of the abdominal nervous system (Truman (1973) J.Exp.Biol. 58:821). This release is rapid - 10 min. - and predictable - within 2 min. of a behavioral marker (Reynolds et al (1979) J.Exp.Biol. 78:77).

Several lines of evidence were used to identify the bursicon neurons and these included: surgery to assess the ganglionic source of the hormone, electron microscopy to determine secretory axons and pathways, neurosecretory and cobalt chloride staining and hormonal assays of individual cell bodies. The combination of these results has provided an unambiguous identification of a set of neurons with the following characteristics. There are four bursicon neurons per abdominal ganglion (two symmetric pairs). Each pair of cell bodies lies in a relatively consistent dorso-lateral position. The bursicon neurons consistently send their axons out the ipsilateral 'ventral' nerve; they terminate in the neurohaemal transverse nerve via an anastomosis between the two nerves.

Centrally, the neurons share a unique and characteristic dendritic morphology. However, when comparing homologous neurons between animals, variations in the basic pattern do emerge. The major dendritic branches are consistently ventral in the neuropile; fine branching exists in a series of 2 to 4 ventral to dorsal columns. While column position is constant, the routes taken to column positions by major dendritic branches and which positions are reached at all is subject to variation.

869 MUTATIONS AFFECTING THE GIANT FIBER SYSTEM OF DROSOPHILA MELANOGASTER. Mark A. Tanouye* (SPON: R.J. Wyman). Biol. Dept., Yale Univ., New Haven, Conn. 06520.

Little is known about how the genome effects connections between neurons and establishes neuronal circuits. Although it is clear that there are not enough genes to specify each neural connection independently, there are no good theories which account for how single genes or gene combinations might provide the information necessary for proper nervous system connectivity. One method which can be used to investigate this problem is to use genetic mutations to disrupt neural circuits. The subsequent identification and analysis of these mutations would provide information about the nature of the disruption and perhaps ultimately an understanding of genetic contributions to neural connectivity.

In the present study, an attempt was made to identify genes which disrupt the proper functioning of a small neural circuit responsible for the jump response in D. melanogaster. The jump response is mediated via the cervical giant fiber whose connectivity has been described anatomically and physiologically in earlier investigations by our group. Genetic mutations affecting the giant fiber system were isolated in two steps. First, behavioral tests screened for mutants which couldn't jump. Second, electrophysiological screens identified those jumpless mutants with abnormal functioning of the giant fiber system.

The behavioral screen used visual and tactile stimuli to elicit jump behavior. Animals which jumped were eliminated and non-jumpers were saved. In the mutagenesis reported here, 56,805 X-chromosomes were screened behaviorally. These yielded 47 non-jumping mutant lines.

Giant fiber function was tested in non-jumping mutants by electrically stimulating the giant fiber and recording from thoracic muscles known to be driven by giant fiber spikes. A number of unusual responses were seen in the mutant lines including abnormally long response latencies and temperature sensitive paralytic phenotypes. In two mutant lines, thoracic muscles known to be driven by giant fiber spikes could not be driven. Results in these two mutants suggest a functional uncoupling of the giant fiber system.

870 LOCUST DORSAL OCELLI DETECT HORIZON DURING FLIGHT. Charles P. Taylor* (SPON: C. H. F. Rowell). Grad. Group in Neurobiology, Univ. of California, Berkeley, CA 94720.

The function of the ocelli, simple eyes located on the heads of many insects, was investigated in Schistocerca nitens and Schistocerca gregaria using neurophysiological and laboratory behavioral techniques. A survey of intracellular recordings of thoracic neurons revealed excitatory input to flight motor neuronsfrom ventral cord units activated by light flashes to the ocelli alone. This prompted behavioral investigations which made use of a visual horizon display (dark beneath, translucent above) which was rotatable about the animal's long axis. With compound optic lobes severed, the animal still tracked movements of the "horizon" with its head using the ocelli alone. A large tonically active axon in the ventral nerve cord consistantly showed correlation of spiking with ocellar-induced head motion toward one side and also had excitatory input from the cephalic wind-detecting hairs, and probably from other sensory modalities as well. This unit may represent a common neural pathway for roll axis orientation information from the head to the neck and thorax. The amplitude of head movements induced by the ocelli alone was small unless the animal was induced to tethered flight. During flight, however, the ocellar optomotor reaction was increased greatly in amplitude and was accompanied by corresponding flight steering behavior; the abdomen made rudder-like movements and the timing of wing depressor muscle unit (first basalar) firing changed so as to correct the visually detected "roll." Behavioral and optical evidence suggest the ocelli do not form a focussed retinal image, and that they probably detect horizon position by measuring average illuminance only.

The compound eyes alone can mediate a similar head-turning response which has been studied previously. However, with ocelli removed, the animal's ability to track movements of a diffuse horizon stimulus (sinusoidal light intensity gradient) during flight is greatly reduced. This may be because the extensive lateral inhibitory network of the compound eye, while enhancing sensitivity to sharp edges, makes it relatively insensitive to a continuous intensity gradient. Both ocellar and compound eye optomotor responses (measured separately) adapt to darkness sufficiently to operate on a dimly moonlit night. It is suggested that ocellar and compound eye-induced flight steering act synergistically, and posibly through a common neural pathway.

871 CONTROL OF SUPERFICIAL FLEXOR EFFERENTS BY ABDOMINAL CONNECTIVE FIBERS IN THE LOBSTER. Charlie S. Thompson* and Charles H.Page. Dept. Physiol, Bureau Biol. Res., Rutgers U., Piscataway,N.J. 08854.

The five excitatory motorneurons and the peripheral inhibitor which innervate the superficial flexor muscles (SFMs) in each half-abdominal segment of the lobster, Homarus americanus, were identified using electro physiological and cobalt staining techniques. Intracellular recordings from the cell bodies of the peripheral inhibitor (f5) and the largest motorneuron (f6) revealed three kinds of potentials: subthreshold depolarizing potentials (DPs), IPSPs and attenuated action potentials.

Abdominal connective fibers (ACFs) were divided into two groups depending upon their effects on the intracellular activity of the f5 and f6 neurons. First category ACFs elicited DPs in those neurons whose dendritic trees were located ipsilateral to the stimulated ACF. These DPs followed the stimulus with a fixed delay up to 50 Hz. The amplitude of the DPs varied with the stimulus frequency.

The second category of ACFs included those whose stimulation evoked DPs or IPSPs in f5 and f6 neurons which were not phase-locked with the stimulus. These fibers, which correspond to the extension and flexion command fibers (CFs) described in crayfish by Evoy and Kennedy (1967), produce strong bilateral effects when stimulated. Some fibers (extension CFs) elicit IPSPs in f5 neurons and an increase in DPs in f6 neurons while others (flexion CFs) produce an increase in DPs in f5 neurons and an apparent inhibition of DPs in the f6 neurons.

872 LOCUST OVIPOSITION: A SYSTEM FOR THE STUDY OF MOTOR PATTERN GENERATION. Karen J. Thompson, Dept. of Biology, Univ. of Oregon, Eugene, OR 97403.

Locusts, and other Acridids, have ovipositors which are unique among insects, since the four terminal processes work by a divergent motion instead of sliding upon each other (Quadri,M.A.H.(1940) Trans. Roy. Ent. Soc. Lond.90(6):121-175). At oviposition these structures on the female abdomen tip are used to dig a deep hole into which the eggs are laid. The dorsal and ventral valves, although derived from serially homologous embryonic appendages, have different functions; the ventral pair levers the abdomen down while the dorsal pair excavates the hole (Vincent,J. F.V.(1975) J. Ent.(A)50:175-181). Specializations found only in the female allow the motive force of the ovipositors to stretch the abdomen from a normal length of 2.7 cm. to 8.3 cm. (data apply to Shistocerca nitens).

A single ganglion of the locust nervous system, the terminal abdominal ganglion, is capable of driving the rhythmic oviposition movements made by the dorsal and ventral valves. Furthermore, this rhythmic behavior is reliably elicited by severing the ventral nerve cord. Once released, movements continue autonomously for hours.

The movements of the ovipositor valves are entirely controlled by six pairs of bilaterally symmetrical muscles. The ventral valves, sternal appendages of the eighth segment, are innervated by the 8th sternal nerves. The dorsal valves, sternal appendages of the ninth segment, are supplied by a serially homologous pair of nerves, the 9th sternal nerves. The somata and dendritic fields of the neurons whose axons travel in these nerves are compartmentalized into two separate regions of the ganglion.

This behavior can only be elicited in sexually mature adult females. Extracellular nerve and muscle recordings were made and show an autogenic cyclic motor pattern which is comprised of two major classes of alternating burst activity. These experiments were designed as a framework for intracellular analysis of the mechanisms underlying initiation and maintenance of oviposition behavior.

Supported by PHS 5 T32 GM07257.

873 CORRECTION OF TURNING BEHAVIOR AFTER UNILATERAL CERCAL ABLATION IN THE COCKROACH. Noga Vardi* and Jeffrey M. Camhi. (SPON. F. Delcomyn). Section of Neurobiology and Behavior, Cornell, Ithaca, NY 14853.

Cockroaches (Periplaneta americana) respond to minute wind currents by turning away from the wind source and running. They use this wind-mediated response to escape from the strikes of natural predators (Camhi et. al. J. Comp. Physiol. 128, 203-212, 1978). The wind receptors are filiform hairs located on the cerci — two posterior abdominal appendages. These receptors excite 7 bilateral pairs of giant interneurons (GI's) which appear to be involved in mediating the directional motor output of the legs (Westin et. al. J. Comp. Physiol. 121, 307-324, 1977; Ritzmann and Camhi, J. Comp. Physiol. 125, 305-316, 1978).

We have studied the turning responses of the cockroach and the physiological responses of its giant interneurons to wind, following unilateral cercal ablation. In our behavioral experiments, standard wind puffs were presented to nymphal or adult cockroaches from different directions, and their turning responses filmed. Then the left cercus was ablated and the behavior was retested after 1 day, and again after 1 month and longer periods of time. During this time, the cockroaches did not regenerate a new cercus or any new cercal hairs. A few animals molted and developed a cercal bud which we ablated within two days. Prior to cercal ablation, all animals turned away from the source of wind stimulation. One day after ablation, on most trials, the animals responded to wind from either the right or the left by turning to the left. This presumably results from the fact that 6 of the 7 GI's on each side receive most of their sensory activation from the ipsilateral cercus. Thus removing the left cercus renders all but one of the right GI's more responsive than their left homologs. By one month the animals had corrected their turns in response to wind from the left. In most of the trials these animals made turns to the right in response to wind from the left. Statistically, this correction was highly significant (T test; χ^2 test).

To examine the cellular mechanisms of the behavioral correction, intracellular recordings are in progress from identified GI's before, during and after the period of behavioral correction. Immediately after covering or ablating once cercus, certain ipsilateral GI's become nearly or totally unresponsive to wind. These include GI's 1 and 3. So far, we have recorded only from these two GI's after long term behavioral correction. One GI 1 and three GI's 3 each gave about 1/3 the number of action potentials seen in normal unablated animals. The directionality of these cells was the same as in normal animals. This enhanced responsiveness of these GI's following ipsilateral cercal ablation could contribute to the observed correction of the turning behavior.

Supported by NIH grant NS 09083 and NSF grant BNS 79-09663.

874 PENICILLIN AND PENTYLENETETRAZOL DECREASE THE CONDUCTANCE OF SINGLE ACETYLCHOLINE-INDUCED CHLORIDE CHANNELS IN APLYSIA NEURONS. Ruth E. Wachtel and W.A. Wilson. Dept Pharmacol, Duke Univ Med Ctr, Durham, NC 27710 and Epilepsy Ctr, VA Hospital, Durham, NC 27705.

In Aplysia, the convulsants penicillin (Pen G) and pentylenetetrazol (PTZ) attenuate chloride-dependent responses to iontophoretically applied transmitters. At the same concentrations, they have little effect on sodium-dependent responses. This attenuation of chloride-dependent responses is independent of the transmitter used to elicit the response, suggesting that Pen G and PTZ are interacting directly with the chloride ionophore, rather than the transmitter-receptor complex (Science 197:912, 1977).

Individual sodium and chloride channels were studied by examining the current fluctuations produced by the application of acetylcholine (ACh). Steady-state responses were elicited by iontophoretic application of ACh to neurons of the pleural and pedal ganglia of Aplysia californica. Currents were recorded utilizing a single microelectrode voltage clamp which was modified for low noise measurements. Frequency response studies indicated that the clamp was effective to at least 400 Hz.

The elementary conductance of a single channel was determined from the relation $g_{el} = i_{el}/(V-V_{eq})$, where the elementary current i_{el} = variance of current fluctuations/mean current.

The elementary conductance of a chloride channel is 8×10^{-12} ohms^{-1} at 21°C. Pen G and PTZ reduced g_{el} in a dose-dependent fashion; the decrease in g_{el} paralleled the decrease in mean steady-state current evoked by ACh application. Concentrations of Pen G (1mM) and PTZ (2mM) which reduced the elementary conductance of chloride channels had little effect on the sodium channel, although higher concentrations of these drugs did produce a reduction in sodium channel conductance.

This data confirms previous studies that Pen G and PTZ depress transmitter-induced chloride responses at concentrations which spare sodium responses. It also supports the hypothesis that Pen G and PTZ attenuate responses by interacting directly with, and possibly physically blocking, the chloride channel.

875 ASSOCIATIVE LEARNING IN APLYSIA CALIFORNICA. E.T. Walters*, T.J. Carew and E.R. Kandel. Div. of Neurobiol. & Beh., Depts. of Physiol. & Psychiat., Columbia Univ., P&S, New York, N.Y. 10032

Aplysia has proven to be useful for cellular analyses of non-associative learning. We now report that Aplysia also is capable of associative learning.

The behavioral paradigm that we have used is based on Pavlovian fear conditioning (Rescorla & Solomon, 1967). 'Paired' animals (N=18) received a conditioned stimulus (CS, shrimp extract delivered to the oral veil) for 90 sec. Sixty sec after the onset of the CS an aversive unconditioned stimulus was applied to the head. The US was 30 sec of pulsed electric shock (400 ma) delivered through sea water via spanning electrodes. Explicitly 'unpaired' controls (N=18) received the CS 90 min after the US. 'Untrained' controls (N=12) received neither CS nor US. Training consisted of 3 trials per day for 2 days. The intertrial interval was 3 hours. Testing was carried out (blind) on the third day: the CS was delivered for 60 sec and then escape locomotion was triggered with a weak (50 ma) shock applied across the tail. Escape was measured as mean number of steps taken in 5 min following tail shock. Paired animals showed significantly greater escape ($\bar{X}$=11.22 steps) than unpaired ($\bar{X}$=2.22, $p<.005$) or untrained ($\bar{X}$=3.25, $p<.005$) animals. This experiment was replicated and the same results were obtained using blind training in addition to the blind testing procedure: paired animals (N=8) showed greater escape ($\bar{X}$=11.75 steps) than unpaired animals (N=8) ($\bar{X}$=2.13, $p<.005$). Thus, specific temporal pairing of the CS with a noxious US endows the CS with properties which can subsequently facilitate an escape response. By contrast, training with CS or US alone does not produce facilitated escape.

These results indicate that Aplysia can form a powerful, temporally specific association between a chemical CS and an aversive US. That the learned association can be demonstrated by testing the effects of the CS on a response system not directly involved in the training (escape locomotion to tail stimulation) supports the idea that associative learning exhibited by Aplysia may be analogous to 'learned fear' produced in vertebrates by Pavlovian fear conditioning.

Several other forms of associative learning have now been described in gastropod mollusks, including avoidance learning, baitshyness, and intersensory associations (Mpitsos & Davis, 1973; Mpitsos & Collins, 1975; Gelperin, 1975; Crow & Alkon, 1978). Thus, it may soon be possible to achieve cellular analyses of different types of associative learning in gastropods and to examine their relationships to each other and to nonassociative learning, both within a single species and across related species.

876 MOTOR OUTPUT TO A COCKROACH LEG IN RESPONSE TO WIND FROM DIFFERENT DIRECTIONS. Joanne Westin* and Roy E. Ritzmann, Dept. Biol., CWRU, Cleveland, OH 44106 (SPON: Leo S. Demski)

Giant interneurons (GIs) in the nerve cord of the cockroach Periplaneta americana are thought to be involved in triggering and orienting the cockroach's escape from a wind source. It is likely that several GIs are involved in controlling an escape, and that the ones involved vary with wind direction. Evidence for this is: 1) For any given wind direction 8-12 GIs are excited, and the ones excited vary with wind direction (Westin, et al., J. comp. Physiol. 121, 307-324, 1977). 2) More than one GI excites any given leg motor neuron, and different GIs excite different leg motor neurons to different degrees (Ritzmann and Camhi, J. comp. Physiol. 125, 305-316, 1978). 3) For turns of different directions, different leg motor neurons must be excited in any given leg (Camhi and Tom, J. comp. Physiol. 128, 193-201, 1978). My work is designed to determine which GIs are necessary to produce the motor outputs which turn the animal away from wind from different directions.

I recorded the responses of depressor motor neurons (in nerve branch 5r1) and levator motor neurons (in nerve branch 6Br4) of a metathoracic leg to wind puffs from different directions before and after cutting the ipsi- or contralateral half of the nerve cord. In an intact animal the output from depressor motor neurons to a metathoracic leg is always greater when wind is delivered from the ipsilateral rear than when the wind is from the contralateral rear. The output of levator motor neurons is generally greater when wind is from the contralateral rear than when it is from the ipsilateral rear. These results are as expected since a wind puff from the left rear generally produces an initial depression of the left metathoracic leg and often levation of the right metathoracic leg (Camhi and Tom, 1978).

Sectioning the ipsilateral side of the nerve cord greatly reduces the output of the depressors caused by wind from the ipsilateral rear, while having little effect on activity in the levators caused by wind from the contralateral rear. The converse is also true. Thus, it appears that some ipsilateral GIs (and/or smaller ipsilateral interneurons) provide the major input to the depressor motor neurons of the metathoracic leg when wind is from the ipsilateral rear, while contralateral GIs (and/or smaller interneurons) provide the major input to the levator motor neurons when wind is from the contralateral rear. Experiments are now in progress involving elimination of individual identified GIs.

878 CHARACTERIZATION OF COMMAND INTERNEURONS EVOKING ABDOMINAL EXTENSION IN CRAYFISH. Benjamin J. Williams* and James L. Larimer. Univ. of Texas, Austin, TX 78712.

We have mapped the thoraco-abdominal (T5-A1) connective for "command" interneurons which evoke abdominal extension in P. clarkii. Preparations included behaving animals and/or animals with immobilized abdomens; up to 6 motor roots were simultaneously recorded. Over 80% of the 150 command fibers (CFs) examined were located in 6 loci in cross-section of a T5-A1 hemiconnective. CFs are characterized by loci-specific rostrally or caudally biased gradients of extensor output from ganglia 1 to 4. Two of the loci typically produced metachronous swimmeret beating in addition to extension; these loci correspond to those mapped by Wiersma and Ikeda (1964). Coactivation of 2 extension CFs at low (20-30Hz) frequency sometimes produced recruitment of previously inactive motoneurons. Interaction of strong flexor-biasing sensory input with an extensor CF at similar low frequencies revealed competition in the motor output. However, when the CF was stimulated at higher (75-100Hz) frequencies, the extensor drive was dominant irrespective of the frequency of sensory drive. Substituting one extensor CF for another after the first one was driven to fatigue resulted in immediate extensor motoneuron activation. This result may imply the presence of more than one driver interneuron. Furthermore, the most labile synapses are located at the connection between the CF to driver interneuron. Stimulating CFs in the T5-A1 connective and recording from the CFs in the 5-6 connective showed that at least 3 of the loci have uninterrupted axonal projections through homologous areas of the abdominal cord. No CF so isolated could be activated by stimulation of any other CF. In addition, CF stimulation produces little or no activation of other elements in the abdominal cord. Cinematographic analyses were performed on normal and cord-lesioned animals during extensions evoked by platform-drop stimuli. These data show that information must pass from a rostral site through the T5-A1 connective. Also, only one abdominal hemiconnective need be intact for the animal to produce extension equal in speed and amplitude to the normal animal. (Supported by NIH grant NS05423-15)

877 A SELF-INHIBITORY SYNAPTIC POTENTIAL ALTERS INITIAL FIRING FREQUENCY, BUT NOT SYNCHRONY, OF APLYSIA BUCCAL GANGLIA NEURONS. Roy L. White* and Daniel Gardner. Dept. of Physiology, Cornell Univ. Medical Coll., New York, N.Y. 10021

Each of the two buccal ganglia of Aplysia contains a coupled pair of identified cholinergic neurons. Each neuron monosynaptically inhibits itself, producing a self-inhibitory synaptic potential (SISP) after every action potential (AP). The SISP decrements with repetitive stimulation. The synaptic current decays with 43 msec time constant (Gardner, J. Physiol. 264:883, 1977).

As prelude to AP frequency studies, we measured synaptic current decrement under clamp, using a variable number of conditioning APs preceding each test AP and SISP. SISP current fell by 50% after 5 conditioning APs. To assess the SISP effect on firing patterns, constant current pulses lasting 1 sec were injected into resting cells and the resulting AP trains recorded digitally. Protocols in sea water (SW) were repeated with ganglia bathed in d-tubocurarine $5x10^{-4}$ to 10^{-3} g/ml (dTC) to permit comparison of AP trains with SISP intact to those with the cholinergic SISP blocked. The SISP prolongs initial interspike intervals (ISI) of each train, but declines in efficacy sharply over 300 msec, then slowly. ISI and post-stimulus time histograms show smaller interval variance within each train, and greater trial-to-trial regularity with SISP intact. AP frequency vs. injected current (f-I) curves in both SW and dTC show single-range near-constant slopes over the range 5-18 nA, with average threshold 7 nA. The SISP increases the initial instantaneous firing rate [1/(first ISI)] 6-fold without affecting firing rate at the end of each train.

The two cells in each ganglion receive common input and are electrotonically interconnected (Gardner, Science 173:550, 1971). Blocking the SISP with dTC reduces the hyperpolarizing component of the electrotonic coupling potential without affecting coupling coefficient (0.135), input resistance (1-2 MΩ) or common input. To determine the effect of the SISP on synchrony of firing of cell pairs, we depolarized cells near threshold with 10 sec constant-current steps and recorded the resulting AP trains in both neurons. Cross-correlation histograms from early or late times in the epoch with or without dTC were identical: a strong peak around t=0, reflecting high synchrony due to common input and the depolarizing component of the coupling potential.

We conclude: 1) The SISP prolongs initial ISIs, providing an early analogue to accommodation and ensuring a constant firing frequency for constant input current. 2) Neither the more regular firing nor the larger hyperpolarizing component of the coupling potential produced by the SISP contributes markedly to synchrony of the coupled neurons.

879 THERE ARE UNIQUE, IDENTIFIABLE LOCAL NON-SPIKING INTERNEURONS. John A. Wilson, Department of Zoology, University of Cambridge, Cambridge CB2 3EJ, England.

A feature of simpler systems neurobiologists have taken advantage of is that certain neurons are unique and identifiable. In the locust Schistocerca gregaria many leg and flight motor neurons and some large interganglionic interneurons have been identified using a combination of anatomical and physiological criteria. Local interneurons constitute a large part of the population of neurons in insect ganglia, and a variety of local non-spiking interneurons have been described in the metathoracic ganglion (Siegler & Burrows, 1979 J. comp.Neurol. 183). It was not known whether or not any of these interneurons are unique. It will be shown that there are local interneurons in the locust mesothoracic ganglion which are unique and identifiable.

A distinct local non-spiking interneuron has been studied in several individuals. The neuron is the apparent serial homologue of the neuron shown in fig. 4 of Siegler and Burrows. It was impaled with a microelectrode and subsequently injected with cobalt ions after its effects on leg motor neurons were studied. In all cases, the interneuron strongly excited flexor tibiae, levator trochanter, and coxal motor neurons. After silver intensification of the cobalt stain, the neuron was seen to have its major region of dendritic branching on the side of the ganglion contralateral to its cell body. A region of dendritic branching ipsilateral to the cell body was also seen.

Examination of whole mounts of ganglia in which this neuron has been filled reveal the neuron's structure to be very similar in different individuals. Its primary neurite has been found to pass through the same neuropillar regions. Sections reveal that in the region between the connectives, two larger (greater than 10 μM) and four smaller neurons follow a similar course. No other processes this large or larger are found within 30 μM of these neurons. One of the two larger neurons was revealed to be this neuron and the other larger neuron its presumed contralateral homologue. Thus there are unique and identifiable local non-spiking interneurons.

880 CONSTANCY AND VARIABILITY IN SYNAPTIC CONNECTIONS BETWEEN IDENTIFIED NEURONS. Jeffrey J. Wine & Grace C. Hagiwara, Department of Psychology, Stanford University, Stanford, CA. 94305

Variability of synaptic connections was recently demonstrated in Locusts (Pearson & Goodman, J. Comp. Neurol. 184, 141, 1979). We tested the hypothesis that synaptic connections among neurons are variable to the extent that they are redundant. By a redundant synapse we mean one which has no effect beyond increasing the safety factor for transmission. Redundancy is a graded property, such that a very weak synapse in parallel with a very strong, suprathreshold synapse is considered highly redundant. We have evidence for redundant synapses in the crayfish central nervous system and find that such synapses are often missing. In contrast, synapses judged to be crucial for behavior were invariably present in the population we tested. Two sets of giant neurons were studied.A pair of giant interneuron axons (LG axons) form electrical, 1:1 synaptic contacts with each other, and each axon contacts one member of a pair of giant motoneurons (MoGs). An impulse in one LG axon invariably excites the other LG axon and thus excites both MoGs, one directly,and one indirectly via the contralateral LG axon. The regions of synaptic contact between the LG axons and the MoGs can be visualized by filling the MoGs with cobalt sulfide. In prior studies, where a perfect correlation was obtained between anatomical and electrophysiological measures of synaptic transmission (Mittenthal & Wine, Sci. 179, 182, 1973), we saw extensive synaptic contact between ipsilateral LG and MoG axons, and occasionally saw tenuous branches from the MoG to the contralateral LG axon. We have now backfilled a large number of MoGs (n = 52) and intensified the wholemounts with a modification of the Timm's technique. We found connections with the ipsilateral LG axon in 100% of these ganglia, and with the contralateral LG axon in 33% of the ganglia. Homologous sets of LG axons and MoGs exist in the three anterior abdominal ganglia. By ganglion, the percentage of crossed (redundant) connections was: G1: 28% (5/18), G2: 44% (8/18), and G3: 25% (4/16). We conclude that the motoneurons can make synaptic connections with both ipsilateral and contralateral LG axons. The strong, ipsilateral connection has a high probability of forming, while the redundant, contralateral connection is usually omitted. Since the strong coupling between the LG axons renders the contralateral connection redundant, its absence should have no behavioral consequences. We suggest that nervous systems may be overconnected to a significant extent, and that redundant connections will tend to be variable, since natural selection can neither eliminate nor reinforce them.

882 AN ORDERLY PROJECTION OF AFFERENTS IN INSECT PERIPHERAL NERVES. Sasha N. Zill*, Mary A. Underwood*, J. Carter Rowley,III* and David T. Moran* (SPON: W. Proctor). Dept. Anat., Univ. Colo. Med. Sch., Denver, CO 80262

Although many vertebrate sensory systems are somatotopically organized, the organization of afferents in invertebrates remains largely unexplored. Several early observations suggest that afferents may be discretely organized in insect peripheral nerves. Wigglesworth noted that sensory axons, which develop from cell bodies in the epidermis, follow preexisting afferents in their path to the central nervous system. Edwards and Palka found that removal of the cercus tip in crickets resulted in a defined area of degeneration in the cercal nerve. These studies imply that afferents from a defined body surface gather together and remain grouped in peripheral nerves.

Does this grouping produce an overall organization of afferents? To answer this question we took advantage of the fact that insect axons degenerate rapidly after separation from their somata and produce changes detectable by light and electron microscopy. Degenerative changes include clumping of axonal organelles, separation and expansion of glial wrappings and final resorption of axons. We used axonal degeneration to map sensory projections in the leg nerves of two orthopteran insects, the cockroach (Periplaneta americana) and the grasshopper(Melanoplus bivittatus). Mesothoracic legs of anaesthetized animals were transected at different leg segments. Seven days later, cuticle overlying the mesothoracic ganglion was removed and fixative perfused into the hemocoel. The main leg nerve (nerve 5) was cut at its entrance to the coxa and removed with the attached mesothoracic ganglion. After dehydration and embedment, thin and thick cross-sections were taken from the nerve's cut end.

Images of leg nerves of control animals showed a tightly packed, continuous array of axon profiles. In experimental animals, when the most distal leg segments were removed, a discrete area of degeneration was repeatedly found in the leg nerve along its posterior edge. More proximal ablations produced larger areas of degeneration that progressively extended into the anterior half of the nerve. Overlays of acetate copies of patterns of degeneration from different ablations showed a posterior-to-anterior layering that generally corresponded to a distal-to-proximal map of the leg. Remarkably similar patterns of degeneration were seen in both cockroaches and grasshoppers.

These experiments indicate that insect peripheral nerves possess a higher level of organization than had previously been recognized. We are currently investigating whether this arrangement is preserved in projections into the central nervous system.

881 METHYLXANTHINE ENHANCEMENT OF INWARD AND OUTWARD CURRENTS IN APLYSIA GIANT NEURONS. Kerry L. Zbicz* and Wilkie A. Wilson. Dept. Pharmacol., Duke Univ. Med. Ctr., Durham, N.C. 27710 and Epilepsy Ctr., V.A. Med. Ctr., Durham, N.C. 27705

The methylxanthine phosphodiesterase inhibitors have been shown to increase membrane calcium fluxes and cause the release of calcium from intracellular storage sites. We have investigated the effect of two methylxanthines, caffeine and theophylline, on the slow currents regulating firing frequency in the giant neurons R2 and LPG of Aplysia californica. We have previously demonstrated the calcium dependence of the slow outward current underlying adaptation in these neurons (Zbicz & Wilson, Soc. Neurosci. Abstr., Vol. 4, p. 211, 1978). Voltage clamp studies have demonstrated that depolarization of the giant neurons to potentials more positive than -40 mV activates a transient inward current which is followed by a gradually increasing K^+ current which mediates adaptation. When the current-voltage relationship of a cell is plotted using current data taken at the time of maximum inward current (0.5-1.0 sec after the voltage step change), a negative resistance region is present at potentials more positive than -40 mV. Removal of sodium or calcium from the external solution depresses or eliminates the inward current and negative resistance region as does application of 1-3 mM lanthanum.

Both caffeine and theophylline (1-10 mM) increase the magnitude of the inward current, steepen the negative resistance region, and increase the development of the slow outward K^+ current. Neither the non-methylxanthine phosphodiesterase inhibitor papaverine nor the dibutyryl derivative of cAMP or cGMP enhance the inward transient current or steepen the negative resistance region. These substances are also ineffective in enhancing the development of the slow outward K^+ current.

The effects of methylxanthines on cell firing in response to stimulation by transmembrane current passage are complex, with enhancement of firing frequency generally occurring. In those neurons showing a large enhancement of outward K^+ current the initial firing frequency may be enhanced while the frequency after several seconds of stimulation is depressed. It is concluded that the methylxanthines can enhance firing in the giant neurons by increasing the magnitude of an inward current carried by sodium and/or calcium with depression of firing occurring only when the slow, calcium dependent K^+ current is greatly increased.

LIMBIC SYSTEM

883 EFFECT OF EXPERIMENTAL BILATERAL ISCHEMIA ON ENERGY METABOLITES IN THE MONGOLIAN GERBIL HIPPOCAMPUS. Marc S. Abel* and David W. McCandless* (SPON: J.W. Haycock). Dept. Neurobiol. & Anat., U. Tex. Med. Sch., Houston, Texas 77025.

Bilateral occlusion of the common carotid artery was used to produce ischemic attacks of varying duration in the Mongolian gerbil (Meriones Unguiculatus). The gerbil is uniquely sensitive to this procedure, perhaps due to the lack of a posterior communicating artery. In an attempt to discern the effect of ischemia on energy metabolism, levels of glucose, ATP and phosphocreatine were measured in the CA_1 and CA_3 regions of dorsal hippocampus. The hippocampus was chosen for its well-defined architectonic structure. Further, this allowed a comparison of the effect of ischemia to the well-known effect of hypoxia on Sommer's sector (CA_1). Ischemia was produced as follows: both common carotid arteries were loosely ligated with surgical thread while the animal was anesthetized. After recovery from anesthesia the vessels were occluded with Heifetz aneurysm clips. Animals were sacrificed by immersion in liquid nitrogen. This procedure freezes the brain at a rate of 2-3 sec/mm, thereby altering the dorsal hippocampal tissue environment sufficiently to stop metabolic activity within 5-10 seconds. After sectioning on a cryotome (-20°C), the tissue was lyophilized and further dissection was performed at room temperature. The samples were weighed on quartz-fiber fishpole balances. Levels of glucose, ATP and phosphocreatine were analyzed using enzymatic assays which take advantage of the fact that NADPH fluoresces while $NADP^+$ does not. The data presented describe how the energy metabolism in two regions of the gerbil dorsal hippocampus respond to the metabolic pertubation of experimental ischemia.

884 DISCRIMINATION LEARNING AND REVERSAL FOLLOWING ELECTROLYTIC MEDIAN RAPHE LESIONS. Karen E. Asin, David Wirtshafter and Ernest W. Kent. Dept. Psychology, University of Illinois at Chicago Circle, Chicago, Il 60680.

Anatomical and electrophysiological studies have demonstrated profuse interconnections between the median nucleus of the raphe and certain limbic structures. At past meetings of this society we (Asin et al., 1976, 1977, 1978) have noted that a number of the behavioral effects of median raphe lesions resemble those seen after damage to limbic structures, especially the septum and hippocampus. In the present report we extend our previous findings by describing the effects of median raphe lesions on the acquisition and reversal of several food reinforced T-maze discrimination tasks.

Similar to what has been reported following hippocampal damage, electrolytic median raphe lesions were without effect on the acquisition of a T-maze position habit, but severely impaired its reversal. It is likely that this deficit, in part, reflects damage to serotonergic elements since a similar, but less pronounced, deficit was obtained following treatment with p-chloroamphetamine (pCA) (2 X 10mg/kg). When trained on a simultaneous brightness discrimination and eight consecutive reversals, median raphe lesioned animals did not differ from controls. A similar dissociation between position and brightness reversal has been reported following septal and hippocampal damage. The acquisition of a successive brightness discrimination was extremely impaired following median raphe damage; reversal was not studied since a number of lesioned animals failed to reach acquisition criterion despite extensive training. This deficit may reflect damage to non-serotonergic elements since pCA altered neither the acquisition nor the reversal of this task. Impaired acquisition of successive discriminations has also been reported following limbic damage.

The current results provide further behavioral evidence for the anatomically derived concept of a limbic-midbrain circuit.

885 NEUROGENESIS IN THE RAT HIPPOCAMPAL REGION. Shirley A. Bayer, Dept. of Biol., Purdue Univ., West Lafayette, IN 47907

Neurogenesis in the rat hippocampal region was examined with ^{3}H-thymidine autoradiography. The rats in the prenatal groups were the offspring of pregnant females given two injections of ^{3}H-thymidine on consecutive days in an overlapping series: embryonic day (E) 13+14, E14+E15, ... E21+E22. The rats in the postnatal (P) groups were injected in a nonoverlapping series: the day of birth (P0) and P1, P2+P3, ... P18+P19. On 60 days of age, the percentage of labelled cells and the proportion of cells added during each day of formation were determined at several anatomical levels within each structure of the hippocampal region (entorhinal cortex, parasubiculum, presubiculum, subiculum, Ammon's horn, and the dentate gyrus). The neurons in each structure arise in overlapping, but still significantly different, waves: the entorhinal cortex between E15-E17; the para- and presubiculum between E16-E19; the subiculum between E16-E18; large cells in strata oriens, radiatum, lacunosum-moleculare of Ammon's horn between E15-E17; Ammon's horn pyramidal cells between E17-E19; large cells in the dentate hilus and molecular layer between E15-E19. Dentate granule cells begin to originate on E17, and 10% of the population forms after P18. There are three characteristic gradients of formation within structures: deep cells are generated before superficial cells; cells closer to the rhinal fissure are formed before those lying farther away ("rhinal to dentate" gradient); later forming cells are flanked by earlier forming superficial and deep cells ("sandwich gradient") in the entorhinal cortex, Ammon's horn, and the dentate gyrus. There is a "rhinal to dentate" gradient between structures: first, entorhinal cortex; second, the subiculum; third, field CA3 of Ammon's horn; fourth, the dentate gyrus. The para- and presubiculum are exceptions and form significantly later than the subiculum; CA1 forms significantly later than adjacent CA3 cells. This late neurogenesis may be related to prominent thalamic input to both structures.

Neurogenetic gradients between the cells providing laminated afferent input to the Ammonic pyramidal and dentate granule cells correlates with their order of termination: afferents from progressively later-originating cells terminate progressively closer to the cell body. Topographic hippocampal projections along the dorsoventral axis correlates with formation patterns in target structures: dorsal hippocampal fibers project to zones occupied by earlier-forming cells in the lateral septal nucleus and pars posterior of the mammillary body; ventral hippocampal fibers project to zones occupied by later-forming cells in these structures.

886 EPILEPTIC PHENOMENA FOLLOWING INTRA AMYGDALOID INJECTIONS OF KAINIC ACID: AN ELECTROGRAPHIC, BEHAVIORAL AND NEUROPATHOLOGICAL STUDY. Y. Ben-Ari*, O.P. Ottersen*† and E. Tremblay* (SPON: D. Lawrence). LPN-CNRS Gif-sur-Yvette 91190 France and †Anatomical Institute, Oslo 1, Norway.

We have undertaken a series of experiments to explore the possibility that the distant lesions seen after intracerebral injection of kainic acid (KA) may be due to the epileptogenic action of the toxin rather than a direct action (i.e. through diffusion). Unilateral injection of KA (0.4-2 µg in 0.1-0.4 µℓ phosphate buffer, pH 7.4) into the amygdala of rats which had been chronically implanted with a cannula (0.2 mm i.d.) as well as cortical and deep electrodes, rapidly elicited severe recurrent motor and electrographic seizures for 2-6 h. Subsequently, irregular or regular spikes occurred continuously (for 4-30 h) without motor signs. The first brain damage to appear (after 2 h epileptiform activity) was restricted to the site of injection and the ipsilateral CA3 a field in the rostral pole of ammon's horn. The apical dendrite of the pyramidal neurons showed strong argyrophilia, the cell bodies were shrunken and distorted and the neurophil of stratum lucidum appeared vacuolated. At longer survival, additional damage was present in the contralateral amygdala and bilaterally in the claustrum, lateral septum, hippocampus (areas CA1 and 4), midline thalamic nuclei and neocortex.

Several observations suggest that the distant damage is causally related to the epileptiform activity induced by the toxin: 1) a positive correlation was found between the severity of epileptiform activity (in particular the post-ictal depressions) in the ipsilateral hippocampus during the first few hours and the subsequent CA3 pathology; 2) repeated administration of an anticonvulsant (diazepam, valium, Roche) reduced the distant damage without affecting the local lesion at the site of injection; 3) the rostral (septal) hippocampal pole was more vulnerable than the caudal (temporal) pole, even though the latter is closer to the site of injection; 4) thalamic nuclei contralateral to the injection site often displayed more damage than the ipsilateral nuclei; 5) control injections in structures closer to the rostral hippocampus (such as the septum) did not readily induce hippocampal lesions; 6) unilateral transection of the perforant path considerably reduced the distant brain damage without affecting the local (amygdaloid) damage. We conclude that a) intra-amygdaloid injections of KA constitute a particularly suitable model for investigating the relationship between epilepsy and brain damage; b) the perforant path may play a significant role in the propagation of epileptiform activity and its pathological consequences; c) that the widespread use of KA injections to produce circumscribed lesions is unwarranted, notably in chronic studies.

887 MOTOR EFFECTS INDUCED BY INTRA-ACCUMBENS INJECTIONS OF DOPAMINE IN THE SQUIRREL MONKEY. Sherry L. Berg*, Daniel L. Jones, Roy L. Dorris* and Russell E. Dill. Dept. of Microscopic Anatomy, Baylor College of Dentistry, Dallas, Texas 75246.

Naive male squirrel monkeys, Saimiri sciureus, were used to test drug-induced changes in motor activity. Drugs were infused through chronically implanted cannulae in the nucleus accumbens. Changes in motoric activity were indexed by computerized analyses of photocell interruptions in the four quadrants of the test cage. Animals were pretreated with RO 4-1284 and then infused with dopamine. The study is an extension of the findings of Dill, R.E., et al., Neurosci. Abst. '78, and is designed to assess the role of the nucleus accumbens in the integration of gross levels of motor activity. (Supported by NINCDS Grant NS 15020.)

888 RECIPROCAL ANATOMICAL CONNECTIONS BETWEEN CINGULATE-RETROSPLENIAL CORTEX AND ANTEROVENTRAL THALAMUS IN THE RABBIT STUDIED WITH HORSERADISH PEROXIDASE. Theodore W. Berger, Teresa A. Milner*, Gerald W. Swanson*, Gary S. Lynch and Richard F. Thompson. Dept. Psych., Univ. of Pittsburgh, Pittsburgh, PA 15260, and Dept. of Psychobio., Univ. of California, Irvine, CA 92717.

While previous investigations have established that reciprocal anatomical connections exist between the cingulate-retrosplenial cortices and anterior thalamic nuclei, few studies have utilized transport techniques. Data are particularly lacking with respect to transport documentation of the terminal fields for thalamofugal fibers.

Injections of 0.02-0.50 ul, 35% horseradish peroxidase (HRP) were centered in the anteroventral (AVT) nucleus of thalamus. Following 1-2 days of recovery, animals were perfused with 1.3% gluteraldehyde and 1.1% paraformaldehyde in phosphate buffer. Frozen sections were taken and reacted either with benzidene dihydrochloride or tetramethylbenzidene. Both orthograde and retrograde products were examined in posterior cingulate and retrosplenial cortices.

Orthograde and retrograde results were nearly identical for both limbic cortical areas. In addition, all results were described from animals showing heavy retrograde labeling of cells in ipsilateral mammillary nuclei. For both retrosplenial and cingulate cortices, HRP-positive neurons were almost exclusively restricted to layer VI. Retrograde-filled cells were sometimes, though very infrequently, identified in layer V, with no other limbic cortical layers showing the presence of retrograde HRP transport. Examination of orthograde HRP product revealed a highly localized terminal distribution that did not overlap with retrograde cell fields. Orthograde transport from AVT neurons was found to terminate in layers I and IV of both cingulate and retrosplenial areas.

These results clearly delineate the origins and sites of termination for cortical regions reciprocally connected with areas of anteroventral thalamus--AVT regions that are the target for mammillary efferent projections.

889 DIFFERENTIAL EFFECTS OF PREOPTIC AND ANTEROVENTRAL SEPTAL LESIONS ON INTRASPECIFIC AGGRESSION IN MALE HAMSTERS. Alan Blau*, Michael Potegal and Murray Glusman (SPON: D.E. Hutchings). Dept. Behavioral Physiology, N.Y. State Psychiatric Institute, New York, NY 10032.

Septal lesions are reported to increase aggression among male hamsters (e.g. Sodetz & Bunnell, Physiol. Behav. 5:78, 1970) while preoptic area lesions decrease it among females (e.g. Hammond & Rowe, Physiol. Behav. 17:507, 1977). It would be of interest to compare these lesions in a single gender. Furthermore, these studies have involved unrestrained encounters in which a lesion's effects on the operated subject's aggressiveness is confounded with its effects on his aggression-eliciting characteristics vis-à-vis his opponent. We report here that anteroventral septal (AVS) and preoptic area (POA) lesions have differential effects on male hamsters' attacks on a standard, non-aggressive, muzzled and analgesic-treated male target hamster.

Twenty-four adult male hamsters selected for moderate preoperative aggressiveness were subjected to radiofrequency AVS or POA lesions or sham surgery. After a two week recovery, subjects were given (a) three 45 min sessions with a standard target, (b) one 45 min session with an estrogen/progesterone primed female and (c) one 45 min session on an activity meter. All tests took place in the subject's home cage with a 48 hr. intersession interval.

A statistically significant difference in attack rate among the groups was largely due to the elevated rate of AVS subjects (mean of 9.6 biting attacks/session) compared to POA subjects (1.1 attacks/session) and sham subjects (1.3 attacks/session). These differences in aggressiveness were confirmed by unrestrained pair encounters: AVS subjects defeated POA subjects in every contest. Twenty-eight per cent, 85% and 100% of the AVS, POA and sham subjects, respectively, copulated with the female. Their respective activity counts were 1501, 368 and 256. Activity counts and attack rates were significantly correlated for AVS subjects but not for the others. In contrast to these differential effects, AVS and POA subjects were similar in their deficiencies in nest-building and food-hoarding relative to sham animals.

Our aggression testing technique eliminates the possibility that AVS lesions act solely by altering the aggression-eliciting characteristics of operated hamsters but raise the possibility that attack rate increases are secondary to activity level changes. 890 EFFECTS OF ELECTRICAL STIMULATION OF THE SUBSTANTIA INNOMINATA UPON HYPOTHALAMICALLY-ELICITED AGGRESSIVE BEHAVIOR IN THE CAT. C.H.Block*, A. Siegel, H.Edinger. Departments of Physiology and Neurosciences, College of Medicine and Dentistry of New Jersey-New Jersey Medical School, Newark, NJ 07103.

The substantia innominata (SI) supplies afferents to the lateral hypothalamus, ventral tegmental area, and amygdala. Initiation or modulation of attack behavior can be generated by electrical stimulation of the three brain areas noted above. Accordingly, the present investigation was undertaken in order to determine the possible role of the SI in the control of aggressive responses.

Electrodes for both stimulation and recording were bilaterally implanted in SI and hypothalamus in ten cats. Postoperatively, the effects of stimulation of sites in SI upon either the quiet biting attack (QBA) or affective display generated by hypothalamic stimulation were determined by the use of a dual stimulation paradigm which compared stimulation of the hypothalamus alone with stimulation of hypothalamus and SI. The findings suggest a possible differentiation of function within SI. Specifically, stimulation of sites in lateral SI significantly inhibited QBA ($p < 0.02$) while stimulation of more medially placed SI electrodes facilitated the occurrence of QBA ($p < 0.02$). Stimulation of any portion of the SI alone produced no observable behavioral response. Those sites that significantly modulated QBA were further studied for their possible effects upon the sensory component of the attack response. It was observed that stimulation of SI sites that suppressed QBA also reduced the extent of the lipline that, when probed, would elicit a jaw opening response, while stimulation through electrodes associated with facilitation of attack produced an opposing effect. The effects upon motor components of QBA were also studied by probing the region of the midline of the lip that consistently elicited a jaw opening response during either single or dual stimulation and the latency for the response was measured. The possibility of a modulatory effect upon the motor component of the attack response was suggested as well.

The effects of SI stimulation upon affective display were tested from seven electrode sites and in no instance did stimulation significantly alter the response latency ($p > 0.1$).

Presently, these data imply that the SI differentially modulates the quiet biting form of attack and it appears to do so primarily by acting upon the sensory component of the response mechanism.

891 DIFFERENTIAL EFFECTS OF LESIONS IN POSTERODORSAL SEPTUM AND DORSOMEDIAL FRONTAL CORTEX ON SPATIAL ALTERNATION AT TWO INTERTRIAL INTERVALS. G. N. O. Brito and G. J. Thomas, Center for Brain Research, School of Medicine & Dentistry, University of Rochester, Rochester, N. Y. 14642.

Successful alternation in a T-maze is not based on discriminations of currently available environmental stimuli but is based on a brain-constructed "cognitive map" involving a "memory" of the direction turned on the previous trial. Rats were trained preoperatively for 9 sessions (13T/day, 1 session/day) to perform reinforced alternations with a minimal intertrial interval (ITI, c.a. 6 sec). Then they were trained for 9 more sessions by running them in squads of 4 (ITI, c.a. 90 sec). By the 9th session all animals were running near perfectly. The rats were then divided into 3 matched groups. One group (N=9) received small bilateral stereotaxically guided electrolytic lesions in the posterodorsal septum (1 ma. for 7 sec). Another group (N=9) received strip-like bilateral lesions in the dorsomedial frontal cortex produced electrolytically (1 ma. for 10 sec at each location). The third group (controls, N=5) received bilateral strip-like lesions in either the dorsolateral frontal cortex (2 mm from the midline) or in posterdorsal cortex. After postoperative behavioral testing, lesions were evaluated from whole-brain photographs and celloidin-embedded, cresyl-violet stained histological material.

As has been reported previously (Thomas, JCPP 92-1128, 1978), and also found in the present results, rats with lesions in the posterodorsal septum, when tested 2 wk postoperatively, dropped to random choices during early testing, but by the 9th session, they recovered to perform near perfectly as did all controls. When subsequently tested in squads of 4 (c.a. 90-sec ITI), controls were slightly impaired but they quickly recovered to near perfect alternation within 9 sessions. Rats with posterodorsal septal lesions never achieved better than random choices. On the other hand, lesions in dorsomedial frontal cortex had no differential effect, compared with controls, on alternation at either short or long ITIs.

The data suggest that interference with septo-hippocampal circuitry temporarily reduces the ability of rats to cope with spatial alternation at short ITIs, but at long ITIs they are permanently (at least for 9 sessions) unable to perform above a random level. On the other hand, lesions in part of the cortical projection field of mediodorsal thalamic nuclei have no effect on the animals' "memory-for-directions" at either ITI.

892 ACQUISITION OF HIPPOCAMPAL SELF-STIMULATION IS FACILITATED BY KINDLING OF THE CONTRALATERAL HIPPOCAMPUS. Kenneth A. Campbell* and N. W. Milgram. Dept. Psychology, University of Toronto, Scarborough College, West Hill, Ontario, Canada.

We have previously reported that while rats are usually very slow to learn to bar-press for hippocampal stimulation, acquisition is markedly facilitated by a pretreatment of 22 single daily electrical stimuli to the hippocampal electrode, leading to a gradual development of convulsive activity (kindling) (Brain Research, 159, 458). When applied to various limbic and cortical loci, this repeated stimulation program is known to produce two types of long-term changes: increased excitability near the electrode tip (Racine, EEG clin. Neurophysiol., 32, 269) and facilitation of neuronal transmission to secondary sites (Racine et al., Brain Research, 47, 262). We were interested in separating these two neurophysiological effects and determining which is necessary for obtaining facilitated acquisition of hippocampal self-stimulation. The "transfer" paradigm provides such a means: the facilitation of transmission produced by repeated stimulation to one site is largely transferable to homologous contralateral loci, and this transfer is especially rapid in the hippocampus. While 20-30 daily electrical stimuli may be required to elicit convulsive activity from a primary hippocampal electrode, only 1-3 stimuli then applied to the contralateral hippocampus will elicit a seizure. This transfer effect cannot be explained in terms of local excitability changes, since it occurs even after lesion of the primary site.

Twenty rats were implanted bilaterally with electrodes in the dorsolateral hippocampi: 14 received 30 single daily stimuli in one hippocampus; 6 controls were handled identically but not stimulated. All animals were then tested for self-stimulation: 7 prestimulated rats were tested on the prestimulation electrode (ipsilateral group), and the other 7 on the contralateral electrode. Acquisition time was expressed as the number of 15 min periods required to reach a criterion of 25 presses in 15 min. As expected, the control group learned very slowly ($\bar{X}$ = 24.8) and the ipsilateral group much faster ($\bar{X}$ = 9.1). The contralateral group learned almost as quickly as the ipsilateral group ($\bar{X}$ = 9.7), suggesting that facilitated acquisition is not dependent on an excitability change in the tissue surrounding the prestimulation electrode tip. The results are consistent with the hypothesis that development of hippocampal reward depends upon increased neuronal transmission to secondary sites.

893 EVOKED POTENTIAL AND ELECTROENCEPHALOGRAPHIC CHANGES CHARACTERISTIC OF THE STAGES OF KINDLING. David B. Chandler*, Dorothy E. Woolley* and Stephen R. Overmann. Department of Animal Physiology, University of California, Davis, CA 95616.

Adult female Long-Evans rats were implanted under anesthesia with bipolar electrodes in the right prepyriform cortex (PPC) so that the tips straddled the pyramidal cells, in the right hippocampus with the short tip in CA1 and the long tip in the hilus of the dentate gyrus (DG), and bilaterally in the amygdaloid complex (AMYG). Following recovery each animal was kindled by a daily 1-sec tetanizing burst (TTB), consisting of 300 µA, 0.1 msec pulses at 62.5 Hz, to the right AMYG. Averaged evoked potentials (AEPs) produced by AMYG stimulation (300 µA, 0.1 msec pulses at 1/sec) were recorded from the PPC and DG and were averaged over 30-sec periods by a programmable computer. Behavioral parameters described by Racine (1971), EEG and AEPs were recorded for 2.5 min before and 10 min after the TTB during the various stages of kindling. The animals were sacrificed after they exhibited 5 successives days of Stage V seizures. Positions of electrodes were verified histologically. After the TTB the AEPs recorded from the CA1 and DG showed a progression of changes in waveform, amplitude and peak latencies associated with the stages of kindling, whereas the AEP recorded in the PPC showed only a slight increase in latency and amplitude. In Stage I the DG waveform was a single positive wave (P1) with a peak latency of 20 msec. With the appearance of Stage II this waveform increased slightly in amplitude and latency following the TTB. In Stages III and IV the amplitude and latency of P1 increased progressively. In addition, a second positive wave (P2) appeared in Stage III and became more prominent than P1 during Stage IV. Stage V was characterized by further increase in amplitude of P2 and marked oscillations in the waveform. As the number of Stage V seizures increased, the waveform following the TTB was depressed. Prior to kindling the AEP from CA1 was a negative wave with a peak latency a few msec shorter than that of the DG AEP. Although reversed in polarity from the potentials recorded in the DG, CA1 AEPs showed a similar progression with the stages of kindling. As the severity of the seizures increased, the duration of the EEG after-discharge following the TTB increased progressively to reach a maximum in Stage IV. The after-discharge showed a spike and wave pattern which increased in frequency to reach a maximum in Stage IV or V. The results demonstrate that changes in AEPs were greater in the hippocampus than in the PPC during kindling. The changes in hippocampal AEPs occurred predictably with the progression in the stages of kindling and indicate that kindling produces an increased effectiveness of the amygdala input to the hippocampus. (Supported by NIH grant ES01503.)

894 THE ACCUMBENS CONNECTION: INPUT FROM MIDBRAIN AND HINDBRAIN. R. B. Chronister, L. E. White, Jr., R. W. Sikes, J. R. DeFrance. Dept. Anat. Neurosc. Univ. So. Ala., Mobile, 36688 and Dept. Neurobiol. Anat., Univ. Texas Houston, Houston, 77025.

Injections of HRP (RZ-3.0) were made into nuc. accumbens in rats and rabbits. Delivery was made either via regulated pressure injections or iontophoretically. Following a 24 hr. recovery the animals were perfused, the brains removed, sectioned and processed with the TMB technique. All sections were counterstained with toluidine blue. One striking feature of the HRP positive neuron is the relationship of many of labeled systems to regions of the periaqueductal grey around sulcus limitans. This area is characterized by both retrogradely labeled neurons and presumed anterograde transport of the HRP. For example, HRP positive axons can be seen running at the level of the inferior colliculus from the central grey to a localized zone in the cuneiform nucleus. Associated with these fibers are retrogradely labeled neurons in a restricted focus. In addition, labeled neurons can be found scattered throughout the ventral regions of the central grey down to regions of the caudal medulla where the system continues as labeled neurons in nucleus solitarius and the dorsal motor nucleus of X. As stated above, labeled neurons can be found in the caudal regions of the medulla Most of these are in the parvocellular regions of nucleus solitarius and in the dorsal motor nucleus of X. The solitarius projection is impressive and indeed bilateral. The positive cell appear to diminish near the commissural nucleus and is restricted to the caudal solitarius region. Scattered HRP neurons are also found in the regions of the caudal ambiguus-ventral reticular nucleus. With the exception of isolated HRP positive neurons in the reticular nuclei, little else is seen in medulla. Pontine levels are characterized also by scattered cells in reticular nuclei. In rostral pontine levels, a few HRP positive neurons can be seen in the ceruleus system. HRP positive neurons are also found in the medial parabrachial regions. Throughout pons, scattered neurons or neuron-like cells can be found in the marginal zone surrounding the ventral portions of IVth ventricle. In mesencephalon two systems stand out. One is the midline raphe system and the other the tegmental area. The raphe system extends from centralis superior through the nuclei associated with the MLF (annularis and linearis) to the dorsal raphe. Indoing so it crosses the decussation of the superior cerebellar peduncle. The ventral tegmental area has its strongest focus in the paranigral nucleus (especially pronounced in rabbit). It extends cadually across the midline and is bilateral. At these caudal levels it extends also up into the fibers of the ventral tegmental decussation. As noted by others, HRP positive neurons can also be found in the subs. nigra. (NIMH 1RO3MH32418-01).

895 TRANSECTION OF DIRECT SUBICULO-ANTERIOR THALAMIC FIBERS: EFFECTS ON SEQUENTIAL LEARNING. ROBERT E. DAVIS AND ERNEST W. KENT. Dept. of Psych., Univ. of Illinois, Chicago, Illinois 60680.

In previous studies we have demonstrated that selective transections of the direct subiculo-anterior thalamic fibers after they exit from the postcommissural fornix produce behavioral changes similar to those reported following large hippocampal or total fornix lesions (Davis and Kent, 1979; Hirsh and Davis, 1979). As an extension of this work the effects of damage to these fibers on the acquisition and performance of an operant response sequence was examined (SLT). This task involved learning to press in any order 4 closely placed levers extending from one wall of an operant chamber. Only the first response on any given bar was reinforced. After all 4 bars had been depressed at least once a trial was complete and the levers were retracted to a position outside the chamber as a reset signal to the animals. The number of total and perseverative errors were recorded separatively for each trial.

Initial procedures consisted of 14 days of CRF training. Following this animals were run for 14 days on the SLT; 10 trials/day. Animals with transections of the subiculo-thalamic fibers (AT) were impaired only on the initial days of SLT making more total errors than normals. On later days the performance of AT animals was not different from operated controls (OC) on either error measure. However, further analysis of the response patterns of both groups revealed that AT animals were adhering to different response strategies than were OC animals. Usually brain damaged animals adopted rigid response chains which they repeatedly performed. Controls exhibited a much more flexible response pattern.

The addition of more easily discriminable manipulanda (patterned stimuli on the bars) transiently disrupted performance of both groups. The total number of errors made by all animals was elevated on the first day of this manipulation but quickly returned to baseline levels. Cuing also increased the frequency of perseverative errors on the first day of introduction. Thereafter, cues selectively reduced the number of perseverative errors made by AT animals. Taken together these results suggest that AT and OC animals learn this task in two entirely different ways.

896 A COMBINED INTRACELLULAR HRP AND GOLGI ANALYSIS OF THE NUCLEUS ACCUMBENS SEPTI. J.F. DeFrance, J.E. Marchand, R.B. Chronister, R.W. Sikes, and J.I. Hubbard. Dept. of Neurobiology and Anatomy, Univ. of Texas Medical School, Houston, Texas 77025 and The Dept. of Anatomy, Univ. of South Alabama, Mobile, Alabama 36688.

The nucleus accumbens septi (NAcS) is an important paralimbic structure standing in relation to both the limbic system and basal ganglia. The cytoarchitectural appearance of the NAcS resembles that of the caudate-Putamen complex (Fox, 1940), but receives numerous limbic system projections. Most prominent among these are the ventral subicular projection via the fimbria (IFim) (Siegel et al., 1971; Swanson et al., 1977) and the amygdaloid projection via the stria terminalis (ST) (DeOlmos, 1972). The present study was undertaken to determine the morphological appearance of the NAcS neurons receiving monosynaptic IFim and ST input.

Rabbits were acutely prepared under Urethane anesthesia. The cortex and corpus callosum were removed to allow for the visual position of the microstimulation and recording electrodes. The recording electrodes were filled with HRP (4%-10%) in Tris buffer plus 1M NaCl. Extracellular unitary responses were recorded following IFim and ST stimulation and characterized with power and paired-stimulus testing. The cells were then injected with HRP. For the correlative Golgi analysis, NAcS tissue was prepared according to the Rapid Golgi and Golgi-Kopsch techniques.

Monosynaptically excitatory input via the IFim and ST is largely restricted to dorsal-caudal halves of the NAcS. From the HRP analyses, there are two distinctly different cell types which are the recipient of both inputs. Firstly, there is a small (8μ-15μ) cell with spiny dendrites. The dendritic pattern is spherical with the dendrites themselves being delicate. The cell body is spine-free with spine appearance commencing on the primary dendrites. Secondly, there is a large cell type (12μ-20μ) whose dendrites are essentially spine-free. The dendritic pattern is again spherical, but the dendrites are thicker. These appear to reside more medially and ventrally in the NAcS.

The Golgi analysis confirmed that these two cell types indeed exist in the NAcS. It further shows that the small spiny neurons are the dominant cell type being scattered throughout the nucleus.

This study was supported by NSF GB-55552 and Scottish Rite Schizophrenia Foundation.

897 KAINIC ACID AND ELECTRICAL STIMULATION OF THE LATERAL SEPTUM: CARDIOVASCULAR AND ELECTROMYOGRAPHIC EFFECTS. Ariel Y. Deutch, L. Scott Clark*, and Lelon J. Peacock. Dept. Psych., Univ. GA., Athens, GA, 30602.

At sites in the lateral septum in which electrical stimulation (0.5 - 1.0 sec train of biphasic waves; pulse duration, 0.5 msec; frequency, 100 cps; 2.0 - 14.0 V) produced cardiodeceleration in the anesthetized rat (Equithesin, .25cc/100g), subsequent injection of kainic acid (4 μg in 1.0 μl, injected at 0.2 μl/min) typically results in a pronounced tachycardia. Within minutes after the conclusion of the kainic acid administration, sustained myoclonus is observed bilaterally in forelimbs, jaw, and neck. Equivalent volumes of saline in these locations do not result in these effects. Chemical and electrical stimulation of the caudate nucleus (1.5 mm lateral to the septal sites) produces no observable cardiovascular or muscular responses. The effects of electrical stimulation of the lateral septum are in agreement with the findings of Holdstock (Psychon. Sci., 9:37-38, 1967). The effects of kainic acid administration to the lateral septum on cardiovascular and electromyographic variables have not been previously reported.

898 PERCEPTUAL CUES OF REINFORCING BRAIN STIMULATION. Philippe De Witte and Michel Meulders. Lab. Neurophysiol. Univ. Louvain, av. Hippocrate 54/49, B-1200 Brussels, Belgium.

Rats with rewarding electrodes in the lateral posterior hypothalamus were trained to an avoidance paradigm. A brain stimulation delivered through the rewarding electrode is used as conditioned stimulus (CS). Test for generalization to other brain stimuli (substitute stimulus, or SS) were made by modifying the values of the electrical stimulus parameters (i.e. intensity, frequency, pulse duration, and train duration).

The results show that two types of gradients were obtained. A two-way gradient was obtained for pulse frequency and for train duration while intensity and pulse width modifications produced a one-way gradient. Three hypotheses could explain the generalization and discrimination phenomena observed : (1) Generalization may occur to the quantity of charge offered by the substitute stimuli ; (2) Generalization may depend critically on one or more than one specific parameter of the electrical stimulus ; (3) The gradient of the rate of self-stimulation behavior for the same electrical parameters as those tested for generalization shows a close relationship with these generalization gradients. With other words, SS should be generalized in terms of the reinforcement induced. To test this hypothesis, we considered the percentage of avoidance responses as a scale of perceptions of the reinforcing stimulations. We then calculated the efficiency percentage of all the brain stimulations to elicit a self-stimulation behavior. The function relating the strength of the reinforcing sensation, as estimated by the percentage of avoidance responses during the generalization tests, and the rewarding intensity, as measured by the scaling of the self-stimulation behavior was then computed. In all cases, the data fitted a power function. It appears thus that the perception of the rewarding value through a reinforcing brain area follows the same law as with other sensory modalities. It should be noted that the value of the exponents does not deviate much from unit. These data thus indicate that the calculated functions are isometric. In other words, a relative change in the rewarding intensity elicited by brain stimulations is accompanied by the same relative change in avoidance response. This may serve to suggest that, in the brain, no noise occurs between the transformation from the input, i.e. the intensity of the brain stimulation, and the output, i.e. the reinforcing sensation as estimated by the generalization tests. Our experiments show that "degree of reward" is a perceived dimension and that it is being processed according to the psychophysiological laws.

899 DIRECT AND ORTHODROMIC ACTIVATION OF NEURONS IN THE PARAVENTRICULAR NUCLEUS: INTRACELLULAR RECORDING AND STAINING IN SLICES OF RAT HYPOTHALAMUS. F. Edward Dudek, Brian A. MacVicar and Glenn I. Hatton. Dept. of Zool.and Erindale College, Univ. of Toronto, Mississauga, ONT. L5L 1C6 and Depts. of Psych. and Zool., Mich. State Univ., E. Lansing, MI 48824.

Electrophysiological analyses of the afferent and efferent pathways of the paraventricular nucleus (PVN) have been restricted almost exclusively to extracellular techniques, primarily because of the difficulty in obtaining intracellular records in vivo from the mammalian hypothalamus. In vitro studies with slices of rat hypothalamus have revealed that many cells in the PVN fire spikes spontaneously and can be stimulated extracellularly while recording intracellularly (Hatton et al., Soc. Neurosci. Abstr. 4: 346, 1978). We have combined these techniques with intracellular staining to study the inputs and outputs of anatomically identified cells in PVN.

Coronally oriented, hypothalamic slices (400-500 µm)were prepared from mature rats. Intracellular recordings were obtained with micropipettes filled with 5% Lucifer Yellow (LY) in 1M LiCl. An array of tungsten, stimulating microelectrodes was positioned ipsilaterally between the fornix column (FX) and the supraoptic nucleus (SON).

Intracellular recordings (40-70 mV action potentials) have, so far, been obtained from >15 cells with LY electrodes; ten of these cells were injected with LY before loss of the impalement and six were successfully stained and identified. Four of the stained cells were magnocellular neurosecretory cells, one was a parvocellular neuron in anterior PVN, and another was a medium-sized cell in posterior PVN. All of these cells could be activated with extracellular stimulation. The parvocellular neuron fired an antidromic spike to stimulation midway between FX and SON, but not to stimulation near FX. The medium-sized cell in posterior PVN and two of the magnocellular elements could be activated orthodromically by stimulation near FX. It has also been possible to record, stain and stimulate cells in SON. Although these data must be considered preliminary until a larger number of cells have been studied with more rigorous controls for current spread and mode of activation, they do indicate that it is possible to study the functional anatomy of afferent and efferent pathways of PVN and other hypothalamic nuclei with intracellular recording and staining.

900 RELATIONSHIP BETWEEN HIPPOCAMPAL RSA AND SNIFFING DURING REVERSAL ODOR DISCRIMINATION LEARNING. Howard B. Eichenbaum, Foteos Macrides and Karen J. Shedlack*. Dept. Biol., Wellesley College, Wellesley, MA 02181, Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545 and Dept. Psych. and Brain Sci., Massachusetts Institute of Technology, Cambridge, MA 02139.

In rodents, active investigation is characterized by vigorous sniffing and the presence of hippocampal rhythmic slow wave activity (RSA) in the theta range. These two cyclic activities have been observed to entrain while the animal appeared to be investigating an odor. Quantitative analysis of this phenomemon would be aided by a method which induced an animal to sniff at odorous stimuli on repeated trials and under conditions in which the chemical compositions and concentrations of the stimuli can be well regulated. For this purpose, a paradigm involving multiple reversal odor discrimination was devised and the relationship between hippocampal RSA and sniffing during reversal learning was characterized with retrospective computer analyses based on the Fast Fourier Transform (FFT). Rats were trained in a shielded arena with a port in one wall behind which clean air or odors, generated by a flow-dilution olfactometer, were passed. Proximity to the odor was recorded with a photocell beam at the port. An animal could initiate a trial by crossing another photocell beam located 36 cm from the port, after which a door covering the port opened allowing access to one of two odors. For an S+ odor stimulus the rat could hold its nose in the port continuously for 2 sec in order to obtain a water reward delivered at a well below the port. No reward was given for S- odor trials, and animals learned not to hold their nose in the port on such trials. Sniffing was monitored with a thermocouple placed in the nasal cavity via an implanted guide-tube, and slow wave activity was monitored in the dorsal hippocampus with implanted bipolar electrodes.

Rats rapidly acquired a discrimination of phenethyl alcohol versus geraniol, and with increasing rapidity acquired successive reversals. The animals typically investigated the stimuli with bouts of three or more successive sniffs whose repetition rate often corresponded with the principal frequency component of the ongoing hippocampal RSA. Moreover, the FFT analyses verified that the rats timed these sniffs with a preferred phase relationship to individual cycles of the hippocampal RSA. The entrainments did not occur on every trial during criterion-level performance, but were particularly prominent soon after the onset of a reversal and before criterion was achieved. This suggests that the entrainments are not critical for odor discrimination, per se, but may be associated with the assessment of an odor's behavioral significance.

901 THE COMPARATIVE EFFECTS OF STIMULATION OF SUBSTANTIA INNOMINATA, INSULAR-TEMPORAL CORTEX, AND LATERAL OLFACTORY TRACT ON SINGLE-UNIT ACTIVITY IN THE AMYGDALA OF THE ANESTHETIZED CAT. Philip A. Femano, Henry M. Edinger, and Allan Siegel. Depts. of Physiology and Neuroscience, Coll. Med. Dent. NJ, NJ Med. Sch., Newark, NJ 07103.

The effects of electrical stimulation of the substantia innominata (SI) on amygdaloid unit activity were compared to those observed during stimulation of the sylvian gyri (SG) and lateral olfactory tract (LOT) in the ketamine anesthetized cat. Glass microelectrodes were used to record extracellular unit activity from the basal, lateral, central, cortical, and medial nuclei of the amygdala. Stimuli were delivered through stainless steel electrodes located in the SI, SG, and LOT.

In the basolateral group, many more units responded to SI stimulation than to any other site. The proportion of responses that were excitatory differed markedly depending on the source of stimulation. Of all responses elicited by SI stimulation, 90% were excitatory. Likewise, the percentages of excitatory responses obtained from SG and LOT stimulation were 70% and 65%, respectively. The relative invariability of the onset latencies of most of these excitatory responses, together with other criteria, imply monosynaptic activation of amygdaloid units.

Of the more than 100 units in the basolateral amygdala tested by stimulation of all three sites, 92% were affected by stimulation of SI and/or SG. Only 10% of these showed a response to stimulation from both sites. This suggests that the SI and SG project to different populations of cells. Furthermore, these populations appear to be anatomically intermingled since no topographical segregation of responses was observed.

It is concluded that the SI may have as much, if not more, excitatory influence over amygdaloid neurons than the sensory processing areas. This suggests that the SI may influence the amygdala in the limbic control of motivated behaviors.

(Supported by NIH Grant NS 07941-10)

902 EFFECTS OF ELECTRICAL STIMULATION OF THE FORNIX AND HIPPOCAMPUS ON NEURONAL ACTIVITY IN THE SUBICULUM. David M. Finch and Thomas L. Babb. Brain Research Institute and Reed Neurological Research Center, UCLA, Los Angeles, CA 90024.

Male Long-Evans strain rats were prepared for acute neurophysiological experiments under Nembutal (50 mg/kg, ip) or Equi-Thesin (3 ml/kg, ip) anesthesia, supplemented as necessary. Twisted bipolar stimulating electrodes were implanted in the fimbria-fornix and hippocampus under physiological control. Micropipets (30-90 Mohms, filled with 4% Pontamine Sky Blue Dye in 1 Molar K Acetate) were lowered through overlying neocortex to the subiculum, where extra- and intracellular neuronal activity was recorded. Electrical stimulation was with 0.2 msec pulses, usually of 50-200 uA intensity, presented at 1/2sec.

The great majority of subicular neurons responded to electrical stimulation of the fornix or hippocampus with inhibition. Response latencies ranged from about 5 to 15 msec and response durations from 50 to more than 500 msec. Intracellular recordings showed prominent IPSPs that could be inverted by passing 1-3 nA of hyperpolarizing current through KCl-filled electrodes. Less common, but still reliable, were excitatory responses in subicular neurons after stimulation of the fornix or hippocampus. These responses were usually characterized by a single action potential, immediately followed by an inhibitory period. Neither fornical nor commissural afferents were necessary for the responses described here; both inhibitory and excitatory responses remained in animals that had received sections of the fornix and hippocampal commissures prior to (by at least one week) the neurophysiological experiments.

The prominent inhibitory responses were similar to those reported for cells of the hippocampus proper after fornix stimulation and we propose a similar mechanism; antidromic activation of subicular cell axons projecting via the fornix (e.g. Meibach and Siegel, 1977, Brain Research, 124, 197-224), with consequent activation of a recurrent inhibitory circuit. We propose that the excitatory responses reflected activation of the caudally directed hippocampal efferent system (e.g. Swanson et al., 1978, J. Comp. Neurol., 181, 681-715).

903 INTRAHIPPOCAMPAL INFUSION OF NOREPINEPHRINE OR CARBACHOL INCREASES LOCOMOTOR ACTIVITY IN RATS. Charles Flicker* and Mark A. Geyer. Dept. Psychiatry and Neurosciences, Sch. Med., UCSD, La Jolla, CA 92093.

Intracerebroventricular infusion of either norepinephrine (NE) or the cholinergic agonist carbachol has been reported to increase spontaneous locomotor activity in rats. One site at which this response may be mediated is the hippocampus. A NE input to the hippocampus has been demonstrated via the dorsal noradrenergic bundle originating in the nucleus locus coeruleus. The septohippocampal pathway is an establised cholinergic input arising from the medial septal nucleus. In this study we endeavored to mimic the presumed effects of transmitter release from these two projections by the direct infusion of appropriate agonists into the hippocampus of awake, behaving animals.

Male Sprague Dawley rats (350-400g) were chronically implanted under Nembutal anesthesia with guide cannulas aimed bilaterally for the rostro-dorsal hippocampus. After a week of recovery from surgery the animals were connected to sham infusion lines and acclimated to the experimental chamber for 30 minutes. The experimental chamber consisted of a 12"x24"x15" holeboard box with 11 holes in the floor and walls.

A 30-gauge needle at the end of each infusion line was attached to each cannula, the needle's tip protruding 1.5mm deeper than the cannula's. Animals were then placed in the holeboard where - in addition to visual observation of behavior - locomotor activity and hole pokes, as measured by beam breaks, and rearings, as measured by electrical contacts with a steel wall plate, were monitored by computer.

After a 20 minute pre-infusion period, the animals received a 40 minute infusion of d,l-norepinephrine HCL, carbamylcholine chloride (3 µg/µl dissolved in saline), or physiological saline at a rate of 25 nanoliters per minute. Each animal received all three treatments in counterbalanced order at intervals of 5-7 days. Some animals were pre-treated with systemic injections of a muscarinic antagonist, either atropine sulfate or methyl atropine (i.p. 1 mg/kg).

The mechanical disruption caused by the insertion of a 30-gauge needle or the slow infusion of saline into the hippocampus of the rat frequently induces "wet dog" shakes which are commonly associated with electrical seizure activity in the structure. Despite these symptoms of abnormal baseline activity, infusion of either NE or carbachol into the hippocampus produced a transient increase in spontaneous locomotor activity as compared to saline controls. Results obtained with the various treatments are compatible with the hypothesis that this behavioral activation is mediated by a noradrenergic-cholinergic interaction at the level of the hippocampus.

904 OBSERVATIONS OF FEAR BEHAVIOR IN RATS RECEIVING NEONATAL HIPPOCAMPAL X-IRRADIATION. Dennis Gallant*, Robert B. Wallace, and Evan R. Susser*. Laboratories of Developmental Psychobiology, University of Hartford, West Hartford, CT 06117.

The purpose of this study was to determine whether there were significant behavioral changes in rats that have undergone hippocampal degranulation as contrasted to non-irradiated control animals in a fear provoking situation. Based upon the types of behavior observed, inferences could be drawn concerning the possible role of the hippocampus in mediating a fear response in rats. 30 male Long-Evans hooded rats, inbred in our laboratories, were randomly selected for this study; 15 received focal neonatal irradiation of the hippocampus while the other 15 served as non-irradiated control subjects. Testing began when the animals were 90 days old. Each animal was tested over a three-day period in an apparatus designed so as to moniter general activity as well as proximity of each rat to an enclosure containing a live cat. On Day 1 of testing, baseline measures were obtained - the cat was introduced into the apparatus on Day 2 and removed 24 hours later - day 3 then allowed for a second set of readings in the absence of the cat. A fear index was computed for each subject (Kim et al. 1970). At the conclusion of the study all animals were perfused transcardially and the brains prepared for histology. Examination of the dorsal hippocampus in matched sections showed about a 70% reduction in the granule cells of the dentate gyrus in the irradiated animals. Behavioral results indicated that the degranulated animals were significantly more willing to approach the part of the apparatus that contained the cat than were the control subjects; they were also willing to drink from a water bottle placed at that end of the apparatus whereas the control subjects would never do so. Based upon these observations we find support for the conclusions of Kim et al. (1971); not only were the animals in their study that had undergone gross aspiration lesions of the hippocampus less fearful in the presence of a live cat but this also seems to characterize the animal that has undergone hippocampal degranulation. Possible implications of these results in terms of the response suppression model of hippocampal functioning are suggested.

905 EFFECTS OF AMYGDALOID AND HIPPOCAMPAL LESIONS ON FREE-OPERANT AVOIDANCE LEARNING IN THE RAT. Michael G. Gaston* (SPON: E. H. Gregory). California State Univ., Los Angeles, CA 90032

Amygdaloid lesions have been shown to produce marked deficits in all forms of avoidance paradigms so far investigated. Hippocampal lesions decrement an animal's ability to acquire passive avoidance responses, but are often found to enhance performance in active avoidance tasks. In the usual procedure, the aversive stimulus (shock) is cued by an external warning signal or by distinctive situational stimuli. The present study explored the effects of amygdaloid and hippocampal lesions in a nondiscriminated active avoidance (Sidman-type) situation which did not entail the use of external cues. In this free-operant paradigm, the subject was shocked at regular (shock-shock) intervals unless it made the correct response (lever press), in which case shock was postponed for a specified period of time (response-shock interval).

Subjects were 48 male Long-Evans rats. Sixteen animals received bilateral lesions aimed at the basolateral amygdala, 16 subjects were bilaterally lesioned in the dorsal hippocampus, and 16 rats served as sham-operated controls. The apparatus was a commercially available Skinner box. The shock-shock and response-shock intervals were, respectively, 10 and 30 seconds. Thus, shock could be avoided entirely if the animal responded at least once every 30 seconds; complete failure to respond resulted in a 300 msec, 1 ma pulse of shock being delivered every 10 seconds. All animals received 24 hours of training, four hours per day for six consecutive days.

Amygdala lesioned rats were severely impaired--they made only about half as many avoidance responses as Controls and received about twice as many shocks. They displayed little improvement across days and showed deterioration of performance within sessions. In terms of number of shocks received, the hippocampal rats improved across days and within each four-hour session. Their performance, however, was characterized by its inefficiency. They received almost as many shocks as Controls, despite making nearly twice as many bar presses. Control animals learned to space out their responses--to delay responding until the latter part of the response-shock interval. Hippocampal rats showed little evidence of such temporal discrimination. They tended to emit bursts of responses, although only the first bar press in such a flurry appreciably postponed the next shock.

Amygdala lesions seem to interfere with an animal's ability to attach an appropriate instrumental response to the internal cue of conditioned fear. Further, the results are consistent with the view that the hippocampus mediates mechanisms of response inhibition.

906 DISCRIMINATION LEARNING IN ADULT RATS AFTER EARLY NEONATAL X-IRRADIATION OF THE HIPPOCAMPUS. Russell A. Gazzara* (SPON: L. J. Pellegrino). Dept. Biol. Sci., Purdue Univ., W. Lafayette, IN 47907.

Focal X-irradiation of the hippocampus during the early neonatal period (200 R on days 2,3; 150 R on days 5,7,9,11,13,15) in rats results in an 85% reduction in the number of granule cells normally forming in the dentate gyrus. Among the behavioral effects common to both reduction in dentate granule cells and classical hippocampal lesions are: deficits in passive avoidance learning and spontaneous alternation, hyperactivity in the open field, and facilitated acquisition of two-way active avoidance. One of the etiological factors underlying this syndrome of behavioral abnormalities could be some form of attentional dysfunction. A discrimination learning paradigm is well suited to an analysis of attentional dysfunction since it allows control over the stimulus environment of the subject. Three aspects of discrimination learning were studied: task difficulty (low, moderate, or high), sensory modality (visual or tactile), and cue property (localized or diffuse). Seven experiments assessed the effect of dentate granule cell reduction on discrimination learning in a T-maze.

Three of the experiments in the visual sensory modality varied only in task difficulty: low (Bright/Dark), moderate (Bright/Dim I), and high (Bright/Dim II). The X-irradiated rats showed a learning deficit only in the reversal phase of Bright/Dim I but both in the acquisition and reversal phases of Bright/Dim II. The remaining experiment in the visual sensory modality, Black/White, differed from the Bright/Dim I experiment only in that the Black/White cue was located in the walls of the T-maze (localized cue) whereas the arms of the T-maze were diffusely lit in the Bright/Dim I experiment (diffuse cue). The X-irradiated rats showed a learning deficit in both the acquisition and reversal phases of the Black/White experiment. The remaining three experiments were in the tactile sensory modality. As in the first three experiments, these three studies varied only in task difficulty: low (Rough I/Smooth), moderate (Rough II/Smooth), and high (Rough III/Rough IV). The X-irradiated rats showed no learning deficit in either the acquisition phase or the reversal phase of both the Rough I/Smooth and Rough II/Smooth experiments. The Rough III/Rough IV experiment is still in progress.

These results are discussed in light of current theories of hippocampal function.

907 EFFECTS OF NEONATAL DEPLETION OF HIPPOCAMPAL DENTATE GRANULE CELLS ON RADIAL-MAZE PERFORMANCE. Lauren Gerbrandt*, Gary Thomasson* and Joel L. Davis. Dept. Psych., Calif. State Univ., Northridge, CA 91330, and Psychobiol. Res. Lab., V.A. Hosp., Sepulveda, CA 91343.

About 90% of presumed hippocampal CA 1 pyramidal cells show feature-extraction responses selectively to only certain spatial positions on an 8-arm radial maze (Olton et al., 1978a). That these spatial codes contribute to spatial performance by rats is suggested by the finding that extrinsic lesions of fornix or entorrhinal inputs to hippocampus result in a loss of these codes (Best, pers. comm.) and inefficient attainment of the 8 rewards placed at the end of each maze arm (Olton et al., 1978b). The present study investigates whether selective disruption of intrinsic dentate granule-cell inputs to the cornu ammonis, induced by neonatal x-irradiation, also results in inefficient radial-maze performance. Specifically, 4 groups of rats (6/group) were x-irradiated on postnatal days 2,3 (200R), and 5,7,9,11 (150R), on days 2,3 (200R), on days 2 (200R),7 (150R), or sham-irradiated, in order to induce varying amounts of dentate granule-cell agenesis. At 150 days of age (± 60 days), animals were trained to retrieve the 8 food pellets placed on each arm of the maze. Preliminary results indicate that even x-irradiation schedules which deplete up to 82% of dentate granule cells result in normal radial-maze performance (>7/8 correct choices). However, with this amount of granule-cell agenesis, rats abnormally continue to run the maze after all rewards are obtained. Attempts are made to increase the spatial difficulty of the task by reducing the number of extra-maze cues available, and to eliminate sequential-response strategies by maze rotation and delays after each choice. Groups are also tested for differences in general activity and passive avoidance. Rats with fimbria/fornix ablations are compared in maze performance to granule-cell-depleted groups. The results are relevant to spatial versus response-inhibition hypotheses of hippocampal function (O'Keefe and Nadel, 1978) and to whether sparing or recovery of function (Bayer et al., 1973) occurs in dentate-granule-cell depleted rats.

908 SUBSTRATES OF INTRACRANIAL SELF-STIMULATION OF THE THALAMUS IN THE RAT. Charles R. Gerfen* and Ronald M. Clavier. Dept. Anat., Northwestern U. Med. Sch., Chicago, Ill 60611 and Dept. Anat., U. British Columbia, Vancouver, V6T 1W5, Canada.

Intracranial self-stimulation (ICSS) has been reported previously with electrode placements in midline and intralaminar thalamic nuclei of the rat thalamus (Cooper and Taylor, 1967). The recently described anatomical relations of these nuclei with ICSS regions in the dorsal agranular insular (sulcal prefrontal) cortex and the substantia nigra have led us to initiate a series of studies of the substrates of thalamic ICSS. First, ICSS probes were placed into those thalamic nuclei in which labeled cell bodies were seen (in a previous study) after injections of horseradish peroxidase into the sulcal prefrontal cortex. Specifically the parafascicular and ventromedial thalamic nuclei were examined for ICSS properties. To date, it appears that ICSS is obtained from these nuclei, but not from the nuclei in their immediate vicinity. Further mapping of the thalamus for ICSS-related areas is in progress. A second study examined catecholaminergic (CA) and non-CA fiber pathways related to these thalamic ICSS sites. After stable bar-pressing rates were obtained from thalamic electrodes, anodal electrolytic lesions (1 mA/5 sec.) were made via the ICSS probes. After a 4-day post-lesion recovery period, the animals were sacrificed and perfused with ice-cold 4% paraformaldehyde solution in phosphate buffer, via an intracardiac needle. The brains were removed and treated in 2 ways: 1) The region within 1-2 mm caudal to the lesions was blocked and sectioned on the Vibratome for histochemical fluorescence examination of possible build-up of CAs; 2) The remaining parts of the brain were sectioned after 1 week of immersion in 10% formalin for silver impregnation treatment with the method of Fink and Heimer (1967). The pattern of CA and non-CA fibers in the vicinity of the ICSS electrode tips was then compared with that seen after similar lesions made via non-ICSS electrodes in the thalamus. In several cases, lesions made via ICSS probes resulted in CA build-up in axons caudal and medial to the electrodes. These axons may be related to the dorsal periventricular system. In a third study, we are trying to determine which systems, whether or not they contain CAs, that originate in, pass through, or terminate in thalamic ICSS regions are related causally to that behavior. This is being studied with pharmacological and histochemical experiments, and with the use of electrolytic or (where appropriate) 6-hydroxydopamine-induced lesions of their cell bodies of origin.

909 CHANGES IN THE DENTATE GRANULAR CELLS FOLLOWING TETANIC STIMULATION OF THE ENTORHINAL AREA. J. B. Glenn, Margherita Marzotto* and Eva Fifková. Dept. Psych., Univ. Colorado, Boulder, CO 80309.

Since tetanic stimulation of the entorhinal area has a pronounced effect on spine dimensions of the dentate molecular layer which might be caused by increased protein synthesis, the aim of this paper was to study the effect of tetanic stimulation of the entorhinal area on the dentate granular pericarya. In EXPERIMENT I 6 controls, 3 of them with a sham procedure and 5 stimulated mice (30/sec for 30 sec) which survived stimulation for 15-90 min were used. The parameters examined were: the nuclear cross section area, the number of nucleoli and the density of membrane-bound ribosomes. There was no significant difference in these parameters between the shams and controls. However, following stimulation the nucleus was significantly larger (by 40%, $p<.05$), the number of nucleoli was increased by 22% ($p<.05$), the density of ribosomes remaining unchanged. Because of the effect of ACTH on protein synthesis and electrical activity in the hippocampus, EXPERIMENT II combined tetanic stimulation with the administration of $ACTH_{4-10}$. Twelve controls were injected either with saline (group 1) or ACTH (group 2) 15 min before sacrifice. Six saline injected mice which survived the stimulation for 1.5 min were used as another control (group 3). In 12 experiments ACTH was administered 5 min prior to the tetanic stimulus and 6 mice survived the stimulation for 10 min (group 4) and 6 mice for 55 min (group 5). In another 6 mice stimulation preceded ACTH administration by 15 min and the survival time was 70 min (group 6). In group 3 the nucleus was larger by 28% ($p<.01$) than in group 1 without a change in the number of nucleoli or ribosomal density. In comparison with EXPERIMENT I where longer poststimulation intervals showed both the nuclear enlargement and increased number of nucleoli, this result suggests that nuclear enlargement develops very quickly after stimulation and is within 10-15 min followed by an increased number of nucleoli. Between groups 1 and 2 there was no difference in all the parameters studied indicating that ACTH per se had no effect within the interval examined. Combination of ACTH with tetanic stimulation induced in group 4 nuclear enlargement (by 31%; $p<.01$) and increased number of nucleoli (by 39%; $p<.01$). Furthermore, also the density of membrane bound ribosomes became higher by 15% ($p<.05$). In group 6, where ACTH was applied 15 min after stimulation, the results were similar to those of EXPERIMENT I: nuclear enlargement by 40% ($p<.01$), increased number of nucleoli by 24% ($p<.01$) and unchanged ribosomal density. Tetanic stimulation affects the protein synthetizing system of granular cells which can be further accentuated by ACTH. [Supported by NIMH Grant MH 27240-04.]

910 CHARACTERIZATION OF POSSIBLE NEURONAL CIRCUITS IN THE OLFACTORY SYSTEM BY ELECTROPHYSIOLOGICAL AND HISTOLOGICAL METHODS. R. Guevara-Aguilar, L.P. Solano-Flores* and H.U. Aguilar-Baturoni. Departamento de Fisiología, División de Investigación, Facultad de Medicina, U.N.A.M., México 20, D.F.

The goal of our work has been to characterize the neuronal circuits and their possible function in the olfactory system. On this paper we described the results obtained applied three different techniques: horseradish peroxidase, evoked potentials and unit activity.

Horseradish peroxidase (HRP, Sigma type VI, 25%) was applied unilaterally in the olfactory bulb (OB) and in the olfactory tubercle (OT), of 20 rats and 4 cats. The HRP was delivered by microiontophoretic ejection by positive DC current (2.0-2.5μA 10 min) from glass micropipettes with tips of 25-40 μm. After 24 hr of survival time the animals were fully anesthetized and their brain perfused. The histological sections 50μ were processed following the Nauta technique. Labeled neurons were identified in the OT, prepyriform cortex (PPC), nucleus of the diagonal band, preoptic region, hypothalamus, zona incerta, mesencephalic reticular formation and other mesencephalic structures. A few cells had been observed in PPC and hypothalamus of the contralateral side.

Locus coeruleus (LC) electrical stimulation produced homolateral and contralateral evoked potentials in OB, OT and PPC. The latency of the first component of the evoked potential in the OT was 3.6 ms. In 10 rats unitary activity of the OB, OT and PPC was recorded with a glass micropipetted of 3-10 MΩ. The stimulation of the LC or the hypothalamus induced changes of the single unit activity. This results evidence olfactory afferent projections to the different structures and the electrophysiological results allowed us to give further support to the existence of centrifugal influences upon the olfactory system.

911 SENSORY BASIS FOR FIRING OF SPATIAL UNITS IN DORSAL HIPPOCAMPUS OF RATS. A. J. Hill (SPONS: P. J. Best) Dept. Psych., Univ. Virginia, Charlottesville, VA 22901.

"Spatial" units have been identified in micro-electrode recordings fron dorsal hippocampus of rats. Such units fire at their maximum rates only when rats are in specific regions of the recording space, called the units' "fields", and seem to be independent of details of the animals' behavior.

Spatial units were recorded from rats which had been trained to perform a spatial alternation task in an enclosed automated T-maze. Observations were made during and after various changes made within the recording environment. Visual changes included covering parts of the maze with striped cloth, varying the level and location of light sources and covering the rats' eyes with a rubber mask. Olfactory tests included thorough cleaning of the apparatus, and introduction of strong odors (cologne, acetone) or other rats into the field region. Auditory stimuli were changed by placing a speaker which emitted sharp clicks at various locations around the maze, and by inserting baffles or opening the top of the maze to change its acoustical properties. The rat's running path was altered by introducing hurdles and baffles into the maze. Finally rats were spun at 70 rpm in the start box between trials to produce spurious vestibular cues.

Spatial firing was eliminated in 3 out of 12 cases by visual alterations and in 6 out of 12 cases by changes in running path. No other changes were found. Results indicate that hippocampal spatial firing is based upon multi-modal sensory cues. In order to explore this aspect of sptaial firing in more detail, groups of rats were selectively deprived of either vision (by masking or enucleation), hearing (by chronic administration of neomycin antibiotic), olfaction (by intranasal $ZnSO_4$), or vibrissal input (by shaving). Spatial firing was found reliably in rats from each of the four groups. (Criterion was at least 2 cases from 2 different rats in each group. Mortality and treatment effectiveness varied between groups, making comparisons using large numbers of subjects unreliable.) Preliminary observations indicate that there are no differences between spatial firing found in any of the sensory-deprived rats and that found in normal animals. Results show that spatial firing is not, in general, a purely sensory response via any one of the above modalities.

912 FREQUENCY POTENTIATION OF RESPONSES TO FIMBRIAL STIMULATION IN RABBIT MEDIAL PREOPTIC NUCLEUS. John I. Hubbard* and Jon F. DeFrance. Dept. of Neurobiology & Anatomy, University of Texas Medical School, Houston, TX 77025.

Field potentials recorded in the medial preoptic nucleus (MPO) of urethane anaesthetized rabbits following ipsilateral fimbrial stimulation consisted of an initial spike-like negativity (latency to peak 2 msec) followed by a negative wave (latency to peak 5 msec). This in turn declined into a positive wave (latency to peak 10 msec). The position of recording and stimulating sites was confirmed by passage of fast green dye from the electrodes and later examination of fixed tissue in 120 µm frozen sections. The field was maximal in the MPO about 1 mm below the anterior commissure and 100 µm lateral to the midline.

All components of the field had similar thresholds and recording of single units suggested that the field was explicable by an entering volley, the excitation of MPO cells and the recurrent inhibition of these cells.

The negative and positive waves increased 2-4 times in amplitude during 8 stimuli at 2-12 Hz, the maximum effects being seen at 6-8 Hz, the natural output frequency of the hippocampus. There was 1-3 sec of post-tetanic potentiation.

913 PERICALLOSAL LIMBIC FORMATIONS OF DOLPHIN BRAIN. M.S. Jacobs*, P.J. Morgane and W.L. McFarland. Dept. of Path., NYU Coll. Dent., New York, NY 10010; Worcester Found. Exp. Biology, Shrewsbury, MA 01545; NIH, Bethesda, MD 20014.

Our initial cytoarchitectonic studies of the limbic lobe (LoL) in the cetacean brain have concentrated on the pericallosal (superior) limbic formations which are sharply and constantly delineated on the medial surface of the hemisphere by the callosal sulcus (SCC) and by the cetacean homologue of the sulcus cinguli we term the limbic cleft (ClL). Several significant differences are evident as compared to terrestrial mammals including man.

The cell architecture of the limbic cortex nowhere shows sharp transitions but exhibits very gradual and subtle changes as it is followed both outward from the limbic bank of SCC (peritectal area, Pt) over the free surface of the LoL (limbic area proper, ArL) to the limbic bank of the ClL, and also anteroposteriorly from the subgenual region to the splenium of the corpus callosum. In the cetacean brain the internal granular layer (layer IV) is weakly developed throughout the neocortex and is totally absent from the posterior limbic region in sharp contrast to the terrestrial pattern. Anterior limbic sectors are, overall, paucicellular as compared to posterior limbic sectors. Many of the cells present, however, are larger than found posteriorly. Cell density increases very gradually towards the posterior limbic region, the cells that appear being predominantly small in size. This increased cellularity in supragranular layers posteriorly results in the boundary between layers II and III being less distinct than anteriorly. The presence of these small cells in layer V and the tendency for larger pyramidal cells in that layer to scatter into the deep levels of layer III also make the boundary between layers III and V less clear than anteriorly.

Layers I and VI are wide, and the latter contains polymorphic cells of about the same size as in layer III. There is only a weak tendency for cells to organize into columns, a pattern distinctly different from that of primates. The area Pt is marked by the transition from archicortex to neocortex with gradual organization of the layers to the pattern found in ArL. From SCC to ClL the cell patterns of anterior and posterior limbic sectors become more definitive.

In summary, significant cytoarchitectonic variations from terrestrial patterns indicate that the cetacean limbic cortex reflects a special organization not found in land mammals. However, despite such differences, the dolphin shows a well laminated limbic cortex and areal differentiation into subsectors.

914 SINGLE NEURONAL ACTIVITY IN THE ANTEROMEDIAL CORTEX DURING MOTIVATED BEHAVIOR. John P. Kanki*, Terry M. Skinner*, Harry M. Sinnamon. Lab. Neuropsych., Wesleyan University, Middletown, CT 06457

The anteromedial cortex (AMC) supports intracranial self-stimulation (ICSS) and is a site of orthodromic and antidromic activation from stimulation of other ICSS sites. The purpose of this study was to determine, in the unrestrained rat, the activity patterns of AMC neurons during ICSS, motivated behavior related to drinking, and the response to various sensory stimuli.

Rats were tested in a cylindrical chamber, the walls of which contained three holes set 90 degrees apart. Contact with a bar presented through any of these holes produced 50Hz stimulation of the ventral tegmental area which continued until the animal contacted a 15x15 cm. plate on the wall opposite the middle hole. The water-deprived rat was provided .01% saccharine through a tube presented also via these holes. Tests for sensory responsiveness included the presentation of a moving black-white grid, single clicks sufficient to elicit a startle response, various odors including conspecific urine, and tactile stimulation of the dorsal body and face. Neural activity was differentially recorded through any pair of 25 micrometer stainless steel wires, twisted into a bundle of four wires. The bundle was lowered without rotation by means of a chronically implanted microdrive. Well isolated units could be typically held for more than one hour.

A total of 51 single units have been studied in three rats. The most common well-defined class of neurons was related to orienting behavior (n=14). They increased in activity when the rat actively investigated any of several classes of stimuli. These units lacked any consistent pattern of activity during ICSS trains or during drinking, but they tended to show an increase at the behavioral response which produced stimulation onset. Activity in another seven units was related to head movements (six units increased while one decreased). Activity in three units was associated with sniffing, and another two units increased activity when the rat oriented to, or was situated at the locus of the offset plate. The largest class of neurons (n=19) showed no discernible pattern consistently correlated with any of the stimuli or behaviors studied. A final class of neurons (n=6) seemed to code aversive and rewarding states by increases or decreases respectively in rates of activity. Increases were seen when the animal showed distress to tactile stimulation, noxious odors, or the experimenter's hand. Decreases were seen when the rat oriented to conspecific urine, and to the holes in the chamber wall. Removal of the experimenter's hand, drinking, and the onset of stimulation were also associated with decreases in activity. These patterns of activity support the tentative suggestion that the AMC might be a site at which motivational information influences systems which participate in the control of orienting behavior.

915 MATHEMATICAL MODEL OF NEURONAL FUNCTIONS IN VARIOUS SUBPOPULATIONS OF THE HIPPOCAMPUS. W. R. Klemm, N. W. Naugle*, and G. M. Barnwell.* Dept. Biology, Texas A&M University, College Station, TX 77843.

We have developed a mathematical model of hippocampal function that is intended to describe the interactions of input activity with the activity of various intrahippocampal populations of neurons. The pools of neurons that are assumed to be functionally homogeneous include the septal and entorhinal sources of input, and the granule cells, CA field pyramidal cells, and basket cells. The model is bilaterally symmetrical, with activity of each homogeneous population in each hemisphere described as a first order nonlinear differential equation. Parameters are simulated, with activity defined in relative units ranging from 0 to 1.0. The 26 equations (13 identified pools in each hemisphere) are solved simultaneously by computer to produce plots of the time course of activity changes in each of the populations.

Each neuronal pool has its own specific version of the equation that is based on its known functional connectivities, but the general form of the equation is:

$$dX_i/dt = (X_i/X_{max})(X_{imax}-X_i)(IE_{xi} + \Sigma_j EE_{ij}X_j + \Sigma\ NnE_{xi}) - (\Sigma_k EI_{ik}X_k + \Sigma\ NnI_{xi}) - D_{xi}$$

where X_i = relative activity in any given pool, X_{imax} = maximum possible activity in any given pool, IE = internal (recurrent) excitation within a pool, EE = external excitaton from each of the various inputs to the pool, NnE = nonneural sources of excitation, EI = external inhibition from inputs to the pool, NnI = nonneural inhibition, and D = a decay constant (i.e. rate at which activity would decay in a given population if input ceased).

The simulations performed thus far seem to be useful in evaluating the population dynamics that might underlie such hippocampal phenomena as the electrographic "theta" rhythm. Solutions to certain of the equations can be made by appropriate parameter assignment to oscillate at different frequencies or made to reach a non-oscillating steady state of activity.

916 THE HIPPOCAMPAL CA1 REGION IN THE CHRONIC IMPLANTED RAT: A STUDY OF ANESTHETIC ACTION AND BEHAVIORAL STATES. L. Stan Leung. Dept. Psych., U. Western Ontario, London, Ont., Canada, N6A 5C2.

Stimulation of varying intensity was delivered via electrodes implanted in the anterior alveus (AA), Schaffer collaterals (Sch) and posterior alveus (PA) and averaged evoked potentials (AEPs) were recorded at different depths in CA1 region. Previous reports (Leung, Neurosci. Abst. 4: 224, 1978) showed that at least three synapses are involved in the generation of the AEPs in sodium pentobarbital (NEM) anesthetized rats: (1) excitatory (E-) postsynaptic potentials (PSPs) in str. radiatum; (2) EPSPs in str. oriens; and (3) inhibitory (I-) PSPs in str. pyramidale and radiatum. Similar AEPs with different component amplitudes could be found in the waking, immobile rat.

AEPs and behaviors were studied following treatment with ether (ETH) or NEM. From the AEPs, it was inferred that (1) both ETH and NEM attenuated the population EPSPs at doses that immobilized the animal except for the str. radiatum EPSP which was resistant to NEM; (2) population spikes evoked by high stimulus intensities were suppressed under ETH or NEM; (3) the population IPSP was only slightly affected by ETH but its amplitude and duration increased greatly at low intensity stimulation under NEM (>10 mg/kg i.p.). The results showed a non-uniform action of ETH and NEM in the hippocampus.

During behaviors that are accompanied by a hippocampal theta EEG, e.g., walking, rapid-eye-movement sleep, the Sch-AEPs (and less apparently, the AA-AEPs) characteristically showed a decreased initial peak and an increased second (and possibly third) peak occurring at an earlier latency as compared to AEPs during behaviors that are not accompanied by theta, e.g., immobile awake and slow-wave sleep. This behavior-AEP relation however virtually disappeared after a 50 mg/kg i.p. dose of atropine sulfate while the behavior-EEG relation could still be seen. Extension of a reported model (Leung, Biol. Cybernetics 31: 219, 1978) suggests that theta related behaviors increase the negative feedback gain within an interactive population of excitatory and inhibitory neurons, possibly mediated by muscarinic cholinergic synapses.

917 RELATIONSHIP BETWEEN THE LIMBIC THETA RHYTHM AND NEURAL ACTIVITY IN THE OLFACTORY BULB. Foteos Macrides, William M. Youngs and Barry J. Davis. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

The present study examined the temporal relationship between the limbic theta rhythm, monitored as rhythmic slow wave activity (RSA) in the dorsal hippocampus, and the slow wave and spontaneous single unit activity recorded simultaneously in the main olfactory bulb (MOB). Adult male hamsters were paralyzed with d-tubocurarine and artificially respired with a mixture of nitrous oxide and oxygen. Pulsatile nasal airflow was eliminated so as to remove this influence on slow wave and unit activity in the MOB. In some preparations, infusions of physostigmine salicylate were used to increase the incidence of hippocampal RSA. Antidromic stimulation of the lateral olfactory tract was employed to distinguish recordings from output neurons versus interneurons.

Retrospective computer analyses of tape recorded data revealed a strong relationship between hippocampal RSA and neural activity recorded in the MOB. When the principal frequency component of the hippocampal slow wave record was in the theta range (as determined by the Fast Fourier Transform), slow wave activity of the same frequency also was prominent in the MOB. The FFT analyses demonstrated that these frequency components of the MOB slow wave activity bore consistent phase relationships to the corresponding components of the hippocampal RSA. Under these conditions, zero crossing analyses demonstrated that single units in the MOB fired with consistent temporal relationships to individual cycles of the hippocampal RSA. Significant correlations were found both for output neurons and for interneurons of the MOB, and in some cases the temporal relationships were as striking as those reported for neurons in the hippocampus itself. Additional analyses ruled out the possibility of spurious correlations introduced by heart- or respiration-related pulsation artifacts.

These results are interesting in view of our previous findings that MOB units fire in odor-specific, inhalation-related patterns which can be selectively enhanced or suppressed by appropriately timed activation of centrifugal inputs to the MOB, and our demonstration that during investigation of behaviorally relevant odors hamsters and rats often time their sniffs with a consistent temporal relationship to individual cycles of the hippocampal RSA. Our HRP studies have revealed centrifugal projections to the MOB from the vertical limb of the diagonal band, which is thought to be part of the pacemaker system for the limbic theta rhythm. The present results suggest that these or related centrifugal projections may interact with local circuits in the MOB to modulate the temporal firing patterns of MOB output neurons.

918 MORPHOLOGY AND ELECTROPHYSIOLOGY OF DENTATE GRANULE CELLS: INTRACELLULAR RECORDING AND STAINING IN THE HIPPOCAMPAL SLICE PREPARATION. Brian A. MacVicar and F. Edward Dudek. Dept. Zool. and Erindale College, Univ. Toronto, Mississauga, Ont. L5L 1C6.

The granule cells of the dentate gyrus form a major relay in the basic circuitry of the hippocampal formation and represent an unusually homogeneous population of short-axon neurons. Although these cells have been the subject of numerous studies with extracellular recording, their small size (~10 μm) has limited electrophysiological analyses with intracellular recording techniques. The main purpose of these experiments was to determine whether granule cells exhibit fast prepotentials (FPPs), which have been extensively analyzed in hippocampal pyramidal cells.

Conventional, high-resistance micropipettes were used to impale granule cells in slices of rat hippocampus maintained in vitro. FPPs occurred in 9 (53%) of the 17 cells (action potential amplitude 40-70 mV) so far examined. In this group of 9 cells, 3 (33%) had spontaneously occurring FPPs. Excitatory postsynaptic potentials (EPSPs) from perforant path (PP) stimulation evoked FPPs in 5 (55%) of these cells whereas in 7 (77%) of these cells antidromic mossy fiber stimulation evoked FPPs. The FPPs of granule cells had many characteristics similar to dendritic spikes of pyramidal cells. They were constant amplitude (range 4 to 15 mV in different cells), occurred in an all-or-none fashion and had fast rising and falling phases. During orthodromic activation by stimulation of PP, they were observed on the peak of the EPSP or were revealed by hyperpolarizing current injection which blocked the soma spike. Antidromic activation also elicited short-latency FPPs that had a lower threshold than the full spike.

FPPs could arise from several mechanisms which are not mutually exclusive: 1) dendritic spikes; 2) electrotonic coupling; 3) axonal spikes. We are presently using intracellular staining with Lucifer Yellow to examine dendritic anatomy and to investigate the possibility of dye-coupling. These anatomical observations, combined with further electrophysiological tests, should help delineate the underlying source(s) of the FPPs.

919 CONVERGENCE OF LIMBIC PROJECTIONS UPON SINGLE NEURONES IN THE VENTROMEDIAL NUCLEUS OF THE HYPOTHALAMUS OF THE RABBIT. J.E. Marchand and J.F. DeFrance. Department of Neurobiology and Anatomy, The University of Texas Medical School at Houston, P.O. Box 20708, Houston, Texas.

Electrophysiological techniques were used to record extracellular unitary potentials of neurones within the ventromedial nucleus (VMH). Stimulating electrodes (glass micropipettes, filled with 2 M NaCl) were placed in the dorsal and ventral components of the stria terminalis (ST) and the lateral portions of the fimbria. Animals were anesthetized with urethane (1g/kg, i.p.).

Cells within the VMH were activated from all three stimulation sites. Central ST stimulation evoked action potentials with little variability in latency, 8-10 msec. Dorsal ST stimulation activated the same neurones with a considerable variability in latency, 25-35 msec. Lateral fimbria stimulation activated the same neurones, also with a considerable variability of latency, 15-20 msec.

In addition to the excitatory influence dorsal ST and lateral fimbria stimulation effected upon neurones in the VMH, both stimulation sites produced an inhibition of spontaneous activity. This inhibitory period coincided in onset with the positive field potential evoked by each of these stimulation sites when recording within the VMH. This suggests that the positive field potential represents IPSP's evoked intracellularly, as first suggested by Murphy and Renaud (1969).

These studies provide evidence for convergence of ST fibers, which arise largely from the amygdala (De Olmos & Ingram, 1972) and lateral fimbria fibers, which arise from the ventral subiculum (Swanson & Cowan, 1977), upon single neurones within the VMH. The excitatory responses to dorsal ST and lateral fimbria appear to relay through one or more synapses, as evidenced by their variable latency. These relay centers might be located in more anterior areas of the hypothalamus or basal forebrain to which these fiber pathways are known to project (Swanson & Cowan, 1977, and DeOlmos & Ingram, 1972).

This study was supported by NSF GB-55552 and Scottish Rite Schizophrenia Foundation.

920 DELAYED DEFICIT IN NEST BUILDING AFTER LATERAL OLFACTORY TRACT CUTS IN THE HAMSTER. David M. Marques, Robert J. O'Connell, Nicholas Benimoff* and Foteos Macrides. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

The lateral olfactory tracts of male hamsters were severed between the posterior end of the olfactory peduncle and the posterior end of the olfactory tubercle to determine the involvement of bulbar efferents in nest building and sexual behavior. Animals were tested during the week preceding surgery and during the first and third weeks after surgery for 1) nest building in large clean cages, and 2) sexual behavior with cycling females. They also were rated daily for the quality and size of nests and food piles in their home cages. Before sacrifice, animals were given a food sniffing test. Although, as expected (Devor, BRAIN RES. 64: 437, 1973), sex behavior was eliminated immediately in animals with complete cuts, most animals continued to build good nests during the first week after surgery. Nest building disappeared completely in these animals by the end of the second week. This unusual delayed deficit was observed both in home cage nest building and in the more sensitive clean cage nest building tests. Concurrent activity in the LOT thus appears unnecessary for nest building, but an intact LOT seems to be important for the continued normal functioning of a neural system which supports nest building. Slow degenerative changes in that system may account for this interesting delay in the appearance of the behavior deficit.

921 THE EFFECT OF KAINIC ACID ON CHOLINERGIC ACTIVITY IN THE AMYGDALA-PIRIFORM CORTEX OF THE RAT. James McCaughran, Jr.* and Nisson Schechter. (SPON: A. Orr). Departments of Psychology, Psychiatry and the Long Island Research Institute, SUNY at Stony Brook, Stony Brook, New York 11794.

The local intracerebral injection of kainic acid, an analogue of glutamate, reportedly destroys intrinsic neuronal cell bodies but not afferent fibers. In the present study, kainic acid or phosphate buffer alone were injected into the amygdala-piriform cortex area of the rat. The effects on the cholinergic enzymes, choline acetyltransferase (CAT) and acetylcholinesterase (AChE), and the binding of the muscarinic ligand, ^{3}H-quinuclidyl benzilate (QNB), and the nicotinic ligand, ^{125}I-alpha bungarotoxin (aBuTX), were investigated. Twenty-four hr following the injection of kainic acid, CAT activity in the amygdala-piriform cortex area was reduced to 85% of the control. The reduction in CAT activity was time-dependent with the maximal reduction occurring at 5 days post-injection of kainic acid. Kainic acid also reduced the AChE activity by 17% at 24 hr and remained unchanged. At 24 hr, the binding of QNB and aBuTX was also unchanged. By 72 hr, the number of QNB and aBuTX binding sites were reduced to approximately 65% of the control. The number of sites fell to approximately 45-50% of the control by 5 days and remained at this level. In addition, at 72 hr the binding of QNB and aBuTX in the amygdala-piriform cortex area contralateral to the kainic acid injection was reduced to 85% of that of the same area in the control rats. The binding of QNB in the area contralateral to the injection site remained at 85% of the control. However, binding of aBuTX in the area contralateral to the kainic acid injection site fell to 60% of the control by 5 days and remained unchanged. The results indicate that the loss of QNB and aBuTX sites after kainic acid injection approximates the loss of CAT activity. Whether these binding sites are located on the proposed intrinsic cholinergic neurons or on some, as yet undefined, post-synaptic structure is not clear. The rapid and differential loss of aBuTX sites in the contralateral amygdala-piriform cortex after 5 days suggests either a presynaptic locus of these sites (presumably lost due to anterograde degeneration) or a postsynaptic locus of these sites (presumably lost due to retrograde degeneration). Regardless, the differential loss of aBuTX sites in the contralateral structure may reflect a difference in the neuronal localization of the muscarinic and nicotinic receptor sites in the amygdala-piriform cortex area, and further suggests the existence of reciprocal monosynaptic connections between these two areas.

922 LOCAL CIRCUIT NEURONS OF THE OPOSSUM BASOLATERAL AMYGDALA: A GOLGI STUDY. Alexander J. McDonald* (SPON: N. S. Shah). West Va. Univ. Med. Ctr., Morgantown, WV 26505.

In this study 46 adult opossum brains were stained with the zinc chromate and Kopsch modifications of the Golgi technique. The neuronal morphology in all nuclei of the basolateral amygdala was found to be similar and four major neuronal classes were recognized. Class I neurons are spiny projection neurons which resemble those described in the cat, except that the axon hillocks and initial segments of these cells bear spines in the opossum. Class II, III and IV neurons appear to be local circuit neurons. Class II neurons are characterized by a paucity of dendritic spines and a moderate to very dense local axonal arborization. In the lateral nucleus these cells have small, round somata with 4-6 primary dendrites, while in the basal nuclei they have medium-sized fusiform or multangular cell bodies with 2-4 primary dendrites. Another variety of Class II neuron resembles the "chandelier cell" of the cat neocortex (Szentagothai, '75). The axons of these amygdaloid neurons have several major branches which give rise to beaded collaterals. These collaterals coil and fold back on themselves within a restricted area to form "axonal nests" that are 3-5 μm wide and 10-25 μm long. One neuron may form as many as 40 such nests and these are often interconnected by collaterals to form an extensive local axonal network. Axonal nests are randomly-oriented and have been seen embedded in an amber-colored, glial-like sheath. Class III neurons have small, spherical somata with 6-9 short, tortuous dendrites which sometimes appear to contact spiny dendrites of class I neurons. Dendrites have a moderate covering of spines; some of these spines have two swellings in series and an elongated stalk. Axons are rarely observed. Class IV neurons have very small cell bodies (6-10 μm) with 2-4 thin processes which branch sparingly and never extend more than 100 μm. It is often difficult to determine which, if any, of the processes is the axon.

923 AFFERENT CONNECTIONS OF THE AMYGDALA IN THE CAT. William R. Mehler, Patrick W. Mantyh* and Kevin D. Phelan*. Ames Res. Ctr., Moffett Field, CA 94035 and Dept. Anat. Univ. Cal. San Francisco, CA 94143.

Previous horseradish peroxidase (HRP) studies of the subcortical amygdalar afferent connections in the monkey (Mehler, et al., Anat. Rec. 190:477, 1978) and in the rat (Pretorius, et al., Anat. Rec. 193:657, 1979) confirmed the presence of some amygdalopetal cells described in the nucleus of the tractus solitarius and a large number of cells from the parabrachial nuclei at pontine levels in the rat (Ricardo and Koh, Brain Res. 153:1-26, 1978). In addition to these cells, HRP injections into various parts of the amygdalas in monkeys and rats also labelled cells in the dorsal and medial (Bechterew and linearis) raphe nuclei in the midbrain.

HRP injections of amygdalae of 18 cats (3.0 - 0.5 ul, 50%$^{+}$ solution, 24-52 hr survival, 1.5% glutaraldehyde - 0.5% paraformaldehyde/ pH 7.4, DAB or BDHC substrate) demonstrate comparable patterns of HRP-positive (HRP+) cells at pontine and mesencephalic levels. Large numbers of HRP+ cells delineate from the medial geniculate body the feline homologue of the simian and rodent peripeduncular nuclei.

In the hypothalamus, varying populations of HRP+ cells appear most consistently in the dorsomedial nucleus and in the lateral hypothalamic area at tuberal and mammillary levels. Labelled cells appear throughout the ventromedial nucleus only in the most medial amygdala injections.

The most imposing pattern of amygdalopetal cell labelling appears in certain ipsilateral subdivisions of the midline nuclei of the dorsal thalamus, namely; the paraventricularis (PA) and a cell group interposed perpendicularly between PA and the nuc. centralis medialis (Cem), the latter of which may also send axons to the amygdala. Cem, however, appears to project chiefly to the claustrum or adjacent cortical areas (Mantyh and Mehler, In preparation). Small HRP injections involving only the dorsal part of the amygdala fail to label PA but uniquely label nuc. subparafascicularis, for example, and also selectively labels cells in the bed nucleus of the stria terminalis not seen even in large ventral or lateral quadrant amygdala injections.

Although amygdalopetal labelled cells have been found to exist in the medial part of the nuc. medialis dorsalis in the rat (Pretorius, et al., 1979) there is no evidence, to date, for such connections in either the cats of the present series or in the monkey previously studied (Mehler, 1979, In press).

924 PLACE UNITS ARE DIFFERENTIALLY DISTRIBUTED WITHIN HIPPOCAMPAL FIELDS IN THE RAT. Virginia M. Miller and Phillip J. Best, Dept. of Psychol., Univ.of Va., Charlottesville, Va. 22901.

Correlation between hippocampal unit activity and an animal's location in space has been reported during a variety of spatial discrimination tasks. Units which show significant change in firing rate dependent only on an animal's location in space and independent of the animal's activity in that location are called place units. Manipulations such as maze rotation which do not disrupt the animal's spatial task performance, do not disrupt place unit integrity. Further, if spatial task performance is debilitated by lesions of hippocampal connections, then place unit integrity is also disrupted.

The flow of information through the hippocampus proceeds from the entorhinal cortex to the dentate gyrus and then to CA-3 and CA-1. The present study addresses the questions: What is the relative distribution of place units within the hippocampal fields and dentate gyrus, and do lesions of hippocampal connections differentially affect the integrity of place units within each field?

Rats were trained to continuously traverse a radial 8-arm maze for food reward. Hippocampal unit activity was recorded and compared among 3 groups: control (C), no lesion; fornix lesion (FL); and bilateral entorhinal lesion (EL).

All of the 18 units recorded in the regio-superior (RS) from the C group were place units. That is, firing rate significantly increased when the rat traversed 1 or 2 particular arms of the maze. Upon 90^{o} rotation of the maze, all units in the C group persisted with increased activity in the original directional orientation. Either lesion, FL or EL, significantly reduced the number and degree of persistence of place units in the RS: in the FL group, 22 of 29 units were place units, 10 of 22 persisted; in the EL group, 10 of 19 units were place units, 1 of 10 persisted.

Fewer place units were found in the regio-inferior (RI) than in the regio-superior in all groups. Only 3 of 8 in the C group, 1 of 7 in the FL group and 4 of 7 in the EL group were place units in the RI. The degree of persistence during maze rotation was not different between the regios-inferior and superior within groups.

The reduction in number of place units in both RS and RI following lesion of hippocampal connections suggests that convergence of input is necessary for the establishment of a unit's place field. The differential distribution of place units within the hippocampal fields has implications as to the sequence of processing of spatial information. (Supported by grants NSF #SER7618457 and NIMH #16478 to PJB).

925 COHERENCE SPECTRAL STUDIES OF THE ELECTRICAL ACTIVITY OF THE LIMBIC SYSTEM AND CEREBRAL CORTEX. R. J. Morgan, C. C. Turbes and G. T. Schneider*. Dept. Biophysics and Physiol., Colorado State Univ., Ft. Collins., CO 80721 and Dept. Anat., Sch. Med., Creighton University, Omaha, NE 68178.

Estimates of coherence functions are used to investigate the relationships between signals in two areas of the brain. Some of these signals have been recorded from frontal, occipital and temporal cortex, amygdala, septal and accumbens nuclei. Recordings are made with cats using hardwire and radiotelemetry. This permitted analysis of electrical activity of the brain during free moving and limited motor behavior states.

The coherence of a signal, as 40 Hz rhythm and sensorimotor rhythm (12-14 Hz) (SMR) is a function of frequency. At each frequency of the power spectrum the coherence function has a value between zero to one which gives a measure of correlation or phase locking of the signal in two areas in the brain.

The coherence estimates of 40 Hz, SMR and theta rhythm are made during certain behavioral states, and during the action of central nervous stimulants and depressants. During action of depressants there is a decrease in coherence in the 15 Hz to 40 Hz frequency range. There is a decrease of coherence first between areas of the cerebral cortex followed by cortex and amygdala. In the 1 Hz to 5 Hz range, signals between the cortex and amygdala showed coherence levels higher than those between two areas of the cortex.

Central nervous system stimulants, the amphetamines, increased coherence in the 30 Hz to 50 Hz range between cortical areas and cortex and subcortical nuclei. In the 1 Hz to 5 Hz range there was an increase in coherence whether the data came from two cortical areas or a cortical and subcortical area. There is a shift of increased coherence in signals in the 40 Hz to 50 Hz range and higher frequencies. These findings were more evident in the cerebral cortex and amygdala data.

926 HIPPOCAMPAL INFLUENCES ON AMYGDALA UNITS IN THE AWAKE MONKEY. Frederic Morrison and Charles Poletti*. Massachusetts General Hospital, Boston, MA 02114.

Amygdala extracellular unit activity in the awake, restrained squirrel monkey was studied in response to hippocampal electrical stimulation. Hippocampal volleys elicited responses in 20% (96) of 476 units tested in three monkeys. The spontaneous firing rate of responsive units was higher than that of nonresponsive ones. Ipsilateral anterior hippocampal stimulation was more effective than posterior or contralateral stimulation. Hippocampal influence was topographically organized. In the six areas with more than 25 tested units, the basomedial nucleus has the highest percentage of responsive units (39%), followed by the accessory basolateral (33%), central (22%), basolateral (21%), and lateral (5%) nuclei, and the anterior amygdala area (4%). Initial excitation (E) was more prevalent than initial inhibition (I) in the central (90% E vs. 10% I) and basomedial (82% E vs. 18% I) nuclei; but initial inhibition was more common in basolateral (37% E vs. 63% I) and accessory basolateral (33% E vs. 67% I) nuclei. The mean response latency was 30.8 msec, ranging from 12-130 msec.

The basomedial nucleus appears to receive the most potent hippocampal influence with the highest percentage of responses to single and multiple shocks and smallest mean latency. In this nucleus there was a preponderance of short latency (12-20 msec), brief (less than 20msec duration) excitatory responses with little variability in latency to single shock stimulation; 16% of tested units in basomedial nucleus had these characteristics compared to only 1% of units in other amygdala nuclei. These response characteristics are consistent with a hypothesized relay of nonfornix hippocampal influences on basal forebrain and hypothalamus via the basomedial nucleus (Poletti and Sujatanond, Soc. Neurosci. Abstr. 3: 203, 1977).

927 INSULAR CORTEX AND AMYGDALA HAVE RECIPROCAL CONNECTIONS IN THE RHESUS MONKEY. Elliot J. Mufson, M.-Marsel Mesulam, and Deepak N. Pandya. Bullard and Denny-Brown Laboratories of the Beth Israel Hospital and Harvard Medical School, Boston, MA 02215 and the V.A.M.C., Bedford, MA 01730.

Connections of the insular cortex are currently being investigated with ^{3}H amino acid (AA) autoradiography as well as with horseradish peroxidase (HRP) histochemistry. In this report we present initial observations regarding the connections between insula and amygdala. Following ^{3}H-AA injections in the rostral part of the insula, widespread labeling was observed in the amygdaloid nuclei rostral to the anterior commissure, as well as in the central, lateral, and basal medial nuclei. On the other hand, injections of ^{3}H-AA confined to the caudal parts of the insula showed a more restricted pattern of label predominantly concentrated in the central and lateral amygdaloid nuclei. Our observations also indicate that there is further topographical organization among certain projections from the insula to individual nuclei of the amygdala. As far as the lateral nucleus of the amygdala is concerned, ^{3}H-AA injections into the rostral insula showed distinct concentrations of labeling in its anterior part while injections of more caudal parts of the insula showed a discrete locus of labeling in the more caudal and dorsal parts of this nucleus. In the basal medial nucleus, injections within the rostral insula resulted in labeling restricted to its medial aspect while more caudal injections resulted in additional labeling more laterally in the same nucleus.

In other experiments, HRP was injected into insular cortex. When the injection remained confined to the anterior insula, HRP-positive neurons were observed in several amygdaloid nuclei rostral to the anterior commissure. On the other hand, injections which also involved more caudal parts of the insula resulted in additional HRP-positive neurons within the lateral and basal medial nuclei.

Even though the enzyme and amino acid injections in most cases spread into parts of the claustrum, the extent of this involvement was quite minor. In conclusion, the data would indicate that the insular cortex and the amygdala in the rhesus monkey have reciprocal connections that are topographically organized.

928 KAINIC ACID NEUROTOXICITY TOWARD HIPPOCAMPUS: DEPENDENCE ON SPECIFIC EXCITATORY PATHWAYS. J. Victor Nadler and Gilbert J. Cuthbertson*. Dept. Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

The potent convulsant, kainic acid (KA), readily destroys rat hippocampal neurons when injected locally or intraventricularly. In several regions of brain the neurotoxic action of KA depends on the integrity of excitatory inputs which are thought to be glutamatergic. We have investigated this issue by making selective lesions of hippocampal afferents and 3 days later injecting KA either intraventricularly (3.75 nmol) or locally (2.34 nmol) over a 30-min period. At the doses used in this study, intraventricular KA destroys only the CA3-CA4 cells, whereas locally injected KA destroys the majority of each neuronal type in the hippocampal formation.

Both destruction of hippocampal mossy fibers with colchicine and transection of these fibers markedly attenuated or abolished the subsequent toxicity of intraventricular KA toward CA3 cells. These pretreatments conferred no protection against KA injected locally. Conversely, removal of projections from the entorhinal cortex protected dentate granule cells and, to a somewhat lesser extent, hippocampal pyramidal cells from destruction by locally injected KA, but little affected the hippocampal toxicity of intraventricular KA. A commissurotomy did not greatly change the hippocampal lesion made by either route of administration. The entorhinal projection to dentate granule cells is probably glutamatergic, and some of the commissural fibers may be also, but the mossy fibers probably are not. Intraventricularly and locally injected KA destroyed somewhat different populations of neurons outside the hippocampal formation. All three types of deafferentation appeared to reduce this extrahippocampal damage.

These results emphasize the dependence of KA neurotoxicity on excitatory circuitry, in accordance with the idea that generalized and sustained seizure activity plays an important role in the etiology of KA-induced neuronal degeneration. The critical excitatory pathways probably need not be glutamatergic. Finally, the neurotoxicity of intraventricularly and locally injected KA involves somewhat different mechanisms. (Supported by NSF grant BNS 73-13051).

929 CONDITIONING OF HIPPOCAMPAL THETA ACTIVITY IN AWAKE, FREE-RANGING CATS. Arden V. Nelson*, William J. Jackson and June Kearns*
It has been shown that theta conditioning of Flaxedilized animals can be readily accomplished (Black, Am. Sc.,1971, 59:236-245; Glazer, JCPP, 1974, 86:267-273) but little work has been done with animals in their normal awake state. In the present study an attempt was made to condition the unique 4-7 Hz slow wave activity (theta waves) of the dorsal hippocampus in awake free-ranging cats. We used two different methods to detect the occurence of theta activity. One method calculated the ration of 4-7 Hz filtered activity to broad-band filtered (0.1-40 Hz) activity, and if the ratio was greater than the target value, a reward was given. The other method measured the wavelength and amplitude of the hippocampal activity and when a fixed number of waves met the wavelength and amplitude criterion, a reward was given. The rewards for both groups was electronic stimulation to a pleasure center in the lateral hypothalamus.

Two groups (one for each detection method) of three cats each were first trained to lever press for a reward to establish that the electronic stimulation had rewarding properties. Once this had been confirmed, the cats were conditioned for at least 30 days using a differential training method. At the end of the training period, each animal was also tested during an extinction trial. Initial examination of the learning curves indicated that only one cat learned the task, but closer examination of its learned activity showed that it had not learned to increase theta activity. Power spectrial analysis coupled with step-wise discriminate analysis did show that changes in the hippocampal theta activity did occur in some animals.

930 SELECTIVE DISTRIBUTION OF PROJECTIONS FROM AMYGDALA TO PREFRONTAL CORTEX IN RHESUS MONKEY. Linda J. Porrino* and Patricia S. Goldman. Sec. Devel. Neurobiol., NIMH, Bethesda, MD 20205

The projections of the amygdala to prefrontal association cortex in rhesus monkey were studied using horseradish peroxidase histochemistry and autoradiography for tracing neural connections. Microquantities of HRP were injected into one of the five following subdivisions which together comprised virtually the entire prefrontal association cortex: (1) the superior prefrontal gyrus on the dorsomedial wall of the hemisphere; (2) the dorsal bank of the principal sulcus and adjacent dorsal convexity; (3) the ventral bank of the principal sulcus; (4) the lateral inferior convexity; and (5) the medial orbital and rectus gyri. After two days, the monkeys were perfused with mixed aldehydes and frozen sections were reacted with benzidene dihydrochloride.

Following HRP injections in the superior prefrontal, medial orbital and rectus gyri, labeled neurons were located in the lateral and basolateral nuclei of the amygdala. However, no reaction product could be located in neurons in any part of the amygdala following HRP injections into the cortex of either the dorsal or ventral banks of the principal sulcus or the cortex of the lateral inferior convexity.

To expose the full extent of amygdalo-prefrontal projections directly, all nuclear components of the amygdala were injected with tritiated amino acids. In serial sections processed for autoradiography, radioactivity was distributed in sharply circumscribed territories of the prefrontal cortex. Supporting our HRP data, silver grains were found only over the orbital cortex and gyrus rectus on the ventral and ventromedial aspects of the lobe and also over the superior prefrontal gyrus on the medial surface of the hemisphere. In marked contrast, label did not exceed background levels over the territories of the entire dorsolateral convexity that extend from the edge of the hemisphere to the longitudinal fissure, including the principal sulcus.

Thus, on the basis of amygdalofugal projections, the primate prefrontal cortex of rhesus monkeys may be divided into two sharply segregated systems: i) a ventromedial system which constitutes the entire prefrontal projection of the amygdala and ii) a dorsolateral system which is essentially devoid of amygdalofugal projections. The ventromedial subdivision seems to correspond to the prefrontal cortex of the rat in which projections from the amygdala, the mediodorsal nucleus of the thalamus and the ventral tegmentum overlap (Krettek and Price, 1977; Divac, et al., 1978). However, there appears to be no obvious homologue in the rodent comparable to the extensive amygdala-free dorsolateral convexity so prominent in primates.

931 BACLOFEN DOES NOT BLOCK THE SYNAPTIC ACTION OF THE PERFORANT PATH ON HIPPOCAMPAL CELLS. W. Reinhardt*† and Y. Ben-Ari*+(SPON: B. Milner). Dept. Research in Anaesthesia, McGill University, 3655 Drummond St., Montreal PQ Canada. H3G 1Y6

The β-(4-chlorophenyl) derivative of GABA (approved name, baclofen; proprietary name, Lioresal) depresses the release of endogenous excitatory transmitters - in particular glutamic acid - evoked in cortical slices by electrical stimulation (Potashner, J. Neurochem. 32 (1979) 103). Furthermore, Fox *et al.* (Neuroscience, 3 (1978) 495) have suggested that systemic baclofen blocks primary afferent synapses by a presynaptic action, perhaps due to a depression of glutamate release. We have investigated the effects of baclofen on transmission from the perforant path (originating in the entorhinal cortex and projecting to the fascia dentata, and CA3 area). The excitatory transmitter released from the perforant fibers is believed to be glutamic acid (Nadler Nature, 360 (1976) 538). Baclofen (CIBA-Geigy) was administered systemically (i.v. or i.p., 0.2-20 mg/kg) or *in situ* (see below) in male Sprague-Dawley rats. The animals were kept under nembutal or dial anaesthesia and bipolar concentric metal electrodes were placed in the entorhinal cortex, fascia dentata and CA3. The field potentials (negative in the dendritic layer, positive in the cell body layer, latency 5-8 msec) were similar to those previously described by Lømo (Exp. Brain Res. 12 (1971) 18). They also manifested the typical frequency potentiation, and post tetanic potential which are characteristic of the perforant path response (ibid). Systemic baclofen, in doses which abolished the withdrawal reflex in response to electrical stimulation of the paws, had no effect on the hippocampal field potentials. In another experimental series, hippocampal responses were recorded using a micropipette (filled with NaCl 2M) and baclofen (5 μg/μℓ applied *in situ* via an adjacent pipette (50 μ tip diameter, 100 μ distance from the recording pipette). Baclofen (up to 10 μℓ) did not provoke the prolonged depression previously described in the spinal cord (Fox *et al., ibid*). In contrast, local applications (via another pipette) of Mn (250-1000 mM, 1 μℓ) completely blocked the responses.

These results suggest that if the perforant path indeed releases glutamate, then one must conclude that this system differs from other glutaminergic terminals. One cannot exclude the possibility that baclofen blocks transmission by another mechanism.

932 DIENCEPHALIC AND BRAINSTEM AFFERENTS TO THE HIPPOCAMPAL FORMATION OF THE RAT. J.N. Riley, E.R. Marchand, and R.Y. Moore: Dept. Neurosciences, Univ. California San Diego, La Jolla, CA 92093

The afferents to the hippocampal formation (HF) of the rat were studied with the horseradish peroxidase (HRP) retrograde tracing method. Our results indicate that the HF receives a projection from virtually the entire hypothalamus, several thalamic nuclei, and portions of the brainstem that have not been reported previously to project to the HF.

HRP was injected or deposited microelectrophoretically in the dorsal or ventral HF of 25 adult female Sprague-Dawley rats. Following survival times of 16-28 hrs., animals were perfused and frozen sections were processed by a modified benzidine dihydrochloride procedure.

In the thalamus, labeled neurons were found in the nucleus reuniens, paraventricular nucleus, ventromedial nucleus, and zona incerta. The projection from nucleus reuniens appears to be topographically organized: dorsal HF injections label cells predominantly in the dorsomedial part of the nucleus; ventral HF injections label cells predominantly in the ventrolateral region.

In the hypothalamus, scattered neurons were observed in virtually all hypothalamic nuclei and areas. Hypothalamic regions containing labeled neurons are too numerous to list here. The supramammillary region contained the largest number of labeled cells. This projection appears to be topographically organized: dorsal HF injections label cells in the anterior-lateral region; ventral HF injections label cells in posterior-medial region.

In the brainstem, labeled neurons were observed in the mesencephalic raphe (both raphe dorsalis and central superior) and nucleus locus coeruleus, as reported previously. Labeled neurons were also observed in a restricted portion of the interpeduncular nucleus (pars dorsalis magnocellularis) and surrounding ventral tegmental area, the region corresponding to the location of group B9, the so-called dorsal tegmental nucleus pars lateralis, and the region caudal to the nucleus raphe dorsalis apparently corresponding to the nucleus paramedianus dorsalis of Ziehen.

These results indicate that the HF receives a larger number of diencephalic and brainstem afferents than has been reported previously and provide additional anatomical support for Nauta's (1958) formulation of a "limbic midbrain" region.

933 EFFECTS OF MORPHINE AND OPIOID PEPTIDES ON CELLULAR ACTIVITY IN THE HIPPOCAMPAL SLICE. J.H. Robinson* and S.A. Deadwyler* (SPON: J.G. McCormick). Dept. of Physiology and Pharmacology, Bowman Gray Med. Sch., Winston-Salem, NC 27103.

Morphine, methionine enkephalin and other opioid peptides were investigated with respect to their influence on hippocampal neural activity. Field potentials and spontaneous cellular activity were studied following the addition of morphine sulfate, methionine enkephalin or [D-Ala,^{2} Met]-enkephalin to the bathing media of rat hippocampal slices maintained in vitro. Recordings from the CA1 molecular and cell layers showed that morphine sulfate (5.0×10^{-5} -1×10^{-3} M) produced a dose-dependent increase in the amplitude and number of population spikes elicited by Schaffer collateral stimulation. These changes were not accompanied by increases in the dendritically located synaptic current or the presynaptic fiber volley. Input-output curves revealed that morphine sulfate (concentrations > 1.0×10^{-4} M), 1) decreased the threshold for initiation of the CA1 population spike 2) increased the amplitude of the population spike at lower stimulus intensities, and 3) increased the number of population spikes per stimulus pulse at higher stimulus intensities (creating a multiple discharge effect). The effects of morphine at the lower stimulus intensities could be partially reversed by the addition of naloxone hydrochloride (1.0×10^{-4} M) to the bathing media, but the multiple population spikes elicited at higher stimulus voltages were not affected by naloxone. However, pentobarbital sodium (2.0×10^{-4} M) was effective in reducing the number of population spikes elicited by orthodromic stimulation in morphine treated slices at all stimulus intensities, without significantly changing the amplitude of the primary population spike.

Intracellular analyses verified the morphine induced hyperresponsiveness in CA1 cells. Increases in the rate of spontaneous discharges, decreases in the amplitude of stimulus induced IPSPs and the appearance of depolarizing after potentials (DAPs) were observed within 5-20 min following localized opiate application to the dendritic and somatic regions by microperfusion technique. In most cases, these treatments lead to spontaneous after discharges in CA1 cells which persisted well beyond the time of drug application. Other opioid compounds mimicked these results. These effects are similar to those reported by other investigators following the application of penicillin to the hippocampus (1). Our results indicate that specific as well as nonspecific influences of opioids may be responsible for the excitatory effects of these agents on hippocampal tissue

934 ACCUMBENS CONNECTIONS: INPUTS FROM THE TELENCEPHALON AND DIENCEPHALON. R.W. Sikes, R.B. Chronister, J.E.Marchand, and J.F. DeFrance. Department of Neurobiology and Anatomy, The University of Texas Medical School at Houston,P.O. Box 20708, Houston, Texas and The University of South Alabama, Mobile, Alabama.

Iontophoretic and micropressure injections of horseradish peroxidase through glass cappillary electrodes were made into the nucleus accumbens of fifteen adult rabbits. The size of the injections varied considerably but were usually restricted to the anterior part of the nucleus with minimal diffusion into adjacent regions. The animals were allowed to survive for one to two days. The tissue was processed with either the diaminobenzidine(LaVail,1973) or the tetranitrobenzidine technique (Mesulam,1976) The later method proved to be quantitatively superior to the diaminobenzidine method, and the following results were derived from animals processed with this method.

Marked concentrations of labeled neurons were found in the ventral subiculum. The cells were restricted to the part of the subiculum adjacent to the CA1 field of the hippocampus. The numbers of labeled cells decreased dorsally, but the location of the neurons was constant. Many labeled neurons were also found in the medial and lateral entorhinal cortex. Scattered neurons were labeled in layer five of the cingulate gyrus beneath the lateral sulcus and in the midline frontal cortex. Amygdaloid projections originate in the caudal central,basal,and cortical nuclei, and septal projections originate in the caudal dorsal septal nuclei.

The dorsal and ventral periventricular nuclei of the thalamus contained many labeled neurons. Scattered neurons were also seen in the dorsal medial and centromedial nuclei. Labeled neurons in the hypothalamus were restricted to the lateral anterior, lateral preoptic, and paraventricular nuclei.

Finally, neurons were located in the region surrounding the habenulopeduncular tract, the area just lateral to mammilary peduncule, and the ventral striatal region.

935 EFFECT OF RAPHÉ STIMULATION ON GRANULE CELL ACTIVITY IN THE HIPPOCAMPAL DENTATE GYRUS. Robert S. Sloviter* and John D. Connor. Department of Pharmacology, Pennsylvania State University College of Medicine, Hershey PA 17033

Neurons in the entorhinal cortex innervate (via the perforant path) the dendrites of granule cells in the hippocampal dentate gyrus. Stimulation of this pathway evokes a field potential which reflects EPSPs in granule cell dendrites. Superimposed on this potential is a "population spike" which represents action potentials generated simultaneously in many granule cells. The amplitude of the spike is proportional to the number of granule cells firing (Lømo, 1971).

During stimulation of the perforant path, coincident stimuli to the median raphé nucleus cause a rapid increase in the granule cell spike amplitude (often 7-10 fold). This response is highly reproducible and site specific (n = 40). Injection of 5-methoxy-N,N-dimethyltryptamine (5-MeODMT), a serotonin (5-HT) receptor agonist, mimicked the effect of raphé stimuli, but only at parameters of entorhinal stimulation where raphé stimuli were effective (n = 8).

Anatomical evidence (Moore & Halaris, 1975) suggests that 5-HT neurons innervate basket cells which lie in the hilus of the dentate gyrus. These basket cells are believed to be responsible for a γ-amino butyric acid (GABA) mediated recurrent inhibition of granule cells. Intravenous injection of bicuculline and picrotoxin (GABA antagonists) also increased the spike amplitude at all perforant path stimulus parameters (n = 6). Strychnine was without effect (n = 6). A number of cells with firing characteristics expected of these inhibitory interneurons i.e., high frequency and long duration, have been recorded in the hilar region. Efforts are underway to determine the effects of raphé stimulation on the firing characteristics of these cells and of granule cells.

While single unit studies show mainly inhibitory effects of raphé stimulation (e.g., Segal, 1975), our experiments suggest that the net effect of 5-HT release in the dentate gyrus, under these design conditions, is excitatory. Although not proven, the available evidence favors an inhibitory action of 5-HT on inhibitory interneurons.

936 THE EFFECT OF MORPHINE ON THE EXCITABILITY OF HIPPOCAMPAL PYRAMIDAL CELLS. Stanley, J.C., DeFrance, J.F., Taber, K. and Dafny, N. Dept. of Neurobiology and Anatomy, Univ. Texas Medical School, Houston, TX 77025.

The hippocampal formation (HF), a major component of the brain's limbic system, is thought to mediate part of the opiate response (Simon and Hiller, 1978). Therefore, the effect of morphine with respect to the excitability of hippocampal pyramidal cells was studied in rabbits acutely prepared under Urethane anesthesia.

Glass microelectrodes configured in either a 3-barrel or a 4-barrel array were used for recording and the iontophoresis of drugs. The drug ejection barrels contained either morphine sulfate (0.1M, pH 6.5) or naloxone hydrochloride (0.1M, pH 6.3) mixed in de-ionized H_2O.

The analysis of the morphine effect was based upon HF field potential changes. Monosynaptically activated field potentials were recorded in CA1 following microstimulation of the contralateral field CA3.

The results indicate that: (1) morphine has a potent excitatory effect upon hippocampal pyramidal cells, (2) the most effective layer is within the pyramidal cell body stratum, (3) the excitatory effect is readily reversed by naloxone, and (4) there appears to be a "supersensitivity" phenomenon.

The fact that at subthreshold stimulus intensities for the population spikes, the positive component is diminished by morphine with a subsequent appearance of the population spike is consistent with the conclusion of Siggins et al. (1978) that morphine enhanced pyramidal cell excitability by the inhibition of interneurons.

937 EVIDENCE FOR THE ACTION OF DIAZEPAM ON BOTH HIPPOCAMPAL PYRAMIDAL CELLS AND INHIBITORY INTERNEURONS. K.H. Taber, J.F. DeFrance and J.C. Stanley. Dept. of Neurobiology & Anatomy, Univ. of Texas Medical School, Houston, TX 77025.

Diazepam is known to alter the excitability of hippocampal neurons. We have found that diazepam, administered iontophoretically, suppressed the post-tetanic potentiation (PTP) of hippocampal pyramidal cells, while at the same time enhancing tetanic potentiation (TP). This study was undertaken to clarify the mechanism of the enhanced TP following diazepam administration.

Rabbits were acutely prepared under Urethane anesthesia. The cortex and corpus callosum were removed to allow for the placement of electrodes under visual control. Glass microelectrodes configured in a 3-barrel array were used for recording and the iontophoretic delivery of diazepam (0.05-0.1M, pH 3.5). Analysis of the diazepam effects were based upon field potential changes in various layers of hippocampal field CA1. Monosynaptically activated field potentials were recorded following microstimulation of the contralateral field CA3.

A paradigm was used which included 7 control stimuli at 0.5Hz, 8 tetanic stimuli at 6Hz, and up to 15 post-tetanic stimuli at 0.5Hz. With the recording electrode in the pyramidal cell layer, and utilizing a stimulus intensity subthreshold for the appearance of the population spike, the response is dominated by a large positivity. This component appears to be the current flow associated with IPSPs within the pyramidal cells. The positivity undergoes marked TP. Diazepam, however, has the effect of suppressing the TP. When using stimulus intensities sufficient to generate population spikes, diazepam has the effect of enhancing spike TP. It is suggested that diazepam has an effect upon the interneuronal population hereby enhancing pyramidal cell excitability at high rates of stimulation.

938 PRESUBICULAR, PARASUBICULAR, AND POSTEROMEDIAL TEGMENTAL PROJECTIONS TO THE RAT HIPPOCAMPAL FORMATION. Konrad Talbot (1) and Glenn J. Giesler, Jr. (2). Department of Psychology, UCLA, Los Angeles, CA 90024(1) and Marine Biological Institute, Galveston, TX 77550(2)

Hippocampal formation (HF: hippocampus + dentate area) afferents have been repeatedly studied in the rat with diaminobenzedine (DAB) horseradish peroxidase (HRP) histochemistry (e.g., Pasquier & Reinoso-Suarez, Br. Res. Bull. 3:373, 1978).Recently, however, Giesler et al.(J. comp. Neurol. 184: 107, 1979) have demonstrated that the de Olmos o-dianisidine (OD) HRP technique (Exp. Br. Res. 29: 541, 1977) can reveal far more completely the number and morphology of retrogradely labelled neurons than does the standard DAB method of Graham and Karnovsky (J. Histochem. Cytochem. 14: 291, 1966). We have thus reexamined HF afferents utilizing OD HRP histochemistry.

Albino rats were injected with 0.04-0.08ul of 30-50% Type VI HRP solutions into (1) medial (N=6) or lateral (N=4) dorsal HF, (2) ventral HF (N=4), or, for control material, neocortex adjacent to the dorsal (N=3) or ventral (N=2) HF. Animals were sacrificed 1-2 days postoperatively and brain tissue reacted for HRP according to the de Olmos (1977, loc. cit.) OD method.

While all HF afferents reported in previous HRP studies were confirmed, several additional input sources were discovered: (1) many nerve cells in the ipsi- and contra-lateral principal external lamina of the pre- and para-subiculum following enzyme injection into the dorsal HF, (2) an appreciable number of neurons in the ipsi- and contra-lateral principal external lamina of the parasubiculum after HRP infusions into the ventral HF, and (3) a small group of neurons in the posteromedial tegmental nucleus of Morest (J. Anat. [Lond.] 95: 229, 1961) after enzyme injections into the dorsal and, to a lesser extent, ventral HF, unilateral in the former case and bilateral in the latter.

Two other findings were not predicted by earlier HRP work. First, nerve cells in the principal internal layer of the entorhinal cortex are labelled only when a high enzyme concentration has been delivered to the posterior HF (crus and/or ventral HF). Second, HF commissural neurons linking strictly homolateral HF areas constitute most, if not all, of the nerve cells in the dentate hilus and stratum pyramidal of CA3, as well as an appreciable number in stratum pyramidal of CA2.

939 ELECTRICAL ACTIVITY OF THE CEREBRAL CORTEX AND LIMBIC NUCLEI DURING REPEATED DRUG INDUCED DESYNCHRONIZATION. C. C. Turbes, G. T. Schneider* and R. J. Morgan. Dept. Anat., Sch. Med., Creighton University, Omaha, NE 68178 and Dept. Biophysics and Physiol., Colorado State Univ., Ft. Collins, CO 80721.

Recordings were made on cats using radiotelemetry. This made it possible to study the electrical activity of the brain during free movement behavior. Early spectral analysis studies, after repeated doses of dextro and levo amphetamine, had shown changes in power in the theta, sensorimotor rhythm (SMR) and the 40 Hz rhythms. The loss of power in these signal rhythms seen in the initial treatment with amphetamine showed an increase in power in the second and third doses with a persistence of specific drug related symptoms.

In this paper we are looking at the coherence functions of these rhythms in the same areas of the brain and on the same data used in frequency spectral studies. Technically, we estimate coherence functions since all of our experimental data are time limited. It is important in relating signals, in recordings of brain electrical activity, to behavioral or drug induced events that averaging of spectrograms is very important. A sufficient number of data samples must be averaged to satisfy normal statistical criteria. During action of amphetamines coherence spectral estimates show an enhancement of the 30 Hz to 50 Hz frequency range between cortical areas and cortical and subcortical nuclei. There is also an increase in power and coherence in frequencies above 100 Hz. These findings were apparent between the amygdala and nucleus accumbens, amygdala and sigmoid gyrus, and sigmoid gyrus and nucleus accumbens of the same side. Also, there is an increase in power and choerence in the 1 Hz to 5 Hz frequency range. This is associated with increased respiration and heart rate and stereotypy.

940 EFFECT OF REGIONAL MICRO-INJECTION OF MORPHINE ON SOMATOSENSORY, MOTOR, AND ANALGESIC ASPECTS OF SEPTAL HYPERREACTIVITY: A MULTIVARIATE ASSESSMENT. James J. Valdes*, Fred H. Gage, III, and William R. Cameron. Chemistry of Behavior Program, Texas Christian University, Fort Worth, Texas 76129.

Rats with septal lesions demonstrate a quantitative increase in reactivity to noxious stimuli as well as a qualitative change in their responsiveness to non-noxious stimuli, responding as if both were noxious. Morphine analgesia is characterized by a diminished reactivity to noxious stimuli without a change in the sensory threshold for such stimuli. Morphine has thus been said to alter the affective component of behavioral responsiveness to stimulation. Many of the same brain systems involved in aspects of septal hyperreactivity are also involved in morphine analgesia, and the endogenous opiate system may provide a common substrate for these effects. The fact that the endogenous opiate system more closely parallels limbic systems involved with affective components of behavioral responsivity rather than primary sensory pathways supports the contention that morphine may act by altering behavioral responsivity to, rather than sensation of, noxious stimulation.

Rats given either septal or sham lesions were injected with either morphine (10ug) or vehicle, followed by either naloxone (10mg/kg i.p.) or vehicle. Morphine injections were into either the corticomedial amygdala (CMA), posterior hypothalamus (PHYPO), or the ventral hippocampus (VHIP). The rats were tested after each injection on a battery of behavioral tests designed to measure reactivity to both noxious (hotplate and footshock) and non-noxious (somatosensory) stimuli, as well as gross motor abilities. Discriminant function analyses revealed that the greatest morphine effect was to attenuate septal hyperreactivity to non-noxious somatosensory stimuli, although morphine did show a significant, though less pronounced, attenuation of reactivity to noxious stimuli. These effects were site-dependent, with morphine achieving complete reversal of the lesion-induced hyperreactivity when injected into the CMA and VHIP, and only partial reversal when injected into the PHYPO. Naloxone showed specific reversal of the morphine effect in rats with morphine injections in the CMA, exhibited partial reversal of the morphine effect in the VHIP, and in addition had unspecified effects which were independent of both the lesion and morphine effects in rats with morphine injections in the VHIP and PHYPO.

The data suggest that the primary mechanism by which morphine alters behavioral responsivity is by modulating limbic systems involved with reactivity to somatosensory stimulation. In addition, the naloxone data suggest the existence of multiple opiate receptors in the VHIP and PHYPO.

941 HIPPOCAMPAL SYNCHRONIZATION AND DESYNCHRONIZATION ELICITED BY STIMULATION OF SPECIFIC BRAINSTEM LOCI. Robert P. Vertes. Dept. Physiol., Univ. of Mich., Med. Sch., Ann Arbor, MI 48109.

We have previously shown that cells of the medial magnocellular reticular formation discharge at high rates of activity during both waking-movement and REM sleep and at low rates during quiet waking and slow wave sleep (Vertes, Brain Res. 128:146, 1977 and J. Neurophysiol. 42:214, 1979). We suggested that these reticular cells may be involved in the generation of hippocampal theta rhythm since they fired maximally during the identical states (general movement and REM sleep) in which theta is selectively present in the hippocampus of the rat.

In the present investigation the involvement of the brainstem in hippocampal theta generation was tested by systematically mapping the entire brainstem with stimulation and determining its effect on hippocampal activity. Under sodium pentobarbital anesthesia rats were fitted bilaterally with bipolar hippocampal electrodes, indifferent and ground leads. Only rats showing distinct high amplitude theta (1 mV or more) in a free moving situation in at least one pair of the bipolar hippocampal electrodes were used in the stimulation phase of the experiment. Stimulation was done under either methoxyflurane or urethane anesthesia. Stimulation was delivered through bipolar electrodes as they were lowered in 0.5 mm steps through tracts (4-6/rat) in the brainstem. Rectangular pulses (0.2 ms, 300 Hz, 50-150 μA) were applied for a duration of 4-6 sec at approximately 1 min intervals. The results of stimulating the entire width, depth and length of the brainstem from the bulbo-spinal junction to the caudal midbrain were as follows. (1) Unexpectedly, the most effective sites for eliciting theta were located in medial longitudinal fasciculus (MLF) at the pontine and caudal midbrain level. (2) The only nuclei from which theta could clearly be elicited belonged to the magnocellular reticular chain. The nucleus pontis oralis was most effective in driving theta followed by pontis caudalis and rostral gigantocellularis, respectively. (3) Brainstem nuclei such as locus coeruleus, dorsal raphe, and raphe magnus as well as the lateral reticular areas and cranial nerve nuclei were ineffective in eliciting theta. (4) The only electrode locations that produced desynchronization were located in the median raphe. Desynchronization at this site was accompanied by a dramatic decrease in the amplitude of hippocampal activity. The results suggest that there are two separate brainstem systems controlling hippocampal activity--one originating in the medial raphe and producing desynchronization and the other in the rostral magnocellular reticular field whose fibers primarily course in the MLF producing synchronization.

942 ORIGIN OF HIPPOCAMPAL COMMISSURAL PROJECTIONS IN THE RAT. Theodore J. Voneida, Stephen E. Fish* and Richard M. Vardaris. Department of Neurobiology, Northeastern Ohio Universities College of Medicine, St. Rt. 44, Rootstown, Ohio 44272 and Department of Psychology, Kent State University, Kent, Ohio 44240.

Pressure (.005-.02μl) and iontophoretic injections of horseradish peroxidase were employed to study the origin of the hippocampal commissures in the rat. Infusion of discrete amounts of HRP into hippocampal fields CA1, CA2, CA3 or into the hilus fasciae dentatae (CA4) invariably resulted in the labeling of cells within the hilus of the contralateral dentate gyrus. In addition, a small number of labeled cells was also identified in areas homotopic to each injection site. Thus, injection of area CA1 resulted in labeled perikarya in the contralateral homotopic area CA1. Injections restricted to CA3 gave rise to labeled cells in contralateral CA3, etc. The number of homotopically labeled cells resulting from the injection of specific hippocampal fields was always very much samller than labeled hilar cells.

It appears, therefore, that cells within the hilus of the dentate gyrus (CA4) may influence widespread areas within the contralateral hippocampus.

943 EARLY POSTNATAL DEVELOPMENT OF THE MEDIAL AND LATERAL NUCLEI OF THE AMYGDALA. Caroline L. Wakefield. Dept. Anat., Sch. Med. Sci., UNR, Reno, NV 89557.

The postnatal development of the amygdaloid complex was studied in kittens, age newborn to 34 days, using Golgi and EM techniques. The development of the medial nucleus, a phylogenetically older nucleus, and the lateral nucleus, a phylogenetically newer nucleus of the amygdala will be compared in this report.

At birth, all the nuclei of the amygdala which have been described in the adult cat can be identified in the kitten. The neurons in the medial nucleus are stellate shaped and have long fine processes with few spines. The synaptic boutons contained round vesicles and a small population of dark-core vesicles at all ages studied. Many of the boutons were filled with vesicles, others were larger and contained few vesicles in proportion to their size. There was little myelin formation until 23 days of age.

The cells of the lateral nucleus are pyramidal in shape, with thick primary dedritic branches. Long spines with club endings were seen to increase in number up to 14 days of age. The axons of both the medial and lateral nuclei were oriented toward the stria terminalis and a few collateral branches within the nucleus were observed. The myelin in the lateral nucleus is very sparse compared to the medial nucleus. Boutons in the lateral nucleus are similar to those in the medial nucleus and are less numerous.

944 TAIL PINCH INDUCES SEXUAL BEHAVIOR IN OLFACTORY BULBECTOMIZED MALE RATS. Lolin Wang and Elaine M. Hull. Dept. Psych., SUNY, Buffalo, NY 14226.

Bilateral olfactory bulbectomy disrupts copulatory behavior in some inexperienced male rats. Tail pinch has been shown to facilitate copulatory as well as feeding, maternal, and aggressive behavior. The present experiments were conducted to determine whether tail pinch would induce male sexual behavior in noncopulating bulbectomized rats.

Bilateral olfactory bulbectomies (BOB) were performed on 34 male Long Evans rats, 90 days of age; 4 animals underwent sham surgery (SC), while 3 served as unoperated controls (UC). In tests with a primed, ovariectomized female 24 BOB animals failed to ejaculate on two separate 40 min tests. All control animals exhibited normal sexual behavior, and 10 BOB animals ejaculated at least once during the two trials. Later histological examination revealed a correlation between size of lesion and behavioral deficits.

After a third test to verify the continued disruption of sexual behavior, 16 of the nonejaculatory animals received approximately 6 applications of a clip to the tail. Similar 60 sec applications to normal animals had induced eating and/or drinking within 5 to 6 trials. Mating tests were conducted as before, and were repeated four days later. The remaining 8 nonejaculatory animals were tested similarly, but without application of the clip. Ten of the 16 tail pinch (TP) animals began to mount, intromit, and ejaculate on the first test following the TP procedure, and an additional 2 began to exhibit complete sexual behavior on the second test. Only 1 of the 8 animals not receiving TP ejaculated on these trials. Thus, TP applied shortly before sexual behavior tests can induce copulation in some males whose behavior had been disrupted by olfactory bulbectomy.

945 FUNCTIONAL CORRELATES OF THE HIPPOCAMPAL FORMATION IN THE RAT: A 14-C-2DG ANALYSIS. Robert E. Watson, Jr*., Allan Siegel, Jennifer Poulakos*, and Raymond Troiano*. Departments of Neuroscience and Physiology, N.J. Medical School, Newark, N.J. 07103.

In an attempt to develop a better understanding of the functional organization of the hippocampal formation, we employed 14-C-2-deoxyglucose (2DG) radioautography following electrical stimulation of the various regions along its longitudinal axis in both awake and anesthetized rats.

The experimental paradigm consisted of electrical brain stimulation delivered continuously over 30 sec on and 30 sec off for periods of 45 minutes following injection of 2DG. Brains were then removed and processed for radioautography.

The most significant observations were as follows: (1) in unstimulated (control) animals the molecular layer of the hippocampal formation was normally densely labeled; (2) stimulation of the anterior dorsal hippocampus rostral to the level of the subiculum resulted in bilateral activation of all pyramidal cell fields with a marked reduction of label in the hippocampal molecular layer. The dorsomedial septum was only poorly labeled and no evidence of label was seen in the hypothalamus; (3) stimulation of the dorsal hippocampal formation at the level of prosubiculum and subiculum proper also resulted in bilateral activation of all pyramidal cell fields and a reduction in label over the molecular layer. In contrast, label was clearly noted throughout the extent of the dorsomedial septum and medial mammillary nucleus. There appeared to be no activation of either the ventral hippocampus or other portions of hypothalamus; (4) stimulation of the presubiculum at the level of the posterior hippocampus resulted in activation of only the medial mammillary and anteroventral thalamic nuclei. Stimulation of this region produced no diminution in label over the molecular layer nor did it result in activation of either the hippocampal pyramidal cell layer or other regions of hypothalamus; (5) stimulation of the ventral hippocampus at the level of the subiculum proper resulted in activation of the entire extent of the lateral part of the lateral septal nucleus and the medial corticohypothalamic tract (and hypophysiotrophic zone of hypothalamus). No evidence was noted for the presence of bilateral activation of the pyramidal cell layer of the ventral hippocampus, or of any part of dorsal hippocampus; nor did the stimulation alter the pattern of label present over the molecular layer.

946 CIRCADIAN MODULATION OF GRANULE CELL SENSITIVITY TO PERFORANT PATH SYNAPTIC INPUT IN THE RAT. M.O. West and S.A. Deadwyler.* Dept. of Physiol. and Pharmacol., Bowman Gray Sch. of Med., Winston-Salem, NC 27103.

Circadian variations in dentate gyrus monosynaptic field potentials elicited by stimulation of the perforant path were recorded from chronically implanted rats entrained to a 12:12 light-dark cycle (0700 ON, 1900 OFF). Localization of the recording electrode to either the granule cell somal layer or the dendritic region of perforant path synapses was accomplished through the use of a miniature microdrive system which allowed maximization of field potentials prior to each data collection period. Input-output curves for both the population spike and synaptic potential were constructed daily at five 2 hr intervals (1400, 1600, 1800, 2000, 2200). Population spike I-O curves for eight rats showed a 22-28% reduction in mean amplitude at all stimulus voltages at 2000 and 2200 relative to 1600. Population spike laminar profiles also showed a 22-28% reduction in amplitude at 2000 and 2200; the decreases depicted in the I-O curves therefore were not due to differences in location of the recording electrode. Similar reductions in population spike amplitude at 2000 were observed even on selected days when the light period was extended to 2100, indicating that the population spike decreases were related to the entrained circadian cycle and not to the presence or absence of light. In further experiments, comparisons were made at 1600 and at 2000 among different behavioral states previously shown (1) to produce changes in granule cell population spike amplitude. Neither the magnitude nor the direction of the circadian related decrease in population spike amplitude could be accounted for by alterations in behavioral arousal.

The hourly alterations in amplitude of the granule cell layer population spike were not accompanied by significant variations in the dendritically located perforant path synaptic current, suggesting a change in granule cell sensitivity to this input. To test whether this change might be influenced by cycling levels of corticosterone, a glucocorticoid actively taken up by hippocampal tissue, four animals were tested before and after adrenalectomy. Circadian cyclicity in granule cell population spike amplitude was unchanged by the elimination of corticosterone via adrenalectomy. The circadian controlled oscillation of dentate granule sensitivity to perforant path synaptic input appears to be independent of alterations in corticosterone levels and must therefore be controlled by some other as yet unknown modulatory influence.

947 SENSORY AFFERENT RESPONSE OF HUMAN LIMBIC NEURONS. Charles L. Wilson, Thomas L. Babb, Eric Halgren and Paul H. Crandall. Brain Res. Inst., Reed Neurol. Res. Cntr., and Dept. of Surg. (Neurol.) Sch. Med., UCLA, Los Angeles, CA 90024.

Considerable interest exists in sources of sensory afferents to the hippocampal formation and adjoining temporal lobe structures, largely because of this area's role in memory function. Anatomical evidencefrom the monkey indicates that the parahippocampal region receives multisynaptic projections from all major sensory modalities, although visual projections are most prominent(e.g. Seltzer and Pandya, Exper. Neurol. 50: 146-150, 1976). Electrophysiological investigation substantiates the visual responsiveness of neurons in monkey posterior hippocampal gyrus and adjacent areas(MacLean et al. J. Neurophysiol. 31: 870-833, 1968). Recently, the response properties of human limbic neurons to diffuse retinal illumination have been described(Babb et al. Neurosci. Abstr., 1976, 380; Halgren et al. Electroenceph. clin. Neurophysiol. 45: 585-601, 1978). In the present investigation, action and field potentials were recorded from microwires implanted chronically in temporal lobe epilepsy patients (Babb and Crandall, Electroenceph.clin. Neurophysiol 40: 225-243, 1976) in order to 1) compare relative responsiveness of different limbic regions to simple visual, auditory and somesthetic stimuli, 2) determine the relationship between unit and field potential measures of sensory response, and 3) search for receptive field properties during presentation of complex patterned stimuli.

Analysis of over 200 hippocampal gyrus, pes hippocampi, and amygdala units indicated that 1)responses were substantially more common to visual than to auditory or somesthetic stimuli, 2) convergence was unusual, 3) responses showed rate increases, rate decreases, or sequences of both, and 4) the greatest proportion of responsive units was encountered in the posterior hippocampal gyrus. Field potentials evoked by sensory stimuli were of largest amplitude in posterior regions of hippocampal formation, but local responses in anterior hippocampus and amygdala were more prominent than might be predicted from the smaller number of responsive units. Photically evoked potentials were of larger amplitude than those evoked by stimuli of other modalities. Onset latencies ranged from 40 to 120 msec, depending upon the structure from which the recording was derived, with shortest latencies in posterior hippocampal gyrus. Preliminary results of tests with patterned stimuli such as reversing checkerboards suggest that response to such stimuli may not occur in isolation from response to diffuse photic stimulation.

948 NEURONAL TRANSMISSION FROM PERFORANT PATHWAY THROUGH DENTATE GYRUS: DUAL BRAINSTEM ACTIVATING SYSTEM. Jonathan Winson, Rockefeller University, New York, NY 10021.

Previous work in this laboratory has shown that the population action potential evoked in granule cells by perforant path (pp) stimulation (the EAP) is greater during slow-wave sleep (SWS) than during the alert state (Winson & Abzug, J. Neurophysiol. 41, 1978). Further, a stimulus applied to the median raphe nucleus (MR) prior to the activation of the pp produces a marked augmentation of the already elevated EAP during SWS but not during the alert state (Winson, Neurosci. Abstr. 3, 1977). In studies reported here, prestimulation (1 or 3 pulses) has been applied at various brainstem locations followed by a test pulse applied to the pp. Extracellular responses were recorded at the granule cell level.

In freely moving rats with prestimulation applied to MR, the minimum delay time (time from MR to pp stimulus) at which the augmented EAP appeared during SWS was 4 msec. It was also found that a fast field potential (FFP) was elicited consistently at the granule cells, due solely to MR stimulation. The FFP latency was approximately 4 msec and its magnitude depended on behavior. The FFP was largest during SWS, smaller during alert, and was suppressed during REM sleep.

In rats anesthetized with Urethane, midline dorso-ventral penetrations were made at rostro-caudal levels encompassing the entire pons and medulla to ascertain areas in which prestimulation was effective in producing EAP augmentation and the FFP. EAP augmentation was obtained at low stimulus currents ($\leq$ 30 μA) from raphe nuclei (dorsalis, MR, magnus, and pallidus) but low currents were ineffective at other midline locations and along laterally placed penetrations. FFP responses could not be elicited by low currents at any location. Further investigation showed that the FFP produced by MR stimulation in freely moving animals was eliminated by Urethane. FFPs could be re-elicited by a prior conditioning pulse applied to MR.

FFPs could be elicited at low stimulus currents in animals anesthetized with Chloropent. Studies in such preparations confirmed the midline loci at which the EAP was enhanced by low stimulus currents and delineated a closely apposed but distinct series of midline loci at which low currents ($\leq$ 30 μA) elicited the FFP. FFPs could also be evoked at low currents from reticular formation locations. Further revealed was a second and slower potential (latency about 15 msec) evoked by brainstem stimulation. These results suggest a dual brainstem system activated by midline stimulation which elicits behaviorally dependent responses in the dentate gyrus.

949 MEDIAN RAPHE LESIONS IMPAIR THE ACQUISITION AND PERFORMANCE OF AN 8-ARM MAZE TASK. David Wirtshafter, Karen E. Asin and Ernest W. Kent. Dept. Psychology, University of Illinois at Chicago Circle, Chicago, Il 60680.

Several authors have demonstrated impaired performance of an 8-arm maze task following damage to the hippocampus or a number of closely related structures including the septum and the entorhinal cortex. Since a number of similarities between the behavioral effects of median raphe and hippocampal lesions have been reported (Asin et al., this meeting), we investigated the effects of median raphe lesions on the acquisition of a food reinforced 8-arm maze task.

Rats with electrolytic lesions of the median raphe were profoundly impaired on the acquisition of an 8-arm maze task and showed virtually no improvement across 16 days of training. Median raphe lesioned animals showed pronounced response perseveration such that a given animal would often repeatedly enter a particular sequence of arms. Seventy one percent of the errors made by median raphe lesioned animals could be accounted for by such responding, in contrast to only 18 percent of control errors.

We next examined the effects of median raphe lesions in animals who were overtrained on the 8-arm maze task. Despite the near perfect performance of these animals prior to surgery, median raphe lesions produced an immediate disruption of maze performance which was similar in magnitude to that seen in animals lesioned before training.

The current results demonstrate that the median raphe, like the hippocampus, contains elements essential to the normal performance of an 8-arm maze task in the rat. Although the impairment may reflect a deficit in the utilization of spatial information, other explanations (e.g. alterations in attention or memory) cannot be excluded at this time.

950 THETA CELLS IN DORSAL CA1, CA3 AND DENTATE FIRE MAXIMALLY ON THE POSITIVE PHASE OF DENTATE THETA RHYTHM IN WALKING RATS. S. Wolfson*, S.E. Fox and J.B. Ranck, Jr., Dept. of Physiology, Downstate Med. Ctr., SUNY, Brooklyn, NY 11203.

Any theory of the cellular basis of theta rhythm must account for the fact that the rhythm is phase-reversed between the CA1 and dentate cell layers, yet the phase-locked variations in the amplitude of the monosynaptic population-spikes wax and wane simultaneously in the two cell layers (Fox, Rudell and Ranck, Fed. Proc. 38:1310, 1979). Such a theory must also account for the present result, namely that theta cells in all areas of dorsal hippocampus achieve their maximal firing rates simultaneously. Theta cells, which double their rate of firing during hippocampal slow wave theta rhythm, are presumed to be interneurons. These theta cells are generally phase-locked to theta rhythm and may participate in generation of theta by producing PSPs in projection cells.

Fixed reference electrodes in dorsal hippocampal formation and neocortex, and moveable microelectrodes aimed at hippocampus were stereotaxically implanted for chronic recording in 11 rats. The rats walked on a motor-driven treadmill. Slow wave theta rhythm was recorded from the fixed electrodes and both slow waves and units were recorded from the moveable microelectrode. Multiple slow wave recording sites allowed many internal checks on reference theta rhythm. Phase histograms were made by measuring the interval between two positive peaks of dentate theta rhythm and dividing this into 36 bins.

To describe the results, the first bin of the histograms was assigned the value of 90° (the positive peak). The mode of the phase histogram was measured for each unit. Seven theta cells in CA1 had their modes at 50 $\pm$ 30° ($\bar{X}$ $\pm$ s.d.). Four of five theta cells in CA3 had modes at 100 $\pm$ 30° (one was not phase related). Eight theta cells in the dentate area had modes at 60 $\pm$ 30°. Eight other theta cells (not histologically verified) had modes at 80 $\pm$ 40°. Firing during REM sleep was recorded in six cells and was the same as during walking. Complex-spike cells were also recorded in these areas. Twelve of 14 seemed to have phase relations similar to those of theta cells. (Two had no phase relation). The number of complex-spike cells recorded thus far is too small to make strong conclusions.

Thus both monosynaptic evoked potentials and the firing of theta cells covary with the theta rhythm simultaneously, independent of hippocampal subfield. Furthermore, CA3 theta cells appear to have the same phase relation as those in CA1 and dentate, even though CA3 does not generate a theta rhythm.

951 EVIDENCE FOR A HYPOTHALAMIC INPUT TO THE DENTATE GYRUS IN THE RAT AND CAT. J.M. Wyss. Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Although it has been known for some time that there are cells in the supramammillary region that project to the hippocampal formation (Segal and Landis, 1974; Pasquier and Reinoso-Suarez, 1976), the site of termination of these axons has been difficult to establish. We have examined this issue by placing relatively large injections of tritiated amino acids in the posterior hypothalamus (including the supramammillary region) in a series of rats and cats. In every case in which a significant proportion of the cells in the supramammillary region was labeled, there was a clear indication of axonally transported label in the outer one-half of the stratum granulosum of the dentate gyrus, and over the adjacent 20 µm of the stratum moleculare immediately deep to the zone of termination of the commissural and associational afferents. The projection is to both blades of the dentate gyrus, and extends over the entire septo-temporal extent of the dentate gyrus. However, for reasons that are not yet apparent, the labeling is always appreciably heavier over the suprapyramidal rather than the infrapyramidal blade. In experiments in which the injections were strictly unilateral, labeling in the dentate gyrus was always bilateral; but in every case, the labeling on the side ipsilateral to the injection was significantly heavier than that on the contralateral side.

The supramammillary fibers reach the dentate gyrus by way of the medial forebrain bundle, the septal complex and the dorsal fornix and fimbria The supramammillary region also projects to the anterior hippocampal rudiment. This projection is similar to that seen in the dentate gyrus, in being both bilateral (but heavier on the ipsilateral side) and limited to the outer part of the cellular layer and the adjoining part of the overlying molecular layer.

952 SEPTAL CORRELATES OF CONDITIONED INHIBITION AND EXCITATION. Elna Yadin* and Earl Thomas. Dept. Psych., Bryn Mawr College, Bryn Mawr, PA 19010.

The recording of multiple units was introduced into the study of the role of the septum in Pavlovian conditioned inhibition. This technique enabled the monitoring of septal activity in the freely moving rat throughout a long-term acquisition period of classical conditioning.

In Experiment 1, a Pavlovian aversive discrimination paradigm was used in which one CS was followed by a shock US and another CS was presented unpaired with shock. Another group of animals received a truly random control procedure in which the shock USs were presented randomly with regard to the CSs. Septal activity was recorded during CS+ and CS-, during a preCS period and during a post-shock period.

The results may be summarized as follows: (1) septal unit activity was found to increase during presentations of CS- only in the conditioning group. (2) Presentations of CS+ caused a marked suppression of septal unit activity in the conditioning animals. (3) The baseline unit activity during the preCS period remained unchanged throughout the experiment in the conditioning animals while decreasing in the truly random controls. (4) Termination of the shock US was marked by a large burst of firing in the conditioning group but no such rebound was found in the controls.

The results are interpreted in terms of a fear-relief hypothesis which suggests that the septal area is importantly involved in the mediation of relief from fear. The differential patterns of firing between the experimental and control groups suggest the importance of the predictability of shock to the expression of relief.

In Experiment 2, a Pavlovian appetitive discrimination paradigm was used in which the CS+ was followed by a food US. The results were virtually the opposite from those seen in the aversive case: (1) Septal activity to CS- was suppressed. (2) Unit responding to CS+ was markedly enhanced.

The findings from the appetitive experiment were interpreted as indicating that increased septal activity during CS- seems to be quite specific to the nonoccurrence of a noxious stimulus and does not represent the mechanism underlying all types of conditioned inhibition.

MEMBRANE BIOPHYSICS

953 CALCIUM CHANNELS PERMIT THE PASSAGE OF Mn^{++} IONS: A POSSIBLE EXPLANATION. Margaret Anderson. Dept. of Biol. Sci., Smith College, Northampton, MA 01063.

The myoepithelial cells that make up the proventriculus of the marine polychaete worm Syllis spongiphila undergo calcium spikes which are associated with contractions. (Spikes elicited by direct intracellular stimulation are (a) reversibly abolished in Ca-free artificial sea water (ASW), (b) not abolished in low-sodium ASW or in ASW containing 10^{-6} - 10^{-5} M TTX, (c) abolished reversibly by Co^{++} ions, D-600 (1 mM) and verapamil (1 mM) and essentially irreversibly by La^{+++} ions (1 - 10 mM), and (d) supported in Ca-free ASW containing either 1 mM Ba^{++} or 10 mM Sr^{++} ions). Mn^{++} ions appear to pass through the calcium channels. ((a) Regenerative responses not associated with contractions can be elicited in Ca-free ASW containing 5 - 50 mM Mn^{++}. (b) In Ca-free ASW containing Mn^{++}ions, spikes are abolished by Co^{++} and La^{+++} ions, D-600 and verapamil at concentrations similar to those effective in abolishing Ca-spikes. (c) In Ca-free ASW containing varying $[Mn]_o$'s, amplitudes of spike overshoots increase about 27 mV for a 10-fold change in $[Mn]_o$ (this value approaches that predicted by the Nernst equation for a membrane permeable to a divalent cation); in ASW containing 10 mM Ca^{++} and varying $[Mn]_o$'s, the amplitudes of overshoots increase about 15 mV for a 10-fold change in $[Mn]_o$ (these data suggest a competition between Ca^{++} and Mn^{++} ions for the same channels)). Of the divalent first transition series metals, Mn^{++} exhibits the lowest energy of hydration. It seems probable that Mn^{++} ions can relatively easily shed their waters of hydration and pass through the Ca-channel. On the basis of this hypothesis, divalent cations of the first transition series with higher energies of hydration should block the Ca-channel. The effectiveness of blocking should increase as the energy of hydration increases; the prediction of effectiveness would be

$$Fe^{++} < Co^{++} < Ni^{++}.$$

The relative effectiveness of Fe^{++}, Co^{++} and Ni^{++} ions was tested by applying a series of concentrations of each ion to the preparation in Ca-containing solutions and determining the concentration required to abolish Ca-spikes elicited by direct stimulation. (During the application of Fe^{++} ions the preparation was bathed in nitrogen-bubbled, low-oxygen solutions). Ni^{++} (1 - 10 mM) consistently abolished the Ca-spike at lower concentrations than Co^{++}; Co^{++} (5 - 20 mM) abolished the Ca-spike at similar or lower concentrations than Fe^{++} (10 - 20 mM). These data support the idea that the capability of an ion to block the calcium channel increases as the energy of hydration increases. Supported by USPHS Grant # NS12196.

954 MEMBRANE CONDUCTANCE INCREASE IN THE GIANT ABDOMINAL NEURON (R_2) OF APLYSIA INDUCED BY LOW-SODIUM SOLUTIONS. J. P. Apland and D. R. Livengood. Department of Neurobiology, Armed Forces Radiobiology Research Institute, Bethesda MD 20014.

The effects of low-sodium (low-Na) solutions on membrane conductance (G_m) in the giant abdominal neuron (R_2) of Aplysia were investigated with electrophysiological methods. We have previously shown (Apland and Livengood, Soc. Neurosci. Abstr. 3: 659, 1977) that perfusion with low-Na solutions, using choline, glucosamine, mannitol, tetraethanolammonium, and tetramethylammonium as sodium substitutes, caused an increase in G_m in the majority of experiments with all substitutes. This increase in G_m was consistently blocked by addition of cobalt to the perfusion solution. In those cells that did not show an increase in G_m in low-Na solutions, application of cobalt caused a decrease in G_m during perfusion with low-Na solutions. This finding was attributed to a high resting G_{Na} in the latter cells. We also observed that cobalt blocked anomalous rectification in all cells studied.

Low-Na solutions characteristically caused a transient hyperpolerization followed by a persistent depolarization. After treatment with ouabain, the cell exhibits a persistent hyperpolarization in low-Na solutions, indicating that the depolarization seen without ouabain present is due to inactivation of the electrogenic sodium pump as intracellular sodium becomes depleted. When barium was substituted for calcium, results similar to those with cobalt were produced. Anomalous rectification was blocked by barium, and a decrease in G_m in low-Na perfusion solution was produced where no change in G_m had previously been shown in low-Na solution. Deletion of potassium from the perfusion solution, or replacement of potassium with rubidium, blocked the increase in G_m previously observed in low-Na solutions and also blocked anomalous rectification. Cold temperatures, which block anomalous rectification, also block the G_m increase in low-Na solutions. Finally, a lowered extracellular pH blocks the G_m increase in low-Na solutions. Meech (Ann. Rev. Biophys. Bioeng. 7: 1, 1978) has shown that lowered pH blocks G_K.

The observations with cobalt and barium suggest that calcium is involved in the G_m increase in low-Na solutions. The results using potassium-free solutions, rubidium, cold, and reduced pH suggest that the increased G_m is to potassium. This conclusion is reinforced by the fact that all treatments abolishing anomalous rectification, which is presumed to involve the potassium-conductance system (Marmor, Progr. Neurobiol. 5: 169, 1975) also block the G_m increase in low-Na solutions. Reduction of the extracellular sodium probably inactivates the sodium-calcium exchange mechanism, causing intracellular calcium to accumulate and increase G_K. The fact that cobalt and barium, which interact with calcium channels, abolish anomalous rectification, suggests that calcium also may be involved in that phenomenon.

955 MEMBRANE CURRENTS IN INSECT MUSCLE FIBRES. Frances M. Ashcroft* and P.R. Stanfield*. Dept. of Physiology, University of Leicester, Leicester, U.K. (SPON. G.F. Gwilliam).

Membrane currents in the ventral longitudinal muscle fibres of the stick insect, Carausius morosus, were investigated with a 3-electrode voltage clamp. Experiments were carried out at 2-5°C, in hypertonic saline to block contraction. The membrane current consisted of an early inward current, an early outward current and a delayed outward current. The presence of the early outward current is probably responsible for the graded (as opposed to all-or-none) action potentials which are characteristic of insect muscle. The inward current was studied in Ringer containing 120mM TEACl to reduce outward currents. In normal Ringer (20mM $CaCl_2$) the maximum inward current was -77.6± 9.5 $\mu A./cm^2$ (n=10) at a membrane potential of 0mV. Peak inward currents were increased in 50mM Ca^{2+}-Ringer (Mg^{2+}-substitution) and reduced in 5mM Ca^{2+}-Ringer, and there was a 31.0mV shift in the potential at which the membrane current reversed in sign for a 10-fold change in external calcium. At high $[Ca^{2+}]_o$ the peak inward current showed saturation. Inward currents were blocked by 1mM La^{3+} and halved by 10mM Ni^{2+}. These results indicate that the inward current is carried by calcium ions. The inward current (I_{Ca}) shows voltage and time-dependent inactivation. Steady-state inactivation was described by $h_\infty = \{1+\exp(V_1-V_h)/k_h\}^{-1}$ where V_h= -21.0±1.8mV (n=5) and k_h=5. The time constant of inactivation depended on the experimental protocol. Inactivation followed a single exponential with a time constant of 55msecs at -10mV when determined with 2-pulse experiments; however the decay of I_{Ca} during a single voltage step was best fitted by the sum of 2 exponentials. The activation kinetics of the Ca channel are currently under study. As insect muscle is readily voltage-clamped it provides a favourable preparation for the study of muscle calcium channels. Supported by the M.R.C.

956 LOCUS COERULEUS AXONS EXHIBIT PRONOUNCED ACTIVITY-DEPENDENT VARIABILITY IN IMPULSE CONDUCTION LATENCY. G. Aston-Jones[1,2], M. Segal[3] and F. Bloom[1]. [1]A.V. Davis Ctr. for Behav. Neurobiol., Salk Inst., La Jolla, CA 92037.

It is generally conceived that axons carry impulses with constant velocity and act as simple transmission lines between soma and synapse. Recent studies, however, have suggested that certain axons can modulate their own impulse flow; indeed, we now report that this ability is especially pronounced in the axons of noradrenaline-containing locus coeruleus (LC) neurons.

Chloral hydrate-anesthetized rats were implanted with stimulating electrodes in anterior cingulate cortex and olfactory bulb. Glass micropipettes recorded isolated impulses from single LC neurons, subsequently identified histologically. While studying antidromic (AD) conduction properties of these neurons, we observed striking alterations in AD latency not previously reported. Each of 12 antidromically activated LC neurons tested in 8 rats exhibited a pronounced gradual and continuous increase in latency (in some cases > 20 msec) during 2 to 10 Hz stimulation, and a gradual and continuous recovery to basal AD latency (mean=55.3 ± 4.2 msec) over 1-2 minutes when stimulus frequency was reduced. During trains of constant frequency stimulation, the AD latency increased somewhat asymptotically to a new, fairly stable value after 50 to 400 stimuli. In addition to these AD latency increases, closer examination revealed that the second and closely succeeding stimuli in a 10 Hz train yielded decreased latencies, followed by the larger increases in AD latency during subsequent stimuli in the train. In neurons tested with pulse pairs, a decrease in AD latency of .5 to 3.5 msec for the second stimulus was consistently observed. The magnitude of variation in AD latency was positively correlated with three factors: 1) the initial AD latency of the neuron, 2) the frequency of stimulation and 3) the number of pulses in a train of stimuli. Preliminary experiments have revealed marked AD latency alterations in the raphe and substantia nigra systems as well.

Data are presented which demonstrate similar conduction time variability as a consequence of non-stimulated activity and suggest that changes in conduction velocity along the axon itself underlie these AD latency fluctuations. These fluctuations may allow long, unmyelinated axon systems to transfer information most effectively with short bursts of activity, and suggest that large axon diameters and myelination may be necessary for high fidelity as well as high velocity of impulse flow in nervous tissue. (Supported by USPHS Grant #AA 03504 and NIH Training Grant #GM 02031. [2]California Inst. of Tech., Pasadena, CA. [3]Weizmann Inst., Rehovot, Israel.

957 STIMULATION OF EXCITABLE TISSUE BY RAPIDLY CHANGING MAGNETIC FIELDS. Charles P. Bean, General Electric Corporate Research and Development, Schenectady, N.Y. 12301

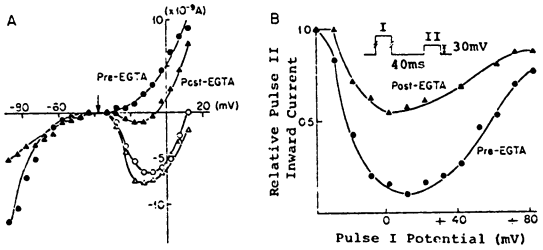
Recent interest in whole-body exposure to time varying magnetic fields has been stimulated by the proposal and development of imaging techniques using nuclear resonance. Some methods require rapidly ramped magnetic fields. Theoretical insight can be gained into the circumstances under which such exposure will stimulate excitability of such tissue. The mechanism of stimulation is taken to arise from the electric fields created by exposure to time varying magnetic fields. The assumptions of the present treatment are standard. A cell of nervous tissue is presumed to have a threshold value of transmembrane depolarization, ΔV_c. The cell is taken to be in a medium of uniform electrical properties and all calculations are made for the limit of steady excitation, i.e. the rheobase limit. Two cases are considered: the direct excitation of a cell body and excitation of an extended process--an axon or muscle fiber. Consider a spherical cell body of radius a in a uniform electric field E, the potential difference between inside and outside, ΔV, is $\Delta V = (3aE/2)\cos\theta'$ where θ' is the angle that an internal radius vector makes with the field direction. In the incorrect approximation that the cell is uniformly excitable, the critical field for excitation, E_c, is expressed by $E_c = 2\Delta V_c/3a$. Owing to the small size of most cell bodies this excitation limit is much higher than that for fibrous structures. For an extended process we assume a defined electronic coupling distance, λ, for small signals. Further, it is taken that the electric field, E, makes an angle θ with the fiber axis and sensibly exists over a length L of the long fiber. A remarkable early paper by W.A.H. Rushton (J. Physiol. 63, 357-377 (1927)) treats this case to obtain for the critical field, $E_c = (2\Delta V_c/\lambda)[1/(1-\exp(-L/\lambda))]$. The factor of the second parenthesis approaches unity as $L/\lambda >> 1$. To connect this criterion to changing magnetic fields, I presume a uniform flux rate of change, $\dot{B}$, to exist within a circle of outer radius R. By Faraday's law of induction, the maximum field is along the periphery and is given by the formula $E = 10^{-8}\dot{B}R/2$. Equating this to the earlier expression for a long axon gives for a critical rate of change, $\dot{B}_c$; $\dot{B}_c = 4\cdot10^{-8}\Delta V_c\cos\theta/\lambda R$. Even for the most easily excited fast fibers where $\lambda \sim 0.5$ cm and $\Delta V_c \sim 10$ mV well over one million gauss/sec would be expected to be required for excitation in cases most liable to such excitation. Further such rates would have to be maintained for a time on the order of a millisecond. These theoretical expectations will be compared to experiment.

958 ELEVATION OF INTERNAL FREE Ca^{++} IS REQUIRED FOR INACTIVATION OF Ca CONDUCTANCE IN PARAMECIUM. P. Brehm* and R. Eckert (SPON: D. Junge) Dept. of Biology, UCLA, Los Angeles, CA.

Inactivation of the Ca conductance in Paramecium does not exhibit the voltage dependency characteristic of Na channels. Instead, the inactivation requires the entry of Ca (Brehm and Eckert, Science 202:1203-1206, 1978). To further investigate the role of Ca, we injected the Ca chelator EGTA to limit the elevation of free Ca^{2+} within the cell during Ca entry.

Specimens were clamped with holding voltage equal to V_{rest} in 1 mM $CaCl_2$ + 4 mM KCl+1 mM HEPES at pH 7.2. EGTA was iontophoresed from a separate intracellular electrode filled with 100 mM K-EGTA while under steady voltage clamp. Inactivation of Ca current was measured before and after EGTA iontophoresis using the following regime. Two 20 msec depolarizations, P_I and P_{II}, were delivered with a 40 msec interval. P_{II} was fixed at 30 mV, a level at which little late outward current was observed. P_I was presented over a wide range of amplitudes. The amount of inactivation remaining after the 40 msec interval was determined from the reduction in peak P_{II} current resulting from presentation of P_I.

Prior to EGTA injection the P_{II} Ca current showed prominent inactivation for the midrange of P_I potentials (Fig. B). Little inactivation was seen at low or high P_I potentials, for which Ca entry should be minimal. Separate evidence has indicated that this behavior does not result from altered potassium currents (Brehm and Eckert, 1978; Eckert and Brehm, Ann. Rev. Biophys. Bioengin., 1979). Following EGTA injection, P_{II} inactivation for the P_I midrange was significantly diminished (Fig. B), and as a result of the reduced inactivation a late inward current developed (Fig. A). These actions of injected EGTA provide further evidence that it is the rise in intracellular ionized Ca that leads to inactivation of the Ca channel. Supported by NSF BNS 77-19161.



959 CESIUM CARRIES LARGE OUTWARD CURRENTS IN INTERNALLY-DIALYZED SNAIL NEURONS. Lou Byerly, Susumu Hagiwara, Masako O. Masuda*, and Mitsunobu Yoshii*. Dept. of Physiology, UCLA Medical School, Los Angeles, CA 90024.

We have applied a modified version of the internal-dialysis, voltage-clamp method developed by Lee, Akaike and Brown (J. Gen. Physiol. 71:489, 1978) to ganglion nerve cell bodies of the freshwater snail, Limnea stagnalis. The ganglia are treated with trypsin to facilitate isolation of the cell bodies and to increase the shunt resistance (typically > 100 MΩ) between the suction electrode and the neuronal membrane. Cells from the visceral and right parietal ganglia with diameters between 70 and 120 microns have been studied.

When both internal and external K^+ are replaced with Cs^+, voltage and time dependent outward currents are still observed when the cell is clamped to positive potentials. The I-V plot measured at 60 msec has a slope at potentials greater than +50 mV that is 20-100 times greater than the slope at potentials negative to the holding potential (-70 mV). This outward current, which has both fast and slow components, causes the net current measured to reverse at potentials less than +50. The slow component, which is still increasing at the end of a 70 msec voltage pulse, may account for the apparent inactivation of the inward current (carried by Ca^{++}) observed at potentials above -30 mV. When 10 mM EGTA is added to the internal Cs^+Aspartate$^-$ solution, the inward currents become more prolonged; even with 10 mM EGTA the slow component accounts for about half of the total outward current at potentials greater than +50 mV. Under no conditions have we seen the calcium current decay with a time constant less than 100 msec.

The outward currents are not affected by replacing external Cl^- with methanesulfonate$^-$, but are greatly reduced by replacing internal Cs^+ with Tris$^+$, TEA$^+$, or Arginine$^+$. Internal Na^+ only slightly reduces the outward currents observed with internal Cs^+. There is a striking correlation between the amplitude of the calcium current and the Cs-mediated outward current. Any treatment that reduces the calcium current (Ca-free external solution, external verapamil or La^{+++}, aging) also reduces this outward current. In converse, replacing Cs^+ with Tris$^+$, which greatly reduces the outward current, reduces the calcium current. We doubt that this Cs-mediated current is carried by the Ca-dependent K channels because there is no N-shaped region, it is not reduced when Ca^{++} is replaced by Ba^{++}, and there is 10 mM EGTA in the dialyzing solution.

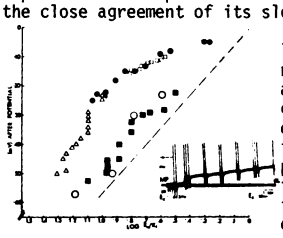
960 A COMPARISON OF OUABAIN-SENSITIVITY AND HYPOXIA ON THE INTRACELLULAR POTASSIUM ION ACTIVITIES IN IDENTIFIABLE NEURONS OF Aplysia californica. Philip E. Coyer. Dept. of Neurol. and Neurosciences Program, Univ. of Ala. Medical Center, Birmingham, Alabama 35294.

In different types of neuronal activity, either regenerative action potentials or decremental generator signals, hypoxia often causes membrane depolarization and concomitant alterations in the action potential frequency or the amplitude of the potential. Three independent explanations or possibly a combination thereof may account for these phenomenae: (i) inhibition of the existing electrogenic pump resulting in (ii) a change in the equilibrium potentials of the principal ions contributing to membrane potentials or (iii) a membrane conductance change.

To test these hypotheses, identifiable neurons from the abdominal ganglion were impaled with double-barrel, potassium ion-selective microelectrodes capable of measuring intracellular potassium ion activities and membrane potential. Neurons were maintained in a constantly-suffused chamber supplied by normal bathing solution held at 18°C. After nitrogen bubbling, gaseous equilibration of the normal saline was detected by pO_2 microelectrodes placed in the recording chamber. While the relative potassium ion activities on either side of the neuron's membrane were determined with the ion-selective electrodes, external sodium, calcium, and potassium ion concentrations were altered. Upon calculating the potassium equilibrium potential at the point of the after-potential reflecting the maximum potassium conductance (see figure), the effects of hypoxia were compared to that of 4×10^{-4} M ouabain exposure (open triangles). Control data were assembled by substituting choline for sodium and subsequently rearranging the external potassium ion concentration (10-40 mMK). The effects of hypoxia were initially expected to mimic pump inhibition resulting in alterations of the equilibrium potential of potassium and sodium. However, not all cells responded in this way. As expected from control points (open circles), a neuron depolarized in a predictable Nerstian manner, which is shown by the close agreement of its slope and that of the expected result (solid squares fit slope of dashed line). Several other neurons did not follow this prediction; it was apparent that a change in membrane conductance to potassium had occurred. Removal of the inactivation factor by a hyperpolarizing current pulse resulted in spiking indicating that a change in conductance and not the equilibrium potentials had occurred.



961 A MOLECULAR ORBITAL APPROACH TO SELECTIVE ION BINDING BY MACROCYCLIC ANTIBIOTICS. C. Zuazaga de Ortiz. Lab. of Neurobiol., U.P.R. Med. Sci. Campus, San Juan, P.R. 00901.

A qualitative hypothesis, based on molecular orbital theory is proposed to account for the alkali metal ion selectivities exhibited by the macrocyclic antibiotics valinomycin and enniatin B. Even though the complexes formed between the metal ions and the macromolecules are of low molecular symmetry, the bonding parts of the complex have relatively high local symmetries. Spectroscopic studies have shown that in both valinomycin and enniatin B, the six oxygen atoms which bind the central cation form a trigonal antiprism (Shemyakin, M. et al., J. Membrane Biol. 1:402 (1969). Therefore, the bonding parts of the complex are assumed to belong to the D_{3d} point group. Binding is explained by the sharing of electrons from the oxygen atoms of the macromolecule and the vacant valence orbitals of the cation. Group theoretical methods are used to determine the allowed orbital interactions. The observed specificity is explained in terms of the bonds that are symmetry-allowed and qualitative considerations of orbital overlap and steric effects. On this base, the observed selectivity sequences of the macrocyclic antibiotics can be accounted for. Experimental ways of verifying some of the bonding features proposed to explain the selectivities are also suggested.

962 NEUROTRANSMITTER MODULATION OF VOLTAGE-SENSITIVE CALCIUM CURRENTS IN SENSORY NEURONS. K.Dunlap* and G.D.Fischbach (SPON: C.L.Weill). Dept. Pharmacology, Harvard Medical School, Boston, Ma. 02115

The action potential recorded from the soma membrane of embryonic chick sensory neurons in culture has both a fast Na^+ component and a slower Ca^{++} component, responsible in part for a plateau on the falling phase of the spike. GABA, nor-epinephrine and serotonin (10^{-7}-10^{-4}M) decrease the duration of this plateau without affecting the resting membrane potential or input conductance, Fig A (Dunlap and Fischbach, Nature, 276:837, 1978). This could result from either a decrease in inward current or an increase in outward current. The voltage clamp experiments reported here show that this decrease in action potential duration results from a direct interaction of these neurotransmitters with a voltage-sensitive Ca^{++} conductance in the soma membrane. If the action of the neurotransmitters on the soma Ca^{++} current parallels their action at the nerve terminal, these results suggest a novel mechanism for presynaptic modulation of transmitter release.

The calcium current (I_{Ca}) is defined as a tetrodotoxin-resistant inward current which is dependent upon the extracellular Ca^{++} concentration and is blocked by Co^{++}. It follows a slower time course than the inward sodium current, reaching an average peak of about 250μA/cm^2 in 4ms. Application of low concentrations of the neurotransmitters decreases the peak inward current, I_{Ca}, without affecting the net outward K^+ current (I_K) measured at the end of the depolarizing voltage step (Fig B).

The effects of these drugs on I_{Ca} isolated from I_K was studied in two ways. First, depolarization to activate membrane conductance was followed by repolarization to the K^+ equilibrium potential (defined as the potential at which the tail current reverses in a solution containing TTX and Co^{++}). Application of the neurotransmitters decreases the magnitude of the inward tail current at E_K. Second, the outward K^+ current was completely eliminated in 125mM tetraethylammonium chloride (substituted for NaCl). The transmitters decrease I_{Ca} without affecting the time course or the voltage-dependence of current activation. Neither is the Ca^{++} equilibrium potential affected by drug application. It is concluded that these neurotransmitters decrease I_{Ca} through a reduction in the maximum, or limiting, Ca^{++} conductance.

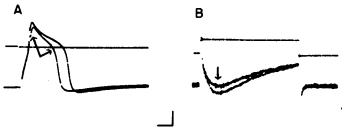

Figure: Effect of 10^{-5}M norepinephrine (arrows) on spike duration (A) and inward Ca^{++} current (B) in TTX. Cal: A-20mV,5ms; B-50mV/5nA,2ms.

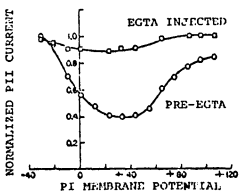
963 NEW THEORY OF KINETICS DESCRIBES EXCITABLE MEMBRANE BEHAVIOR. Dexter M. Easton. Dept. Biol. Sci., The Florida State University, Tallahassee, Florida, 32306.

According to conventional kinetics, the rate coefficient of a primary process is constant during the progress of the process. When this assumption is found to be incorrect, ad hoc adjustment is made. Thus, in Hodgkin-Huxley type equations, rate constants, implicit in initial assumptions, generate m,n,h processes, but their changing relation to V_M is subsequently found empirically. A more realistic initial assumption is that the rate coefficient of a primary process changes systematically during the course of the event, because conditions change as the system adjusts to a new equilibrium or steady-state. Rate constants then specify the rate of change of the rate coefficients of the primary process. This assumption, yielding simple equations of great power, has been used to model the conductance data of Hodgkin and Huxley, as well as oxyhemoglobin dissociation curves (Easton, Biophys. J. 22, 1978, J. Theoret. Biol. 76, 1979). The assumption that the rate coefficient changes exponentially with the independent variable is particularly well suited to such systems, involving asymmetric sigmoid relations between dependent and independent variables. Current-voltage-time records of voltage clamp data can now be modelled directly (rather than via conductance) from the following assumptions of the new (expo-exponential) kinetics: following a voltage step, current increases exponentially, but the rate coefficient of that growth decreases exponentially with time and increases exponentially with voltage. From this assumption, prediction of the V clamp results may be made by use of a single equation (with appropriate constants) derived to describe either specific ion current I_K or I_{Na}. (Aided by Psychobiology Center and Computer Center, Florida State University)

964 INTRACELLULAR EGTA INTERFERES WITH INACTIVATION OF THE Ca CURRENT IN APLYSIA NEURONS. R. Eckert and D. Tillotson.* Dept. of Biology UCLA, Los Angeles, CA 90024

Ca current, largely uncontaminated by other currents, can be examined in neurons in which most of the intracellular K is replaced with Cs through the use of the ionophore nystatin (Russell et al, J. Memb. Biol. 37:136-156, 1977; Tillotson and Horn, Nature 273:312-314, 1978). Inactivation of the Ca current is seen both as a relaxation of the current and as a decrease, following a prior depolarization, in the magnitude of the early inward current evoked by a given depolarization (Tillotson and Horn, 1978). The process of inactivation has been ascribed to Ca entry as opposed to membrane depolarization (Tillotson, 1979 PNAS 76:1497-1500; Brehm and Eckert, 1978 Science 202:1203-1206). Thus the Ca entering during the first depolarizing pulse (P_I) seems to cause inactivation during that pulse as well as a residual inactivation of the Ca current evoked by a subsequent pulse (P_{II}).

We further tested the role of Ca by interfering with the accumulation of intracellular free Ca^{2+} during Ca entry. The Ca chelator EGTA was iontophoresed into Cs-loaded neurons of the Aplysia abdominal ganglion while they were held at -40 mV under voltage clamp. The bath contained 100 mM $CaCl_2$+ 50 mM $MgCl_2$+410 mM Tris-HCl. Membrane currents in response to depolarizing steps were tested at intervals, and iontophoresis was continued until no further EGTA-related changes occurred. Following injection the relaxation of the inward current was greatly curtailed so that the inward current remained relatively strong under steady depolarizations lasting hundreds of milliseconds and longer. In the Figure it can be seen that the strong depression of the P_{II} inward current normally associated with P_I potentials that elicit large Ca entry (Tillotson, 1979) was largely abolished by the injection of EGTA. These results provide further evidence that inactivation of the Ca current depends on intracellular accumulation of free Ca^{2+} during depolarization. Supported by USPHS NS08364.



965 MEMBRANE EXCITATION PROPERTIES FROM A STATISTICAL EVALUATION OF IMPULSE TRAINS. Jürgen F. Fohlmeister, William J. Adelman Jr. and Richard E. Poppele. Lab of Neurophysiol., Univ. of Minn. Minneapolis, MN 55455 and Lab of Biophys. NINCDS, NIH, Woods Hole, MA 02543.

Impulse trains (fig. 1) generated by the space clamped squid giant axon in response to, and phase locked to the current $I(t) = I_o(1+\sin 2\pi f_o t)$ were modulated by a second, small amplitude sinusoidal current. The resulting impulse density was estimated for a complete period of the modulation sine wave from an impulse train with a duration of many modulation cycles (fig 2). For sufficiently small modulation amplitudes this impulse density

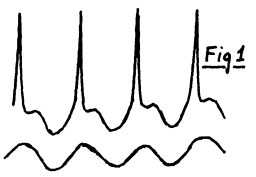


Fig 1

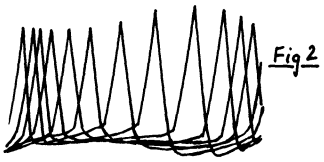

Fig 2

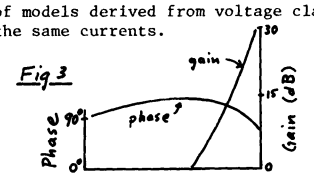
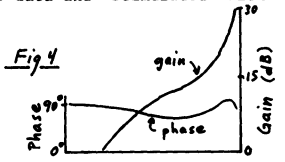
function is itself a sinusoid with the same modulation period. Gain and Phase (shift relative to stimulus modulation cycle) of the impulse density are determined as a function of the modulation frequency (Bode plots, figs. 3,4). Model studies have shown that a corner frequency and a gain resonance determine the magnitude of membrane conductance. The phase curve is a function of the conductance time course. Additional structure in the Bode plots may suggest the presence of "summing" phenomena (variables which are not reset by an impulse), and specify the relaxation times of those variables. The Bode plots of the squid axon membrane (fig. 3, for example) and of several models including the Hodgkin-Huxley model (fig. 4, for example) are qualitatively different. The necessary stimulus current and the measured conductance level are considerably higher for the axon. More importantly, the relaxation times of "recovery variables" (K-conductance and/or Na-inactivation) appear to be considerably longer for the axon when stimulated with sinusoidal currents than those of models derived from voltage clamp data and "stimulated" with the same currents.





966 ANOMALOUS RECTIFICATION IN FROG MUSCLE FIBERS: KINETICS AND VOLTAGE-DEPENDENT BLOCK BY CESIUM IONS. Shaul Hestrin* (SPON: Ann Kammer). Dept. of Physiology, UCLA Medical School, Los Angeles, CA 90024.

The time-course of anomalous rectification potassium current of frog twitch fibers was analyzed using Hille and Campbell type voltage clamp, which gives a time resolution of 1-5 msec. When muscle fibers are hyperpolarized an "instantaneous" inward current is observed, which is followed by a time dependent increase of the current. Both "instantaneous" and steady-state I-V relations have the property of an inward rectifier. The time-dependent current can be described by first-order kinetics. The "instantaneous" I-V relation may reflect the inward rectification of a single channel. Alternatively, the "instantaneous" I-V relation might reflect a change in the number of open channels which is complete within a few msec, and thus cannot be resolved with the present technique.

When Cs^+ ions are present in the external solution a decrease, or blockage of inward rectification is observed. As the membrane is hyperpolarized to a more negative potential a reduction of the current is observed. This voltage-dependent blockage causes a negative slope region in the steady-state I-V relation. When the membrane potential is stepped between two levels, the ratio of blocked to unblocked channels is changed in a time-dependent process.

Inward rectification channels of starfish egg cells (Hagiwara et al., J. Gen. Physiol. 67:621, 1976) have remarkably similar properties. However, the time course of the conductance increase is more than ten times faster in muscle fibers, but the kinetics of blockage by Cs^+ ions is on the same order of magnitude. This might indicate that Cs^+ blocking and channel gating are separate mechanisms.

967 SENSITIVITY OF A Na^+ PUMP TO MEMBRANE POTENTIAL. S. F. Holloway* (SPON: G. W. King). Lab. of Neurophysiology, University of Minnesota, Minneapolis, MN 55455.

In the crayfish stretch receptor neuron, a train of antidromically evoked action potentials is followed by a post tetanic hyperpolarization that has been shown to be due to the action of an electrogenic Na^+ pump. The same phenomena also underlies a post tetanic depression of firing in an active neuron (A below;) and also the adaptation of firing to a constant current (C below). It has been proposed that the small sodium influx associated with each action potential is sufficient to trigger the electrogenic pump. Alternatively, the following evidence suggests that electrogenic pumping is activated by the changing electric field associated with the action potential.

The application of a hyperpolarizing pulse shortly after an action potential will not effect the sodium influx but will alter the electric field across the membrane. As shown below, a hyperpolarizing pulse (100 mV in amplitude, 5 ms in duration; applied intracellulary to the neuron soma 10 ms after each antidromic action potential) abolishes the post tetanic depression normally observed after a 1 s antidromic train (50/s) (B). The adaptation to a step change in current can also be abolished when the hyperpolarizing pulse is applied after each action potential (D).

968 VOLTAGE-CLAMP ANALYSIS OF CA3 NEURONS IN HIPPOCAMPAL SLICES. Daniel Johnston and John Hablitz. Sect. Neurophysiol., Dept. Neurol., Baylor Coll. Med., Houston, TX 77030.

CA3 pyramidal neurons in the hippocampus fire in spontaneous bursts of action potentials (APs) at fairly regular intervals (Kandel and Spencer, 1961). These neurons are reputed to act as the presynaptic elements in the production of epileptic-type discharges in CA1 neurons after treatment with convulsant drugs. Moreover, long-term posttetanic potentiation of the mossy-fiber input to CA3 may have a postsynaptic locus. In an attempt to better understand these and other phenomena, a voltage-clamp study was initiated in order to identify some of the membrane currents in these neurons. Guinea-pig hippocampal slices, 400-500 μm thick, were maintained in vitro, using standard techniques. Neurons were impaled with 30-50 MΩ electrodes filled with either 3M KCl or 4M KAcetate. Voltage-clamping was performed, using a single microelectrode, based on the technique described by Wilson and Goldner (1975). Only cells meeting stringent criteria for viability were used for clamping. The cable properties of these neurons were determined by analyzing the current and voltage transients, as outlined by Rall. The equivalent electrotonic length of the CA3 cells was found to be, on the average, less than one space constant; therefore, a reasonable space clamp could be maintained for some distance from the soma. The average dendritic to soma conductance ratio was less than 2. Hyperpolarizing voltage-clamp commands of 100 msec duration elicited an inward-going current or anomalous rectification in most cells. This also was quite evident in current clamp and was seen as a "drooping" voltage transient. With depolarizing commands, large, fast inward currents were observed which could not be resolved by our clamping techniques. These were tetrodotoxin-sensitive and presumably were AP currents. In some cells, a much slower inward current also was seen with depolarizing commands. This current was increased by Ba^{++}, blocked by Co^{++}, and met the usual criteria for a voltage-dependent Ca^{++} current. In these same cells, a slow outward current was observed which persisted following the depolarizing command, decayed with a time constant of 1 sec, and was blocked by Co^{++}. These data would suggest a Ca^{++} activated K^+ current. Although difficult to resolve with our clamping techniques, a fast transient outward current observed with depolarization also may be present in these neurons. The results thus far indicate that CA3 neurons have a large repertoire of membrane currents similar in many respects to those described in other preparations, especially invertebrates. The role these currents may play in the behavior of CA3 neurons will be discussed. Supported by NIH Grant NS 11535.

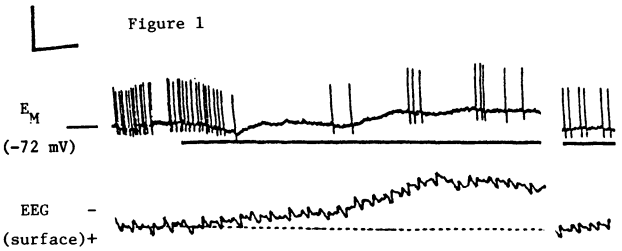
969 MEDIATED Cl^- TRANSPORT IN PRIMARY RAT ASTROGLIAL CULTURES. H.K. Kimelberg *, S. Biddlecome*, and R.S. Bourke, Albany Medical College, Albany, N.Y. 12208.

Astroglia are known to readily swell in vivo when the central nervous system is subjected to a variety of insults. Their perivascular location is also well suited to elaboration of brain extracellular fluid and pH control. These effects are clearly based on the ion transport characteristics of these cells and we have previously emphasized the role of Cl^- in astroglial swelling. Since ion transport in glia is difficult to define precisely in intact tissue, we are using a primary culture started from the cerebral hemispheres of 1-2 day old rats as a suitable in vitro model of astroglial cells. We have found that 70-90% of the cells in these cultures stain positively for glial fibrillary acidic protein (Stieg et al. this volume).

The rate of the steady state undirectional efflux or influx of Cl^-, measured with $^{36}Cl^-$, was reduced by up to 80% by 0.1 to 1.0 mM of the anion inhibitor SITS at 37°C pH 7.4. Furosemide and derivatives of ethacrynic acid were also found to inhibit the rate of influx, and the final steady state levels of Cl^-. Measurements of the initial steady state rate of uptake of Cl^- at varying external chloride concentrations gave saturation kinetics with an apparent Km for Cl^- of 40 to 60mM. These data suggest that a significant amount of Cl^- transport in these cells occurs by a mediated process, possibly involving an exchange carrier similar to that found in red blood cells. The intracellular chloride concentration, based on an estimated internal volume of 4.8µl/mg protein from K^+ distribution studies, and a Cl^- content of 0.145µmoles/mg protein from steady state $^{36}Cl^-$ levels, was calculated to be 30mM. This was 3 times greater than would be in equilibrium with a measured average membrane potential of -70 mV. Other indications that $[Cl^-]_i$ was not at Donnan equilibrium was that steady state $[Cl^-]_i$ was the same with $[Cl^-]_o$ reduced at either constant $[K^+]_o$, or with $[K^+]_o$ increased to maintain a constant external K x Cl product. Furthermore, pretreatment of the cells with ouabain, which resulted in a reversal of the normally high intracellular K^+:Na^+ ratio, had no effect on Cl^- uptake or final steady state levels as measured with $^{36}Cl^-$. At present it is unclear whether the high $[Cl^-]_i$ is due to operation of a Cl^- pump, a Na^+-Cl^- symport or increased uptake of Cl^- on a SITS-sensitive carrier in exchange for another anion, such as HCO_3^-. In brain slices, however, the occurrence of HCO_3^--dependent and SITS-sensitive swelling involving increased NaCl uptake and swelling of astroglial cells, suggests exchange of intracellular HCO_3^- for Cl^-. Since addition of Na^+ to cells incubated in Na^+-free medium led to an increased rate of acidification of the medium, increased uptake of Na^+ could be due to Na^+-H^+ exchange. Supported by NINCDS grant 13042.

970 SLOW MEMBRANE POTENTIAL SHIFTS IN CORTICAL NEURONS OF THE CONSCIOUS CAT IN RESPONSE TO MEANINGFUL STIMULI. Gregory L. King* and James E. Skinner. Neurophysiol. Sect., Neurology Dept., Baylor College of Medicine, Houston, Texas 77030.

When a conscious animal or human is presented with a tone that forewarns electric shock, a novel object, or a strong stimulus, an extracellular slow potential (SP) is evoked in the frontal and parietal association cortices. In different situations in which these same stimuli have no meaning, they do not evoke SPs, and are therefore evoked by the context of the stimulus, not its physical attributes. Current evidence suggests that these cerebral event-related SPs may be generated by the same cellular mechanism that is thought to produce SPs in the sympathetic ganglion neurons. In the isolated ganglion the SP is accompanied by slow postsynaptic potentials and is correlated with shifts in the intracellular levels of cyclic AMP (cyclic 3',5'-adenosine monophosphate). Our laboratory has shown that the amplitude of an event-related SP in the rat parietal cortex is negatively correlated with the local tissue level of cyclic AMP (Skinner et al., J. Neurochem., 1978). Our most recent observations show that slow 20-30 sec membrane depolarizations occur in some neurons in the frontal cortex of the conscious cat during a surface-negative event-related SP that is recorded from the same local area (Figure 1). These large depolarizations are associated with a reduction in the spontaneous action potential discharges, and, in some cells, are accompanied by a conductance increase. Other cells do not manifest detectable changes in the current-voltage relationship during the evoked slow membrane potential shift. By employing a "floating" micropipette method of recording, we have been able to perform several replications of the observations in the same cell.



Cal: 20mv (upper), 1 mV (lower), 167 msec

971 THE EFFECT OF THE INSECTICIDE TETRAMETHRIN ON THE SODIUM CHANNEL OF CRAYFISH GIANT AXONS. A. E. Lund* and T. Narahashi, Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

A variety of natural and synthetic toxins have proved useful in studying ionic conductance mechanisms in nerve membranes. They synthetic pyrethroid insecticides are a relatively new group of toxins with potent and unique actions on axonal membrane. Using the sucrose-gap, voltage clamp technique, we have studied the effect of one of these, tetramethrin, on crayfish giant axons. Median giant axons were isolated from crayfish and internally perfused with a solution containing 220 mM K^+, 15 mM Na^+, 170 mM glutamate, 50 mM F^-, 15 mM Cl^-, and 96 mM sucrose with a pH of 7.3. The holding membrane potential was -100 mV for all experiments.

Tetramethrin, applied at a concentration of as high as 300 µM internally or externally, had no effect on the time course or the steady-state amplitude of the potassium current measured in the presence of 300 nM tetrodotoxin. However, the (+) optical isomers of tetramethrin had a specific effect on the sodium current as measured with an internal perfusate in which Cs^+ was substituted for K^+. A concentration of 10 µM applied to either side of the axonal membrane caused the inward sodium currents to become biphasic, a normal initial transient sodium current being followed by a secondary inward current of much slower time course. This slow inward current was observed without the initial sodium transient at membrane potentials between -70 mV and -50 mV. Thus the voltage dependence of the slow current is shifted in the direction of hyperpolarization with respect to the initial transient sodium current. The time course of the sodium tail current, which followed the first order kinetics in the control axon, became the second order in the tetramethrin-treated axon. The first time constant (< 1 msec) coincided with the control tail current time constant, and the second time constant was on the order of hundreds of millseconds. Increasing the concentration of tetramethrin had no effect on the tail time course, but increased the amplitude of the tail current. Experiments in which depolarizing pulses of varying duration were applied showed that the development of the slow phase of the tail current closely followed the development of the slow inward current. These observations suggest that a population of sodium channels is modified by tetramethrin to give rise to drastically slowed activation and inactivation. The "slow channels" activate with a time course of 50-500 msec and inactivate with a time course of several seconds. Supported by NIH grant NS14143.

972 LONG-TERM AFTEREFFECTS OF SUBTHRESHOLD ELECTRICAL STIMULATION OF PERIPHERAL NERVE AXONS. Kenneth McLeod* and Stephen A. Raymond. Research Laboratory of Electronics, MIT, Cambridge, MA 02139.

In cat dorsal horn, Merrill, et al, reported aftereffects that linger for 20 msec or more following single subthreshold electrical pulses (J. Physiol. 284:127-145, 1979). Gasser (Am.J.Physiol. 121:193-202, 1938) showed indirect evidence for such long-term aftereffects in his study of "recruitment" of nerve fibers in whole nerve given near threshold tetanic stimulation. We find that when an excised frog sciatic nerve is bathed in Boyle-Conway Ringers at constant pH 7.0-7.7 and constant temperature, stimulation of the nerve with current pulses that are near but below threshold results in brief transient increases in excitability that decay within 2 msec. The last stimulus in a short burst of such subthreshold stimulation is followed by the same transient superexcitability that follows a single pulse or the last stimulation of a subthreshold tetanus. Under these conditions there are no detectable long-term aftereffects of subthreshold stimulation as assayed either by threshold hunting or by raising the amplitude of subthreshold stimuli gradually.

The pH of the Ringers solution was set by adjusting the mixture of 5% CO_2 in air, 30% CO_2 in O_2, and O_2 bubbled through reservoirs of Ringers. After several hours at pH 9.0, rapid restoration to pH 7.5 produced prolonged rises in threshold lasting for more than an hour. During such depressed excitability, individual fibers given repeated stimulation showed a superexcitability es having a minimum threshold about 10% below resting level that was detected for more than 50 msec following the last pulse in a train. This superexcitability appears to account for recruitment:

1) It appears after acid shifts (as does recruitment).

2) It lasts about as long as the maximum period between stimuli in trains that produce some recruitment in gross sciatic nerve.

3) The amplitude of the threshold change diminishes (as does the rate of recruitment) as the period between stimuli gets longer.

We are investigating relations of pH-induced depression to depression induced by activity, which is thought to depend on electrogenic Na^+ pumping.

973 COMPARTMENTAL ANALYSIS OF ELECTRICAL CONSTANTS IN CULTURED MOUSE DORSAL ROOT GANGLION NEURONS. Jane C. Norris*, Thomas H. Brown and Donald H. Perkel. Depts. of Neurology and Biological Sciences, Stanford University, Stanford, California 94305

Cultured mouse dorsal root ganglion (DRG) neurons offer both experimental and theoretical advantages for evaluating the electrical constants in a mammalian neuron. Their simple geometry makes it possible to represent the cell by an isopotential soma compartment (consisting of a capacitance C_S in parallel with a conductance G_S) which is attached to a single dendritic cylinder (represented by a resistive-capacitive network in parallel with the soma compartment) having an electrotonic length L. We have developed and applied to these cells a convenient method for obtaining specific membrane properties and electrotonic structure.

The DRG cell soma was penetrated with two independent microelectrodes, one for delivering current steps and the other for recording voltage responses. Current-voltage curves were obtained and subsequent analysis was restricted to the voltage range in which the cell membrane gave an ohmic or linear response to hyperpolarizing current steps. The slope of the hyperpolarizing charging curve was fitted by the function

$$-\frac{dV}{dt}(t) = \Sigma a_i e^{-t/\tau_i} ,$$

where t is the time from the onset of the current step. The dendritic to somatic input conductance ratio ρ was obtained from the relation

$$\rho = \frac{G_N \tau_0}{I} \Sigma a_i - 1 ,$$

where G_N is the input conductance of the whole cell, τ_0 is the membrane time constant, and I is the amplitude of the current step. The remaining parameters could then be obtained as follows

$$G_S = G_N/(\rho + 1) \quad , \quad C_S = G_S \tau_0 \quad , \quad L = \pi \left(\frac{\rho/(\rho + 1)}{\tau_0/\tau_1 - 1}\right)^{1/2} ,$$

where τ_1 is an "equalizing" time constant. The cell soma area A_S was determined and, from A_S and the values of C_S and G_S, we calculated the specific membrane resistivity R_m and specific membrane capacitance C_m.

All of the electrical constants were within the usual range for vertebrate neurons except ρ, which fell between 0 and 2. The assumptions underlying this analysis were assessed with computer simulations, using the compartmental analysis of Perkel and Mulloney (Amer. J. Physiol. 235,R93,1978), and were found to be reasonable for cells with the general shape of a DRG neuron. The applicability of these analytical methods to some neurons with very different cellular geometries is currently under investigation. (This research was supported by NS 06161, NS 12151 and NS 09744).

974 PRESSURE INCREASES MEMBRANE CONDUCTANCES IN VOLTAGE CLAMPED MOLLUSCAN NEURONS. James L. Parmentier, Brij B. Shrivastav and Peter B. Bennett* Dept. of Anesthesiology, F.G. Hall Laboratory, Duke University Medical Center, Durham, North Carolina, 27710.

The narcosis induced by general anesthetics and excitability produced by raised hydrostatic pressure are known to be mutually antagonistic in whole animals, including man. The cellular mechanisms involved in these responses remain unclarified. The "critical volume hypothesis" (Miller, Fed. Proc. 36:1663-1667, 1977) states that anesthesia will occur when the volume of a hydrophobic region of the membrane is caused to expand beyond a critical value by the absorption of an inert substance. An applied pressure will then oppose this expansion and reverse the narcosis by restoring the membrane region to its former functional position. This hypothesis assumes that pressure acts directly at the site of anesthesia to alter its effect. We have tested this assumption in three seperate single neuron preparations using voltage clamp techniques to study membrane currents associated with 1) the action potential in squid giant axons, 2) the slow inward current controlling burst formation in R15 of Aplysia, and 3) the slow outward current underlying adaptation responses in R2 and LP1 of Aplysia.

Following exposure to the volatile anesthetic halothane all three preparations showed a reduction of excitability and an increase in membrane permeability. Compression to 150 ATA caused an increase in potassium conductance in the squid axon and an increase in the ultra-slow outward current, thought to be carried by potassium in the giant cells of Aplysia. The rate of adaptation of the Aplysia neurons was increased by pressure in a manner similar to that caused by the anesthetic. When pressure and the anesthetic were applied simultaneously both effects were noted, and no indication of pressure reversal was apparent. In each case the anesthetic appeared to act in a manner functionally distinct from the applied pressure. For the squid axon it was possible to calculate changes in the membrane time constants associated with the pressure enhancement. It is concluded that pressure reversal is a function of multicellular homeostasis in central nervous organization rather than direct interaction at the level of the unit membrane and that the "critical volume hypothesis" may have to be refined to account for pressure reversal observations in whole animals.

975 ANION CHANNEL SIZE IN CEREBELLUM DURING SPREADING DEPRESSION. J.M. Phillips* and C. Nicholson. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., New York, NY 10016.

Extracellular Cl^- (diameter 3.6 Å) falls transiently during spreading depression (SD) in the cerebellum (Kraig & Nicholson, Neuroscience 3: 1045, 1978), presumably due to entry into cells (Van Harreveld & Schadé, Am. J. Physiol. 189: 159, 1957). Using ion-selective micropipettes (ISMs) we have studied the behavior of several "probe anions" i.e. exogenous anions larger than Cl^-, during SD to determine characteristics of anion permeability.

ISMs were made from theta-glass capillaries and contained, as anionic exchanger, either Aliquat 336 or Crystal Violet dissolved in 3-nitro-O-xylene (Senkyr & Petr, in Ion Selective Electrodes, ed. by E. Pungor, Elsevier 1978). They had Nernstian responses to Na-salts of the following anions: thiocyanate (SCN), hexafluorophosphate (PF_6), hexafluoroarsenate (AsF_6), hexafluoroantimonate (SbF_6), salicylate (SAL) and α-naphthalene sulfonate (α-NS). The selectivities over Cl were: SCN, 500:1; PF_6, 7000:1; AsF_6, 15,000:1; SbF_6, 600:1; SAL, 800:1; α-NS, 1500:1. Rats were anesthetized with urethane and the exposed cerebellum superfused with warm saline. Anion probes (1-5 mM) were introduced into the extracellular space by adding them to the superfusate, except for SAL which was introduced by local iontophoresis. Extracellular anion concentration was measured with an ISM at a depth of 50-100 μm. Local potential change was measured from the reference barrel of the ISM. SD was induced by switching the superfusate to a hypotonic, low NaCl (25 mM) Ringer and then locally stimulating briefly at 50 Hz.

SD was defined by the characteristic slow negative transient in extracellular potential. SCN^- (diameter 4.2 Å), PF_6^- (5.6 Å) and AsF_6^- (6.35 Å) all decreased in extracellular concentration by about 40% of baseline concentration during SD. SbF_6 (7.30 Å), SAL (8.9 Å) and α-NS (11.2 Å) all increased in concentration by about 50% baseline value, during SD.

These findings suggest that during SD a channel of size 6.35 - 7.30 Å diameter becomes active. Anions larger than 7.30 Å are concentrated in the extracellular space by the entry of smaller ions (residual Cl^- and Na^+) into cells together with water (3.0 Å) and consequent cellular swelling at the expense of extracellular volume. While this anion channel size exceeds that postulated for several IPSPs, it is in excellent agreement with the Cl channel of skeletal muscle and erythrocytes. Our results thus show the existence of widespread anionic channels of defined size which can be demonstrated during SD. (Supported by USPHS Grants NS-13742 and GM-07308 (JMP).

976 IONIC CURRENTS UNDERLYING THE ACTION POTENTIAL OF NEUROBLASTOMA CELLS F. N. Quandt* and T. Narahashi (Spon: A. I. Farbman) Dept. Pharmacol., Northwestern Univ. Med. Schl., Chicago, IL 60611.

The action potential recorded from N1E-115 neuroblastoma cells exhibits a fast depolarizing phase followed by a transient repolarization, and finally a depolarizing after-potential that decays to the resting potential level in 0.1 to 10 sec. Through voltage-clamp experiments, Moolenaar and Spector (J. Physiol. 278, 265, 1978) found voltage-dependent Na, K and Ca channels in these cells. We have performed experiments to clarify the ionic basis of the components of the action potential and to examine the pharmacology of the channels in more detail. A two microelectrode voltage-clamp technique was utilized. The cell body was found to be isopotential during an action potential and series resistance was minimal. Early inward currents were recorded in response to step depolarizations to potentials less negative than -40 mV from a holding potential of -80 mV. The inward currents became maximal (-90 to -240 nA) at a depolarization to 0 mV, exhibited a time-to-peak of 2 msec (16 -17°C) at this potential, and rapidly inactivated. This current has a reversal potential of 45 mV and was completely blocked by 1 μM tetrodotoxin. Delayed, steady-state outward currents became prominent for depolarizations beyond -20 mV. The reversal potential for these outward currents measured from tail currents following step repolarizations was -70 mV. This current was reduced 90% by 15 mM tetraethylammonium and 30% by 1 mM 3, 4-diaminopyridine. While the fast depolarization and repolarization of the action potential appear to be primarily due to the early inward and delayed outward currents, respectively, current through the Ca channel is responsible for the depolarizing after-potential. The after-potential was found to be associated with an increase in membrane conductance, measured with constant current pulses. Application of 1 μM tetrodotoxin with 15 mM tetraethylammonium enhanced the slow potential. Substitution of 62 mM Sr^{2+} for Na^+ in this solution resulted in a prolonged action potential. Under these conditions, slow inward currents could be measured in response to step depolarizations to potentials less negative than -40 mV. These currents exhibited a maximum (-10 nA) at a depolarization to 0 mV with a time-to-peak of 20 msec. Inward current lasted for more than 150 msec at this potential. Cd^{2+} (1 mM) reversibly blocked this inward current. This study was supported by NIH grant NS 14144.

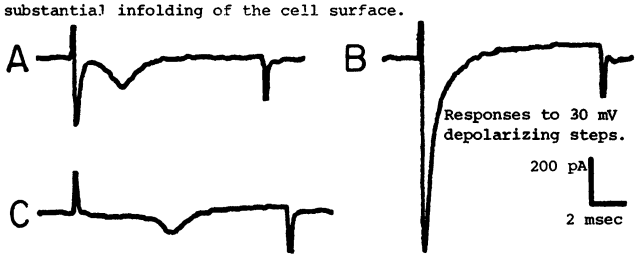
977 CRAYFISH STRETCH RECEPTOR NEURONS HAVE DIFFERENT SODIUM CHANNELS IN AXONS AND DENDRITES. William M. Roberts* (Spon: William B. Kristan). Dept. of Neurosciences, UCSD, La Jolla, CA 92093.

A modification of the technique of Neher and Lux (Pflugers Arch. 311: 272, 1969) was used to measure current through small (5-9 μ diameter) membrane patches in tonic abdominal stretch receptor neurons of the crayfish *Pacifasticus leniusculus*. Two intracellular electrodes were used to voltage clamp the cell. The extracellular patch electrode was positioned close to the intracellular voltage electrode; the membrane was not well clamped at distances greater than 50 μ.

Three major components of the active spike currents in the dendrites, soma, and proximal axon were found: a non-inactivating outward K^+ current and two transient inward Na^+ currents. Both of the inward components are present in the soma (A), while the axon (B) shows only the fast component and the dendrites (C) show only the slow component. The outward current was present at all locations studied. Both inward components were blocked by 2 nM-TTX and showed similar dose-response characteristics. Both were abolished in Na^+-free (choline substituted) saline and were unaffected by Li^+ substitution for Na^+, by low Ca^{++}, or by addition of Ba^{++} or Co^{++}. The two inward components observed in the soma could be separated by applying a 4 msec duration depolarizing step (to inactivate both components) with a test step 2 msec later. By this time the fast component had recovered while the slow component was still inactivated.

The slower inward current in the soma and dendrites causes a broadening of the dendritic spike and often produces a notched waveform of the soma spike. This current is probably involved in double-spiking seen at elevated temperature (Calvin and Hartline, J. Neurophys. 40:106, 1977). A similar mechanism could be present in other neurons which show notched soma spikes and double-spiking (Calvin and Sypert, J. Neurophys. 39:420, 1976).

Capacitance measurements give values of 2-5 $\mu F/cm^2$ (compared to 1 $\mu F/cm^2$ found in most lipid bilayer membranes), suggesting a substantial infolding of the cell surface.



978 A MUTATION AFFECTING MEMBRANE STABILITY IN PARAMECIUM TETRAURELIA. Youko Satow. Lab. Molecular Biology, Univ. Wisconsin, Madison, WI 53706.

It is well known that an increase in external Ca concentration changes the surface-charge pattern and stabilizes the membrane as shown by a shift in the voltage sensitivity of Na or Ca channels. teaB, a mutant P. tetraurelia, appears to have a more stabilized membrane. The curve of voltage sensitivity of the Ca channels (G_{Ca}-V relation) in teaB is about 10 mV more positive than that of wild type. The inactivation curve (max G_{Ca}-V_h relation) of the mutant is about 8 mV more positive than that of wild type. However, the mutant and the wild type have the same maximal G_{Ca} of 40 nmho/cell. The K conductance responsible for the anomalous rectification also appears more stabilized in the mutant.

Wild-type paramecia grown at a high temperature (34°C), but tested at room temperature (22°C), differ from those that never experienced the high temperature. The G_{Ca}-V relation shifted toward less sensitivity and both the activation and inactivation of the Ca channel are slowed down in the 34°C-grown wild type. teaB mutant, however, shows little change after incubations at 34°C. The maximal G_{Ca} is not affected by the growth temperature in both the wild type and the mutant. It is known that ciliated protozoa can detect temperature and redirect their phospholipid fluidity. The teaB mutation may damage this mechanism and cause a loss in thermo-responsiveness (corresponds with the behavioral observation by T. Hennessey). This would lead to perturbation in membrane lipid compositions, surface-charge pattern and membrane stability.

The experiments were done under a voltage clamp. The Ca currents were given by the subtraction method using non-leaky pawnA, pwA_{500}, since pwA locus has a defective site on a number of functional Ca channels (Satow & Kung, submitted to J. Exp. Biol.) and +115 mV for E_{Ca} was used for the calculation of G_{Ca} as a chord conductance. The external Ca concentration was 0.91 mM and the external K concentration was 4 mM through the experiments. This work was supported by NSF grant BNS77-20440 to C. Kung.

979 THE ACTION OF POTASSIUM CURRENT ANTAGONISTS ON CAT SPINAL MOTONEURONS STUDIED BY VOLTAGE CLAMP. P.C. Schwindt* and W.E. Crill. Dept. Physiol. & Biophysics, and Medicine, Univ. Washington, Seattle, WA 98195.

Depolarizing voltage steps from resting potential activate two kinetically distinct, persistent, outward current components in cat motoneurons, I_K^f, a fast component, and I_K^s, a component having time constants about 10 times slower. Since these are likely to be potassium (K^+) currents, we have examined their alteration during voltage clamp while extracellularly iontophoresing K^+ itself, and while iontophoresing extra- or intracellularly various agents known to depress K^+ currents in invertebrate neurons. Extracellular K^+ depressed both I_K^f and I_K^s, presumably by raising K^+ equilibrium potential. Agents depressing I_K^f without significant effect on I_K^s included intra- or extracellular tetraethylammonium (TEA) or barium (Ba^{++}) and intracellular 4-aminopyridine (extracellular not tried). Extracellular TEA and intracellular Ba^{++} produced the most powerful and rapid effects. Extracellular Ba^{++} apparently had to enter the cell before exerting its blocking effect. In cells where a persistent inward current (I_1) had deteriorated, only a relatively small widening of the action potential occurred after all I_K^f appeared to be blocked, suggesting that the large leak conductance and a fast transient outward current existing in motoneurons are sufficient to rapidly repolarize the spike in the absence of I_1. Slow K^+ currents in several invertebrate and vertebrate neurons appear to be calcium (Ca^{++}) mediated, but the Ca^{++} blockers, cobalt and manganese, depressed both I_K^f and I_K^s in cat motoneurons. Either these divalent cations have non-specific K^+ blocking effects in cat motoneurons, or both fast and slow K^+ currents are Ca^{++} mediated. Supported by VA Research Grant MRIS 1610.

980 VOLTAGE CLAMP STUDIES OF A-CURRENT VARIABILITY IN NEURONES OF ARCHIDORIS MONTEREYNSIS. Elba E. Serrano* and Peter A. Getting. (SPON: P. Lennard). Department of Biological Sciences, Stanford University, Stanford, CA 94305.

Voltage clamp studies of molluscan neurones demonstrate the existence of several ionic currents with voltage and time dependent conductance changes. Presumably the characteristic firing patterns of cells require the integration of these ionic currents in space and time across the membrane. Differences in the kinds of currents, their relative contribution to membrane excitability and/or variations in the nature of the specific voltage and time dependent conductance changes of the individual currents could all contribute to the observed variation in cell repetitive firing. This study focuses on characterizing the intracell and intercell variability of the A-current system under voltage clamp. The transient outward potassium current, I_A, is particularly suitable for these measurements since using the appropriate voltage paradigms it can be activated in isolation from other membrane currents without need for pharmacological blocks.

Isolated neurons from the cerebral, pleural and pedal ganglia of Archidoris montereynsis were voltage clamped at 10°C. The population of cell types is comprised of five neurons. Cells were chosen on the basis of constancy of location from prep to prep, ease of removal from the ganglion, reproducible firing patterns. Between cell types, however, there is a variation in the f-i responses under current clamp.

Variability has been examined in the following parameters: a) magnitudes of currents b) steady state activation and inactivation c) peak current activation and inactivation d) time constant for decay of I_A (τ_B) e) time constant for activation (τ_A) f) time constant for removal of inactivation. In this group of cells, the variation in the activation and inactivation curves within cells was of the same order as the variation between cells. The most striking variability between cells seems to be in the kinetics of their response to changes in potential. In particular, the time constants for decay of inactivation show constancy within a cell and variability between cells. Cells segregate into two populations: in one, the τ_B is of the order of 60-90 ms, in the other, it is between 260 and 330 ms.

981 EXCITATION OF SQUID AXON MEMBRANE INTERNALLY AND EXTERNALLY EXPOSED TO SINGLE-SALT SOLUTIONS. Susumu Terakawa* (SPON: S. Judge). NIH, Bethesda, Md. 20205

Squid axons were perfused both internally and externally with a solution containing $CoCl_2$ or $MnCl_2$ only (tonicity was adjusted using 12% (v/v) glycerol). At a divalent-cation salt concentration 1-10 mM, the potential difference across the membrane was close to zero. Upon application of a constant inwardly-directed current through the membrane, periodic variations of the voltage across the membrane were observed. These periodic variations of the voltage were very similar to repetitively-fired action potentials. They appeared even in the virtual absence of the concentration gradient across the membrane. The amplitude of these responses was commonly found to be 100 mV. The periodic responses obtained were accompanied by changes in the membrane conductance. The anions tested as cobalt salt included fluoride, chloride, acetate, citrate, and gluconate. There was no qualitative difference in the electrophysiological responses obtained with these anions. Nickel chloride and barium chloride were also able to elicit the periodic responses. The internal and external salt concentration could be varied independently without losing excitability. When the $MnCl_2$ concentration in the external medium was reduced from 10 mM to 2 mM, the duration of the response obtained by passing an inward current was prolonged. Reducing the $MnCl_2$ concentration of the internal medium from 5 mM to 1 mM shortened the duration of the response and enhanced its amplitude. An effect similar to that of reducing the internal salt concentration could be obtained by increasing the inward current. Tetrodotoxin (2 μM) added to the external medium did not suppress the excitability. This simplest ionic condition achieved may help advance the physico-chemical theory of nerve excitation.

982 QUANTIFICATION OF ELECTROMAGNETIC FIELD STRENGTHS IN MEDICAL LINEAR ELECTRON ACCELERATORS AND THEIR IMPLICATIONS FOR PATIENTS WITH ARTIFICIAL CARDIAC PACEMAKERS; P. J. Tetenes* and P. A. Anninos, Department of Radiology Albert Einstein College of Medicine, Bronx, New York (10461) and Department of Physics Concordia University, Montreal, P.Q.

Behavioral changes in the neurophysiological responses of living organisms exposed to radiofrequency and microwave radiations have been well documented in the scientific literature. The character and intensity of these changes are dictated, among others, by the high sensitivity of many compartments of the CNS to such radiation exposures, the variability of electrophysical properties of biological media, and the inherent characteristics of the ambient electromagnetic fields. Consequently, this vast array of interactive variables hampers the development of generalized but exact mathematical expressions to describe the many significant and novel bioeffects resulting from exposures to such wide energy spectrum. The specificity with which all pertinent parameters can be described may decrease the uncertainty in explaining the phenomenology of the effects both experimentally and theoretically. A unique biophysical problem with clinical implications involves individuals with artificial cardiac pacemakers exposed to pulse-modulated, 3000MHz, radiation emissions from medical linear electron accelerators. This work will describe the experimental methodology employed in the quantification of the field gradients present in these facilities. A theoretical analysis will follow of the extraneous and induced electric field intensities in the chest walls of humans. The level of susceptibility and functional disturbances of representative models of pacemakers will be investigated for " free-field" and "simulated-implant" conditions. Preliminary test results will be discussed in connection with their clinical implications.

983 CONDUCTANCE CHANGES ACCOMPANYING THE MATURATION OF MYOTUBES IN CULTURE. C.M. Thomson* and W.F. Dryden. Department of Pharmacology, University of Alberta, Edmonton, Alberta, T6G 2H7, Canada

During maturation, the resting membrane potential of myotubes in culture increases over a period of several days from a low level (-10 mV) to that found in mature muscle fibres. Ionic conductances have been investigated during this time using a variety of supposedly specific blocking agents. Breast muscle was obtained from 11 day chick embryos and grown in monolayer culture. The membrane potential and conductances were measured at daily intervals from the third day of culture, just after myoblast fusion. Standard current-voltage graphs were prepared directly from steady state membrane potential shifts in response to the application of small currents through the recording glass microelectrode. Input resistances were correlated with measured fibre diameters and values for specific membrane conductance were calculated. Measurements were made on identified fibres both before and after the application of ion conductance blocking agents.

Previously communicated results (Thomson and Dryden, Proc. Physiol. Soc., Dec. 1978) indicated that chloride conductance (G_{Cl}) declined with development and rising membrane potential, but that the decline in G_{Cl} was less than that observed for the unblocked membrane (G_m). In the present work tetraethylammonium (TEA) and Cs^+ have been used to block potassium conductance. Both agents gave similar results and revealed that potassium conductance declined between the third and fourth day of culture (from 0.2 mS cm^{-2} to 0.1 mS cm^{-2}) and thereafter remained constant. Replacement of Na^+, K^+ and Cl^- in the bathing solution by choline iodide revealed a considerable conductance (0.7 mS cm^{-2}) in young fibres which was attributable to Na^+ and was TTX insensitive. This conductance declined rapidly between the third and fifth days of culture and disappeared by the sixth day. The use of calcium channel blocking agents such as verapamil revealed that this Na^+ conductance could be further reduced suggesting that the Na^+ ions were permeating through channels capable of allowing the passage of a calcium current.

It is concluded that the low resting membrane potential of young myoblasts and myotubes is attributable to this substantial Ca^{++} and Na^+ conductance; and that the rise in membrane potential associated with development is a result of the loss of such steady state cation channels.

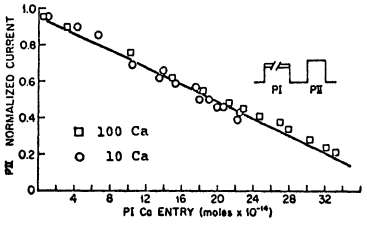
984 Ca INACTIVATION IN APLYSIA NEURONS IS QUANTITATIVELY RELATED TO PRIOR Ca ENTRY. D. Tillotson* and R. Eckert. (SPON: A.L.F. Gorman) Dept. of Biology, UCLA, Los Angeles, CA 90024

Neurons of the abdominal ganglion of A. californica were loaded with Cs^+ by means of the nystatin method (Russell et al, J. Memb. Biol. 37:137-156, 1977), replacing internal K^+. Sodium and K were omitted from all solutions so that Ca current was relatively free from contamination by other currents. With this approach it was found that the Ca current exhibits inactivation (Tillotson and Horn, Nature 273:312-314, 1978), and that the inactivation depends on prior Ca entry (Tillotson PNAS 76:1497-1500, 1979).

The role of Ca was further tested by comparing the degree of inactivation (i.e., depression of peak early Ca current) seen during a non-varying pulse (P_{II}) with the amount of Ca having entered the cell during a prior pulse (P_I) in Cs-loaded cells R2 and R14. The bath solution contained 100 mM $CaCl_2$, 50 mM $MgCl_2$, 410 mM Tris-HCl. To produce a wide range of Ca entry, the amplitude and duration of P_I were varied, with extracellular Ca concentrations of both 10 mM and 100 mM. The difference in $[Ca]_o$ was made up with Mg in the 10 mM Ca solution. The time-integral of the P_I inward current was taken to approximate the number of Ca ions entering the cell during P_I, since the current is nearly eliminated by cobalt substitution for Ca. The Figure shows a plot of relative P_{II} Ca current (i.e., relative to the full current recorded during P_{II} under the prevailing conditions in the absence of a prior pulse I) plotted against moles of Ca having entered during the corresponding P_I. Inactivation of the P_{II} Ca current was a linear function of the quantity of Ca entering during P_I irrespective of P_I potential or duration. This provides further evidence that inactivation of the Ca channel following depolarization is a consequence of Ca entry rather than depolarization. Supported by USPHS NS 08364.



985 EFFECTS OF LOWERED INTRACELLULAR pH ON EXCITABILITY IN PARAMECIUM. Joy A. Umbach* (SPON: Peter M. Narins). Dept. Biology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Ammonium rebound acidification (Boron and deWeer, J. gen. Physiol. 67: 91-112, 1976; Aickin and Thomas, J. Physiol. 273: 295-316, 1977) was used to lower intracellular pH of P. caudatum. Paramecium, which normally exhibits regenerative but graded calcium responses (Naitoh, Eckert and Friedman, J. exp. Biol. 56: 667-681, 1972), produces all-or-none overshooting calcium action potentials under conditions of internal acidification.

The control bath solution consisted of 1mM $CaCl_2$, 3.5mM KCl, 0.5mM KOH, 0.1mM EGTA and 1mM Hepes (N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid) buffer at pH 7.1. The ammonium solution consisted of the control saline to which NH_4Cl was added to a concentration of 50mM. Specimens were bathed in the NH_4Cl solution for two 15-minute periods separated by a 15-minute interval in the control saline. The paramecia were then returned to the control solution for intracellular current clamp or voltage clamp experiments. All-or-none activity in response to depolarizing current developed within 15 minutes after the final return to the control solution.

Hyperpolarizing and depolarizing current pulses of 200msec duration were passed to determine steady-state current-voltage relations. These relations were not altered from control values in those cells that were acidified and expressed all-or-none activity. The resting potentials of the acidified cells were also normal. In preliminary voltage clamp measurements the conversion to all-or-none behavior was not seen to be accompanied by any changes in the late currents. In contrast, conversion from graded to all-or-none activity as a result of lowered internal pH has been found in arthropod muscle to be associated with a reduction in delayed rectification (Moody, Soc. for Neuroscience Abst. 4: 236, 1978). The present experiments suggest that in Paramecium, lowered intracellular pH leads to all-or-none activity through an action other than an interference with late outward current. Supported by USPHS1 T32M MH15345 and NSF BNS 77-19161.

986 MECHANISMS UNDERLYING DEPOLARIZING AFTERPOTENTIALS IN HIPPOCAMPAL CA3 PYRAMIDAL CELLS. R.K.S. Wong and D.A. Prince. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

We have previously reported that the depolarizing afterpotential (DAP) is important in sustaining burst firing in hippocampal CA3 pyramidal cells (Wong & Prince, Brain Research 159: 385, 1978). In the present study we have examined the mechanism of DAP generation by using the in vitro slice preparation which enabled us to perform various ionic manipulations. Afterpotentials which followed directly or antidromically-evoked spikes could be arbitrarily divided into two events. These consisted of 1) the DAP, and 2) the afterhyperpolarization. Maximum spike repolarization in these neurons typically reached a level depolarized to the resting potential (i.e., there was no undershoot of the baseline). Spike repolarization was followed by a DAP which had two components. One was a depolarizing hump which reached a maximum amplitude of 5-10 mV in about 5 msec and usually crossed the threshold for spike generation, thus functioning to sustain burst firing. When the membrane potential was manipulated with intracellular current pulses, this depolarizing hump occurred at a threshold level of depolarization and could be blocked by hyperpolarizing pulses which were insufficient to block the antidromic spike. Perfusion with Ca^{++}-free solution containing 2 mM Mn^{++} blocked the depolarizing hump (and the succeeding afterhyperpolarization; see Hotson et al., Neurosci. Abstr. 3: 218, 1977). A second component of the DAP was obvious in the 0Ca^{++}, 2 mM Mn^{++} solution. This consisted of a slow depolarization which fell exponentially from the foot of the fast spike repolarization to the baseline with a time constant similar to the membrane time constant. This portion of the DAP had no threshold per se; its amplitude varied as the membrane potential level was manipulated in relation to the constant point of maximum spike repolarization. Focal application of 5 mM Ba^{++} caused almost immediate reappearance of the depolarizing hump of the DAP and the development of burst firing.

These data show that the DAP consists of two components. One is an active event evoked by the spike, and presumably mediated by a slowly decaying Ca^{++} conductance. The DAP also has a passive compoennt which results from the fact that active repolarization of the spike terminates at some level depolarized to the resting potential. During the burst the combined depolarization produced by these two components reaches threshold for spike generation and functions to sustain repetitive firing. This same mechanism may contribute to burst generation in hippocampal pyramidal neurons during epileptogenesis. (Supported by NS 06477 from the NINCDS).

MEMBRANE STRUCTURE AND FUNCTION

988 BENZODIAZEPINE AND GABA RECEPTORS IN NB_{2a} NEUROBLASTOMA: ACTION ON Cl^- FLUXES. M. Baraldi*, A. Guidotti and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032

In NB_{2a} neuroblastoma cells as in brain the "GABA receptor unit" includes high affinity ^{3}H-GABA and ^{3}H-diazepam, ^{3}H-clonazepam and ^{3}H-flunitrazepam receptors. The thermostable endogenous inhibitor of protein kinase (GABA-modulin) which inhibits both GABA and benzodiazepine binding is also present.

In these cells, as in brain, diazepam and GABA receptors appear to be functional. An expression of this function is that GABA (0.1 mM) increases the binding of ^{3}H-diazepam and ^{3}H-clonazepam. Since in brain GABA receptors are thought to be coupled with Cl^- ionophores we have tested whether also in NB_{2a} cells the activation of GABA receptors with GABA or muscimol causes an increase in the inward flux of $^{36}Cl^-$. In presence of GABA receptor agonist a new steady state in the Cl^- distribution across NB_{2a} membranes is obtained. The extent of this changes is related to GABA (10^{-10} to 10^{-4}M) or muscimol (10^{-10} to 10^{-5}M) concentrations. The increase in Cl^- flux caused by GABA or muscimol is blocked by 10^{-4}M bicuculline. In addition a dose of diazepam (10^{-6}M) which produces a release of GABA-modulin from the cells but by itself fails to change the Cl^- flux, is capable of facilitating the increase in Cl^- flux elicited by threshold doses of GABA or muscimol.

These results suggest that NB_{2a} cells are a suitable model to study the interaction of benzodiazepine and GABA receptors at the molecular level.

989 SOLUBILIZATION AND PURIFICATION OF THE SODIUM CHANNEL STX BINDING COMPONENT FROM RAT SARCOLEMMA. R.L. Barchi. University of Pennsylvania, Philadelphia, PA 19104.

Sodium channel STX binding sites can be solubilized from rat skeletal muscle sarcolemma using medium chain-length nonionic detergents (NP-40, Lubrol-PX, Brij-96). Solubilized binding sites could be identified by specific binding of ^{3}H-STX. These sites were unstable in detergent alone; stability was markedly improved by the addition of exogenous phospholipids (PC, PE but not cholesterol) in mole ratios of 1:4 to 1:6 with detergent molecules. Solubilized binding sites were very temperature sensitive with $T_{\frac{1}{2}}$ for loss of binding in excess of 24 hours at 0°C but less than 20 minutes at 30°C. Binding site stability to changes in pH below 7.0 or above 8.0 was considerably lower after solubilization than in the intact membrane. Specific STX binding in the solubilized material could be eliminated by reaction with the carboxyl modifying reagents TMO or carbodiimide by a mechanism which was blocked by the presence of excess toxin in a manner analogous to that seen in intact membranes.

Initial purification of sarcolemma from muscle resulted in a 30-40 fold increase in concentration of STX binding sites per mg. of protein. An ion-exchange column was synthesized having guanidinium groups immobilized by 20 atom spacers to agarose beads. Application of solubilized membrane protein and elution with 100 mM choline Cl^- elutes 90-95% of total protein and virtually no specific STX binding material. Subsequent elution with 400 mM choline Cl^- yielded >75% of initial binding sites with 10 to 20 fold increase in purification. Subsequent chromatography on Sepharose 6-B or Sephacryl 300 yielded a further 5 to 10 fold increase in specific STX binding activity. The purified STX binding protein had an apparent $S_{w,20}$ by the Ames method of about 9, comparable to that seen in solubilized but unpurified material. Further biochemical studies on the purified protein will be presented.

990 CHARACTERIZATION OF THE GLUTAMATE RECEPTOR-IONOPHORE INTERACTION OF BRAIN SYNAPTOSOMES AND SYNAPTIC MEMBRANES. H. H. Chang* and E. K. Michaelis. Neurobiology Section, Dept. of Human Development, Univ. of Kansas, Lawrence, KS, 66045.

The excitatory amino acid L-glutamic acid (Glu) is known to produce its depolarizing effects through increases in Na^+ conductance of neuronal membranes. Rat brain synaptosomes prepared in Ficoll-sucrose gradients exhibited a rapid and a slow phase of ^{22}Na uptake. This uptake process was enhanced by 0.5mM ouabain, 10μM gramicidin D, and 1μM L-Glu. Whereas both ouabain and gramicidin D inhibited the synaptosomal Na^+-K^+ ATPase (100 and 86% respectively), Glu did not inhibit at all this enzyme. The L-Glu-stimulated ^{22}Na uptake process exhibited dose response characteristics with maximal stimulation obtained at 10μM L-Glu.

Synaptic membrane ghosts prepared according to the method of Kanner (1978) and sealed with an internal K-phosphate concentration of 135mM were found to have primarily one phase of ^{22}Na uptake, a rapid phase. This ^{22}Na uptake was once again stimulated by L-Glu in a dose-dependent manner with maximal stimulation seen at 1μM L-Glu. This Glu-stimulated ^{22}Na uptake was insensitive to tetrodotoxin treatment and partially resistant to preexposure to organomercurials, treatments which are known to inhibit the voltage-dependent Na^+ channels and the Na^+-dependent Glu transport activity. In addition, this ^{22}Na uptake was stimulated by L-aspartate, but was not affected by D-Glu, or glutamine. In addition, concentrations of L-Glu in the 10^{-5}-10^{-4}M range were less effective in stimulating ^{22}Na flux than lower concentrations of L-Glu, possibly a sign of receptor desensitization. These observations are indicative of the similarity of the properties of the Glu-stimulated ^{22}Na uptake in these preparations to the Glu-receptor-activated Na^+ conductance in nerve cell membranes.

991 IMMUNOCYTOCHEMICAL LOCALIZATION OF COATED VESICLE PROTEIN IN RODENT NERVOUS SYSTEM. Toni Po-on Cheng*, Frances I. Byrd* and John G. Wood. Dept. Anat., Univ. Tenn. Center Health Sci., Memphis, Tenn. 38163

Antibody to the major coat protein (clathrin) of coated vesicles has been used to study the distribution of this protein in the nervous system. The coat protein was purified by SDS polyacrylamide electrophoresis, extracted from the gel and used to immunize rabbits. Immunodiffusion assays and immunofixation of polyacrylamide gels indicated the presence of specific IgG in the immune serum against the gel extract protein. This antiserum was used to study the distribution of coat protein in mouse cerebellum. Mice were perfused through the aorta with a fixative containing 4.0% paraformaldehyde and 0.1% glutaraldehyde in 0.12M phosphate buffer. The cerebellum was stored overnight in phosphate buffered 4.0% paraformaldehyde and 40-50 u slices were obtained for immunocytochemistry using a vibratome. The slices were incubated in rabbit preimmune or immune serum (1:2000 dilution) followed by peroxidase conjugated goat anti-rabbit IgG. After processing the slices for electron microscopic peroxidase cytochemistry, ultrathin sections were obtained and identified synaptic contacts on Purkinje cells and in cerebellar glomeruli were studied. In these regions the label was highly concentrated in presynaptic terminals of basket cell axons, mossy fiber axons and Golgi II axons. The antibody present in immune serum reacted with coated vesicles within these three types of presynaptic terminals, but in addition, label was observed within the terminals in areas devoid of coated vesicles. These data suggest that either the coat protein contributes to structures within presynaptic terminals other than coated vesicles or that these presynaptic terminals contain a pool of coat protein which takes part in the assembly and disassembly of coated vesicles. Supported by USPHS Grant NS-12590 (JGW), USPHS Grant GM00202, and the Sloan Foundation (JGW)

992 INSERTION OF NEWLY-SYNTHESIZED ($Na^+ + K^+$)-ADENOSINE TRIPHOSPHATASE SUBUNITS INTO EEL ELECTROPLAX MEMBRANES. Lynn Churchill and Lowell E. Hokin*. Dept. Pharmacology, Univ. of WI Med. Sch., Madison, WI 53706.

Newly-synthesized ($Na^+ + K^+$)-adenosine triphosphatase (Na,K-ATPase) has been investigated by purifying the holoenzyme from eel electroplax membranes after incorporation of L-[3,4(n)-^{3}H] valine in vivo and in vitro. The purity of Na,K-ATPase is sufficient for accurate analysis of the [^{3}H] valine incorporated into the large and small subunits of the holoenzyme. The large and small subunits have similar rates of [^{3}H] valine incorporation in vitro and in vivo. Since the valine concentration is similar in both subunits and the mole ratio of the large and small subunits in the holoenzyme is probably one, the similar rates of [^{3}H] valine incorporation indicate a coordinated synthesis and/or assembly of the subunits into the holoenzyme.

Previously we reported a delay in incorporation of [^{3}H] valine into the subunits purified from eel electroplax membranes (Churchill and Hokin, Soc. for Neurosci. abst., 1977). The total cellular protein as analyzed by trichloracetic acid precipitation did not show a 2.5 to 3 h delay in incorporation. Therefore, the delay could not be explained by slow equilibration of the amino acid precursor. Further evidence that a lag in appearance of newly-synthesized Na,K-ATPase exists is presented. After exposure to the protein synthesis inhibitor, cycloheximide, the total cellular protein ceased to incorporate [^{3}H] valine in vitro; whereas, both the large and small subunits continued to increase in specific radioactivity for 1.5 to 2 h. These two lines of evidence demonstrate that a lag in the appearance of newly-synthesized Na,K-ATPase exists and that both subunits show the same lag. This lag probably represents post-translational intracellular processing prior to entry of the subunits into the plasma membrane. Moreover, the newly-synthesized Na,K-ATPase subunits prior to entry into the plasma membrane must have different physical properties from the holoenzyme in the plasma membrane, as they do not copurify with it.

The fact that the large, non-glycosylated subunit has a delay similar to the small, glycosylated subunit suggests that either (1) assembly of the holoenzyme depends on the availability of the small subunit as a rate-limiting step, or (2) assembly occurs prior to glycosylation of the small subunit so that the large subunit is delayed in the Golgi complex as part of the lipoprotein complex.

993 CHEMICAL DISSECTION OF THE NERVE ENDING MEMBRANE. Garrett D. Crawford*, H. David Potter* (SPON: P. M. Salvaterra). Division of Neurosciences, City of Hope Nat. Med. Ctr., Duarte, CA 91010

A synaptic plasma membrane preparation was exposed to a sequential protocol designed to interrupt only "peripheral" membrane protein interactions, and the resulting treatment products were prepared for electron microscopy. Treatments included isotonic salt with the reducing agent dithiothreitol, EGTA, a low level of nonionic detergent, and EDTA. The scope of this study was limited to Gray's type I profiles, and a classification scheme based upon the components of the junctions was developed to analyse the results. After every treatment, profiles were scored for the following: (a) synaptic vesicles (SV), either normal or enlarged; (b) the presence of a polymorphous material abutting upon the SV and the synaptic membrane that often appears filamentous (ivfs); (c) the presynaptic membrane, and (d) a postsynaptic specialization with a continuously attached postjunctional membrane. The last attribute served as a morphological marker for the modified profiles. In addition the continuity of extrajunctional membranes and cleft structures was monitored.

All modified forms of the profiles were present in each preparation including the starting material; only the distribution changed. This suggests that the effect of the treatments is primarily upon restricted membrane loci, and supports the use of defined chemical media for the dissection of complex microscopic structures. Specifically, the data confirms the structural integrity of the ivfs and indicates the dependence of the SV organization upon it rather than upon the enclosing presynaptic membrane. Major differences in the structure of junctional and nonjunctional membranes are also evident. Supported by NIH grants NS-08309 and NS-09864.

994 IONIC MECHANISMS OF SLOW MEMBRANE POTENTIAL OSCILLATIONS IN APLYSIA NEURONS. Wolfgang J. Daunicht*$^+$) and Manfred R. Klee*. Dept. Neurobiol., MPI Brain Res., Deutschordenstr. 46, D-6000 Frankfurt/M, FRG. (SPON: R. Eckmiller).

Some identified neurons in the visceral ganglion of Aplysia californica contain a membrane system which gives rise to slow relaxation oscillations of membrane potential. The slow system was investigated by conventional voltage clamp. Steady state and dynamic I-V-characteristics, current relaxation times, and membrane capacity were measured using step and ramp commands in different ionic concentrations of the extracellular solution. The shape of diagrams consisting of the single steady state and a family of dynamic I-V-characteristics was found to give the criterion for the stability of the membrane potential at a constant net current.

After changes of the K^+concentration position and slope of the steady state I-V-characteristics are in accordance with the constant field theory at inward currents, while at zero currents they are not. I-V-diagrams undergo transformations which can be described as contractions in the direction of the voltage axis with increase of K^+concentration and as expansions with decrease of K^+concentration.

In Ca^{++}free solution silent cells tend to start oscillating and oscillating ones tend to become bistable. The transformation of I-V-diagrams caused by reduction of Ca^{++}concentration can be explained by a contraction of dynamic I-V-characteristics in the direction of the voltage axis.

In control solution a reversal potential of the relaxing currents could not be found between -80 mV and -20 mV. Reduction of the Na^+concentration strongly decreases the amplitude of the relaxing currents.

These findings support the hypothesis that in the membrane of the slow system a K^+-Ca^{++} ion exchange controls the diffusion of cations, mainly of Na^+ions. The relaxation could be explained by changes of cation concentrations close to the membrane. Oscillations of membrane potential at constant net current could be due to feed back of K^+concentration changes to the ion exchange process.A numerical model based on this hypothesis predicts the experimental results qualitatively.

995 SEASONAL OCCURRENCE OF DELAYED RECTIFICATION IN EEL ELECTROPLAQUE. Donald A. Farquharson*.(SPON:F.C.G.Hoskin). Dept. Biol.,Illinois Intitute of Technology,Chicago,IL 60616.

Heretofore,all reports describing eel electroplaques electrophysiologically have characterizied the electrically excitable K^+ channels as being open at the cell's resting potential and as being closed(inactivated)by either a depolarizing voltage step(depolarizing K^+-inactivation)or by a hyperpolarizing voltage step (hyperpolarizing K^+-inactivation),e.g.see Nakamura et al,J. Gen. Physiol. 49:321,1965;or Ruiz-Manresa et al,J. Gen. Physiol. 55:33, 1970. I report here an interesting seasonal variation in the K^+ channel characteristics of electroplaques examined under voltage clamp.Certain eels,shipped to our laboratory in Chicago in the winter months of 1976 through 1978 had electroplaques which displayed a delayed outward current,apparently a K^+current,in addition to the well-known K^+-inactivation phenomenon. This delayed K^+ current was activated when the cells were depolarized. That is, a depolarization of sufficent magnitude resulted in the steady state conductance suddenly decreasing and then,after a delay,increasing with a complex time course. This K^+-activation was qualitatively and quantitatively simular to the delayed rectification of K^+ currents described for the squid giant axon. The K^+channels activated in these winter electroplaques were insensitive to Ba^{++},but were partially blocked by TEA. Non-winter electroplaques have K^+ channels(those inactivated by depolarizing or hyperpolarizing pulses) which are blocked by Ba^{++} and which are insensitive to TEA. This K^+-activation phenomenon in winter electroplaques was also sensitive to the rate of stimulation(i.e. the frequency of a train of depolarizing pulses)and was affected by prepulse conditioning such that hyperpolarizing prepulses increased the delayed current magnitude while depolarizing prepulses decreased the delayed current magnitude. Prepulses also affected the kinetics of the delayed K^+ current activation in a manner somewhat analogous to that found for squid giant axons(Cole and Moore,Biophys. J. 1:1,1960). The pharmacological data collected suggest that these winter electroplaques have two kinds of voltage-sensitive K^+ channels. However, some of the conductance data argue for a single K^+ channel,in winter electroplaques,with complex dynamics. (Research supported by ARO grant DAAG29-78-G-0090)

996 ARRANGEMENT OF MULTIPLE MONOAMINE OXIDASE ENZYMES ACROSS THE OUTER MEMBRANE OF RAT BRAIN MITOCHONDRIA. Robert Faulkner* and Rosa Huang* (SPON: J-Y Wu). University of South Alabama, Mobile, Alabama 36688.

Phospholipases C and D (LC, LD) were used to remove the surface head groups of membrane phospholipids of an intact, purified rat brain mitochondrial preparation. Both LC and LD treatment under conditions of varying lipase concentration and incubation time attacked only phosphatidylcholine (PC) and phosphatidylethanolamine (PE). PC and PE constituted about 80% of the brain mitochondrial phospholipids. After lipase treatment, the bilayer structure of the outer mitochondrial membrane was retained. In the case of LD treatment, MAO-B sites were inactivated to a much greater extent than MAO-A sites. MAO-B sites were more peripheral. MAO-A sites were located below the alcohol moiety of the membrane phospholipids. LC treatment eliminated the phosphoryl alcohols and thus exposed a few Å deeper into the bilayer midline in contrast to the action of LD. The data indicated that MAO-A sites then became accessible. Further, an additional class of MAO-B sites was exposed by the action of LC. (Supported by NIH Grant #NS-144434)

997 NEW NEURITE MEMBRANE IS ADDED AT THE GROWING TIP. E.L. Feldman*, D. Axelrod*, M. Schwartz* and B.W. Agranoff. Neuroscience Laboratory and Biophysics Research Division, University of Michigan, Ann Arbor, MI 48109.

Explant culture of the adult goldfish retina results in vigorous neuritic outgrowth, provided that the optic nerve has been crushed in vivo 10–14 d prior to explantation. We have used this preparation, coupled with a direct membrane marker, Concanavalin A (Con A) to determine the site of new membrane addition in growing neurites.

We had previously determined that Con A labels neurite cell surfaces. In order for Con A to be a useful marker for studies of membrane addition during neurite outgrowth, it was necessary to determine conditions under which the lectin would not be toxic to the culture (i.e., prevent neurite outgrowth) and also would not diffuse into the new areas of growth. Initial studies indicated that high concentrations of Con A were toxic to the culture while lower doses of Con A, which were non-toxic, diffused rapidly into new areas of growth. This low dose of Con A (10 µg/ml) could be immobilized by the subsequent addition of 100 µg/ml of lectin antibody (anti-Con A). This treatment did not prevent growth. Furthermore, the receptor/Con A/anti-Con A complex was not appreciably internalized, making it an ideal membrane marker for the following experiments.

A 3 d culture was labeled with 10 µg/ml Con A. The neurites were then tagged with 100 µg/ml rabbit antibodies to Con A, washed, and left to grow in medium. After 24 h, the neurites were labeled with fluorescent goat anti-rabbit antibodies. Thus, only old membrane that had been tagged 24 h previously with Con A/anti-Con A would now bind the fluorescent antibodies. On the other hand, any membrane that had been added during the 24 h interval would not have the Con A/anti-Con A complex on its surface and, consequently, would not bind the fluorescent antibodies.

Using this paradigm, we observe bright uninterrupted fluorescence of old membrane, while the entire extent of new membrane, including the growth cone, is unlabeled. These results are in agreement with previous studies of Bray (PNAS 65:905-910, 1970), in which inert particles served as stationary markers during growth of cultured rat sympathetic neurons. In the present studies we have used a more direct membrane marker to indicate that the locus of new membrane addition is at the growing end of the neurite. We believe that, during growth, membrane components are transported via axonal flow and fuse with preexisting membrane in the region of the growth cone.

998 BINDING OF QUINACRINE, A FLUORESCENT LOCAL ANESTHETIC PROBE, TO MAMMALIAN AXOLEMMA: EQUILIBRIUM AND KINETIC STUDIES. Marty Greenberg*, Jonathan Freedman*, and Tian Yow Tsong* (SPON: S.E. Poduslo). Dept. Phys. Chemistry, Johns Hopkins Medical School, Baltimore, MD 21205.

Quinacrine was found to bind specifically to the axolemma (axonal membrane) of bovine corpus callosum. We have studied this binding reaction by monitoring fluorescence changes of quinacrine. Local anesthetics compete for binding at equilibrium and in stopped-flow kinetics, and their efficacy of competition correlates with clinical potency. Binding was abolished by trypsin digestion, had an activation energy of approximately 7kcal/mole above 20 degrees celsius and had an apparent K dissoc. of 6 to 7 X 10^{-7} M.

Barbiturates reduced equilibrium binding of quinacrine, although kinetic analysis indicated that quinacrine binding occurred but was subsequently displaced in the presence of barbiturates. Potassium-channel blockers, Tetraethylammonium and 3, 4-Diaminopyridine, also decreased equilibrium fluorescence. Low concentrations of Tetraethylammonium increased the rate of quin-binding by close to two orders of magnitude.

999 K+ EFFECT ON GLIAL AND PERIKARIAL (Na+K+)-ATPase FROM NORMAL AND PATHOLOGICAL HUMAN BRAIN Thierry Grisar*, George Franck*, and A.V.Delgado-Escueta.Dept. of Neurology, Reed Neurological Research Center, Los Angeles, California 90024 and Dept. of Neurology,, University of Liege, Belgium.

The role of glial cells in the active control of extracellular potassium (K_o) has been documented in animals. This is particularly true when considering the sensitivity of the glial (Na+K+) ATPase to K_o (Grisar et al. Brain Res. 1979)

A first attempt in this field is now available in human brains. The effect of K+ on Na+K+ ATPase activity was determined in cell fractions obtained by ultracentrifugation on discontinuous Sucrose-Ficoll gradient from 3 "normal" patients. As in rabbit, the glial fractions exhibit a higher level of enzyme activity than the neuronal fraction. This may be explained by a higher content of membraneous material in glial fractions. However, like in the animals, glial enzyme is markedly activated by K+ ions between 5 to 20 mM while this phenomena is not observed in perikarial fractions. These findings in human brains confirm the observations in animals on the role of glial cells. These "control" brains were compared with those above from one case of psychosis, one case of Alzheimer Disease and one case of Creutzfeld Jacobs Disease (CJD). In the two first cases, enzyme activities were decreased in both fractions while the K+ ion sensitivity of glial enzyme was not observed. These results will be due to the delay between death and autopsy as well as the technical procedures used. However, the loss of sensitivity to K_o in these glial cells remain unexplained. More studies are needed. In CJD no significant changes were observed. These latter findings do not confirm Bignami and Palladini who hypothesized a defect in membrane enzymes in CJD spongeous state.

1000 RECONSTITUTION OF THE GLUTAMATE RECEPTOR-LIKE PROTEIN IN LIPOSOMES. Robert D. Grubbs and Elias K. Michaelis. Dept. HDFL, Univ. Kansas, Lawerence, KS 66045.

Reconstitution of a putative neurotransmitter receptor protein into a liposome with recovery of ionophore function is crucial to the characterization of the protein as the physiologic receptor. The present study represents the first attempt to reconstitute the presumed glutamate receptor protein purified from rat brain synaptic membranes into liposomes of various phospholipid composition by means of equilibrium dialysis or simple room temperature incubation (Racker, 1978).

The glutamate (Glu) binding protein (GBP) was isolated as previously described (Michaelis, 1975). The concentrated GBP was then dialyzed extensively against 50 mM Tris-HCl buffer, pH 7.4. Following a 30 minute incubation at room temperature, a mixture of GBP and phosphatidyl-serine (total volume 200 1) was loaded onto a Sepharose 6B column and eluted with 50 mM Tris buffer. Preliminary evidence indicates that a high molecular weight aggregate of GBP which eluted in the early fractions exhibited high specific activity of L-(^{3}H)-Glu binding. The aggregate also exhibited high affinity binding for (^{3}H)-kainic acid, which is of interest in light of previous studies from this laboratory indicating that the solubilized, non-aggregated GBP does not bind (^{3}H)-kainic acid (Kuonen and Michaelis, 1978).

Several fractions immediately following the GBP aggregate showed little or no L-(^{3}H)-Glu binding when tested on the same day as the reconstitution. When these fractions were tested five days later, they bound considerably more L-(^{3}H)- Glu than the higher molecular weight GBP aggregate. These fractions contained a sizable amount of the phosphatidyl-serine and appear to represent the reconstituted system. Studies are currently underway to determine whether the time delay between reconstitution and the appearance of L-(^{3}H)-Glu binding in these fractions is due to the co-elution of soluble GBP and liposomes which then form a proteoliposome reconstituted system. This increased binding may also be due to the rearrangement of the GBP in the lipid matrix from an initial low-binding to a higher specific binding conformation.

This research was partially supported by DHEW Res. Serv. Award HD 07066 from NICHHD to the Kansas Center for MR & HD, by a grant from NIGMS, GM 22357, and by Biomed. Res. Support Grant 50706.

1001 FREEZE-FRACTURE OF MUSCLE SPINDLES. William R. Kennedy, Donald C. Quick* and Thomas S. Reese. Departments of Neurology and Anatomy, University of Minnesota Medical School, Minneapolis, MN 55455; and Section on Functional Neuroanatomy, NINCDS, National Institutes of Health, Bethesda, MD 20014.

Isolated muscle spindles from humans, cats, and rabbits were freeze-fractured by conventional methods. Prominent features of the capsule are numerous vesiculations and the presence of occluding junctions. The junctions are extensive, in accordance with the known impermeability of the capsule (Kennedy and Yoon, in press, Muscle & Nerve). Occluding junctions are composed of rows of fused particles associated with the protoplasmic (P) fracture faces. Similar, less extensive junctions are seen in the capsule cells immediately surrounding the intrafusal muscle fibers.

No communicating junctions were observed, indicating that they are rare or absent.

Rectilinear arrays of P-face particles were seen on the spindle muscle fibers; their appearance is identical to those found on extrafusal muscle. The arrays on intrafusal muscle fibers are concentrated in areas tentatively identified as post-synaptic membranes of the 'trail' type motor endings. Rectilinear arrays can be seen occasionally on other parts of the muscle fiber surface, but there are few or none in the sensory zones.

Adhering junctions and invaginations (Kennedy, Webster and Yoon, 1975, J. Neurocytol. 4:675) have been observed in the membranes of sensory endings.

1002 DIFFERENT EFFECTS OF TEA VS. 4-AP AND 3,4-DAP ON THE CALCIUM INWARD CURRENT SYSTEM IN APLYSIA NEURONS. Manfred R. Klee* and Yoshimi Ikemoto* (SPON: John M. Sarvey). MPI Brain Res., Dept. Neurobiol., Deutschordenstr. 46, D-6000 Frankfurt-M., FRG.

4-aminopyridine (4-AP) and 3,4-diaminopyridine (3,4-DAP) have been shown to block potassium channels in the squid axon membrane extracellularly, whereas tetraethylammonium (TEA) acts internally; 3,4-DAP was about 50 times more potent than 4-AP. Two types of neurons can be distinguished within the visceral ganglion of Aplysia with respect to the action extracellular TEA and 4-AP have on their action potentials (APs) and membrane currents (Klee, JP,284:125P,1978). To those data the following results were added: i) F cells possess a slow, non-inactivating, calcium-dependent inward current ($I_{Ca}2+$), which is about 1/10 of that seen in S cells (approx. 20 nA). ii) 4-AP and 3,4-DAP with nearly equal potency delay and reduce the outward current in both F and S cells. At the same time the duration of APs is increased but never to that of plateau spikes, unless TEA is added. iii) The most important difference between TEA vs. 4-AP and 3,4-DAP is the effect the latter have on $I_{Ca}2+$. Even in concentrations which have very little effect on the outward current (100-600 uM), both substances can increase $I_{Ca}2+$ by 100% in contrast to TEA, which produces no increase. The increase of $I_{Ca}2+$ could explain why in those cells having small $I_{Ca}2+$ (i.e. F cells) TEA can induce calcium-dependent plateau spikes only in the presence of 4-AP or 3,4-DAP.

1003 FILAMENTOUS PROTEINS OF SYNAPSES IN RAT BRAIN. L. P. Kleine* and H. R. Mahler. (SPON: R. M. Wightman). Chemistry Dept., Indiana University, Bloomington, IN 47405

The presence of filamentous proteins in close association with synaptic plasma membranes (SPM) now appears well established on the basis of both biochemical and morphological studies. Tubulin, filamin, myosin, actin, tropomyosin, calmodulin and perhaps some of the subunits of troponin all have been claimed to form part of the SPM. Synaptosomes, SPM, synaptosomal junctional complexes, post-synaptic densities and post-synaptic membranes have been isolated and analysed for the presence of the above mentioned proteins both qualitatively and quantitatively. The membrane proteins were identified and interrelationships established by comparison to purified reference proteins using the techniques of one-dimensional fingerprinting and two-dimensional gel electrophoresis (isoelectric focusing and SDS-polyacrylamide electrophoresis). (Supported by Research Grant NS 08309 from the NIH)

1004 DIFFERENT EFFICACIES OF *d*- AND *ℓ*-γ-AMINO-β-HYDROXYBUTYRIC ACID FOR GABA RECEPTOR-RELATED BINDING AND CONDUCTANCE INCREASES. D.N. Krause, E. Roberts, A. Mori*†, E. Wong*, Y.-J. Wang*, and K. Ikeda. Division of Neurosciences, City of Hope National Medical Center, Duarte, CA 91010 and †Institute for Neurobiology, Okayama University Medical School, Okayama, Japan.

The structure of the GABA receptor was investigated by determining the relative effects of two stereoisomers of the GABA agonist, γ-amino-β-hydroxybutyric acid (GABOB), in several quantitative receptor-related assay systems. (3S)-(+)-4-Amino-3-hydroxybutanoic acid (*d*-GABOB) was found to be about twice as potent as (3R)-(-)-4-amino-3-hydroxybutanoic acid (*ℓ*-GABOB) in displacing [^{3}H]muscimol from specific binding sites in mouse brain membrane fractions. [^{3}H]Muscimol is thought to bind to the GABA recognition site of postsynaptic GABA receptor-anionophore complexes. A similar order of potency for the GABOB enantiomers was observed for the cerebrovascular GABA receptor recently characterized in our laboratory with [^{3}H]muscimol binding assays using bovine cerebral blood vessels. In contrast to the binding results, *ℓ*-GABOB was significantly more potent than *d*-GABOB in mimicking the postsynaptic action of GABA, which was measured as increases in membrane input conductance in the isolated crayfish stretch receptor neuron. Both GABOB enantiomers have some affinity for GABA transport processes, and *d*-GABOB was found to be more potent than *ℓ*-GABOB in inhibiting GABA uptake into rat brain synaptosomes and Na^+-dependent GABA binding to mouse brain membranes. For this reason, conductance measurements also were made in the presence of 10^{-3}M nipecotic acid or L-α,β-diaminopropionic acid, two specific GABA transport blockers. However, *ℓ*-GABOB was again more potent than *d*-GABOB. The order of potency in the receptor-related binding assays (*d*-GABOB>*ℓ*-GABOB) could not be altered by detergent treatment, changes in buffer composition, or by preparing the tissue at room temperature. The greater effectiveness of *ℓ*-GABOB in the physiological assay does not appear to be due to species differences. *ℓ*-GABOB, but not *d*-GABOB, is an effective inhibitor of induced seizure activity in cat brain (Y. Katayama and A. Mori (1977) IRCS Med. Sci. 5:437) and rabbit motor cortex (H. Aishita, A. Akimoto, T. Makita (1978) IRCS Med. Sci. 6:115). Thus, *d*-GABOB is more potent than *ℓ*-GABOB in membrane binding and uptake systems, while the reverse is found in physiologically responding systems. While the reasons for this discrepancy are unclear, these findings may suggest that the structural asymmetry of the GABA recognition site in vitro is somewhat different than that related to activation of GABA receptors in vivo. (Supported by USPHS grants NS-05695, 12116 and 01615).

1005 ROLE OF PHOSPHORYLATION ON GABA RECEPTOR ACTIVITY. A. Leon*, A. Guidotti, G. Toffano and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032

"GABA-modulin", a thermostable, acidic (M.W. 15,000 dalton) protein isolated from brain, non-competively inhibits the Na^+-independent high affinity binding of GABA to synaptic junction membranes. Brain preparations of this inhibitor block competively cyclic AMP-independent protein kinase in supernatant of brain homogenates. The inhibitory activity of GABA binding and protein kinase was purified by a number of procedures including SDS polyacrylamide gel electrophoresis. When the extracts were purified to apparent homogeneity it was found that the inhibition of protein kinase and GABA binding reside in the same protein. The content of GABA-modulin is higher in preparations of synaptic plasma membranes (SPM) than in those of synaptic junctions (SJ) which were obtained by repeated freezing, thawing and triton X-100 treatments. The high affinity binding of ^{3}H-GABA and the phosphorylating capacity of the SJ is several fold higher than that of SPM. Endogenous phosphorylation and high affinity GABA binding are reduced after recombination experiments with GABA-modulin. The results suggest that GABA-modulin controls GABA receptor function through the phosphorylation of specific membrane protein(s). The identity of this protein is currently under investigation.

1006 DEMONSTRATION AND PROPERTIES OF AN ENDOGENOUS MACROMOLECULAR INHIBITOR OF NEUROTRANSMITTER RECEPTORS. J. E. Leysen*, P. Van Gompel* and P. M. Laduron* (SPON: Steven E. Kornguth) Janssen Research Laboratories, Janssen Pharmaceutica, B-2340 Beerse, Belgium.

Rat brain extracts contain macromolecular components, apparently proteins, which interfere with the binding of ^{3}H ligands to dopamine, serotonin, opiate and most likely other receptors.

The inhibition obtained with a crude rat brain extract appeared to be competitive in the following receptor models with K_i's, expressed in mg protein of a crude extract per ml incubation mixture: 1 mg/ml for ^{3}H-apomorphine and 10 mg/ml for ^{3}H-haloperidol in rat striatum (dopamine receptors); 16 mg/ml for ^{3}H-spiperone in rat frontal cortex (serotonin receptors); 1 mg/ml for both ^{3}H-naloxone and ^{3}H-fentanyl in rat forebrain (opiate receptors).

These components occur in several brain areas, have a molecular weight of over 200 000 and are positively charged at physiological pH. They can be isolated, purified and further characterized using ion exchange and molecular sieve chromatography, SDS and preparative polyacrylamide electrophoresis and preparative isoelectrofocusing.

We hypothesize that these proteins play a regulatory function in the masking and unmasking of receptors. Because of their positive charge they will easily associate with the negatively charged membranes and hence cover receptor sites. They can be removed from these sites by the competitive action of agonists and antagonists. The possible role of these proteins in the induction of receptor supersensitivity will be discussed.

1007 EFFECT OF CHOLINERGICS, D-TUBOCURARINE AND OUABAIN ON THE MEMBRANE POTENTIAL OF SCHWANN CELLS ASSOCIATED WITH THE CRAYFISH MEDIAL GIANT AXON. E.M. Lieberman and K.A. Smiley*, Dept. Physiol., Sch. Med., East Carolina U., Greenville, NC 27834

In an earlier study (Biophys. J. 25(2):305a, 1979) we demonstrated that Schwann cells surrounding the medial giant axon of the crayfish, Procambarus clarkii, could be impaled with microelectrodes and studied electrophysiologically and pharmacologically. The present investigation extends the work to show that the sensitivity of the Schwann cell membrane potential to cholinergic compounds is due to the presence of acetylcholine receptors on the Schwann cell membrane. The resting membrane potential of control Schwann cells was 42.6±0.6mV (n=63). Immediately following superfusion of the axon-Schwann cell preparation with 10^{-7}M ACh the Schwann cell membrane potential hyperpolarized to -56.6±1.0mV (n=7). Identical concentrations of carbachol and nicotine caused hyperpolarization to -57.7±1.4mV (n=11) and -59.4 ±1.0mV (n=7), respectively. Muscarine had no effect on Schwann cell membrane potential when applied at a concentration 10 times greater than the cholinergics. These agents had no discernible effect on the axon resting or action potential. The action of these drugs was long lasting and readily reversible on washing the preparation with drug-free solutions. Two further series of experiments were performed with the cholinergic drugs. First, the axon-Schwann cell preparation was pretreated with 10^{-9}M d-tubocurarine (d-TC) and then superfused with 10^{-7}M nicotine in the presence of d-TC. In this case nicotine had no effect on the Schwann cell potential. In the second series of experiments the Schwann cells were hyperpolarized by 10^{-7}M nicotine and then exposed to 10^{-8}M d-TC in the presence of nicotine. D-TC caused a rapid reversal of the nicotine effect. On the basis of these experiments we conclude that the Schwann cell membrane has nicotinic cholinergic receptors which are responsive to physiological concentrations of acetylcholine. The effect of ouabain on the membrane potential of Schwann cells was also studied. Ouabain (10^{-3}M) caused a hyperpolarization of Schwann cell membrane potential similar to that caused by the cholinergic drugs. Unlike the cholinergic effect the ouabain hyperpolarization lasted only 15-20 min, whereupon a rapid depolarization to zero occurred. The rapid depolarization was likely due to the loss of internal [K]. The hyperpolarization may be due either to an inhibition of a depolarizing electrogenic transport system or to a ouabain-induced acetylcholine release by the axon-Schwann cell system. Supported, in part, by NSF BNS 77-28510.

1008 K^+-STIMULATED PHOSPHORYLATION OF A 41,000 M.W. POLYPEPTIDE IN L8 MYOTUBE MEMBRANES. Gilbert Magilen*, Adrienne Gordon and Ivan Diamond. Department of Neurology, University of California Medical School, San Francisco, California 94143

The acetylcholine receptor (AChR) is reversibly phosphorylated by endogenous enzymes in AChR-enriched membranes from Torpedo and Electrophorus electric tissues. We are presently examining the L8 myogenic cell line to determine whether the mammalian AChR is phosphorylated and to investigate the role of phosphorylation in the regulation of AChR function. Fused L8 myotubes have greater than 15 times more AChR (measured by the binding of [^{125}I] α-bungarotoxin) than undifferentiated myoblasts. We therefore compared phosphorylation patterns of the L8 myoblast and myotube membrane preparations. When membrane fractions from myotubes and myoblasts were incubated with [γ-^{32}P] ATP in the presence of 20 mM Mg^{+2}, several phosphorylated polypeptides were observed after SDS-PAGE and autoradiography. The pattern of polypeptide phosphorylation was both qualitatively and quantitatively different when myoblasts were compared with myotubes. Of particular interest, myotube membranes showed a polypeptide of 41,000 M.W., whose phosphorylation was stimulated approximately 4-fold by KCl (25-100 mM). This effect was not seen with NaCl. Both cAMP and cGMP at 10^{-5}M had no effect on phosphorylation of the 41,000 M.W. polypeptide. Examination of the phosphorylation pattern of myotube membranes in two-dimensional IEF-PAGE autoradiographs (O'Farrell, JBC 250:4007, 1975) demonstrated an approximate isoelectric point of pH 6.7 for the 41,000 M.W. phosphorylated protein. In contrast to the results with myotubes, membranes prepared from myoblasts did not show potassium-stimulated phosphorylation of a 41,000 M.W. polypeptide.

Several lines of evidence suggest that the 41,000 M.W. phosphorylated polypeptide may be the AChR. The acetylcholine binding subunit of the mammalian AChR from many sources has a M.W. around 40,000. The pI and M.W. for the AChR from fetal calf myotubes in culture is the same as that reported here (Merlie et al, JBC 253:2882, 1978). The appearance of K^+ dependent phosphorylation with differentiation may be related to ionic changes which occur in the vicinity of the AChR during activation. Taken together, these findings suggest that the AChR in L8 myotubes may be phosphorylated.

1009 CONDUCTION BLOCK IN PERIPHERAL A AND C FIBRES FOLLOWING ELECTRICAL STIMULATION. B. Matthews* and S.W. Cadden* (SPON: M. Burrows). Dept. Physiol., Univ. Bristol, England BS8 1TD.

Bishop and Heinbecker (*Am. J. Physiol.* 114: 179, 1935) showed that electrical stimulation of a nerve trunk could leave the fibres in a condition in which conduction through the stimulated region was blocked. More intense stimuli were required to block C than A fibres and the intensity of the stimuli determined the duration of block, which could be irreversible. We wished to know whether it was possible to stimulate all the fibres in a nerve without causing this type of block and have determined the relationship between the thresholds for excitation and the intensities of stimuli that cause block in different groups of nerve fibres.

Three groups of electrodes, about 30mm apart, were applied to the exposed saphenous nerve in anaesthetized cats; one pair to the cut central end for recording, and two pairs for stimulation. Conduction block caused by conditioning stimuli applied to the middle electrodes was assessed by recording centrally while test stimuli were applied distally. The proportion of fibres in a group that were conducting impulses was estimated from the integral of the corresponding component of the averaged compound action potential. A stimulus/response curve relating stimulus strength to this integral was first obtained then a supramaximal stimulus for the group of fibres being studied was used in estimating conduction block. Conditioning stimuli were applied at 1/sec for 10 min, interrupted for 15 sec every 2 min for testing. Test stimuli were applied at 1/sec for 10 sec every 2 min during conditioning and also during the subsequent 10 min to monitor recovery.

With 0.1 msec stimuli, Aβ fibres had thresholds between 0.2 and 0.8V. Block of these fibres was first detected with stimuli of 20V and was complete after 10 min at 40V. Provided more intense stimuli were not applied, conduction had returned in 75% of blocked fibres 10 min after stimulation. The corresponding figures for Aδ fibres were: thresholds, 0.5-5V; block, 25-50V. The corresponding C fibre thresholds were between 5 and 50V and some block occurred with stimuli between 50 and 100V, the maximum available. With 1.0 msec stimuli, the C fibre thresholds ranged from 2.5 to 7.5V and conduction block increased progressively from 7.5V to 100V, at which it was 80% complete.

Thus it was possible to excite all A fibres without causing conduction block but the minimum stimulus required to excite all C fibres caused extensive conduction block in A fibres and was at the lower limit of the range that blocked C fibres.

1010 LIPID-PROTEIN INTERACTIONS IN MEMBRANES CONTAINING THE ACETYLCHOLINE RECEPTOR. Mark G. McNamee, Jeffrey Ellena* and Terrence J. Andreasen*. Dept. of Biochem. and Biophys., UCD, Davis, CA 95616.

Perturbation of the lipid environment of the nicotinic acetylcholine receptor (AChR) in membrane vesicles prepared from Torpedo californica electroplax has profound effects on AChR function including 1) agonist binding and 2) cation permeability control.

Phospholipase A_2 from Naja naja siamensis venom blocks carbamylcholine-induced increases in sodium ion permeability. The inhibition can be correlated with the hydrolysis of phosphatidylethanolamine, and can be prevented or reversed by treatment of the membranes with bovine serum albumin, a protein that can bind the hydrolysis products of phospholipase A_2. The phospholipase A_2 also induces a shift in carbamylcholine binding from low affinity to high affinity, a shift that has been correlated with receptor desensitization.

Exogenous fatty acids can be incorporated into the membranes and at 0° some unsaturated fatty acids (e.g., arachidonic and linoleic acids) block carbamylcholine-induced increases in sodium ion permeability. However, in contrast to phospholipase A_2 treatment, the fatty acids do not induce the increase in agonist affinity. Thus, the fatty acids appear to uncouple ligand binding from ion permeability control by a mechanism different from receptor desensitization. Saturated fatty acids (e.g., palmitic and stearic acids) are relatively ineffective in bringing about inhibition. Further studies indicate that the effectiveness of fatty acids is temperature dependent and a given fatty acid is an effective inhibitor only above its bulk melting point. Spin-labeled fatty acids are now being used to monitor the effects of phospholipase A_2 and exogenous fatty acids on bulk lipid fluidity and on lipid-protein interactions. The fatty acid spin labels can also inhibit AChR ion permeability control in a temperature dependent manner. Interestingly, the effectiveness of the spin labels as inhibitors depends on the location of the nitroxide group along the acyl chain.

1011 CHARACTERIZATION OF THE NA-CA EXCHANGE SYSTEM IN SYNAPTOSOMES AND SYNAPTIC MEMBRANE GHOSTS. Mary L. Michaelis, Elias K. Michaelis, and Sharie L. Myers*. Dept. of Human Development, Univ. of Kansas, Lawrence, Kansas 66045.

The question of how nerve cells maintain low concentrations of free calcium ions in spite of the strong driving force for Ca entry during depolarization has been the subject of several recent investigations. The work of Baker, Blaustein, and their colleagues has revealed the presence of a Ca-Na exchange system in squid axon membranes, and Blaustein has confirmed its existence in synaptosomes from mammalian brain. This exchange system appears to transport Ca against its concentration gradient by the coupled exchange of Ca for Na, thereby utilizing the electrochemical gradient for Na as its energy source. It has been demonstrated in the squid axon that this Na-Ca "carrier" operates in either direction as long as a Na concentration gradient is present. Lithium is not readily exchanged for Ca.

We have confirmed Blaustein's observations of a Na_o-dependent ^{45}Ca efflux in mammalian synaptosomes and have drawn on the pioneering work of Kaback and Kanner in developing a preparation of sealed synaptic plasma membrane vesicles or "ghosts" in which it is possible to study the characteristics of the Na-Ca exchange in neuronal membranes obtained from rat brain. Synaptosomes from ficoll-sucrose gradients are lysed in 10 mM KPO_4 buffer for 15 min at 4°, the synaptic membranes precipitated, and the pellet resuspended in .32M sucrose-.03M K-succinate to a final protein concentration of 15mg/ml. The membranes can then be rapidly frozen in liquid nitrogen and later thawed at 37° for 10 min and allowed to form vesicles in the presence of 50 μM $MgCl_2$. During this step the membrane sacs can be loaded internally with various ions.

The Na-Ca exchange system is most active in freshly-prepared (i.e., not frozen) vesicles, but its activity can be preserved in frozen membranes if they are thawed in the presence of low levels of Mg. Time kinetics studies indicated that the exchange process is linear for about 90 sec in both the fresh and frozen vesicles. Since the membrane sacs can be loaded internally with either Ca or Na, they have enabled us to obtain preliminary results suggesting that the carrier will transport Ca in either direction as long as there is a Na gradient in the opposite direction. Since this preparation is devoid of intracellular organelles or energy-producing capacity, it appears that the Na-Ca exchange system in synaptic membranes does not depend on the presence of intracellular components and apparently relies on a Na gradient for its driving force. (Supported by Institutional Biomedical Research Support Grants RR-07037 and RR-5070G).

1012 ACETYLCHOLINESTERASE: A NEW MARKER ENZYME IN THE ISOLATION AND RESOLUTION OF THE TRIAD STRUCTURE FROM SKELETAL MUSCLE. Robert Mitchell* and Sidney Fleischer* (SPON: N. Ranish). Dept. Mol. Biol., Vanderbilt Univ., Nashville, TN 37235.

The triad structure from skeletal muscle has been isolated by a modification of a procedure previously described by Caswell et al., (Arch. Bioch. Biophys. 176: 417, 1976). Initial studies indicate the presence of acetylcholinesterase (AChE) activity located specifically in the triad fraction and concomitant with other markers described as being present in triad components (Ca^{++} ATPase and pumping, adenylate cyclase, and ^{3}H-ouabain binding). The acetylcholinesterase specific activity in the triad fraction is approximately 60 nmoles/mg-min. Specificity for acetylcholinesterase can be shown using both butyrylcholine and acetylcholine as substrates and by inhibition studies using the AChE inhibitor, BW 284c51, and the BuChE inhibitor, ISO-OMPA. Separation of the structure into its component organelles (i.e., sarcoplasmic reticulum and transverse tubule) can be achieved by first shearing the triad fraction in a french pressure cell followed by isopycnic sedimentation. There is a 10-20 fold enrichment in acetylcholinesterase activity in a light density fraction (equivalent to 25% sucrose density) and co-migrating with known transverse tubule markers (i.e., adenylate cyclase and ^{3}H-ouabain binding). The AChE of the triad exhibits considerable latent activity which can be demonstrated using sucrose as an osmotic effector or the detergents, Lubrol-PX or Triton X-100. This latency is apparent with regard to either substrate or inhibitor and is most fully expressed in fresh preparations. These results indicate that acetylcholinesterase is localized on the inner face of the transverse tubule within the triad structure. (Supported in part by NIH AM 14632 and by Muscular Dystrophy Assoc. of America, Inc.)

1013 STUDIES OF THE INTERACTION OF EEL ACETYLCHOLINE RECEPTOR ANTIBODY WITH HIGHLY PURIFIED BRAIN ACETYLCHOLINE RECEPTOR. Barbara J. Morley and George E. Kemp*. Neurosciences Program, University of Alabama Medical School, Birmingham, Alabama 35294.

Although α-bungarotoxin (Butx) is a specific ligand for the nicotinic acetylcholine receptor (nAChR) in several tissues, it has been suggested that Butx binds to a different molecule in the CNS. Evidence suggesting that CNS nAChRs and the Butx binding site are not equivalent includes: Butx does not prevent the blocking of receptor activation by eel anti-nAChR in the PC 12 nerve cell line, anti-nAChR fails to precipitate ^{125}I-Butx binding site complexes in the PC 12 line, the Butx binding site complex will not block the immunoprecipitation of muscle cell line binding site complexes by anti-nAChR (Patrick & Stallcup, 1977, PNAS, 71, 4689).

We now report the results of studies of the interaction of eel anti-nAChR with a highly purified brain Butx-binding site as part of an investigation of the equivalence of the Butx binding site with brain nAChR.

Purification was achieved by differential centrifugation, α-cobratoxin biospecific adsorption, ion exchange chromatography, and Sepharose 6B gel filtration. The specific activity of the final product was determined to be in excess of 2 pMoles of ^{125}I-Butx sites/μg protein. For immunoprecipitation studies, aliquots of brain toxin-binding site complexes were incubated with dilutions of anti-nAChR (received from M. Eldefrawi) for 0-8 hrs at 4 or 23°C. An excess of goat anti-rabbit IgG (GAR) was added and the samples incubated for 0-24 hrs and centrifuged at 2,000 rpm for 10-240 min. The maximum precipitation was 10% (we obtain 1-2% with non-purified preparations). Additional aliquots were incubated with an excess of anti-nAChR, as above, passed down Sepharose 4B or 6B gel columns and collected in 3 or 5 ml fractions. Each fraction was counted in a gamma counter and the presence of antibody was confirmed by immunoprecipitation. The results clearly indicate a definable peak of antibody associated sites; the number of sites is identical to that found by the standard immunoprecipitation procedure.

In other studies we have shown that antisera prepared against Butx will precipitate 95-100% of the sites; furthermore, anti-nAChR may not prevent immunoprecipitation by anti-Butx.

The validity of our methods has been shown by carrying out these procedures using purified electric fish and denervated muscle nAChR. With these tissues we obtain 60% and 40% immunoprecipitation, respectively. Although we are investigating several interpretations, we currently favor the hypothesis that nAChRs from different sources have dissimilar antigenic determinants.

This research is supported by grants BNS 78-13724 and BNS 78-23604 to Barbara J. Morley and NS 14262 to George E. Kemp.

1014 EFFECT OF INCREASED MEMBRANE CHOLESTEROL CONTENT ON RAT BRAIN SYNAPTOSOMES. Paula North* and Sidney Fleischer* (SPON: A. Burt). Dept. of Molecular Biology, Vanderbilt Univ., Nashville,Tn.37235.

The cholesterol content of isolated rat brain synaptosomes has been increased in vitro by incubation with sonicated liposomes containing a 2:1 molar ratio of cholesterol to egg yolk phosphatidylcholine. Synaptosomes were isolated from rat forebrain by differential and sucrose gradient centrifugation and resuspended in the cholesterol/phosphatidylcholine co-dispersions. Following the incubation, the synaptosomes were collected by centrifugation and washed. Lipids were extracted for cholesterol and phosphorus determination. A three hour incubation at 32°C resulted, for an average synaptosomal preparation, in increasing the cholesterol content of the synaptosome from .158 to .176 mg cholesterol/mg protein and from .64 to .712 mole cholesterol/mole phospholipid. The lipid phosphorus content did not change by more than 3%. A subsequent incubation of the cholesterol-loaded synaptosomes with pure distearoylphosphatidylcholine vesicles decreased the cholesterol content to .150 mg cholesterol/mg protein. Synaptosomes were also incubated with cholesterol/phosphatidylcholine vesicles labeled with either ^{3}H-cholesterol and ^{14}C-phosphatidylcholine or ^{3}H-cholesterol and internally sequestered ^{14}C-dextran. The ratio of ^{3}H to ^{14}C transfered to the synaptosomes was used as a measure of molecular transfer of cholesterol versus that transfered by aggregation or possibly fusion. These analyses of the cholesterol transfer indicate it to be largely consistent with the molecular exchange process described by Bruckdorfer (Eur.J.Bioc.4:512,1968) between liposomes and erythrocyte ghosts. We have now begun to study the effects of increased cholesterol content on synaptosomal plasma membrane-associated activities. We have measured a potassium concentration-dependent synaptosomal membrane potential using the permeant fluorescent dye, diO-C_5-(3), as described by Blaustein (J.Physiol.247:589,1975). Using the level of fluorescence under depolarizing conditions (70 mM K^+) relative to that in a medium containing 5 mM K^+ as a qualitative indication of resting membrane potential, we find that the cholesterol-loaded synaptosomes have approximately 60-80% the control resting potential. Also, cholesterol-loaded synaptosomes depolarized by preincubation without an energy source are less completely repolarized by subsequent addition of glucose than are control synaptosomes. This drop in ability to generate a membrane potential can be roughly correlated with a measured inhibition in ouabain-sensitive (Na^++K^+)ATPase activity in both synaptosomes and isolated synaptic plasma membranes incubated with the cholesterol-containing liposomes. Membrane leakiness as measured by lactate dehydrogenase occlusion was not increased by the liposome treatment. (Supported in part by NIH AM 14632).

1015 RECONSTITUTION AND PURIFICATION OF A SYNAPTOSOMAL ATP-DEPENDENT CA^{++} TRANSPORT COMPONENT. Diane Papazian*, Hannah Rahamimoff*, and Stanley M. Goldin*. (SPON: G.D. Maxwell). Depts. of Pharmacology and Neurobiology, Harvard Medical School, Boston, Mass. 02115.

Recently several groups have presented evidence for the existence of a non-mitochondrial, ATP-dependent Ca^{++} transport system derived from lysates of synaptosomes. This transport system is presumably involved in regulation of Ca^{++} levels in nerve terminals, thus regulating the release of neurotransmitter. Identification and purification of this Ca^{++} transport system is a prerequisite for its immunocytochemical localization in nerve terminals and for further study of its molecular mechanism; this should increase our understanding of the dynamics of Ca regulation of neurotransmitter release.

A synaptosomal ATP-dependent Ca^{++} uptake system (H. Rahamimoff and E. Abramovitz (1978) FEBS Lett. 89, 223) was reconstituted into artificial vesicles by a cholate dialysis procedure employing an 80-fold excess of exogenous phospholipid. Under these conditions, most of the ∿500Å diameter vesicles that result would be expected to have only one or at most a few membrane proteins. The vesicles containing an ATP-dependent Ca^{++} uptake system were purified from the bulk of the preparation on density gradients by increasing their density due to the ATP-dependent intravesicular precipitation of Ca^{++} oxalate; a 100-fold purification of the transport system resulted. The purified Ca^{++}-transporting vesicles contained two major protein components, of M_r 94,000 and 140,000. These components are believed to be responsible for Ca transport in this synaptosome-derived membrane fraction.

This demonstrates the successful use of a new approach, "transport specificity fractionation" (Goldin and Rhoden (1978) J. Biol. Chem. 253, 2575), for the identification and purification of a class of neuronal ion transport proteins--to our knowledge, no comparable degree of purification of any ion transport protein from the CNS has yet been demonstrated.

1016 EFFECT OF VASOPRESSIN ON THE PENETRATION OF ^{14}C-UREA INTO BRAIN COMPARTMENTS PROTECTED BY BARRIER SYSTEMS. Z. Parandoosh* and C.E. Johanson* (SPON: J.A. Madsen). Dept. of Pharmacology, University of Utah College of Medicine, Salt Lake City, Utah 84132

Vasopressin increases the permeability of some epithelia to urea. Since the choroidal epithelium is relatively impermeable to urea, it is conceivable that vasopressin could alter the permeability of the choroidal membrane (and perhaps the cerebral capillaries) to urea. Using an in vitro as well as an in vivo preparation, we have investigated the effects of various doses of vasopressin on the uptake of radiourea by tissues protected by the blood-CSF barrier (choroid plexus) and the blood-brain barrier (cerebellum and cerebral cortex).

Lateral ventricle choroid plexus (LVCP) from adult rats was incubated in artificial CSF with or without vasopressin (100 mU/ml); plexus tissue from one lateral ventricle served as control for tissue taken from the contralateral ventricle.

^{14}C-urea	^{14}C-urea spaces in LVCP	
Incubation Time	Control	Vasopressin
2 min (Preincubated)*	52.3 ± 2.5	51.6 ± 0.1
3 min (Preincubated)*	60.5 ± 3.1	57.6 ± 0.6
5 min (Preincubated)*	55.1 ± 2.6	54.8 ± 2.9
5 min	64.6 ± 1.0	64.2 ± 3.8
15 min	65.7 ± 1.8	52.3 ± 1.7**

*LVCP preincubated for 15 min with vasopressin before exposure to ^{14}C-urea. Values are means ± S.E. for 3-6 rats. **P<0.05, t test.

There is no evidence from the in vitro studies that vasopressin enhances the uptake of ^{14}C-urea from incubation medium; moreover, under some conditions, the ^{14}C-urea space in LVCP may be decreased by vasopressin.

In in vivo studies in which ^{14}C-urea was injected intraperitoneally into animals receiving an intravenous infusion of vasopressin, there was no increase in the 1-hr ^{14}C-urea space in either the cerebral cortex, cerebellum, LVCP or cisternal CSF at the lower doses of vasopressin (750 to 950 mU during 1-hr infusion); at higher doses of vasopressin (1400 to 1500 mU) a 40 to 80% increase in the 1-hr ^{14}C-urea space was observed in these CNS compartments, possibly due to a vasopressin effect related to an increase in arterial blood pressure (to 150 torr) and cerebral blood flow. (Supported by NIH Grants #NS 13988 and GM 07579)

1017 REDISTRIBUTION OF Na AND K IN RAT CNS DURING RESPIRATORY ACIDOSIS AND ALKALOSIS. Lynn K. Pershing* and C.E. Johanson* (SPON: E.C. Beck). Dept. of Pharmacology, University of Utah College of Medicine, Salt Lake City, Utah 84132

Acute distortions of acid-base metabolism can profoundly alter the distribution of Na and K in some tissues. To evaluate the separate influences of plasma [HCO_3] and [H] upon Na-K distribution in CNS tissues, previous studies involving metabolic acid-base distortions (Fed. Proceed. 38: 375, 1979) were extended to include respiratory acidosis and alkalosis.

Anesthetized (150 mg ketamine/g) Sprague-Dawley rats (400-500 g) were tracheotomized and normoventilated on a rodent respirator with air (control) or 5% CO_2 (acidosis), or hyperventilated with air (alkalosis). Animals were sacrificed by exsanguination at 1 hr, at which time blood from the abdominal aorta was analyzed for pH and pCO_2.

Treatment	pH	pCO_2	HCO_3
Control	7.40 ± .02 (12)	37.4 ± 1.8 (12)	25.6 ± 0.5 (12)
Acidosis	7.20 ± .03 (15)	67.1 ± 4.1 (13)	26.8 ± 0.9 (12)
Alkalosis	7.60 ± .01 (13)	22.6 ± 1.5 (10)	20.9 ± 0.6 (10)

Various CNS tissues were sampled and analyzed for Na and K by flame photometry: lateral and fourth ventricle choroid plexus (LVCP and 4VCP), spinal cord (SC-white matter) and cerebral cortex (CC-gray matter). Data below are means for tissue K/Na .

Treatment	LVCP	4VCP	CC	SC
Control	96.6/64.2	106.1/68.6	109.4/44.3	73.5/31.5
Acidosis	*121.7/55.5*	*121.3/67.4	103.4/41.7	72.7/30.1
Alkalosis	104.8/59.8	111.3/66.9	104.8/43.8	75.2/33.6

(P≤0.05, Student's t test, control vs. respiratory distortion)

Changes in CSF and plasma electrolytes were not significant by Student's t test. LVCP [K] increased significantly by 23% while [Na] decreased by 14% during acute acidosis, yet neither CC nor SC displayed any electrolyte changes with the treatments. Contrasts between the responses of neural and choroidal tissues are probably attributable to differences in the chemical composition of the interstitial fluid in contact with the parenchymal cells associated with the blood-CSF and blood-brain barrier systems. Since in both respiratory and metabolic acidosis the elevated plasma [H^+] produces similar changes in LVCP [Na] and [K], it is possible that extracellular [H^+] influences a K-transferring pump at the basolateral surface of the choroid plexus epithelium. (Supported by #NS 13988 and GM 07579)

1018 INTERMITTENT RESPONSE OF SCIATIC AXONS TO REPETITIVE STIMULATION IS GOVERNED BY THRESHOLD SHIFTS. Stephen A. Raymond and Kenneth McLeod*. Research Laboratory of Electronics, MIT, Cambridge, MA 02139

At regions of low conduction safety in dendrites and axons, subthreshold influences (e.g. extrinsic currents, slow potentials, variations in firing threshold) can modulate conduction of impulses. In excised sciatic nerves, continuous stimulation of the whole trunk with brief current pulses leads to a periodic responsiveness of single fibers. Long trains of one-for-one responses alternate with long periods of failure for pulses having a constant amplitude and duration. The phenomenon is called intermittent responsiveness (intermittent conduction is a corresponding phenomenon occurring at regions of marginal conduction safety such as bifurcations rather than at stimulating electrodes). It occurs over a broad range of frequencies (500 Hz to less than 0.3 Hz) and stimulus magnitudes (2% below the charge delivered per threshold stimulus at rest ($\Delta Q/Stim_R$) to 150% or more above the $\Delta Q/Stim_R$).

Conduction latency, which parallels threshold in a variety of experimental conditions, was measured during intermittent responsiveness. The results indicated that threshold rises during the "response periods", and that it recovers during the "off periods". Latency measurements also showed that the initial threshold levels at the beginning of a response period are well below the level of stimulus pulses. However, as the response period becomes prolonged, the latency becomes progressively longer. At the end of the response period, the average value and variance of latency reached those associated with threshold level stimulation at rest, indicating that the threshold had risen to the point where each stimulus was marginal.

Latency shifts and direct measurement of threshold during the off period show that threshold is initially well above the level of stimulation. The threshold recovers rapidly at the beginning of an off period, but descends less steeply as it nears the resting level. As the threshold approaches the level of the maintained stimulation, it again becomes possible for one of the stimuli to be successful, initiating an on period.

Measurements were made of "periodicity" as defined by the cycle times between response periods and off periods. Periodicity was a function of both the frequency and magnitude (pulse current X pulse duration) of stimulation pulses. The results match with periodicity-frequency and periodicity-magnitude relations obtained from a numerical model of the threshold curves subjected to similar conditions of stimulation.

The activity-dependence of threshold appears to be sufficient to account for intermittent responsiveness.

1019 IDENTIFICATION OF EXTERNAL SURFACE PROTEINS OF SYNAPTIC PLASMA MEMBRANES BY PHOTOLABELING. James C. Schaeffer and Daniel J. Bergmann*, Dept. of Chemistry, University of Missouri, Kansas City, Mo. 64110.

In order to investigate the molecular basis of the numerous functions associated with synapses, it would be useful to establish the orientation of proteins found in synaptic plasma membranes. Previously, Wang and Mahler (J.Cell Biol.,1976) have employed lacto-peroxidase iodination while Smith and Loh (J.Neurochem.,1977) have used proteolytic digestion to study this problem. Since both of these methods have drawbacks, we have investigated the topography of synaptic plasma membranes by the photolabeling technique. In our studies, we used a tritiated, photoactivated, membrane impenetrable label: 3-(4-azido-2-nitroanilino)propyl trimethylammonium iodide.

Crude synaptosome preparations from rat brain were labeled at 4°C to insure that the impenetrable label was not internalized by a non-specific cationic transport process and to minimize synaptosomal membrane alterations. After the labeled synaptosomes were thoroughly washed, they were lyzed with 5mM Tris, pH 8.1 and the resulting synaptic plasma membranes were isolated by the procedure of Jones and Matus(Biochim.Biophys.Acta, 1974). The labeled membranes were solubilized and extensively dialyzed to remove lipids. Membrane bound proteins were resolved into eighteen bands ranging in molecular weight from 15kD to 243kD by SDS-gel electrophoresis (5.6% gels). The gels were sliced into 1 mm thick sections and the tritium content of each section determined.

Proteins with apparent molecular weights of 135kD 108kD, 65kD, 54kD and 35kD were heavily labeled while several other gel regions were less prominently labeled. These data suggest that proteins with a wide range of molecular weights are exposed on the surface of synaptosomes. Parallel dark controls showed identical Coomassie Blue staining patterns and contained only 3% of the radioactivity of the irradiated samples. Thus irradiation was necessary for covalent bond formation and labeling does not alter apparent molecular weights.

Supported by a grant from the UMKC Research Council.

1020 HISTOFLUORESCENT IDENTIFICATION OF α-BUNGAROTOXIN BINDING SITES IN THE GOLDFISH VISUAL SYSTEM, M. Schwartz*, D. Axelrod*, E.L. Feldman* and B.W. Agranoff. Neuroscience Laboratory and Biophysics Research Division, University of Michigan, Ann Arbor, MI 48109.

Recent studies suggested the existence of bungarotoxin (α-Butox) binding sites in the goldfish tectum. However, it is not yet clear whether these sites are presynaptic or post-synaptic. The present fluorescent microscopic studies support evidence for the presence of presynaptic α-Butox binding. Binding of rhodamine-conjugated α-Butox (R-α-Butox) was observed on both optic nerve sections and on neurites of cultured retina explanted from adult goldfish whose optic nerve had been crushed 10-14 d previously. Optic nerve sections were obtained from adult goldfish and were fixed in a mixture of ethanol, formaldehyde and acetic acid. R-α-Butox binding to cultures fixed under mild conditions was high, while the binding to unfixed tissue was very low. In both optic nerve sections and neurites in culture, preincubation with 10^{-7}M unlabeled α-Butox blocked the binding of 10^{-7}M R-α-Butox. The pharmacological profile of R-α-Butox binding to the neurites in culture was investigated in the presence of neuroactive drugs. D-α-Tubocurarine and carbamylcholine were effective in inhibiting the binding while atropine was ineffective. These experiments have shown that α-Butox binding is present in optic nerve axons and the in vitro results indicate that re-establishment of synaptic connections is not necessary for its presence. Both in vivo and in vitro, these axonal sites are not accessible from the exterior of the cell. These axonal α-Butox binding sites may play a role other than in events related to neurotransmission.

1021 MEMBRANE POTENTIAL AND TAURINE TRANSPORT IN A CULTURED GLIOMA CELL LINE. B. Seligmann*, W. Shain, and D. L. Martin*. Neurobiol. Dept., Armed Forces Rad. Res. Inst., Bethesda, MD 20014 and Univ. Md., Dept. Chem. 20742.

High-affinity sodium-dependent transport of taurine by a glioma cell line (LRM 55) has recently been described (Martin & Shain, J. Biol. Chem., in press). Since sodium-dependent transport mechanisms for neutral amino acids may involve the cotransport of sodium with the substrate, they are potentially electrogenic. Therefore we have investigated the relationship between taurine transport and membrane potential in LRM 55 cells.

Membrane potential was measured by intracellular recording and also calculated from the distribution of the tritiated molecular probe triphenylmethylphosphonium ion (TPMP+). The average recorded membrane potential was -43 ± 3 mV. The membrane potential decreased in a non-Nernstian manner as the potassium concentration was increased. Thus the membrane of these cells did not act as a pure potassium electrode. Valinomycin (5×10^{-7} M) hyperpolarized the membrane potential to -63 mV in normal potassium solutions and made the dependence of membrane potential on external potassium more nearly Nernstian. Ouabain (10^{-3} M) or taurine (10^{-3} M) had no significant effects. However, if cells were treated for 30 min with ouabain and then exposed to taurine, a depolarization was observed.

TPMP+ required 160 min to equilibrate across the membrane. The dependence of TPMP+ distribution on potassium was similar to the recorded membrane potential, but the absolute calculated values were substantially greater. The calculated membrane potential at normal potassium was -78 mV. If calculated values were corrected for the amount of TPMP+ remaining in fully depolarized cells, the corrected values agreed more closely with those recorded directly. Valinomycin increased the amount of TPMP+ accumulated by cells in agreement with its effect on the intracellularly recorded membrane potential. However, ouabain caused a consistent small decrease in the amount of TPMP+ accumulated by cells, which was not consistent with intracellular recordings. Because of the kinetics of the TPMP+ distribution and the large amount of membrane potential insensitive TPMP+, we conclude that this probe is of limited value in this system.

The effect of membrane potential on taurine transport was measured in normal- and low-sodium solutions. Depolarization with potassium in normal-sodium solutions had no effect on the initial rate of taurine uptake, nor did hyperpolarization with valinomycin. In low-sodium solutions, increasing potassium inhibited the initial rate of uptake but valinomycin still had no effect. Ouabain did not affect the initial rate of uptake unless the cells were first incubated for greater than 30 min with ouabain, even though ouabain inhibited sodium and potassium fluxes (Na^+-K^+ATPase activity) within 15 min. We conclude that alteration of membrane potential of LRM 55 cells at physiological sodium concentrations has no effect on transport.

1022 STIMULATION BY CALMODULIN OF [Ca^{2+}-Mg^{2+}]ATPase AND Ca^{2+}-DEPENDENT CALMODULIN-REQUIRING PROTEIN KINASE IN RAT BRAIN SYNAPTIC PLASMA MEMBRANES. R. Sorensen* and H. R. Mahler Chemistry Dept., Indiana University, Bloomington, IN 47405

The calcium binding protein, calmodulin, initially identified and described as a cytosolic component of brain capable of modulating the activity of cyclic nucleotide phosphodiesterase has been shown to be capable also of modulating the activity of several other enzymes from the same source, including the [Ca^{2+}-Mg^{2+}]ATPase [Sobue *et al.*, FEBS Lett. 99 (1979) 199] and a Ca^{2+}-dependent protein kinase [Schulman & Greengard, Proc. Natl. Acad. Sci. 75 (1978) 5432]. We now describe the conditions under which calmodulin and calcium can modulate these activities in a purified synaptic membrane fraction from rat brain cortex.

Maximal stimulation of the [Ca^{2+}-Mg^{2+}]ATPase occurred at 3-8 μM Ca^{2+} in the presence of 1 mM Mg^{2+} to a level of 76 nmol P_i hydrolized x min^{-1} x mg^{-1} protein above the basal, Mg^{2+}-requiring activity (380 nmol P_i x min^{-1} x mg^{-1}). Addition of calmodulin at 20 μg x ml^{-1} resulted in maximal additional stimulation over the whole range of [Ca^{2+}], with no further increase at higher concentrations. This enhancement by calmodulin was dose dependent with a threshold at 6 μg x ml^{-1} and half-maximal stimulation at 8.5 μg x ml^{-1} (membrane protein concentration 150-360 μg x ml^{-1}).

In the same buffer (50 mM PIPES, pH 7.0, 100 mM NaCl, 20 mM KCl, 1 mM $MgCl_2$, 1 mM DTT, 0.5 mM $EGTA_2$, 0.2 mM ouabain), maximal stimulation (three-fold) of the Ca^{2+}-activated, calmodulin-dependent, protein kinase required 32 μM Ca^{2+} in the presence of 200 μg x ml^{-1} calmodulin (protein concentration ~1.5 mg x ml^{-1}; reaction terminated after 10 s; specific activity 0.32 μmol phosphate incorporated x min^{-1} x mg^{-1}). As with the ATPase, stimulation of kinase activity by calmodulin was dose-dependent but with half-maximum stimulation at 50 μg x ml^{-1}. The membrane-bound, endogenous substrates for this protein kinase, as identified by SDS-PAGE and autoradiography, included at least 12 major components with apparent molecular weights (x 10^{-3}) of 220, 205, 200, 195, 190, 155, 115, 100, 64, 59, 50 and 48. Among these, different subsets appeared to become phosphorylated at low vs high levels of both Ca^{2+} and calmodulin. In particular, p48, p115, p190, p195, p200 and p205 were the principal components phosphorylated at low (≤1.5 μM) Ca^{2+}; p50 and p100 required high Ca^{2+} (≥8.0 μM) and low (≤2 μg/ml) calmodulin, while p59 and p64 made their appearance only at high levels of both Ca^{2+} and calmodulin (>10 μg/ml). Finally, p115 was present only at low, but not at high levels of Ca^{2+}. We are currently exploring the possibility that these differences are due, at least in part, to localization of the proteins on pre- vs post-synaptic membranes. (Supported by Research Grant NS 08309 from the NIH)

1023 ELECTRON MICROSCOPIC STUDIES OF ACETYLCHOLINE RECEPTOR (AcChR) TOPOLOGY IN POST-SYNAPTIC MEMBRANES FROM TORPEDO. Paul A. St. John, Jonathan B. Cohen, Daniel A. Goodenough*. Depts. of Anat. & Pharmacol., Harvard Med. Sch., Boston, MA 02115

The polypeptide compositions of post-synaptic membranes isolated from Torpedo electric tissue and of the nicotinic cholinergic receptor isolated in detergent from that tissue differ mainly in a 43,000 dalton peptide which is present in the membranes, but absent from the isolated AcChR. In order to understand the topographic arrangement of the polypeptides contained in the membranes, and to be able to interpret experiments with membrane labeling, methods have been developed for studying the sealing and the inside-out/outside-out orientation of isolated membrane vesicles.

Sealing of membranes was studied with protein tracer molecules and electron microscopy. When membranes are mixed with ferritin (450,000 daltons) or horseradish peroxidase (HRP,40,000 daltons) and subsequently fixed for EM, over 90% of membranes are found to exclude the tracer protein from their interiors. When membranes are fixed briefly, and then exposed to 0.1% saponin, focal holes are formed and over 95% of the vesicles are found to contain ferritin or HRP in their interiors. It appears that during the isolation procedure the membranes are formed into vesicles impermeable to large proteins and that they can be made permeable without being completely dissolved.

Orientation of vesicles was examined with two different techniques. First, freeze-etching showed that the rosette structure peculiar to the true outer surface of the post-synaptic membrane in situ was found on the outer surfaces of isolated membrane in over 85% of the cases. Second, when non-detergent treated membranes were incubated with α-bungarotoxin and toxin was localized indirectly with ferritin-conjugated antibody, label was found on the outer surfaces of over 95% of the membranes greater than 0.1 μm diameter. Taken together, these results indicate that most of the isolated membranes are oriented extracellular side-out.

In order to determine whether the AcChR is exposed on both sides of the membrane, membranes which had been made permeable with saponin were labeled with antiserum raised against AcChR purified from detergent extracts of Torpedo electric tissue. Under these conditions, label was found on both the inside and outside of those membranes which were labeled. We conclude that the acetylcholine receptor is exposed on both sides of the membrane.

1024 ROWS OF DIMERIC-PARTICLES WITHIN THE AXOLEMMA AND JUXTAPOSED PARTICLES WITHIN GLIA, INCORPORATED INTO A NEW MODEL FOR THE PARANODAL GLIAL-AXONAL JUNCTION AT THE NODE OF RANVIER. Clayton A. Wiley* and Mark H. Ellisman (SPON: C. Spooner). Dept. Neurosci., Sch. Med., UCSD, La Jolla, CA 92093.

Using freeze-fracture techniques, we have analyzed the glial-axonal junction (G-A-J) between Schwann cells and axons in the peripheral nervous system, and oligodendrocytes and axons in the central nervous system. We have identified a new set of dimeric-particles arranged in circumferential rows within protoplasmic fracture faces (P-faces) of the paranodal axolemma in the region of glial-axonal juxtaposition. These particles were observed in both aldehyde-fixed and non-fixed preparations. The dimeric-particles are 260 Å in length, composed of two 115 Å subunits. The rows of dimeric-particles within the axonal P-face leave complementary rows of pits within the external fracture face (E-face) of the paranodal axolemma. These axonal particles are positioned between rows of 160 Å particles occurring in both fracture faces of the glial loops in the region of the G-A-J. In addition to these previously described 160 Å particles, we observed a new set of 75 Å particles within the glial P-faces of the G-A-J. These 75 Å glial particles form rows that are centered between the rows of 160 Å particles and therefore are superimposed over the rows of dimeric-particles within the paranodal axolemma. Our new findings are interpreted with respect to methods of specimen preparation as well as a potential role for the paranodal organ in saltatory conduction. We conclude that this particle rich junction between axon and glia could potentially provide an intricate system of ion exchange between the two cells.

1025 STUDIES OF THE LOCALIZATION OF CALMODULIN AND ITS BINDING PROTEIN IN BRAIN. John G. Wood, Robert Wallace*, John Whitaker and W.Y. Cheung*. Dept. Anat., Univ. Tenn. Center Health Sci., Dept. Biochem., St. Jude Children's Research Hospital and V.A. Hosp., Memphis, TN

Antibodies to a calcium dependent activator protein (calmodulin) and a protein (CaM-BP_{80}) which binds to calmodulin and blocks its activator effect on several enzyme systems have been used to localize these proteins in mouse brain. A dinitrophenyl derivative of purified calmodulin and native purified CaM-BP_{80} were used to immunize rabbits and the antisera were extensively characterized. In order to perform immunocytochemical experiments, C57 Bl/6J mice were perfused through the heart with a fixative containing 4.0% paraformaldehyde and 0.1% glutaraldehyde in 0.12M phosphate buffer, pH 7.2. The brain was stored overnight in paraformaldehyde only. Forty micron slices were obtained with a vibratome apparatus and incubated in rabbit anti-calmodulin (1:200) or rabbit anti-CaM-BP_{80} (1:400) for 30 min in phosphate buffered saline (PBS). After washing 3 min in PBS the slices were incubated in peroxidase conjugated Fab of goat anti-rabbit IgG followed by a 3 hr wash and development of the peroxidase. At the light microscopic level the slices revealed specific staining within the cell somata and processes of large cells within the basal ganglia, cerebellum and cerebral cortex. In the cerebellum these labeled cells were the characteristic neuronal cells of this structure; no glial elements reacted with antibody. At the electron microscopic level the label was restricted to neurons and was concentrated at the postsynaptic density (PSD) and along microtubular profiles of the postsynaptic dendrite. The pattern of localization with both antisera appeared identical. Biochemical studies have also shown calmodulin is associated with the PSD (J. Cell Biol. 79:96a). The localization of calmodulin and CaM-BP_{80} at the PSD and along postsynaptic microtubules implies these proteins play a role in regulating enzymes involved in neurotransmission and in microtubular function. MEMORY AND LEARNING

1026 BRAIN MODEL: A BRIDGE FROM PSYCHOLOGY TO PHYSIOLOGY. J.H.Andreae* (SPON:J.D. Loeser).Dept.Elec.Eng.,Univ.Canterbury,New Zealand.

To connect psychological behaviour with physiological structure, a dual model of the brain is proposed which comprises a well-tested artificial intelligence system, called PURR-PUSS(Andreae: "Thinking with the Teachable Machine",Academic Press.1977), and related neurochemical circuits. Starting with a first assumption that intelligence is the main aspect of human behaviour to be modelled, 3 necessary conditions for intelligence follow, namely, an "open" system, learning from experience, and the self-setting of goals. These 3 conditions imply (i) a "body" to connect the "brain" to the real world so as to avoid the limitations of a formal system, (ii) a "multiple context", comprising short most-recent sequences of events from speech, vision, proprioception, &c., to represent the "here and now", and (iii) "novelty goals", which are events in context that have occurred only once.

The second assumption is that the model must operate at a speed comparable with that of human behaviour so that psychologists can experiment with it. Speed is achievable by using the computer science technique of "hashing". Each new event is stored in LTM (long term memory) at a place determined by hashing its associated context, or event-sequence, in the multiple context. If the associated context occurs again, the context-hashing retrieves the same event together with any other events which had been stored with the same context as "predictions" to be used by the "brain's" decision processes. Context-hashing gives a speed of operation independent of the size of LTM.

Conventional neuron "circuits" allow the multiple context to be translated into biological hardware, but the seeking of novelty goals requires a more subtle mechanism involving the leak-back of chemical code molecules from neurons representing novel events through the neural network to neurons representing current events. This leak-back of "novelty" biases the majority-evidence decisions towards actions which lead the system to novelty goals.

On the organization side, context-hashing corresponds to genetically-controlled neuron growth and the adaptive formation of synapses. The multi-channel interconnection of "brain" and "body" via the multiple context results in a variety of functional and modal subdivisions of the neural network. In this way, the intelligence and speed demanded of the psychological model are related to the neurochemical circuitry and organization of the physiological part of the dual model.

The psychological model has been subject to extensive interaction and teaching, while the operation of the neurochemical circuits has been tested by computer simulation. It remains for foundations to be established at each end of this "bridge" from psychology to physiology.

1027 PUROMYCIN DOES NOT OBLITERATE ALL THE DIFFERENT MEMORIES WHICH OCCUR IN A GIVEN TRAINING SITUATION. D.A. Barraco, E.M. Eisenstein, and K.L. Lovell. Departments of Physiology and Biophysics and the Neuroscience Program, Michigan State University, E. Lansing, MI 48824.

A new one-session training procedure for cockroaches, in which animals are trained to turn right or left to avoid a shock has been developed. This paradigm was utilized to investigate the effects of puromycin, a protein synthesis inhibitor, on learning and memory. The drug was injected before training in does causing approximately 70% protein synthesis inhibition. The number of correct turns and the time taken for the animal to proceed down the runway were the two behavioral parameters measured in the paradigm. In control animals the number of correct choices and the runway time both increased with succeeding trails during training. In addition, control animals showed excellent retention of these responses 5 hours later during testing (n=23). Puromycin also had no effect on aquisition of the two responses. However, upon testing, experimental animals showed a significant retention deficit of the correct turn response but not of the behavioral modification evidenced by increased runway time (n=31). Thus, puromycin may show specificity for the different types of behavioral plasticity that occur in any training situation and that may be mediated at different levels of the central nervous system. (Support in part by the Biomedical Research Support Grant to the College of Natural Science).

1028 VERY LONG SHORT TERM MEMORY IN RATS: EFFECTS OF HIPPOCAMPAL LESIONS. William W. Beatty. Dept. Psychol., NDSU, Fargo, ND 58105.

Rats were trained on a win-shift food searching strategy in an 8-arm radial maze to nearly errorless performance at 0 delay and with a delay of 1 min imposed between the 4th and 5th choices. Then they received dorsal, ventral or combined dorsal and ventral hippocampal lesions or neocortical lesions or control operations. Neurologically intact controls displayed virtually perfect spatial memory (i.e., better than 90% correct on the first 4 choices after the delay) for delays ranging from 1 min to 4 hr; some rats showed comparably excellent memory for 8 hr. Memory deteriorated at 12 hr delays and essentially disappeared by 24 hr. Preliminary results indicate that ventral hippocampal lesions have little effect on spatial memory while dorsal hippocampal lesions cause serious deficits in spatial behavior at the 0 delay condition and deficits in spatial memory in animals that successfully reacquire criterion performance at 0 delay.

1029 ENGRAM LATERALIZATION IN THE INTACT AND SPLIT-BRAIN CHICK. Graham A Bell* and David Ehrlich* (SPON: David G Satchell) Dept.Behav.Biol., Res.Sch.Biol.Sci., Australian National Univ., Canberra, Australia 2601.

Young chicks were trained to suppress their tendency to peck a small bead after it had been dipped in a noxious substance, methyl anthranilate (MeA). Retention was measured by the proportion of a group of chicks pecking an identical clean target. Chicks were able to discriminate between the previously tainted bead and a novel one of different colour, for up to 24 hr after the learning trial. There was good interocular transfer for the task when chicks were trained and tested monocularly.

Recent work with this task using intracranial injection of ouabain or cycloheximide (Bell and Gibbs, Neurosci.Lett., 1979, in press) suggests that monocular learning results in a localized engram in the forebrain hemisphere contralateral to the trained eye. Interocular transfer of the MeA task in the intact chick therefore requires interhemispheric readout of the unilateral engram by the trained hemisphere. A bilateral engram can become established as a consequence of interocular transfer testing; the readiness of engram duplication depends on the recency of formation of the original trace.

We lesioned the dorsal supra-optic commissure (DSO) in three day old chicks 4 hr after monocular learning of MeA-avoidance, and following 48 hr of monocular exposure to an imprinting object. A sham operated control group was taken from the same hatch, similarly housed and trained.

At 24 hr after operation the sham group (n=15) showed good retention of the MeA task with the trained and untrained eyes, and discriminated between the previously tainted target and a novel one. The split-brain group (n=25) showed good retention and discrimination with the trained eye. When tested with the untrained eye, chicks failed to show retention and pecked the learning and novel targets with the same probability. This suggested that monocular learning of MeA-aversion established a lateralized engram and that access to it depends on an intact DSO.

Interocular transfer of imprinting failed in the split-brain and sham groups 24 hr after operation, but succeeded in some individual chicks from both groups, on three subsequent testing days. It appears that imprinting is more sensitive to suture reversal than the MeA task. Further work is required to resolve whether monocular imprinting establishes a bilateral engram or whether retrieval of a unilateral engram is achieved independently of the DSO.

1030 CHOLINERGIC BLOCKADE OF THE CAUDATE NUCLEUS AND AUTOSHAPING IN RATS. Federico Bermúdez-Rattoni* and Roberto A. Prado-Alcalá. (SPON: J.A. Roig). Dept. Physiol., Sch. Med., Natnl. Univ. of México, P.O. Box 70250, México 20, D.F., México.

Commonly, studies on the acquisition of instrumental behaviors involve "shaping" of the animal's responses by the experimenter. Thus, acquisition becomes the result of an interaction between the animal's learning capabilities and the experimenter's ability to shape. Autoshaping procedures, on the other hand, represent an important technical advancement with respect to the method of successive approximations, since the behavior of the animals may change within a standarized experimental environment, without a direct intervention of the experimenter. We studied the effects of cholinergic blockade of the caudate nucleus on the acquisition of lever pressing behavior. Animals were trained in a Skinner box; on day 1, a light-bulb situated above a centrally located liquid dispenser was turned on and then 0.3 ml of water were delivered. This sequence was repeated 50 times with an intertrial interval (ITI) of 30 sec. Twenty-four hr later a light-bulb placed above a lever was turned on 50 times (ITI 30 sec). If during these periods a rat pressed the lever the liquid dispenser was lighted and water was delivered. If the animal pressed while the lever was not lighted, the response was not reinforced. Bilateral microinjections of scopolamine (30 µg into each cannula) or saline solution (NaCl) were performed in independent groups 6 min before the second session, into the anterior caudate nucleus (ACN), the posterior caudate (PCN) or into the parietal cortex (Ctx); there was also an unimplanted (UI) control group. Those groups injected with scopolamine in ACN and PCN showed an impairment in the acquisition of lever pressing, as compared with the Ctx, NaCl and unimplanted groups. These results suggest that cholinergic activity of the CN is involved in the acquisition of instrumental behaviors.

1031 DISTRIBUTION AND RESPONSE CHARACTERISTICS OF RAT MEDIAL GENICULATE NEURONS WHICH SHOW ASSOCIATIVE CHANGE DURING DIFFERENTIAL CONDITIONING AND REVERSAL. D. Birt and M. E. Olds*. Div.of Biol., California Institute of Technology, Pasadena, CA 91125.

We recently reported that in a conditioning paradigm which eliminated a number of previously demonstrated non-associative factors, a proportion of neurons in medial geniculate of rat showed short latency associative change. The present experiment was designed to determine the distribution of such units throughout the subdivisions of the medial geniculate and to identify response characteristics which might differentiate these units from units not showing associative change.

The multiple unit responses on 117 probes distributed throughout MG were recorded during differential appetitive conditioning, extinction, and successive reversals. Seventy-three of these met criteria for responsiveness and stability of recording and were further analyzed. 11 units which showed enhanced response to the positive stimulus relative to the response to the negative stimulus throughout 4 or more consecutive reversals were considered to be associative. These units were largely localized in the far posterior portion of MG where 25% (9 of 36) units were associative. Only 5% (2 of 37) units in the remainder of MG were associative. Associative units were further differentiated from non-associative units by differences in the temporal pattern of their initial response prior to conditioning. Units with a more sustained response were more likely to show associative change than those with a very transient response and the magnitude of change was positively related to the initial duration of response. 71% (5 of 7) of units which initially were responsive for more than 80 ms showed large magnitude associative change during conditioning. Only 9% (6 of 66) of units which were initially responsive for 80 ms or less showed associative changes and these were of small magnitude.

These associative neural changes were shown not to result from behavioral feedback since their latency (as early as 16 ms after stimulus onset) preceded behavioral response and since they were not directly correlated with behavioral change. They appear more directly related to processing of the significance of stimulus information.

The fact that these changes are localized to a discrete portion of MG with known differential afferents and efferents and that associative units have different temporal response patterns which are easily identified leads to the potential for identifying the neural circuitry involved using single unit analysis techniques. (Supported by NSF BNS 77-22289)

1032 CHANGES IN RESPONSIVENESS TO GLABELLA TAP AMONG NEURONS IN THE SENSORIMOTOR CORTEX OF AWAKE CATS. J. Brons*and C.D. Woody. Depts. Anatomy & Psychiatry, Brain Research Institute, Mental Retardation Research Center, UCLA Medical Center, Los Angeles, CA 90024.

Unit responses to glabella tap stimulation were studied in 128 neurons of the sensorimotor cortex in 4 awake cats. The glabella tap, used as an unconditioned stimulus (US) during classical conditioning, elicits an unconditioned eyeblink response of 7-9 msec latency by activation of a brainstem reflex arc (Woody & Brozek, J. Neurophysiol. 32: 704-716, 1969). The effects of the tap US on cortical responsiveness were examined over a two day period (up to 400 tap trials per day, 5 sec ITI). Overt habituation of the eyeblink response occurs at ITI's of 1-2 sec or less.

Unit activity was recorded intracellularly or extracellularly with 15-50 MΩ, 1.4M K+- citrate filled glass microelectrodes. On the first day of recording, out of 55 neurons, 29% showed increased activity to tap; 36% showed decreased activity; and 35% were unresponsive. On the second day, out of 73 units, 55% showed increased activity, 27% decreased activity, and 18% were unresponsive. Analysis indicated that the proportion of cells responding with increased activity had increased significantly from the first day to the second ($P<.01$, X^2 test). PST histograms of the responses to the tap revealed that the mean onset latencies (9 msec for increased activity, 13 msec for decreased activity) and peak magnitudes of the averaged unit responses remained unaltered over the two days. Intracellular recordings indicated that the increases and decreases in evoked activity were supported by EPSP's and IPSP's, respectively.

These data provide evidence that repeated presentations of a glabella tap over a period of two days increases the proportion of cells within the motor cortex responding to the stimulus with increased activity. Furthermore, this US which reinforces eyeblink conditioning produces both EPSP's and IPSP's in the motor cortex. (Supp. by AFOSR 76-3074 and BNS 78-24146.)

1033 THE ROLE OF EXTRACELLULAR CALCIUM IN HABITUATION AND TRANSDUCTION OF ELECTRICAL AND MECHANICAL STIMULI IN THE CILIATED PROTOZOAN, SPIROSTOMUM AMBIGUUM. Donald G. Brunder* and E. M. Eisenstein. Biophysics Dept., Michigan State Univ., East Lansing, MI 48824.

Previous work shows that Spirostomum ambiguum responds to mechanical (vibratory) and electrical stimulation by rapidly contracting. Repeated mechanical but not electrical stimulation (rate 0.1 Hz) leads to a decrement in the probability (habituation) of the contractile response. The independence of the two stimulation modes with respect to habituation suggests separate sites for mechano- and electro-transduction (Osborn et al., Behav. Biol. 8:655,1973). Earlier studies have also indicated that extracellular calcium is important in mechanotransduction (Osborn et al., Behav. Biol. 8:665,1973).

The present study is concerned with the effects of extracellular calcium on the transduction and habituation processes in Spirostomum. Calcium was manipulated by incubating the protozoans in media containing different calcium concentrations and by the addition of the calcium chelator ethyleneglycol-bis (ß-amino-ethylether)N,N'-tetraacetic acid (EGTA). The results indicate that increasing the calcium concentration increases responsiveness to mechanical stimulation over the concentration range studied (0-0.5mM). Initial responsiveness (minute 1 of the stimulation period) to electrical stimulation was depressed in media to which no calcium was added. Such media also resulted in a response decrement to electrical stimulation not seen when free calcium was present. The data suggest that free calcium is the main factor in responsiveness as determined by manipulation of calcium and EGTA levels. EGTA-containing media in which no free calcium was present generally decreased responsiveness to mechanical and electrical stimulation.

The results are consistent with previous studies in supporting the role of extracellular calcium in mechano- and electrotransduction and possibly habituation. In addition it was shown that the lack of extracellular calcium causes a decrement of the contractile response to electrical stimuli; the unavailability of extracellular calcium may be an important feature in the mechanism of habituation to mechanical stimulation as well. 1034 EFFECTS OF L-PROLINE, PROLINE ANALOGS AND OTHER AMINO ACIDS ON MEMORY IN THE CHICK.

Arthur Cherkin and Joel L. Davis. GRECC and Psychobiology Research Laboratory, VA Medical Center, Sepulveda, CA 91343.

The amnestic effect of L-proline (L-PRO) (Van Harreveld and Fifkova, Brain Res. 81, 455, 1974) has been confirmed by two laboratories (Science 193, 242, 1976; Neurosci. Lett. 6, 355, 1977). The latter concludes that the amnestic effect results from interference with brain uptake of amino acids, rather than with glutamate release as postulated by Van Harreveld and Fifkova. Structure-function relationships may clarify the issue. The L-PRO effect is stereospecific and dependent upon molecular size (Brain Res. 156, 256, 1978). We have reported the amnestic effect of DL-3,4 dehydroproline and L-baikiain. We now present data on additional amino acids. We injected chicks intracerebrally with 10 µl/hemisphere of 300 mM amino acid, 1 min after one-trial training to suppress the peck response to a bead. Suppression was conditioned by coating the bead with an aversive liquid (methyl anthranilate). Retention was tested 24 hr later using the uncoated bead; increased peck scores (mean sq. rt. of pecks in 10 sec) indicate impaired memory. The experiment was in block design. The results with D-proline and cycloleucine are similar to those with no injection, eliminating trivial factors, such as injection itself, as causative of memory impairment. The results with L-isoleucine, and with L-serine and L-threonine (albeit borderline), indicate that imbalance of free amino acids in the ventricular fluid does not necessarily impair memory. Of interest is that the amino acids found by Van Harreveld (Neuroscience Abst., this volume) to resemble L-PRO in their dose-response effect upon spreading depression in the chick retina (DL-3,4 dehydroproline, L-baikiain, 4-hydroxy-L-proline) also have an amnestic effect. The amnestic effect of amino acids which do not resemble L-proline in the retina experiment (glycine, L-homoserine, L-glutamine) may result from different mechanisms.

Amino Acid	Peck Score[a]	Amino Acid	Peck Score[a]
4-Hydroxy-L-PRO	1.20*[c]	L-Serine	1.05
L-PRO	1.17*[c]	L-Threonine	0.97
Glycine	1.12*	L-Pyroglutamic Acid	0.92[c]
L-Homoserine	1.09*	Cycloleucine	0.57
D-PRO	0.59[c]	L-Isoleucine	0.71[bc]
		No injection	0.72[b]

* Differ significantly from D-PRO ($p<0.05$; t-test).

[a] N=41-50, except L-isoleucine (N=134). The range of SEM's was 0.08-0.17 in present experiment.

[b] Data from previous experiments. SEM's=0.06-0.10.

[c] EEG records show no seizure or isoelectric activity in these amino acids or in L-baikiain or DL-3,4 dehydroproline; remaining amino acids being studied.

1035 THE NATURE OF REMOTE MEMORY IMPAIRMENT IN THE AMNESIC SYNDROME.

Neal J. Cohen* and Larry R. Squire. Dept. Psychiat., Univ. Calif. San Diego, La Jolla, CA 92093.

Performance of amnesic patients on tests about public events or public figures has previously been evaluated, usually in a single population of patients. The present study assessed memory for photographs of famous individuals who came into prominence at various times from the 1930s through the 1970s. We studied the amnesic patient N.A., a group of alcoholic Korsakoff patients, and three groups of control Ss.

Three major findings emerged: 1) the pattern of impairment demonstrated by N.A. differed markedly from that demonstrated by the Korsakoff patients. N.A. scored at least as well as 16 matched controls on photographs of individuals who were known prior to the onset of his amnesia in 1960. N.A. was severely impaired with photographs of individuals who were known only in the 1960s or 1970s. In contrast, Korsakoff patients were impaired over the entire range of the test, and this deficit was graded such that their performance was poorer for the recent time periods than for remote periods. 2) Yes/No and multiple-choice cuing improved both amnesic performance and control performance, but did not eliminate the amnesic defect. 3) A group of 16 alcoholic inpatients performed at a level intermediate between Korsakoff patients and 16 matched non-alcoholic inpatients. This finding provided support for the notion that the marked temporal gradient of impairment demonstrated by the Korsakoffs might in part reflect the gradual onset of anterograde amnesia over many years. Taken together, these findings emphasize the difference between etiologically distinct amnesias and provide additional evidence for continuity between Korsakoff patients and chronic alcoholics.

1036 AMYGDALA INDUCED AMNESIA GRADIENTS OR ALTERATION OF PERCEIVED AVERSIVENESS? Jeffrey D. Cross and Irving J. Goodman. Dept. of Psychology, West Virginia U., Morgantown, W. Va. 26506

There have been numerous reports of the disruptive effects of electrical brain stimulation (ESB) on memory. The stimulus parameters for ESB in these studies varied widely with regard to both stimulus intensity and duration. The vast majority of these investigations employed some form of avoidance performance as the lone dependent variable. Impaired performance of the avoidance task after some post-treatment delay indicates retrograde amnesia caused by the ESB. Several authors have reported a positive rela-tionship between the intensity of the ESB and the amount of retrograde amnesia observed. The results of these studies are typically referred to as "amnesia gradients". Theoretical explanations of how a memory trace can be more-or-less impaired by varying intensities of ESB are based on the concept of partial destruction of the short-term memory consolidation process. An alternative interpretation of these results is suggested by the present study which proposes alteration of affective quality of memory as the process involved in so-called amnesia gradients.

Thirty adult male hooded rats were anesthetized and implanted unilaterally with a bipolar nichrome electrode in the amygdala. Following a short recovery period, the animals were reduced to 80% of their ad lib. body weight and trained in a step-down apparatus. Training consisted of placing the animal in an enclosed platform chamber and opening a guillotine door. Opening the door permitted the animal to descend from the platform and cross a grid floor to a food cup mounted on the wall. Upon reaching a performance criterion, a 2 mA footshock followed immediately by ESB was administered on the next trial to all animals. The intensity of the ESB was at one of four levels: 0uA; 25 uA; 50 uA; 100 uA. The duration of the single pulse was 0.5 msec. Following the treatment trial, all animals were tested for recall deficits 24 hours later by the administration of a single avoidance trial. During training, treatment, and test trials, the heart rate of each animal was recorded. Heart rates (bpm) were calculated for the five seconds immediately prior to the opening of the door (PRE) and the first five seconds after the opening of the door (POST) for pretreatment and recall test trials. Graded step-down latencies were observed across groups; ESB intensity and step-down latency were inversely related. Heart rate change scores (post H.R. - Pre H.R.) were positively correlated with avoidance step-down latencies. These findings are better explained by alteration of affective quality of the aversive ("to be stored") event rather than the complete or partial destruction of the memory trace.

1037 OPIATES LEAD TO PERSISTENCE OF SPATIAL HABITS WITH SOCIAL REWARDS. Fatma G. DeEskinazi and Jaak Panksepp. Dept. Psychol., Bowling Green State Univ., OH 43403

To evaluate the effects of brain opiate systems in habit-formation, 15 day old rats injected with saline, morphine (0.5-1.0 mg/kg) or naloxone (1 mg/kg) were tested for acquisition and extinction of spatial discrimination in a T-maze using either access to home cage or food as rewards. Although morphine animals ran significantly slower than controls during the first two days of acquisition, they did not differ in terms of errors or trials to acquire the habit. Naloxone animals took reliably fewer trials to reach criterion and made fewer acquisition errors than controls. During 12 days of extinction, morphine treated animals sustained their behavior practically undiminished, running as fast and as correctly, on the last day of extinction as on the first. Saline animals showed a gradual rise in running times till day 5, whereupon latencies became stable. Naloxone animals received only 7 days of extinction, because by the end of 70 trials performance was completely extinguished. The maintenance of the spatial habit by morphine was not state-dependent in that morphine was as effective given only during extinction as during both acquisition and extinction. To determine whether these results are specific for social rewards, animals were tested in the same task using food reward. There was almost no difference in number of trials to criterion by saline and morphine animals, and morphine did not slow the initial acquisition running time. Although morphine did sustain fast running times during extinction, correct-choice behavior was not sustained, suggesting that opiates lead to persistence of social habit more than food-rewarded habits. The capacity of morphine to sustain social-habits is probably mediated by opiate receptors, since the effect was eliminated by pretreatment with naloxone. To further evaluate the perseverative behavior produced by morphine, rats were tested in a position reversal task using social rewards. Whereas controls reversed side preferences within 2 days, morphine animals required 5 days to acquire the reversal. These results indicate that morphine has a strong capacity to modify the expression of learned behaviors, and suggests that brain opiate systems may be important in formation and maintenance of habits, expecially social-habits.

1038 A MODEL FOR PERCEPTUAL CODING BASED ON EEG ANALYSIS. Walter J. Freeman, Dept. Physiology-Anatomy, University of California, Berkeley CA 94720.

Rabbits were implanted with 8x8 electrode arrays spaced .5 mm epidurally on the olfactory bulb. Maps of the EEG rms burst amplitudes showed that (a) amplitudes in waking, motivated rabbits were non-uniform; (b) contour plots showed foci resembling islands with patterns unique to each animal; (c) patterns remained stable for months if no training to olfactory stimuli was undertaken; (d) the patterns changed with discriminant training to give a CER or CR to a warning odor paired with an aversive stimulus; (e) the new pattern restabilized in 1 or 2 further sessions but changed again on training to a new warning odor; and (f) after each new discrimination was established, the new EEG pattern was present whether or not the odor was present.

The results were taken to mean that the EEG patterns were mainly determined by expectation rather than by stimulation. During training a template of synaptic connections is laid down for the warning odor. Thereafter, when the animal searches for that odor, the template is activated. This gives rise to the EEG burst pattern, which conforms to a percept rather than a recept.

A set of nonlinear differential equations, based on behavioral studies of evoked potentials, EEG and unit activity (Freeman, W.J. Mass Action in the Nervous System, Academic Press, New York, 1975), was solved to simulate bulbar space-time activity patterns. It is inferred that (a) during training the template forms by 2-4 fold strengthening of excitatory synapses between co-activated mitral cells, and constitutes a probability map of the variety of spatial forms a given odor can take; (b) when the animal becomes selectively attentive to the stimulus, the template is sensitized by background input from olfactory and other senses, under centrifugal control; and (c) when any portion of the template is stimulated, the entire set of neurons comprising it is activated through the mutually excitatory connections. Thus the template is a generalization over all input for an odor during training, is sensitive to any subset whether or not it occurred during training, and serves to fill in missing detail for small or large input subsets. When a subsidiary mechanism for habituation is introduced, the output for adventitious odors is attenuated, and the pattern of output thereafter reflects the form of the template rather than the pattern of the input, as observed in the EEG.

1039 β-ADRENERGIC MANIPULATION WITHIN THE AMYGDALA ALTERS HEART RATE CONDITIONING IN THE RABBIT. Michela Gallagher, Bruce S. Kapp, Robert C. Frysinger,* and Peter R. Rapp.* Dept. of Psychology, University of Vermont, Burlington, VT 05401.

Previous research conducted in this laboratory to assess the involvement of specific amygdala systems in the development of heart rate conditioning demonstrated that lesions confined to the central nucleus of the amygdala produce impairment of conditioned bradycardia in rabbits (Kapp et al., Neurosci. Abs., 1978). The present investigation was aimed at determining whether catecholamine systems which provide a particularly rich innervation of the central nucleus contribute to heart rate conditioning. To this end the effects of injections of the β-adrenergic antagonist dl-propranolol into the region of the central nucleus on heart rate conditioning were assessed. New Zealand rabbits were surgically prepared with cannulae positioned at the dorsal surface of the central nucleus. Two weeks following surgery all subjects were trained using a standard Pavlovian conditioning procedure. All drug injections were delivered bilaterally in a 1.0 µl volume immediately prior to the conditioning session.

Compared to a vehicle injected control group, a group receiving injections of the β-adrenergic antagonist, dl-propranolol, into the central nucleus exhibited significant attenuation of the conditioned bradycardia response. This effect of dl-propranolol appears to be due to the specific β-adrenergic blocking activity of the drug because a group receiving the same dose of d-propranolol did not exhibit a comparable conditioning deficit. In addition, combined administration of dl-propranolol and l-isoproterenol, a β-adrenergic agonist, reduced the conditioning impairment observed following administration of dl-propranolol. Finally, data obtained from subjects receiving injections of dl-propranolol into other sites within the amygdala complex or into sites dorsal to the central nucleus of the amygdala support the interpretation that the effects of dl-propranolol on heart rate conditioning in this research are due to interference with β-adrenergic activity within the region of the central nucleus.

Recent neurochemical investigations have revealed that the central nucleus receives adrenergic projections from the catecholamine containing cells in the medulla as well as from the locus coeruleus (Fallon et al., J. Comp. Neurol., 1978, 180, 509-532). The innervation from the medulla may in part derive from cells in the A2 region of the nucleus tractus solitarius, a region involved in cardiovascular regulation. Our results, therefore, may reflect the effects of interference with an A2-amygdala system.

1040 DIFFERENTIAL FOOD AVERSION LEARNING BY THE TWO HALF-BRAINS OF MONOCULARLY TRAINED CHICKS. Karen E. Gaston* (SPON: R. W. Sperry). Division of Biology, California Institute of Technology, Pasadena, CA 91125.

It has been shown that young chicks avoid drinking a novel green sucrose solution which has been paired once with delayed LiCl-induced illness, and that this conditioned aversion is mediated by the visual (color) cue and not by taste (Gaston: Behav. Biol. 20: 441, 1977). Tests with monocularly trained chicks demonstrated good interocular transfer of the aversion learning (Gaston: Behav. Biol. 24: 272, 1978). To examine the possibility that novel taste might play some role in acquisition and/or interocular transfer of the visual aversion, the present experiment evaluated the effects of monocular training with novel color in combination with either novel or familiar sucrose taste.

Ten-day-old chicks with one eye occluded were made sick with LiCl after drinking green sucrose solution. Half the animals had been pre-adapted to the sucrose taste. The chicks were tested the following day, with the trained or the untrained eye open, for learned aversions to green or uncolored sucrose. Chicks tested with the trained eye displayed a marked aversion to the colored sucrose, but not to uncolored sucrose, regardless of the taste variable. These results demonstrate that taste adaptation did not interfere with monocular learning and that novel taste was not required for acquisition of the visual aversion. In contrast, animals tested with the untrained eye showed a significant aversion to either colored or uncolored sucrose, but in each case only if the taste was novel during training. The avoidance of uncolored sucrose clearly represents a taste aversion which was acquired only by the hemisphere deprived of direct visual information during training.

The present results, in combination with those of the previous related studies, suggest that the seeing whole or half-brain could utilize only the novel visual information (color) for acquisition and expression of an illness-induced aversion. However, when one eye was occluded and vision through that eye thus eliminated, then the non-seeing half-brain was able to use the novel taste information in forming an aversion. These findings indicate that, in monocularly trained chicks, each half-brain can independently acquire an illness-induced food aversion, with learning in the seeing and non-seeing hemispheres mediated by novel color and taste cues, respectively.

1041 BRAIN NOREPINEPHRINE AND RETROGRADE AMNESIA. Paul E. Gold and James M. Murphy. Dept. Psychology, University of Virginia, Charlottesville, VA 22901.

Most candidates for neurobiological correlates of retrograde amnesia (e.g., seizures, or transmitter or protein synthesis inhibition) have only limited generality across amnestic agents. Recently we found that brain norepinephrine (NE) concentrations are sensitive to several training-treatment combinations. The extent of a transient decrease (maximal 10 min after training) in NE content appears to be a predictor of later retention performance in a variety of situations. Brain NE concentrations decrease by 20% after a training footshock adequate for good retention. Under conditions in which a larger (30-40%) or smaller (0-10%) decrease occurs, later retention performance is poor.

The present experiment examined the relationship between the effects of supraseizure electrical stimulation of frontal cortex on retention and on brain NE content. Rats received footshock (3 ma, 2 sec) in a one-trial inhibitory (passive) avoidance task. Five sec after training, the animals received frontal cortex stimulation (2.5 or 5.0 ma, 1 sec) through chronically implanted screw electrodes. Other animals received no training, training, or stimulation alone. A set of animals in each group was tested for retention performance 24 hr later; both cortical stimulation intensities resulted in brain seizures and in poor retention performance (retrograde amnesia).

Ten minutes after training and/or treatment, the remaining animals in each group were decapitated and the brains were removed and dissected into forebrain and brainstem samples. NE concentrations were measured with a PNMT-linked radiometric assay.

Control NE values were 515±30 and 550±40 ng/gm for forebrain and brainstem samples respectively. Consistent with our previous findings, footshock reduced forebrain NE content by 17% and brainstem NE by 22% as measured 10 min after training. Frontal cortex stimulation administered after avoidance training significantly altered this normal NE response to footshock. In the forebrain, the NE response after footshock was potentiated (32% decrease) while in the brainstem the response was attenuated (2% decrease). Although it is difficult to explain the opposite direction of the effects of stimulation on the two brain regions, the findings are consistent with the general view that a transient posttraining 20% decrease in brain NE content, presumably reflecting NE release, is optimal for memory storage processing. Treatments that result in significant deviations from this pattern appear to produce retrograde amnesia.

1042 HOW DOES A BRAIN BUILD A COGNITIVE CODE? Stephen Grossberg. Dept. Math., Boston Univ., Boston, MA 02215.

This talk addresses the question: where codes of sensory or cognitive events can develop through experience, how are globally self-consistent hierarchies of such codes established and maintained? How is the local ignorance of each feature detector reconciled to yield global consensus? How is a coding error corrected when no individual cell knows that one has occurred? Previous work has shown that feedforward coding mechanisms are either unstable in a complex input environment, or must be shut off by a chemical switch that is insensitive to the behavioral meaning of the code. This paper indicates how competition between afferent data and learned feedback expectancies, or templates, can stabilize the code by buffering committed populations against continual erosion by new environmental demands. The gating phenomena that result lead to dynamically maintained critical periods, whether or not a chemical switch also exists, and to attentional phenomena such as overshadowing in the adult. The functional unit of cognitive coding is suggested to be an adaptive resonance, or amplification and prolongation of neural activity, that occurs when afferent data and efferent expectancies reach consensus through a matching process. The resonant state is a global, context-dependent representation of the data in STM. It embodies the perceptual event, or attentional focus, and its amplified and sustained activities are capable of driving slow LTM changes in the codes and expectancies that define the network. Mismatch between afferent data and efferent expectancies yields a global suppression of activity, and triggers a reset of codes in STM, as well as a rapid parallel search for uncommitted cells. This is accomplished by a nonspecific arousal mechanism that is gated by a chemical transmitter system, probably catecholaminergic, whose relative states of accumulation at antagonistic pairs, or dipoles, of on-cells and off-cells can shift the pattern of STM activity across a field of feature detectors. In particular, a sudden arousal increment in response to an unexpected input, or mismatch, can selectively reverse, or rebound, these relative activities in a graded fashion across all cells, thereby suppressing incorrectly classified populations. The cellular field is hereby conditionalized, and a rapid parallel scheme of hypothesis testing is elicited. A source paper is in Progress in Theoret. Biol., Vol. 5. R. Rosen and F. Snell, Eds. New York: Academic Press 1978.

1043 ENRICHED AND IMPOVERISHED ENVIRONMENTAL REARING: SELECTIVE ALTERATIONS OF PARADOXICAL SLEEP AND MEMORY. Baruch M. Gutwein* and William Fishbein. Psychobiology Lab., Dept. Psych., The City College of New York, New York, N.Y. 10031.

Mice were reared in either enriched, social control or isolate environments for 30 days. Environmental enrichment results in a significant and selective increase of paradoxical sleep (PS, or REM sleep) and also enhances recall of a multiple-trial, brightness discrimination task 28 days after training. Conversely, isolate reared mice exhibit a decrease in PS and impaired task performance relative to controls. These results support the hypothesis that PS plays an integral role in the maintenance and stability of long-term memory.

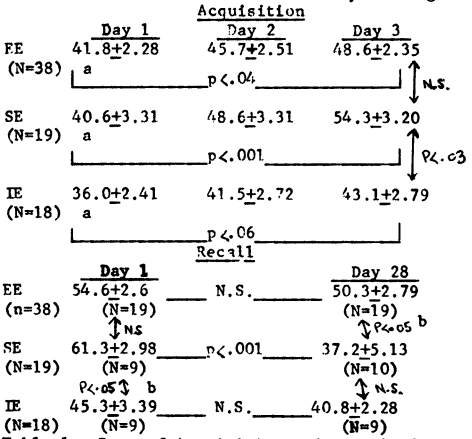

Table 1. Rate of Acquisition and Recall of Y-maze training (mean percent discriminations± SEM) in Enriched, Social Control, and Impoverished reared mice.

a. ANOVA, linear trend component for acquisition.
b. Duncan Range Test.

1044 POSTNATAL MALNUTRITION AND ITS EFFECTS ON FOOD MOTIVATION OF ADULT RATS: IMPLICATIONS FOR LEARNING STUDIES. Edward S. Halas, Patricia A. Burger*, and Harold H. Sandstead*. Dept. Psychology, University of North Dakota and Human Nutrition Lab., USDA, Grand Forks, N. D. 58202

Several studies have shown that prenatal and postnatal malnutrition impaired subsequent performance of animals on learning tasks that involved food motivation. These experiments are difficult to interpret because the food motivation of animals which have been exposed to early malnutrition may not be the same as normal animals. Two different types of postnatal malnutrition were studied. Ten pregnant Long-Evans rats were given a zinc deficient diet (ZD) and deionized water on the day of delivery. The dams were kept on the diet until the pups were 22 days old. Since zinc deficiency causes anorexia, a second group of 10 dams (PF) were fed the same quantity of the diet as was consumed by their pair mates (ZD). The PF dams were given 25 ppm/Zinc in their water. A third group of 10 dams (AL) were fed the diet ad libitum plus the zinc supplemented water. After weaning, all pups were fed Chow ad libitum plus tap water. At 90 days of age, the offspring began their food motivation test. Six males and 6 females were selected from each of the 3 dietary groups for a total of 36 rats. Once a week for the next 8 weeks, each pup was deprived of food for 24 hours and tested for food motivation in an operant box using a progressive ratio schedule. The ratio was increased by one after each reward. The "breaking point" was defined as failure to bar press for 15 min. The PF rats, both males and females, had significantly higher breaking points than the AL males and females. The higher food motivation of the postnatally malnourished rats (ZD and PF) has definite implications for learning studies. Performance on a learning task is affected by two critical variables: learning ability and motivation. When learning is studied, the motivation of the animals must be constant, otherwise a difference in performance between groups cannot be attributed solely to a difference in learning ability. These difficulties of interpretation are further complicated when the Yerkes-Dobson law is taken into consideration.

1045 THE ROLE OF THE HIPPOCAMPAL FORMATION IN HUMAN MEMORY: A MODEL. Eric Halgren. Brain Research Institute,UCLA,Los Angeles,CA 90024.

The preservation of general intellectual processes with the narrow exception of Recent Memory (RecM) after bilateral Hippocampal Formation (HCF) damage implies that those processes are located elsewhere: the model assumes that they are performed by the neocortex (NC) and that the brain processes correlated directly with the specific content of a conscious experience lies in a cell-assembly(CA) distributed throughout widespread NC areas. Residual excitation intrinsic to just-activated NCCAs underlies Short Term Memory. Remote Memory (RemM), also intact after HCF lesions, procedes using cognitive processes such as logical deduction, acting upon general knowledge of the world and specific knowledge of the item to be recalled. When a NCCA is activated, a portion of its efferents converge on a group of Hippocampal Gyrus (HCG) neurons. Very powerful and long-lasting post-tetanic-potentiation is known to occur within the HCF. As a result of this potentiation, a HCGCA activated by a certain set of afferents will fire when a subset of these afferents are later active, i.e., when a semantic cue is re-experienced. Persistent or repeated activation of an HCGCA will evoke progressively stronger excitation of the associated HCF neurons in the same lamella. There are several ways whereby the activation of an HCFCA by a cue could promote the activation of the NCCA associated with its other afferents: (1) direct projections of HCF neurons to NC, several of which have described, although they have not yet been demonstrated to be topographically reciprocal; (2) direct antidromic activation of NCCA synapses upon the HCGCA, perhaps only when the HCGCA is sufficiently excited by positive feedback via the HCF: (3) direct and indirect subicular cortex (HCF) efferents to the nonspecific thalamic nuclei may help focus attention on the relevant NCCA; and (4) Brainstem, hypothalamic, and septal projections of CA3 (HCF) neurons may help release interference from prepotent RemMs. These mechanisms, even if weak and nonspecific, would, in concert with the aforementioned cognitive processes involved in both RecM and RemM, lead to the activation of further cues. A cyclical process would thus be initiated that, if successful, would culminate in an avalanche of cues resulting in the reactivation of the sought-for experience as well as in a feeling of recognition.

Our model is consistent with existing data, integrates with neural and cognitive models elaborated at different levels of analysis, suggests experiments, and makes testable predictions. (Supported by grants NSF-BNS77-17070 and NIH-NS02808. My thanks to Thomas Babb and Paul Crandall)

1046 THE EFFECT OF CAROTID LIGATION ON STRIATAL CATECHOLAMINES AND BEHAVIOR IN THE GERBIL. J.D. Irvin, W.H. Vogel, B.R. D'Amore*, R.K. Ladman* and J.L. Alderman. Depts. of Neurosurgery and Pharmacology, Jefferson Medical College of Thomas Jefferson University., Philadelphia, Pa. 19107.

The effect of unilateral carotid ligation on striatal catecholamine fluorescence (CAF), learning and memory was studied in the gerbil. Animals were anesthetized with ether, the left carotid artery exposed and ligated, and sacrificed at 5 and 15 minutes, 24 and 48 hours and up to 3 weeks post-ligation. The left and right caudate (LC, RC) were examined for CAF by the Falck-Hillarp condensation technique. Learning and memory were studied with a shuttle box by conditioned avoidance response (CAR) acquisition and retention. Animals were observed from 24 hours to 17 days post-ligation for behavioral changes. Although no alterations in parenchymal CAF were observed 5 or 15 minutes post-ligation, there was a marked decrease, more so in the LC than RC after 24 hours, and a further drop by 48 hours. By 3 weeks, there was a return of CAF in the LC and RC. Acquisition of the CAR was delayed by 20% (from 97 CAR/animal to 77 CAR/animal) in animals tested 48 hours post-ligation, and by 28% (from 71 CAR/animal to 51 CAR/animal) when tested 15 days after ligation. Memory seemed little affected by ligation; animals tested at different times between 2 hours and 10 days after surgery showed no decrease in CAR's. The data indicate that biphasic changes occur in caudate CAF of both hemispheres after unilateral carotid ligation which are apparently not correlated with either learning nor memory behavior.

1047 CHOLINERGIC AND ADRENERGIC MODULATION OF CYCLOHEXIMIDE-INDUCED MEMORY IMPAIRMENT. Stanley J. Jackson and Herbert P. Alpern, Dept. Psych., Univ. Colo., Boulder, CO 80309.

A number of physiological mechanisms, such as protein synthesis, and the activity of several neurotransmitters, have been implicated in the formation and maintenance of memory. The primary evidence linking protein synthesis to memory comes from experiments utilizing drugs such as anisomycin, cycloheximide, and pyromycin which inhibit protein synthesis and impair memory. Recent evidence suggests that these agents could also be disrupting memory by several secondary actions that result in altered synaptic efficiency. This experiment was designed to investigate how cycloheximide-induced disruption of memory and learning might be modulated in ways that would support an interpretation based on the secondary actions of protein synthesis inhibitors.

Male and female HS/Ibg mice were trained in a T-maze, with footshock motivation, on a position task. Training continued until the subjects attained a criterion of 5/6 correct responses, or a maximum of 15 trials. One hr after initial training subjects were given 10 trials to the opposite maze arm, and 22 hrs later were retention tested over a block of 10 trials. A 5-min inter-trial interval was used throughout. With respect to drug manipulation individual groups were administered cycloheximide, anisomycin, or the vehicle 30 min prior to initial training, reversal training, or retention testing. All other agents (oxotremorine, clonidine, isoproterenol, and scopolamine) were administered 15 min prior to reversal training.

Neither anisomycin nor cycloheximide had any effect on acquisition of the initial problem. Both agents produced a deficit in acquisition of the reversal problem, which in general was also reflected during retention testing. A sex-dependent protection of the disrupting effects of cycloheximide was observed when noradrenergic agonists were given in conjunction with cycloheximine. Oxotremorine disrupted performance when given with cycloheximide. Scopolamine in conjunction with cycloheximide tended to attenuate the disruption of behavior.

These findings demonstrate that cholinergic and noradrenergic agents can modulate the disrupting effect that cycloheximide has on learning. With respect to the aspect of learning and memory that is impaired, it is clear that cycloheximide did not affect acquisition of the initial problem but did affect the acquisition and retention of the reversal problem. These results suggest that cycloheximide either induced perseveration of the initial behavior or enhanced proactive interference. Therefore, cycloheximide may influence both learning and memory. 1048 LEFT VISUAL FIELD IDENTIFICATION AND BILATERAL CROSS-INTEGRATION IN SPLIT-BRAIN HUMANS. Larry E. Johnson* (SPON: James Bonner). Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Split-brain humans can verbally categorize left visual field (LVF) stimuli and cross-compare visual stimuli presented simultaneously in the LVF and RVF. This contrasts with the theory of 'complete disconnection' in which communication between the two cerebral hemispheres following commissurotomy is severely limited.

All the split-brain subjects tested (4), when required to distinguish tachistoscopically presented letters and numbers from patterns, or identify single digit numbers as greater or less than '5', or odd-even (choice discriminations), can do so very accurately in both visual fields using either manual or verbal responses. And, like normal or partially split controls, they also respond as fast to stimuli in one field as the other. When asked to name stimuli, however, LVF accuracy varies between subjects and differs for various stimuli and sample sizes. Yet, in spite of these individual differences and in contrast with normals and a partial split, all of the split-brain subjects are alike in that they require significantly longer to name, whether correctly or incorrectly, LVF as compared with RVF stimuli.

When stimuli (colors, patterns, numbers, or letters) are presented simultaneously to the two visual fields, the ability to manually or verbally categorize two stimuli as same or different seems to be dissociated from the ability to name the stimuli.

There thus appears to be several mechanisms or pathways by which visual information can pass between the hemispheres of a split-brain subject: one which handles choice discrimination tasks very efficiently, one which operates when stimuli are to be named (but usually permits accurate LVF responses only in the youngest subjects), and one which allows bilateral stimuli to be compared as same or different. There is also evidence that some of these mechanisms may interfere with each other when tasks are combined.

1049 A QUANTITATIVE REGIONAL ANALYSIS OF PROTEIN SYNTHESIS FOLLOWING CYCLOHEXIMIDE INJECTIONS INTO THE RAT BRAIN: POSSIBLE UTILITY FOR THE STUDY OF MEMORY. Raymond P. Kesner and Lester M. Partlow. Depts. Psychol. and Pharm., Univ. of Utah, Salt Lake City, UT 84112.

Previous work has shown that bilateral injection of 10 or 20 µg of cycloheximide (CHX) into the amygdala, but not into the internal capsule, resulted in a time-dependent disruption of long-term retention of passive avoidance training, even though total brain protein synthesis was inhibited by less than 6%. In the present autoradiographic study, rats were subcutaneously injected with L-[methyl-^{14}C]-methionine following intracranial administration of CHX via implanted cannulas in either the amygdala or internal capsule. Autoradiograms from different brain levels were analyzed by use of an image-analyzing computer to quantitate the regional inhibition of protein synthesis. Control experiments showed that the image analyzer produced accurate optical density measurements and that these values were linearly related to the amount of radioactivity. Data indicate that the results obtained with this new histoanalytic technique do not differ from traditional biochemical techniques and the degree of inhibition of protein synthesis within the amygdala, internal capsule, caudate, cortex, hippocampus, thalamus, hypothalamus, and half brain following 20 µg CHX injection into the amygdala is both replicable and internally consistent. Furthermore, a dose-dependent relationship exists between degree of inhibition and amount of CHX injected. In addition, following amygdaloid injections of 20 µg CHX, a profound inhibition of protein synthesis (~60%) is found within the amygdala and internal capsule, while similar injections into the internal capsule result in marked inhibition in the internal capsule, but very little, if any, inhibition in the subjacent amygdala. In general, this new histoanalytic technique provides for a new quantitative approach for analyzing autoradiograms. The technique appears to be accurate, reliable and can be applied to the study of behavioral functions. More specifically, we will suggest that based on autoradiographic and behavioral data amygdaloid injection of CHX impairs memory by virtue of its action upon amygdala function.

1050 FACILITATION OF EYE-BLINK CONDITIONING BY HYPOTHALAMIC STIMULATION. H-J. Kim and C.D. Woody. UCLA Medical Center, Los Angeles CA. 90024.

More than 1000 pairings of click (CS) and glabella tap (US) may be needed to produce stable, short-latency conditioned eye blink responses in the cat (Woody et al. J. Neurophysiol. 1974). Some time ago Murphy and Gellhorn (J. Neurophysiol. 1945) found that hypothalamic stimulation (HS) could facilitate the production of electrocortically-elicited movements in an "enduring" manner. Voronin (Proc. Intl. Union Physiol. Sci. 1974) reported that adding HS to an auditory CS and US consisting of electrical stimulation of the motor cortex resulted in rapid acquisition of a short-latency conditioned startle response. He has suggested that the effect is associative.

We report the following preliminary results of pairing click CS with glabella tap (ISI, 340 ms) and HS (240 ms after tap). A hiss of intensity comparable to click CS was also presented 4 sec after HS as a discriminative stimulus (DS).

1. CRs emerged within 30-50 pairings or less.
2. The onset latencies of the major blink responses to CS, measured electromyographically, ranged between 80 and 320 msec.
3. CRs were extinguished when click and hiss were presented alone.
4. Responses elicited by the DS were smaller and less frequently observed than those elicited by the CS. Initially, before any associative pairing, subliminal myographic activity was greater to DS than to CS.
5. CRs were also smaller and less frequently observed when delivery of HS was moved to before click CS, tap, and hiss DS.
6. The effect of HS was location-dependent within the hypothalamus and was not seen with stimulation of the adjacent optic chiasm, which produced pronounced blinking.
7. Other effects were also produced including some sensitization, a facilitation of the response to glabella tap, and small, short-latency (onset: 15-50 msec) responses to click and frequently to hiss.

Intracellular recordings obtained from awake cats during these procedures indicate that the major effects of HS on the activity of cells in the motor cortex are: a) early excitation, b) late inhibition, and c) later excitation. (Supp. by AFOSR 76-3074 and NSF BNS 78-24146.)

1051 TIME DEPENDENT EFFECT OF POSTTRIAL AMYGDALOID LESIONS ON RETENTION OF AN INHIBITORY AVOIDANCE RESPONSE. K.C. Liang*, James L. McGaugh, Joe L. Martinez, Jr., Robert A. Jensen, and Beatriz J. Vasquez. Department of Psychobiology, School of Biological Sciences, University of California, Irvine, CA 92717, U.S.A.

There is considerable evidence that retention of learned responses is impaired by posttrial electrical stimulation of the amygdala. These findings suggest that the amygdala may be involved in modulating memory storage processes. An alternative possibility is that the amygdala is in some way involved in the permanent storage of memory. If the amygdala is involved primarily in modulating storage, then the impairing effect of a lesion given after training should decrease as the time between training and the lesion is increased. To investigate this issue, bipolar electrodes were implanted bilaterally into the amygdalae of male ARS Sprague-Dawley rats (60 days old). At least 8 days following surgery, the animals were trained on an inhibitory avoidance task using a 2 mA, 2 sec footshock, and tested after one of three retention intervals: 4 days, 7 days, 12 days. Five groups tested at each retention interval: unimplanted control (UC), implanted control (IC), pretraining lesion (IL), and delayed posttraining lesion (DL) (2 days before testing). The time between the training experience and delayed posttraining lesion was 2 days, 5 days, or 10 days for the various training retention intervals used. Control animals from these 5 groups were trained without footshock and tested at the 12 day retention interval. Bilateral amygdaloid lesions were made with radio frequency current (1.5-2.0 mA, 30 sec). Histological results showed the lesion area included primarily the lateral, basolateral, and basomedial nuclei as well as part of the pyriform cortex. As is shown in the table, a retention deficit occurred only when the amygdala was lesioned prior to, or within 2 days, following training. This time-dependency supports the notion that the amygdala is involved in memory modulation rather than as a site of memory storage.

Median Retention Latency (sec)

Retention Interval	UC	IC	PL	IL	DL
4 days	600[a]	417.4	56.9[a]	17.6[a]	42.5[b]
7 days	600[b]	185.9	8.9[a,c]	6.7[a,c]	59.6
12 days	600[a]	100.5	11.7[a,c]	9.8[b,c]	80.6
12 days no shock	10.5	2.3	2.3	2.7	2.4

a: $P < .02$ different from IC; b: $P < .05$ different from IC; c: $P < .02$ different from DL.

1052 DISRUPTION OF RABBIT HIPPOCAMPAL ACTIVITY AND CONDITIONED BEHAVIOR FOLLOWING ADMINISTRATION OF DELTA-9-THC. Laura A. Mamounas*, Donald J. Weisz*, Stephen D. Berry and Richard F. Thompson (Dept. Psychobio., UCI, Irvine, CA 92717).

Previous studies have shown strong correlations between hippocampal activity and classical conditioning of the nictitating membrane (NM) response in rabbit. Hippocampal physiology is known to be altered following administration of delta-9-tetrahydrocannabinol (THC), the major psychoactive constituent of marihuana. To examine further the relationship between hippocampal activity and NM conditioning, acquisition and performance of the NM response were correlated with hippocampal EEG and multiple unit activity (MUA) following i.v. administration of THC.

Microelectrodes were implanted bilaterally in the dorsal CA1 region in rabbit hippocampus. MUA and EEG were recorded prior to, during, and following the conditioning paradigm in which a tone CS was paired with a corneal air puff UCS to evoke NM extension. Daily, 117 trials with a 60 sec average ITI and 250 msec ISI were presented. Samples of hippocampal activity were recorded prior to and 10, 60 and 130 min following injection of drug vehicle, 0.5 mg/kg THC or 1.0 mg/kg THC. Frequency and amplitude of EEG waves were analyzed using a zero crossing program. The MUA from hippocampus will also be analyzed and will be discussed in relation to EEG and behavior.

Behavioral analyses indicated that there was a significant increase ($p < .05$) in trials to criterion (8 conditioned responses (CR) out of 9 consecutive trials) for animals in the 1 mg/kg THC group. In addition to the behavioral effects there was a significant shift ($p < .01$) in EEG frequencies. For the 10 min and 60 min post-drug samples there were shifts from pre-drug values of 4-8 Hz waves to both lower (0-4) and higher (12-22) frequencies. By 130 min post-drug, the EEG frequencies were returning to pre-drug levels. In a second experiment, administration of 1 mg/kg THC abolished CRs in animals conditioned in a non-drug state. The drug effect on CRs persisted for almost the entire conditioning session the first day of THC administration and for approximately one-half the session on the second day. By the third day only a slight effect on the presence of CRs was observed.

The concomitant impairment of hippocampal activity and NM conditioning following THC administration is consistent with findings of hippocampal involvement in learning.

1053 DIAZEPAM IMPAIRMENT OF DELAYED-RESPONSE PERFORMANCE IN YOUNG AND OLD RHESUS MONKEYS. John G. Marriott, Joanne S. Abelson* and Raymond T. Bartus. Pharmacology Department, Warner-Lambert/Parke-Davis Research Laboratories, Ann Arbor, MI 48105.

Benzodiazepines have been found to impair short-term memory (STM) in humans. The effects of diazepam on a non-human primate model of STM were examined to explore further the amnestic effects reported in humans. Both young and aged subjects were studied to test for possible age differences in response to diazepam treatment.

In Experiment I, five young rhesus monkeys (5-8 years, 4.5-5.1 kg) were tested on an indirect delayed-response task. The Automated General Experimental Device (AGED) was used to measure the animals' ability to recall the spatial position of a stimulus presented prior to retention intervals of various durations. Two retention conditions were used: a 0-sec, non-memory control condition; and a 60 sec, STM-dependent condition. Diazepam, at doses of 2.5, 5.0, and 10.0 mg/kg administered orally 30 min prior to behavioral testing, produced a dose-related decrease in delayed response accuracy only at the 60 sec, memory-dependent retention interval (drug X condition interaction, $p<.01$). However, no impairment was found on the 0-sec control condition, indicating that memory per se was affected by the drug and not non-specific, performance aspects of the task.

In Experiment II, six aged rhesus monkeys (18+ years, 4.2-5.6 kg) were tested on the same task using the same apparatus as in Experiment I. However, three retention conditions were used: a 0-sec, control condition; a 'short' delay, adjusted for each individual animal to yield a control performance level of 60-80% correct (range = 10-30 sec); and a 'long' delay, yielding a 40-60% correct performance level (range = 20-60 sec). Diazepam (1.25 and 2.5 mg/kg) administered 30 min prior to testing produced declines in performance only on the two memory conditions ($p<.01$). These effects are similar to those found in young animals, although more severe. Again, the amount of memory impairment was dose-dependent with higher doses of diazepam producing greater disruption of delayed-response performance.

Thus, the short-term memory impairments produced by diazepam in these studies on young and old monkeys appeared similar to those reported in humans. They also correspond to the well-known impairments of STM produced by the administration of anticholinergic drugs to animals and humans. Since diazepam is reported to block the release of acetylcholine in the brain, the amnestic effects of diazepam may be due to its effects on the cholinergic system. Benzodiazepine-induced impairments of STM may provide a useful model of memory impairments commonly associated with human brain disorders.

1054 ADRENAL MEDULLARY CATECHOLAMINES ARE NECESSARY FOR AMPHETAMINE-INDUCED ENHANCEMENT OF LEARNING IN RATS. Joe L. Martinez, Jr., Beatriz J. Vasquez, Robert A. Jensen, Rita B. Messing, Henk Rigter*, K.C. Liang*, and James L. McGaugh. Department of Psychobiology, School of Biological Sciences, University of California, Irvine, CA 92717, U.S.A.

We investigated, (1) the effects of 4-OH amphetamine (4-OH AMPH) a drug with limited ability to cross the blood brain barrier, on retention of an inhibitory avoidance task, (2) the effects of 4-OH AMPH on retention in rats sympathectomized with 6-hydroxydopamine (6-OHDA), (3) the learning ability of sham operated and adrenal demedullated (ADXM) rats, and (4) the effects of 4-OH AMPH and d-amphetamine (AMPH) on retention in ADXM rats.

In all experiments male ARS Sprague-Dawley rats (90 days old) were trained in a one trial inhibitory avoidance task with a 72 hr training-testing interval. In the first experiment rats received either SAL, .05, .21, .82, 3.3, 6.5, or 13.1 mg/kg (i.p.) 4-OH AMPH immediately following training, and were trained using a 500 μA, 1 sec footshock. A .82 mg/kg dose significantly facilitated retention performance ($p < .01$). In the second experiment rats were pretreated with 100 mg/kg 6-OHDA (i.v.) 24 hrs prior to training. Immediately following training they received either SAL, .05, .21, .82, or 3.3 mg/kg 4-OH AMPH. Two footshock levels, 500 μA or 750 μA were used. Pretreatment with 6-OHDA made the rats more sensitive to the effects of 4-OH AMPH. At the 750 μA footshock, a dose of .21 mg/kg 4-OH AMPH enhances retention ($p < .05$). Thus, 4-OH AMPH enhances retention performance and this effect is not dependent upon the integrity of the sympathetic nervous system.

Other experiments addressed the question of whether adrenal catecholamines are necessary for the action of 4-OH AMPH on memory. In one study, learning characteristics of SHAM operated and ADXM rats was studied. The operations were performed 7 days before training. A 500 μA and 750 μA footshock was used. In these conditions, retention performance of SHAM and ADXM rats was not different. In the final experiment ADXM rats were given either 4-OH AMPH (SAL, .21, .82, or 3.3 mg/kg) or AMPH (SAL, .25, 1, or 4 mg/kg) immediately following training. ADXM abolished the facilitatory effects of both 4-OH AMPH and AMPH, suggesting that adrenal catecholamines are necessary for the enhancement of retention. Further, 4-OH AMPH and AMPH enhance memory processes, in this particular task, at equimolar doses (Neurosci. Abs. 1978, 4, 261), even though only AMPH readily crosses the blood brain barrier.

1055 PLASMA CATECHOLAMINE RESPONSES TO TRAINING AND POSTTRIAL MEMORY MODULATORS. Richard McCarty and Paul E. Gold. Dept. Psych., Univ. Virginia, Charlottesville, VA 22901.

Several recent reports suggest that the sympathoadrenal medullary system may play an important role in modulating memory processing and in mediating the effects of various treatments on memory. These findings led us to examine plasma catecholamine responses to several treatments known to modulate memory processes.

In the first experiment, male Sprague-Dawley rats were trained in a one-trial inhibitory avoidance task (3 ma, 2 sec FS). Five sec after training, rats received 5 ma, 1 sec electrical stimulation of frontal cortex (FCX) through chronically implanted cortical screw electrodes. This stimulation is sufficient to produce widespread brain seizures and retrograde amensia. Other groups included home cage controls, rats exposed to the training apparatus without footshock (FS) or FCX, and rats that received FCX only. Plasma samples (0.5 ml) were obtained from previously implanted tail artery catheters immediately and 5, 10, 20, and 40 min after the various treatments. Plasma levels of EPI and NE were determined using a COMT radiometric-thin layer chromatographic procedure.

The results indicated that FS or FS + FCX resulted in an approximately 10-fold increase in plasma EPI immediately after the treatment. FCX alone did not result in an increase in plasma EPI concentration above that of non-footshocked or non-stimulated animals. The concentrations of EPI for all groups returned to basal values within 40 minutes. A similar pattern, but of lesser magnitude, was observed for plasma levels of NE.

In a second experiment (without training), posttraining injections of ACTH (0.3 or 3.0 I.U./rat, s.c.) or an ACTH analog (Organon 2766: 125 or 250 mg/kg) failed to alter either plasma EPI or NE concentrations. An EPI injection (s.c.) at a dose (0.1 mg/kg) that enhances later retention performance resulted in an increase within 5 min in plasma EPI concentrations from 230 pg/ml to approximately 1000 pg/ml that was maintained for 40 min. A higher dose (0.5 mg/kg) that can produce retrograde amnesia resulted in plasma EPI concentrations of approximately 4000 pg/mg during the 40 min after injection. Plasma NE concentrations did not change following the injection.

These results indicate that peripheral adrenergic responses do occur with training. Furthermore, an injection of EPI at a dose that enhances retention performance mimics the extent of the endogenous responses to a training FS. However, other treatments that modulate retention (i.e., FCX or ACTH) may not involve sympathoadrenal medullary activity.

Supported by U.S.P.H.S. research grant MH 31141.

1056 MEMORY, TESTABILITY & AFFECT IN LATE-ONSET DEMENTIA. Miller, N.E. Ctr. for Studies of the MH of the Aging, NIMH, Rockville, MD.

Behavioral measures of memory are important tools in the assessment of treatment efficacy in senile dementia. Yet clinical researchers often report that aged patients with altered brain function are untestable on both standard and newer experimental tests of memory. As part of a continuing investigation of memory impairment in late life psychiatric disorders, a series of information processing tests were administered to subjects positive for diffuse, chronic, organic brain disease. 11 Ss with altered brain function and 17 controls aged 50 and up were tested on a choice reaction time memory scanning task derived from Sternberg. Digit strings ranging in length from 1 to 6 digits were displayed in a sequential format for 3 seconds, followed by a 2 second delay. A single digit was then presented and the S was to decide whether the digit had appeared in the preceding sequence. Despite the presence of a 2 second delay and a warning buzzer, demented Ss appeared to have difficulty distinguishing where the stimulus set ended and the test probe began. They manifested a random level of performance, coupled with signs of fluctuating arousal, labile attention, psychomotor restlessness, impaired object constancy (& catastrophic anxiety in a few cases). It was not possible to determine whether the Ss had failed to understand the nature of the task or whether their primary memory abilities were impaired to such an extent that they could not maintain the stimuli in mind even briefly. Accordingly, systematic modifications were introduced to simplify the nature of the experimental task & to provide for the emotional security of respondents. 35 dements & 33 age-matched controls were tested on a modified scanning task in which the memory set was presented in a simultaneous horizontal array so that distinctions between stimuli & probe were highlighted. Anxiety & restlessness were specifically reduced by having the examiner remain in close physical & visual proximity to the S & by providing immediate verbal feedback regarding response accuracy following the completion of each trial. Performance of Ss with altered brain function was found to be significantly better than chance when both the affective parameters & simplification of experimental task were presented concomitantly. Neither modification alone resulted in improvement. These findings suggest that by lowering anxiety & restlessness, providing for object constancy & the reward aspects of reinforcement & ensuring that level of task difficulty is appropriate, aspects of the test environment that have a deleterious effect on performance are reduced. Once testability was possible, the results revealed serious deterioration in primary memory with senile dementia.

1057 DEGREE OF MEMORY IMPAIRMENT IN MONKEYS RELATED TO AMOUNT OF CONJOINT DAMAGE TO AMYGDALOID AND HIPPOCAMPAL SYSTEMS. Mortimer Mishkin and Richard C. Saunders*. Lab. Neuropsychology, NIMH, Bethesda, MD 20205.

Complete destruction of both the amygdala and hippocampus in monkeys yields a memory impairment resembling the clinical syndrome of global anterograde amnesia (Mishkin, Nature 273: 297, 1978; Spiegler & Mishkin, Neurosci. Abstr. 5: 1979). Two new experiments show that the effect of the combined removal is not all-or-none, but is graded in relation to the amount of conjoint damage to the two systems.

In both experiments, rhesus monkeys were trained preoperatively on a one-trial visual recognition task requiring memory of single objects for 10 seconds each, retrained on this task postoperatively, and then given a performance test in which their one-trial recognition ability was taxed with longer delays (up to 2 minutes) and longer list lengths (up to 10 objects). Their average scores on this performance test were compared with those of previously studied groups that had been given either separate amygdaloid and hippocampal removals (average score, 90%) or combined removals (average score, 60%).

In the first experiment, bilateral amygdalectomy was combined with unilateral hippocampectomy, and vice versa. Both groups obtained average scores near 75%, midway between those of the comparison groups. The results support the view that the amygdala and hippocampus are equally important for recognition memory and that there is a quantitative relationship between the amount of damage to the two structures and impairment of this function. The same conclusion could apply to man (cf. Penfield & Mathieson, Arch. Neurol. 31: 145, 1974).

In the second experiment, bilateral amygdalectomy was combined with bilateral transection of the fornix, a major hippocampal-diencephalic pathway; and bilateral hippocampectomy was combined with bilateral transection of the stria terminalis, a major amygdaloid-diencephalic pathway. Again both groups obtained average scores near 75%. These results point not only to joint participation by the amygdala and hippocampus in short-term memory, but to a wider, limbic-diencephalic circuit underlying this process (cf. Gaffan, JCPP 86: 1100, 1974).

1058 SCOPOLAMINE EFFECTS ON LEARNING AND RETENTION PERFORMANCE IN RATS. D. E. Moss, J. B. Rogers, P. L. Peck*, R. R. Salome*, and E. Hall*. Department of Psychology, University of Texas at El Paso, El Paso, Texas 79968.

Rats injected with 2 mg/kg scopolamine HBr i.p. 20 min before training on a Y-maze brightness discrimination task learned the task to a criterion of 10/10 in an average of 54 trials while placebo injected controls showed nearly identical learning with an average of 49 trials. Rats injected with scopolamine HBr before training, however, showed amnesia when retention tested without any drug or 20 min after an i.p. injection of 0.5 mg/kg physostigmine salicylate at either 1 day ($p<.05$) or 2 weeks ($p<.01$) after training. In contrast to these results, however, animals trained after 2 mg/kg scopolamine HBr and retention tested at either 4 or 6 weeks after training showed good retention when tested either without any drug or after 0.5 mg/kg physostigmine salicylate. A factorial analysis of variance for the 3 drug conditions (control, scopolamine before training only, and scopolamine before training and physostigmine before the retention test) and the 5 retention test intervals (1 day, 2, 4, 6, or 9 weeks) showed the interaction between drug condition and time was highly significant ($p<.001$). The occurrence of amnesia after training under one drug condition (scopolamine) and retention testing under another drug condition (either no drug or an antagonistic drug, physostigmine) is consistent with a "state dependent" explanation of amnesia. The reappearance of memory at the longer time intervals (4 to 6 weeks after training) with retention testing conducted under the same altered drug states, however, is not consistent with a "state dependence" explanation of amnesia. Insofar as amnesia was not produced by pretraining injections of methscopolamine nitrate or injections of scopolamine HBr immediately after training, the observed temporary scopolamine-induced anterograde amnesia was attributed to central nervous system effects of scopolamine that occurred during the learning process itself. These results support the idea that the learning process initiates a time-dependent change in a brain neurotransmitter system, probably the cholinergic system, that is necessary for memory recall. In addition, these results suggest that the function of the neurotransmitter system must be within some optimum limits for normal memory function and the presence of scopolamine in the brain during training seems to change the formation of the memory trace so that it is temporarily outside of the optimum limits and, therefore, memory cannot be recalled for a period of time after training.

1059 ENHANCEMENT OF 24-HOUR RETENTION IN PREWEANLING RATS BY POST-TRAINING HORMONE ADMINISTRATION. James M. Murphy, Susan G. Cooley*, and Paul E. Gold. Dept. of Psychology, Gilmer Hall, Univ. of Virginia, Charlottesville, VA 22901

Immature animals have poorer long-term memory than adults, and the rate of forgetting consistently decreases during early development. Recent evidence indicates that adult memory can be modulated (i.e., enhanced or impaired) by a number of posttraining treatments, including peripheral injections of some hormones such as epinephrine (E), which may mimic the endogenous release of E that occurs with more intense training. Because immature animals may not respond to stressful stimuli with an adult-like release of various hormones, the present study examined the possibility that the poor memory of young rats could be enhanced by post-training injections of agents previously demonstrated to facilitate memory in adults.

Rats 20 days of age and older demonstrated reliable 1- and 24-hr retention after training on a one-trial, shock-motivated (.6 mA/.8 sec) inhibitory-avoidance task, whereas 16 day olds retained the task for 1 but not 24 hr, and 14-day-old rats failed to show reliable retention at either test interval. We next examined the effects of several posttrial treatments on 24-hr retention performance of 16 day olds. Separate groups received subcutaneous injections immediately after training. Saline controls did not evidence 24-hr retention and were comparable to untreated 16 day olds. Posttrial E enhanced retention at .1 and 1 mg/kg, whereas groups receiving lower and higher doses (.01, .05, and 2 mg/kg) did not differ from the saline group and E no-shock controls. Norepinephrine (NE) also enhanced retention at 1 mg/kg but not at lower doses. These results concur with previous findings in adult rats that posttrial E and NE can facilitate memory of an inhibitory-avoidance task. However, ACTH and amphetamine also enhance retention in adults but failed to alleviate the poor memory of 16 day olds. This suggests that some memory modulatory systems may mature at different rates.

We had previously observed that transient posttraining decreases in forebrain NE concentrations in adults proved a reliable index of training-related stress and an accurate predictor of retention performance. In the present study, assay for post-training NE in 16 day olds indicated an adult-like response to the stress of footshock. In contrast to the adult findings, NE levels failed to differentiate between training conditions that predicted poor (footshock alone) and good (footshock + E) memory. These results suggest that this brain NE response occurs independent of 24-hr retention capacities in immature rats.

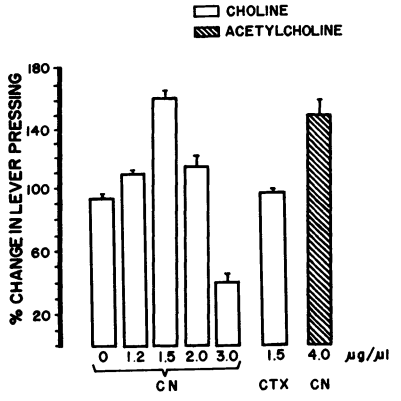
1060 EVIDENCE THAT HIRANO BODIES IN HUMAN BRAIN ARE PARACRYSTALLINE RIBOSOMES. L.V. O'Brien*, K. Shelley*, J. Towfighi* and A. McPherson* (SPON: S.H. Miller). Departments of Biological Chemistry and Pathology, The Milton S. Hershey Medical Center, Pennsylvania State University, Hershey, PA 17033.

Hirano bodies appear in certain forms of presenile and senile dementia such as Pick's and Alzheimer's diseases. They are spindle-shaped highly ordered inclusion bodies, 4 μm to 30 μm, that occur predominantly in the pyramidal layer of the hippocampus, particularly Sommer's sector area, and are associated with both neurons and glial cells. Ultrastructurally they appear as paracrystalline arrays of alternating filaments and electron dense particles occurring in the perikaryon adjacent to the nucleus. These particles have a highly polar distribution within the bodies with respect to the filaments. Orientations have been obtained that show the bodies to be composed of sheets of electron dense particles disposed in a two dimensional rhombic lattice with translations of about 130 Å. The size, distribution, staining characteristics and other morphological features suggest a striking similarity to membrane-bound ribosomes and we believe the Hirano bodies represent a crystalline form of rough endoplasmic reticulum. An Optronics high speed microdensitometer interfaced to a PDP11/40 computer was used to convert periodic images in electron micrographs to digitized data arrays which were subsequently analyzed by sequential Fourier transform methods. A digitally filtered and averaged image of the electron dense particle was produced. This image is virtually identical to that obtained for the 60s subunit of ribosomal particle from rat liver and shows its distinctive asymmetric "skiff" shape. Histochemical analysis of formalin fixed, paraffin embedded autopsy samples included specific staining for nucleic acids. Positive results were obtained with toluidine blue, ethidium bromide, and acridine orange. Concomitant light and fluorescence microscopy shows that the Hirano body binds acridine orange and fluoresces with a red component as expected for RNA; nuclei fluoresce yellow-green which is characteristic of DNA. Nissl substance in adjacent cells also fluoresces red. Negative results were obtained when the bodies were stained for acid mucopolysaccharides with colloidal iron and alcian blue. In conclusion, evidence is presented that Hirano bodies are ordered, crystalline arrays of membrane-bound ribosomes. The hippocampal region is associated with the consolidation of short term to long term memory and the predominant symptom of senile dementia is the impaired capacity to consolidate new memory. Thus the possibility arises that these bodies represent a form of ribosomal storage and the ribosomes are not available for the synthesis of memory associated proteins.

1061 CHOLINERGIC STIMULATION OF THE CAUDATE NUCLEUS AND OPERANT BEHAVIOR, IN CATS. Roberto A. Prado-Alcalá and Guillermo G. Cobos-Zapiaín*. Dept. Physiol., Sch. Med., Natnl. Univ. of México, P.O. Box 70250, México 20, D.F., México.

To test the hypothesis that cholinergic activity of the head of the caudate nucleus (CN) is involved in the processes underlying instrumental performance, the effects of microinjections of several doses of choline into this structure on lever pressing behavior (CRF schedule) were assessed. A dose dependent modification of performance was found: small doses improve while large doses impair lever pressing; choline applications into the parietal cortex were without effect. The facilitatory effects were reproduced by microinjections of acetylcholine into the CN. These data further support our working hypothesis.

Figure 1.- Bilateral microinjections (5 μl) were performed 10 min before experimental sessions. Results are expressed as % change relative to control sessions. CN, caudate nucleus, CTX, parietal cortex.



1062 FACILITATION OR DISRUPTION OF MEMORY BY ELECTROCONVULSIVE SHOCK (ECS): THE ROLE OF THE LOCUS COERULEUS (LC). Lia Prado de Carvalho*, Patricia J. Kubanis*, Steven F. Zornetzer. Dept. Neuroscience, Coll. of Med., University of Fla., Gainesville, FL 32610.

The role of the LC in complex behavior remains elusive. Recent studies from our laboratory reported that unilateral, but not bilateral, post-training LC lesions resulted in a dramatic (7 days) extention of the susceptibility period of recent memory to ECS-produced retrograde (RA) amnesia. The present study extends the analyses of the role of the LC in memory by investigating the effect of pre-training LC lesions on the consequences of ECS upon memory.

Male swiss mice (n=291) received small electrolytic lesions (500 uA anodal current for 10 sec.) delivered through twisted nichrome wire electrodes (125 um). Either 2 or 14 days after lesions, mice were trained in a single trial inhibitory avoidance task (FS 300 uA) and immediately returned to their home cages. After either a 24 hr or 14 day post-training period, transcorneal ECS or sham ECS (15.0 mA for 200 ms) was administered. All mice were tested for retention of the inhibitory avoidance response 24 hrs after ECS.

The results indicate that in all cases unilateral LC damage results in an extended susceptibility to ECS-produced RA. These results are compatible with, and extend, previous data from our laboratory using post-training lesions.

The most interesting result from this experiment is that ECS resulted, paradoxically, in facilitation of performance ($p = .04$) in mice receiving bilateral, but not unilateral, LC damage 28 days prior to ECS. Bilaterally, but not unilaterally lesioned animals not receiving ECS, had accelerated forgetting when compared to control lesioned mice ($p = .01$). This facilitated performance in bilaterally lesioned mice receiving ECS appears to result from the stimulation of the residual memory remaining after 14 days of accelerated forgetting in similarly-lesioned mice not given ECS. Control lesioned mice, either with or without delayed ECS, showed good retention. These data will be discussed in terms of the possible dynamic changes occuring in neurotransmitter systems mediating memory storage processes, and the role of both the LC and of ECS in altering these dynamic changes.

1063 AMYGDALOID MULTIPLE UNIT ACTIVITY DURING CLASSICAL CONDITIONING IN RABBITS. Russell T. Richardson* and Richard F. Thompson. (SPON: Pauline I. Yahr) Dept. of Psychobio., Univ. of Calif., Irvine, CA 92717.

Experimental manipulations of the amygdala can alter learning processes. For example, Kapp et al. (Neurosci. Abst. 3:236, 1977) have shown that lesions of the amygdala can retard conditioning of the nictitating membrane reflex in rabbits. To further investigate the role of the amygdala in learning, we recorded multiple unit activity bilaterally from the amygdalae of New Zealand white rabbits during classical conditioning of the nictitating membrane reflex. The training consisted of a 1 KHz tone (CS) presented 250 msec prior to a 100 msec puff of air to the cornea (US). One group of animals received two days of random presentations of the CS and US prior to two days of paired presentations. The other group received only two days of paired training. Multiple unit counts were made for 250 msec prior to CS onset (PreCS period), 250 msec after CS onset (CS period), and 250 msec after US onset (US period). All CS and US period counts were expressed as percent increases over the preceding PreCS period count.

The multiple unit activity during paired stimulus presentations showed a strong increase (121%) in the US period. However, this increase was not significantly different from that seen during unpaired stimulus presentations, and it did not show consistent changes as animals acquired the conditioned response. There was an average increase of 34% in activity during the CS period on paired training days, but, again, this response was not significantly different from the response on unpaired training days. Several cell populations showed a significant increase in firing in the CS period on both paired training days, and most of these populations were located in or adjacent to the cortical nucleus of the amygdala. Activity during the PreCS period showed a highly significant ($p<.001$) increase in firing over the training session on both paired and unpaired days. The CS and US period counts also increased over the training days, but because they were assessed relative to the PreCS counts, their activity showed no change over the day.

These findings indicate that, in contrast to the hippocampus, (Berger & Thompson, Brain Res. 145: 323, 1978), multiple unit activity in the amygdala does not display changes which can be strongly correlated with acquisition of the conditioned response.

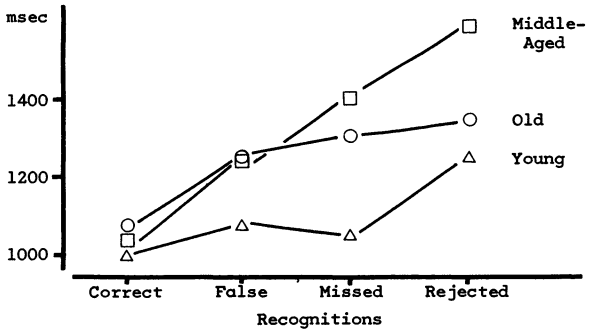
1064 RESPONSE DELAY WITH INCORRECT DECISIONS IN NONVERBAL RECOGNITION MEMORY. Walter H. Riege and Howard F. Wallach.* VA Med. Center Sepulveda & Dept. Psychiatry, Sch. Med., UCLA, CA 91343

It is commonly observed that it takes longer to recall verbal information as a person grows older. There is a reduction in processing effort which may be related either to the rate of scanning of items in memory, to the verbal memory load, or to the decision making (Fozard & Poon, 1978). We hypothesized that the perceived correctness or incorrectness of a recognition response influence decision times and that these would be age dependent.

Young, Middle-Aged, and Old persons (N = 57) were asked to answer as quickly as possible during recognition of 10 visual nonverbal designs recurring randomly in a series of 40. From unweighted means and signal detection analyses we observed that age groups differed in the decision criteria adopted for recurrent recognition ($F = 3.89$, df 2, 54; $p < 0.05$) but not in response times. Regardless of age, however, the response times differed significantly among correct, false, missed and rejected recognitions ($F = 14.00$; df 3, 54; $p < 0.01$). More specifically, the average time for correct recognitions was smaller ($p < 0.01$) than that for false or for missed recognitions. The results argue for a response delay of approximately 100 msec independent of age when nonverbal items fail to meet the parity check for recognition.



AVERAGE RESPONSE TIMES FOR RECURRENT RECOGNITION

1065 POST-STIMULATION ADMINISTRATION OF EITHER ACTH OR CORTISONE HAS INFLUENCES ON TIME-DEPENDENT PROCESSES UNDERLYING KINDLING. Robert P. Rose* and Wagner H. Bridger. Depts. of Neurosciences and Psychiatry, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

"Kindling" is a progressively augmenting convulsive response to intermittent focal electrical stimulation of brain. As a form of neuronal plasticity, kindling may depend on similar underlying mechanisms as other plastic processes, including memory consolidation. Much recent work has pointed to an important modulatory role for hormones upon synaptic plasticity. We have reported that hypophysectomy leads to alterations in kindling rate. The present study examines the effects of ACTH and cortisone on kindling of intact animals.

Male albino rats bearing implanted depth electrodes in basolateral amygdala of one side were subjected to daily electrical stimulation (150 uA, 60 Hz., 1 msec. pulses, 2 sec. train duration). Polygraph recordings of cortical (via calvarium screws) and amygdala activity were made before and after stimulation. After-discharge durations and all behavioral manifestations of seizure activity were noted. Daily stimulation was continued until animals manifested tonic-clonic convulsions on three successive days. Animals were given IP injections of ACTH (.03, .3, 1.0, or 3.0 IU/ animal), cortisone (2.5, 10 or 25 mg./ animal), or saline- either immediately or 4 hours after the seizure evoked by each daily stimulation had subsided. Animals were sacrificed after kindling was completed, and histology was performed (cresyl violet) to confirm electrode localization.

Administration of both ACTH and cortisone had significant dose-dependent influences on the rate of kindling in these animals- if given immediately after each stimulation. If the administration was delayed 4 hours, it no longer altered kindling rate. Therefore, it appears that these hormones can act in a retroactive manner upon processes initiated by the preceding stimulation in a way analogous to their action upon memory consolidation processes following training. These findings provide another example of hormonal modulatory influences upon neuronal plasticity, as well as supporting evidence for the strength of kindling as a model of processes underlying memory consolidation.

Supported in part by NIDA #DA02089 and NIH training grant # 5T32 GM7288 from the National Institute of General Medical Sciences.

1066 LONG TERM RETENTION DEFICITS IN RATS WITH LESIONS OF THE DORSAL HIPPOCAMPUS. Susan J. Sara and Michele David-Remacle. Michotte Ctr. Behav. Biol., U. Louvain, Pellenberg,Belgium.

Facilitation of a visually discriminated avoidance learning was observed in rats one week after they were lesioned in the dorsal hippocampus. While perseveration of a spatial strategy acquired during a pre-training session occurs in sham-operated and cortically lesioned controls, no such perseveration was observed in hippocampals. Elimination of the pre-surgical shaping session reduced the number of spatial strategies in all groups, but differences in trials to criterion and percentage of place strategies remained. Retesting animals 3 weeks after training showed that hippocampals and corticals had poorer retention than shams, while there were no differences in retention groups tested 24 h after training.

If the lesion is made four weeks prior to training, the same effect is seen on rate of acquisition and on perseveration of spatial strategies as when the lesion precedes the training by one week. Thus the behavioral differences seen after the 3 week training to test interval cannot be due to a recovery of hippocampal function.

A further study examined the effect of the lesion on long term retention of the discrimination acquired before surgery. It was found that there was no retention deficit under these conditions. The similarity between these results and the clinical hippocampal syndrome suggests that this preparation might be useful as an animal model for pharmacological studies aimed at alleviation of amnesia.

The nature of the memory deficit (e. g. increased rate of decay or retrieval dysfunction) remains to be investigated. Studies are presently under way to determine under what conditions this deficit can be reversed by increasing retrieval cues at retention testing or by using a reactivation procedure during the training to test interval.

1067 PARADOXICAL SLEEP AND MEMORY: LONG-TERM DISRUPTIVE EFFECTS OF ANISOMYCIN. Priyattam J. Shiromani, Baruch M. Gutwein* and William Fishbein. Psychobiology Lab., Dept. Psych., The City College of New York, New York, N.Y. 10031.

The effects of the protein synthesis inhibitor Anisomycin (ANI) on Paradoxical Sleep (PS or REM sleep), slow wave sleep (SWS), and retention of one-trial inhibitory avoidance training was examined in mice in three separate experiments. In experiment 1, mice injected with ANI 120 mg/kg and 210 mg/kg exhibited reduction of PS for 9 consecutive hours and ANI 40 mg/kg treated mice for 6 consecutive hours with no PS rebound in all three groups. ANI increased SWS commencing 3 hr. post-injection,continuing for 9 consecutive hr. and then returning to saline control levels. This effect was not dose-dependent. In experiment 2, part a, ANI 120 mg/kg and ANI 210 mg/kg but not ANI 40 mg/kg impaired retention measured 72 hr. after training. In experiment 2, part b, ANI 120 mg/kg and ANI 210 mg/kg induced amnesia from 3 to 9 hr. post-training but ANI 40 mg/kg was effective only from 3 to 6 hr. In experiment 3, the gradient of memory trace susceptibility to disruption by ECS was extended to 3 hr. post-training in mice given immediate post-training injections of ANI 40 mg/kg. ANI 20 mg/kg or ANI 10mg/kg alone or in combination with ECS was ineffective in extending lability of the memory trace. The results of this study indicate that PS in the 3 hr. period after aversively motivated training is not essential for memory processing. We suggest that memory stability and maintenance is dependent on PS occurring over a protracted time period.

1068 NEUROCHEMICAL EFFECTS OF AVERSIVE LEARNING IN RATS. D.O.Souza*, E.Elisabetsky*, R.D.Dias*, I.Izquierdo. Dept. Bioquímica, Inst. Biociências, UFRGS (centro), 90000-Porto Alegre, RS, Brasil.

Adult female Wistar rats were submitted to the following behavioral treatments in a shuttle-box: 1. pseudoconditioning (5-sec tones and 1 mA footshocks at random); 2. Pavlovian conditioning (tone-shock pairings on every trial regardless of responses made to the former); 3. avoidance without CS-US pairing (each tone followed at a randomly variable interval of 5 to 35 sec by a shock unless there was a shuttle response to the tone); 4. tones alone; 5. shocks alone. Inter-trial interval was 10-40 sec in all cases. Sessions were 5 or 25 min long. Two biochemical parameters were measured in hippocampus, caudate nucleus, rest-of-the-brain, and liver of these animals: a) in vivo incorporation of 32-P to non-histone acid-extractable chromosomal proteins (NAEP); b) in vitro incorporation of 14-C-leucine to total protein. Data were expressed as dpm/mg NAEP / dpm/mg total protein in the 32-P experiments, and as dpm/mg protein / dpm in total homogenate in the 14-C experiments. Statistics were by multiple-range analysis (Null hypothesis rejected at 1 or 5% level). There was an increased phosphorylation of hippocampal and caudate NAEPs after 5 min of Pavlovian or avoidance learning, and of NAEPS from the rest-of-brain fraction after 25 min of shocks alone. No change relative to intact controls was detected in the other groups. An increased incorporation of 14-C-leucine into hippocampal and caudate total proteins was observed after 25 min of avoidance training, 1 hr later in animals submitted to either tones or shocks alone, and 2 hr later in rats submitted to the Pavlovian procedure. These results argue against a specificity of the biochemical parameters examined in relation to learning or memory processes; but point out, instead, to a selective effect of the learning factors studied on their timing, and to a possible inhibitory influence of pseudoconditioning on their occurrence. The latter is of importance since pseudoconditioning has recently been shown to be an inseparable component of aversive learning, classical or instrumental. (Supported by CNPq, FAPERGS, and FAPESP, Brasil).

1069 ASSOCIATIVE MEMORY SEVERELY IMPAIRED BY COMBINED AMYGDALO-HIPPOCAMPAL REMOVALS. Brenda J. Spiegler* and Mortimer Mishkin (SPON: B. J. Richmond). Lab. Neuropsychology, NIMH, Bethesda, MD 20205.

Damage limited to the hippocampus of monkeys has failed to reproduce the profound anterograde amnesia that has been attributed to such damage in man. By contrast, combined damage to the monkey's hippocampus and amygdala does appear to reproduce the syndrome. A severe memory loss following combined amygdalo-hippocampal ablation was found recently on a visual recognition task in which the animal had to decide on the basis of a single previous experience whether a test object was familiar or novel (i.e., had previously been presented or not) (Mishkin, Nature 273: 297, 1978). The present study demonstrates that the impairment following the combined limbic lesion is not limited to such stimulus recognition memory, but extends to stimulus-reward associative memory as well.

The rhesus monkeys that served as subjects were part of an earlier study of associative memory (Spiegler & Mishkin, Neurosci. Abstr. 4: 263, 1978) in which the animals had to decide on the basis of a single previous experience whether a test object was positive or negative (i.e., had previously been baited or not). It was found in that study that bilateral lesions of either area TE or the amygdaloid complex produced a marked but recoverable deficit, whereas bilateral lesions of either area TEO or the hippocampal complex had only a mild effect. In the present experiment each animal received an additional bilateral lesion, the combined damage being confined either to the temporal cortical area or to the temporal limbic area. Thus, animals originally given TE lesions were now given adjacent TEO lesions, and vice versa; similarly, animals originally given amygdala lesions now received adjacent hippocampal lesions, and vice versa.

The effect of an additional cortical lesion was indistinguishable from the effect of that particular lesion given by itself. That is, the addition of a TE to a TEO removal produced the same marked-but-recoverable deficit as a TE removal alone, while the addition of a TEO to a TE removal produced the same negligible effect as a TEO removal alone. (Only when a bilateral prestriate ablation was added in a third stage did a severe and lasting deficit ensue.) By contrast, the serial limbic lesions produced a seemingly permanent loss irrespective of the sequence of lesions. None of these animals reestablished one-trial learning of object-reward associations within the 2000-trial limit of postoperative testing. Apparently, the amygdala and hippocampus can serve as partial substitutes for each other in a limbic memory mechanism, such that only their combined removal will yield an irrecoverable memory loss.

1070 ANTEROGRADE AMNESIA AND MEMORY FOR CONTEXTUAL INFORMATION: Larry R. Squire, Lynn Nadel* and Pamela C. Slater*. Dept. Psychiat., Univ. Calif. San Diego, La Jolla, CA 92093.

Confusion about the temporal order of events has sometimes been regarded as the fundamental defect in amnesia. Accordingly, it has been suggested that amnesia might reflect a selective defect in assigning context to items that are to be remembered. An alternative hypothesis is that in normal memory as well as in amnesia contextual information is simply more fragile than other kinds of information.

We tested the patient N.A., who has chronic amnesia for verbal material, a group of psychiatric patients receiving bilateral electroconvulsive therapy, and matched control patients. Subjects read two lists of sentences 3 min apart, and then at varying times afterwards were given a yes/no recognition test and were also asked to judge which of the two lists the sentences had appeared on. For all cases, contextual information was deficient in amnesic patients. However, when the recognition memory of control Ss had declined as a result of forgetting to a point where it was equivalent to the recognition performance of amnesic Ss, contextual judgments of control Ss declined such that they matched the levels observed in amnesia. Thus, contextual information is fragile in amnesic patients, but it is fragile as well in normal Ss during the course of forgetting. The evidence suggests that the difference between normal and amnesic Ss may be understood in a quantitative way, and may resemble the difference between normal Ss tested shortly after learning and normal Ss tested long after learning.

1071 ADRENERGIC ANTAGONISTS: ATTENUATION OF RETROGRADE AMNESIA. Debra B. Sternberg and Paul E. Gold. Dept. Psych., Gilmer Hall, Univ. of Virginia, Charlottesville, VA 22901.

Previous results (Gold and Sternberg, Science, 201, 367-9, 1978) indicate that when injected 30 min before training, the α-adrenergic antagonist, phenoxybenzamine (2 mg/kg), attenuates retrograde amnesia produced by most classes of treatments (i.e., supra-seizure frontal cortex stimulation, sub-seizure amygdala stimulation, cycloheximide, pentylenetetrazol, and diethyldithiocarbamate). The present study employed several adrenergic antagonists in order to assess the generality of these findings.

Animals were trained on either a one-trial inhibitory (passive) avoidance task or a visual discriminated avoidance Y-maze. Thirty min prior to training animals received an injection of the β-adrenergic antagonist propranolol (0.5 mg/kg), saline, or one of the following α-adrenergic antagonists: phentolamine (10 mg/kg), piperoxane (5 mg/kg), or phenoxybenzamine (2 mg/kg). Shortly after training, the animals received frontal cortex stimulation (5 ma/1 sec) through implanted cortical screw electrodes. The results indicate that pretreatment of rats with any of these α- and β-adrenergic antagonists attenuates the production of retrograde amensia.

In addition, we examined the effects of α- and β-adrenergic antagonists on amnesia produced by sub-seizure amygdala stimulation. Thirty min before training, animals received injections of either phenoxybenzamine (2 mg/kg), propranolol (0.5 mg/kg), or saline. Animals were trained on either of the tasks described above. Shortly after training, the animals received electrical shock of the amygdala (60 μa, 100 Hz, 0.1 msec monophasic pulses, 10 sec train duration) through bilaterally implanted electrodes. Twenty-four hours later, the animals were tested for retention. Consistent with the findings described above, pretreatment with the α- or β-adrenergic antagonists resulted in attenuation of amnesia produced by amygdala stimulation in both learning situations.

Thus it appears that several adrenergic antagonists can attenuate the amnesias produced by different treatments. These findings add further support to the view that there may be a common adrenergic mechanism underlying retrograde amnesia produced by many amnestic treatments.

Supported by research grants BNS-76-80007 (NSF) and MH 31141 (NIMH).

1072 THE EFFECTS OF CHRONIC ADMINISTRATION OF AN ANTICHOLINERGIC ON VERBAL MEMORY IN PARKINSON'S DISEASE PATIENTS. Karl Syndulko, Eugene R. Gilden*, Edward C. Hansch*, Janet A. Lemmon*. Alfred R. Potvin, and Wallace W. Tourtellotte*. Neurology Svc., VA Wadsworth Med. Ctr., Los Angeles, CA 90073.

Anticholinergics have a long history of use in the treatment of symptoms of Parkinson's disease and are currently in common use either alone, or more often in combination with other antiparkinsonism medications. Recent studies have suggested that the putative neurotransmitter acetylcholine (Ach) may also play an important role in certain types of memory function. Acute injections of central acting Ach agonists have been shown to facilitate performance on memory tasks, while acute administration of Ach antagonists appears to disrupt memory functions transiently, particularly those involved in acquisition of new information. In a double-blind, cross-over study the therapeutic efficacy of the anticholinergic, benztropine mesylate (Cogentin [R] was compared with placebo in Parkinson's disease patients on their best dosage of levodopa-carbidopa combination (Sinemet [R]. Each of 29 male patients (age 45-80 yrs) with idiopathic Parkinson's disease was given incremented dosages of the anticholinergic (max. 2 mg) or placebo over a ten week period, washed out for 5 weeks then crossed-over to either placebo or the anticholinergic for another ten week trial. The patients were tested for acquisition of new verbal information before, during, between and after the two ten week trial periods. On each occasion, they were given four trials to learn a list of twenty words. Patients showed small, but signficant impairment of acquisition and recall while on the anticholinergic as compared to their performance while on placebo. These results with chronic administration of an anticholinergic extend previous findings that implicate central Ach in memory mechanisms, and also suggest that other chronically administered anticholinergics used in medical treatment should be carefully evaluated for their effects on memory function.

1073 PHASESHIFT INDUCED AMNESIA: EFFECTS OF SHOCK INTENSITY AND ACTH 4-10. Walter N. Tapp* and Frank A. Holloway. Dept. Neurosci., N.J. Med. School, E.Orange, NJ 07018 and Dept.Psychiatry & Behav.Sci.,Univ. Okla. Health Sci.Ctr.,Oklahoma City, OK 73190.

Recent studies (Neurosci. Abstr. 3: 241, 1977) showed that phase-shifting circadian rhythms shortly after passive avoidance training can produce retrograde amnesia in rats. In order to further analyze this phenomenon, the effects of shock intensity and ACTH 4-10 (Org OI 63) were studied.

Male, albino rats were entrained to LD 12:12 prior to passive avoidance training. Rats were trained in a one-trial passive avoidance task with one of two levels of footshock (1.4 mA or 0.7 mA). Shortly after training, the LD cycle of phase-shifted groups was shifted by 12 h. Phase-shifted rats were housed in cages equipped for photocell activity recording. Activity records provided a measure of the progress of the phase-shift. Rats were tested 7 days after training, after the phase-shift was complete. One hour prior to testing, rats were injected with ACTH 4-10 (Org OI 63) (100 μg/rat, s.c.) or with an equivalent volume of vehicle.

As in earlier experiments, phase-shifting circadian rhythms after training with 1.4 mA impaired retention performance ($p < 0.01$). In contrast, phase-shifting circadian rhythms after training with 0.7 mA facilitated retention performance ($p < 0.01$). These differences in the effects of phase-shifting after different shock intensities suggest that phase-shifting alters memory by acting as a non-specific stressor.

ACTH 4-10 given 1 h prior to testing facilitated retention performance of a 1.4 mA, phase-shifted group ($p < 0.01$), suggesting that the disruptive effects of phase-shifting are due to retrieval effects. ACTH 4-10 further improved the performance of a 0.7 mA, phase-shifted group ($p < 0.05$). However, ACTH 4-10 did not facilitate the performance of 0.7 mA, unshifted controls, suggesting that phase-shifting facilitates retention by enhancing storage.

Phase-shifting appears to facilitate or disrupt memory as a result of its stressful consequences. However, phase-shifting appears to alter different memory processes depending upon whether it facilitates (storage) or disrupts (retrieval) retention.

1074 RESPONSES OF SINGLE HIPPOCAMPAL NEURONS DURING CLASSICAL CONDITIONING. Richard F. Thompson and Theodore W. Berger. Dept. of Psychobio., Univ. of Calif., Irvine, CA 92717 and Dept. of Psych., Univ. of Pittsburgh, Pittsburgh, PA 15260.

Responses of over 130 single hippocampal neurons recorded during classical conditioning of the nictitating membrane (NM) response in the rabbit were examined. All neurons were first classified as showing antidromic (and thus identified as pyramidal cells) or orthodromic activation following single shock stimulation of the fimbria-fornix. Antidromic identification required short (<3msec) latency activation, low variability in latency and ability of such units to follow high frequency stimulation. Orthodromic classification was made on the basis of longer (>3msec) latency activation, greater variability in latency and an ability to follow only low frequencies of stimulation. All cells were analyzed with respect to several pretraining characteristics of spontaneous activity (i.e., complex vs. simple spike patterns, spontaneous rate, etc.), as well as their subsequent firing patterns recorded during conditioning trials.

Clear correlations were found to exist between cell type as defined by fornix stimulation and their classifications according to the above criteria. The majority of cells identified as pyramidal neurons (i.e., antidromically activated) had lower (<10/sec) spontaneous rates and showed complex modes of unit firing during spontaneous periods. Orthodromically activated cells tended to have high (>10/sec) spontaneous rates and did not show complex modes of discharge. Within conditioning trials, the majority of pyramidal cells increased rate of discharge and showed patterns of unit firing that corresponded closely to the topography of conditioned NM movement. The majority of cells showing orthodromic activation inhibited during conditioning trials. Of cells that could not be activated in any manner after fornix stimulation, a subset having very low (<1/sec) spontaneous rates and showing complex modes of unit firing maintained or decreased firing rate during training trials. The specific pattern of increased unit activity seen for pyramidal neurons was shown to be learning-dependent. That is, pyramidal cells in animals given unpaired control training showed little or no increase in firing rates during CS-alone or UCS-alone trials. In addition, the majority of pyramidal cells recorded from conditioning animals on the first day of training showed growth in the amount of unit increase across initial paired trials.

Supported by research grants from the Alfred P. Sloan Foundation (TWB), the National Science Foundation (RFT BNS76-17370) and the McKnight Foundation (RFT).

1075 SINGLE DIGIT FLEXION-EXTENSION IN THE MONKEY, CALLITHRIX JACCHUS. Thomas J. Tobias and Dao Tien Duong.* C. and O. Vogt Institute for Brain Research, and IV Department of Anatomy, University of Duesseldorf Moorenstrasse 5, 4000 Duesseldorf, West Germany.

The recent application of intracellular recording techniques in operantly reinforced animals engaged in forelimb movement has led to a search for a paradigm which might produce a more tranquil behavioural response than the commonly employed lever press, thereby permitting neuronal penetrations of longer duration (Tobias, 1975,1977; Matsumura,1977). While some improvement might be expected from employing floating electrodes (Woodbury,Baker and York, Voronin, King and Skinner), it would seem reasonable to assume that a narrowly delimited movement of the forelimb might reduce vibrations affecting recording stability.

In the present experiment we report the feasibility of training marmosets to flex and extend a single forelimb digit without employing a manipulandum. These small (300 g) South American monkeys have been selected for several reasons: completely lissencephalic dorsal aspect of the cerebral cortex (35mm A-P), small heart with concomitant reduction in cerebral pulsation, and high fecundity. Of six animals, two, serving as controls, were trained to press a lever using only one finger. The remaining monkeys were reinforced with water on a variable ratio schedule, for alternating their finger in a slot (10mm x 3mm) past either the 4th and 2nd, or the 4th and 6th of eight infrared detecting pin photodiodes, positioned parallel to and 3 mm below the slot in an array 2.5 mm apart. Use of more than one digit was discouraged by occurence of a tone instead of water upon interruption of more than three of the photodiodes. Total responses were counted and stored in RAM for subsequent display on an oscilloscope following each 2 hour session. After 1-3 months of daily training it was possible to obtain from all four animals an uninterrupted pattern of movement throughout the session (2000responses). Photographs of the hand taken at 300 msec intervals reveal the distal and middle phalanges of a single finger serving as a radius moving circumferentially in a 120 degree arc extending from a horizontal position at the distal tip of the slot to a vertical position at the proximal edge. The next step will compare intracellular recording stability in both groups, an experiment which is about to commence.

1076 DELAYED RESPONSE LEARNING AND BRAIN BIOGENIC AMINES IN CATS. Luc Vachon*, Andrée G. Roberge and James Everett*. Dépt. Bioch., Fac. Méd., U. Laval, Québec, CANADA, G1K 7P4.

In an attempt to determine the involvement of CNS biogenic amines in short term memory and learning processes, the effects of a delayed response task (DR) on norepinephrine (NE), dopamine (DA), serotonin (5-HT) and 5-hydroxy-indolacetic acid (5-HIAA) concentrations were investigated in normal cats. Moreover, two groups of cats have received Metergoline (Liserdol, Farmatalia) (14 µg/kg/day) or L-DOPA (30 mg/kg/day) daily, beginning four days before the training period. Cats were given 48-trials a day in a modified WGTA apparatus with two food wells, 24 of which were at 0 sec. delay, and 24 trials with delays varying according to individual performance (titration technic). Treated cats were trained 3 hours after drug administration.

At 0 sec. delay, Metergoline has not produced any change in performance (number of good responses) neither in response latencies. Three of the eight L-DOPA treated cats have not responded at all, whereas cats who have responded showed no difference in performance, but a significant increase in response latencies, suggesting a non mnesic effet of L-DOPA. With delays longer than 0 sec., normal, Metergoline and L-DOPA treated cats have showed a progressive improvement of their performance during the first six days. A plateau is then reached for the controls and L-DOPA treated cats whereas Metergoline treated cats have shown an unexplained decrease in performance. L-DOPA treated cats showed longer response latencies whereas Metergoline treated cats have not shown any significant difference from controls.

Biochemical assays, done on different structures in the brain, show that training on DR in normal cats produces a significant increase of 5-HT and 5-HIAA content in the piriform lobe and mesencephalon (without raphe nuclei), a decrease of NE in the piriform lobe and frontal cortex and of DA content in the piriform lobe. The interaction of training on treatments was also biochemically investigated. The results show that DR training interacted with Metergoline effects on 5-HT and 5-HIAA concentrations in the mesencephalon and on NE and DA content in the frontal cortex and piriform lobe, respectively. On the other hand, such an interaction was also found in L-DOPA treated cats, for NE and DA concentrations in the frontal cortex and piriform lobe, respectively.

These results suggest a selective involvement of the cerebral 5-HT, NE and DA in DR training. A biochemical equilibrium between these neurotransmitters based on different neuroanatomical pathways is suspected: the mesolimbic system and the mesencephalic reticular formation deprived of its raphe nuclei in term of inputs and outputs.

1077 EFFECTS OF L-PROLINE, SOME PROLINE ANALOGS AND SOME OTHER AMINO ACIDS ON SPREADING DEPRESSION IN THE CHICKEN RETINA. A. Van Harreveld. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

It has been suggested (Van Harreveld, 1978) that spreading depression (SD) in the chicken retina can be based on two mechanisms. In one a release of glutamate from the cellular element is primarily involved, in the other a release of K^+. The concept of two mechanisms of SD in the retina can explain the effect of L-proline on this phenomenon. L-proline has been found to suppress SD in the chicken retina at low concentrations (1.5-2.5 mM), at higher concentrations (5-7 mM) it again allows SD in a larger percentage of the experiments. At still higher concentrations (10 mM) it again suppresses SD. The low concentration effect has been postulated to be due to a competition of L-glutamate and L-proline for glutamate receptors. The L-proline attached to these receptors would tend to release intracellular K^+ by an increase in the neuronal membrane permeability. This would facilitate the K^+-based SD observed at L-proline concentrations of 5-7 mM. A similar effect, inhibition at low concentration, and SD at moderate concentration was observed in experiments with a number of proline analogs, such as 3,4 DL-dehydroproline, 4 L-hydroxyproline (both with a 5 member ring), and L-baikiain (which has a 6 member ring). D-proline was without effect as was DL-pipecolic acid (which differs from L-baikiain in the absence of a double bond in the ring). L-azetidine-2-carboxylic acid with a 4 member ring inhibits SD in rather high concentrations. It is of interest that L-proline and those of its analogs which have a biphasic dose effect on SD, exhibit an amnestic effect on one-trial avoidance learning in the chick. A number of other compounds have been tested such as L-glutamine, L-isoleucine, L-norleucine and L-pyroglutamate which did not affect SD in the chicken retina.

1078 PAPAVERINE FACILITATES PASSIVE AVOIDANCE IN MICE.
John W. Villiger,* and Douglas L. Chute, Dept. Psych. Univ. of Otago, Dunedin, New Zealand.

Because of our interest in cAMP as a second messenger potentially mediating memory we decided to test the behavioural effects of the phosphodiesterase inhibitor, papaverine HCl. A preliminary experiment with 8 female NHI/a mice indicated a significant ($p<.025$) performance facilitation in passive avoidance. In a more complete study, 63 male mice of the same strain received a 1 mA 1.5 sec duration footshock after stepping through a guillotine doorway. This shock level was chosen so that undrugged animals showed an intermediate performance level in the 24-hr retention (latencies approx. 300 sec). Maximum latency was 600 sec. Depending upon group designation animals received a 50 mg/kg I.P. injection of papaverine HCl or an equivalent volume of the NaCl vehicle. Group P-20 was injected with drug 20 min prior to training. This time allowed animals to recover from the overtly observable sedative effects of papaverine. Group P+O received the drug immediately *after* acquisition. Group S+O received saline. Group P+60 was given papaverine 60 min after acquisition. A drug side effect control group received the drug but no footshock (PNFS+O).

All groups except PNFS+O showed significant learning ($p<.001$) as measured by increased retention test latencies. However groups differed in retention performance where a Kruskal-Wallis ANOVA showed a significant ($H=22.69$, df 4, $p<.001$) effect across groups. Group P-20, S+O and P+60 showed no significant differences between their respective median latencies (208 sec, 242 sec, 187 sec). Group P+O showed significant performance facilitation (at least $p<.05$) compared to all other groups. (md. Lat 355 sec). Because papaverine was administered after acquisition, and because of the apparent time dependent effect with no observable drug side effects at retention testing we speculate that papaverine may facilitate memory consolidation and/or retrieval. Whether this occurs as a result of changes in blood flow, cAMP or some other effect is as yet undetermined.

1079 Pathophysiologic Correlates of Cognitive Function
Bruce T. Volpe* William Hirst* Michael S. Gazzaniga (SPON:F.Plum). Division of Cognitive Neuroscience,Cornell University Medical School and Rockefeller University, New York,N.Y. 10021.

Two unusually impaired amnesic patients have been extensively evaluated using current methods of cognitve psychology, and their disorders have been subsequently correlated with computerized tomography (CT). Results based on a variety of paradigms revealed that the memory disorder rested in the processes underlying memory function. The first patient,a fifty two year old woman,recovered from a dense retrograde and anterograde amnesia to be left with a devastating inability to remember the temporal order of events. Although she performed substantially below a control group when free recalling a list of unrelated words,her recognition for items in the list was unimpaired. However her recognition for the temporal relation between these items was severely impaired,as evinced by her chance performance on the part of a task in which random queries probed the relative recency of previously presented items. Her CT scan revealed the clips from a successful repair of a ruptured peri- callosal artery aneurysm. Reminiscent of the transient Korsakoff-like syndrome described in the post cingulectomey state,she suffered a qualitatively similar yet permanent injury. The second patient, a fifty six year old man,had severe anterograde amnesia and performed like case H.M. on traditional tests. Analysis on another level however,suggested that impaired transfer from short term to long term memory,commonly called consolidation block could not completely explain this disorder. Techniques,such as semantic ordering tasks and cueing,successfully and predictably facilitated remembering,so that the situation may be viewed more productively as a failure of information processing,either involving encoding or retrieval modes. In spite of this profound cognitive impairment there was no evidence for generalized dementia or destruction of the hippocampus. In sum our evidence is consistent with the hypothesis that a variety of central brain structures and not necessarily the hippocampus are involved in the memory process. (Aided by USPHS Grant No.25643,and the McKnight Foundation).

1080 RECALL IN AMNESIC PATIENTS AS CONTROLLED BY ACQUISITION STRENGTH.
C. Douglas Wetzel & Larry R. Squire. Psychiatry Dept., Univ. of California & Veterans Hospital, La Jolla, CA, 92161.

Amnesic patients benifit from partial information cues to the extent that they initially acquire information. After a single presentation of a word list, control subjects showed better recall with meaningful semantic retrieval cues, compared to recall with either a rhyme cue or a cue consisting of the initial two letters of the word. By contrast, amnesic patients performed poorly and showed equivalent retrieval under all cue conditions. This amnesic pattern of performance could be mimicked in the recall of control subjects who were tested one day after learning instead of 1 minute after learning. In addition, amnesic patients given repetitions of the learning list could mimic the pattern of control subjects tested 1 minute after a single list presentation. Thus, with greater acquisition strength, the amnesic patients showed the normal pattern of performance: superior retention of semantically cued words.

The results suggest that the pattern of performance in amnesic patients can be largely determined by the strength of initial acquisition. As in other studies of anterograde amnesia, apparently qualitative differences between amnesic patients and control subjects can often be understood as quantitative differences in memory strength.

1081 IMPROVEMENT OF MEMORY IN FOUR DIFFERENT SITUATIONS BY SELF-STIMULATION.
Norman White and DanielCoulombe*, Dept. of Psychol., McGill Univ., Montreal, Canada.

Four experiments demonstrating the improvement of memory by contiguous, but non-contingent electrical self-stimulation of the brain (ESSB) are described. The fact that four learned behaviors of such diversity are affected in similar ways by post-training ESSB shows the generality of the phenomenon. The subjects in all experiments were rats with chronic electrodes implanted in the dorsolateral quadrant of the lateral hypothalamus; all bar pressed for ESSB at a rate of at least 180 responses in 5 min. In all experiments the rats were trained on a task in a test apparatus and were then allowed to respond 1000 times for ESSB in a different apparatus. Testing on the learning task was done 24 hrs. later. 1) Secondary Reinforcement. 48-hour deprived rats were allowed to lick a drinking tube 100 times; each lick produced a 0.1 sec tone (paired condition). A control group heard tones randomly throughout the session and licked 100 times (unpaired condition). 24 hrs. later all rats were tested with a dry drinking tube; a tone accompanied each lick. The rats trained in the paired condition with immediate ESSB made significantly more licks to extinction than a group of rats trained in the unpaired condition with immediate ESSB or than a group trained in the paired condition that received ESSB 2 hrs. after training. 2) Conditioned Emotional Response. On day 1 rats were water deprived and placed into a black cage where they heard ten 10 sec tones. On day 2 they were placed into a white cage and given 2 tones with foot shock during the last 0.5 sec of each tone (paired). The control group was given 2 tones and two shocks randomly (unpaired). On day 3 each rat was placed into the black cage with a water spout. When 10 sec of continuous drinking was completed the tone came on for 10 sec. In 10 such trials drinking was supressed by the tone in the paired/immediate-ESSB group, but was not suppressed in the unpaired/immediate-ESSB group or in a paired/delayed-ESSB group. 3) Acceleration of Extinction. Food deprived rats were trained to bar press for food. They were given one session of extinction training, followed by ESSB which they obtained by running in a square-shaped runway. On a second extinction session 24 hrs later the rats failed to show spontaneous recovery as compared to rats that ran for ESSB in the pre-optic area, and rats that received no ESSB. 4) Conditional Discrimination. Food deprived rats were given 12 massed trials in a T-maze. With a white card at the choice point, food was always on the right; with a black card food was on the left. 24 hrs later rats which bar pressed for ESSB after the 12 training trials made significantly more correct choices in the T-maze than rats which did not receive ESSB.

MONOAMINERGIC SYSTEMS

1082 DOPAMINE AND CYCLIC NUCLEOTIDE HISTOFLUORESCENCE IN RAT CAUDATE-PUTAMEN COMPLEX. Marjorie A. Ariano[1] and Larry L. Butcher[2]. Molecular Biology, University of Southern California (1), Los Angeles, CA 90007; Department of Psychology and Brain Research Institute, UCLA (2), Los Angeles, CA 90024.

Using a glyoxylic acid procedure for catecholamines (de la Torre and Surgeon, Histochemistry 49: 81-93, 1976) and a fluorescence immunohistochemical technique for cyclic nucleotides (Steiner, et. al., Adv. Cycl. Nuc. Res. 7: 115-155, 1976), we have determined at the light microscopic level, possible morphologic relationships among striatal tissue elements containing dopamine; cyclic 3',5'-guanosine (cyclic GMP); and cyclic 3',5'-adenosine monophosphate (cyclic AMP). In all experiments, the intensity of fluorescence was greater for cyclic GMP than for cyclic AMP. Furthermore, in material stained for both cyclic nucleotides and for Nissl substance, cyclic AMP appeared primarily associated with neuronal somata whereas cyclic GMP was predominantly associated with processes. Large lesions of the medial forebrain bundle, field H_2 of Forel, and adjacent regions at the level of the subthalamic nucleus resulted in complete loss of dopamine terminals from the caudate-putamen complex, but cyclic GMP and cyclic AMP staining was essentially unaffected as assessed histochemically. We conclude from these data that striatal cyclic nucleotides are associated with caudate-putamen cell bodies and processes originating in that extrapyramidal structure and not with afferent dopamine fibers deriving from the mesencephalon.

This research was supported by grants USPHS AM 05925 (MAA) and USPHS NS 10928 (LLB).

1083 LOCUS COERULEUS LESIONS AND CHRONIC RESERPINE TREATMENT: EFFECT ON ADRENERGIC AND MUSCARINIC RECEPTORS IN RAT BRAIN. S.P. Banerjee, V.K. Sharma*, M. Ganapathi*, R. Busto* and S.I. Harik. Dept. Pharmacology, Univ. of Rochester Medical Center, Rochester, New York 14642, and the Dept. of Neurology, Univ. of Miami School of Medicine, Miami, Florida 33101.

Bilateral, unilateral or sham locus coeruleus lesions were made stereotoxically in Wistar rats by local microinjection of 6-hydroxydopamine (or saline for sham operations). Two weeks after the lesion, the animals were killed and the cerebral cortex and hippocampus were obtained bilaterally. The cerebellum was divided at the midline. For the chronic reserpine treatment experiment, rats were injected intraperitoneally with the drug once daily for 10 days (4 mg/kg was administered on the first day and 1 mg/kg on subsequent days). α- and β-adrenergic (α- and β-AR) and muscarinic cholinergic receptors (MCR) respectively were studied by measuring the specific binding of radiolabeled dihydroergocryptine, dihydroalprenolol and quinuclidinyl benzylate in the particulate fractions of different areas of rat brain. Unilateral LC lesions increased binding to α-AR (15%), β-AR (45%) and MCR (10%) in cerebral cortex. In the hippocampus, unilateral LC lesions decreased binding to α-AR (23%) and MCR (10%) and increased binding to β-AR (61%). Chronic reserpine treatment increased binding to β-AR by 70% in cerebral cortex and 26% in hippocampus and decreased binding to MCR in these two areas of brain by about 10%. Bilateral LC lesions increased binding to β-AR by 32% in cerebral cortex and 53% in hippocampus. Only the changes in the levels of β-AR were statistically significantly different following chronic reserpine treatment and unilateral or bilateral LC lesions. Scatchard analysis revealed that alterations in the levels of β-AR in cerebral cortex and hippocampus were due to changes in the number of binding sites so that there was a 50% increase in B_{max} after bilateral LC lesions as compared to 166% increase seen after chronic reserpine treatment in the cerebral cortex. Neither functional denervation nor structural denervation affected binding to α-AR, β-AR and MCR in the cerebellum. It may be concluded that dysfunction of central noradrenergic nerves mainly leads to augmentation of the levels of β-AR in the cerebral cortex and hippocampus. There are quantitative differences in the magnitude of changes in the levels of β-AR following functional denervation as opposed to structural denervation. This may suggest the presence of presynaptic receptors. In the cerebellum, denervation does not produce an increase in the level of β-AR. (Supported by the Jack Wechter Memorial Fund and HL-18185).

1084 NON-COMPETITIVE INTERACTION OF ERGOT ALKALOIDS WITH DOPAMINERGIC RECEPTORS. M. J. Bannon, K. L. Marek* and R. H. Roth. Depts. Pharmacology and Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06510

Some of the ergot alkaloids seem to possess dopamine (DA) agonist activity. Yet their onset is slow and duration of action prolonged compared to other DA agonists such as apomorphine. The activity of various ergot alkaloids at the presynaptic DA receptors was assessed by measuring dopa accumulation in selected regions of rat brain following inhibition of dopa decarboxylase with Ro4-4602, and the cessation of impulse flow in dopamine neurons induced by γ-butyrolactone (GBL)(Walters and Roth, Naunyn-Schmiedeberg's Arch. Pharmacol. 296: 5, 1976). Ergocornine (2.5 mg/kg, 40 or 95 minutes), lergotrile (5 mg/kg, 40 or 95 minutes), bromocryptine (10 mg/kg, 95 minutes only) and apomorphine (2 mg/kg, 95 and 65 minutes) were all found to possess DA agonist activity in this model, i.e., to reverse the GBL-induced increase in dopa levels in the caudate nucleus. Haloperidol (1 mg/kg) administered 5 minutes prior to ergot administration effectively blocked the agonist effects of the ergots and apomorphine at the DA receptor. However, when given 55 minutes after the agonists, haloperidol did not reverse the action of bromocryptine or ergocornine, although lergotrile's effect was partially reversed, and the effect of apomorphine was completely antagonized. Likewise (+)-butaclamol (4 mg/kg) was effective in preventing but not reversing the effects of bromocryptine when employed with a similar time course. The inactive isomer, (-)-butaclamol, was without effect. Similar results were obtained with bromocryptine and haloperidol or (+)-butaclamol when the olfactory tubercle was studied.

These results suggest a non-competitive interaction of bromocryptine with the DA receptor. If bromocryptine is very tightly bound, a decreased amount of binding of ^{3}H-spiroperidol to DA receptors might be expected. In ^{3}H-spiroperidol binding studies, bromocryptine (10 mg/kg) administered 2 hours before sacrifice caused a 30% decrease in Bmax (number of receptors labeled) with no change in Kd. No similar effect was seen with a shorter (30 minute) pretreatment period, paralleling the data from the GBL model. This decreased Bmax was also not evident 2 days after bromocryptine treatment. Together, the data from the GBL and binding studies suggest that following bromocryptine administration there is a critical time period, after which bromocryptine is no longer easily displaced from the DA receptor, yet retains its receptor agonist properties.

This research is supported in part by a U.S.P.H.S. grant, MH-14092, and the State of Connecticut.

1085 EM AUTORADIOGRAPHIC STUDIES OF THE ADRENERGIC-SEROTONERGIC INTERACTION IN THE DORSAL RAPHE. Jay M. Baraban* and George K. Aghajanian, Depts. of Psychiatry and Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06508

The dorsal raphe and the adjacent central grey receive a dense adrenergic input as demonstrated by biochemical, histofluorescence and immunocytochemical techniques. Previous pharmacological studies have suggested that adrenergic terminals located near serotonin (5-HT)-containing cells exert a tonic activating influence which maintains 5-HT cell firing activity (Baraban et al. Eur. J. Pharmacol., 52:27, 1978). Recent studies have demonstrated both non-5-HT as well as 5-HT neurons within the dorsal raphe nucleus (Aghajanian et al., Brain Res., 153:169, 1978). To determine the relationship of the adrenergic input to these neuronal types, we have undertaken the localization of adrenergic terminals at the ultrastructural level by EM (electron microscopic) autoradiography.

H^3-l-Norepinephrine (NE, 200 μCi, 25-35 Ci/mM) was injected intraventricularly in chloral hydrate anesthetized rats. Animals had been pretreated with the 5-HT uptake inhibitor fluoxetine (10 mg/kg, i.p.) and the monoamine oxidase inhibitor pargyline (100 mg/kg, i.p.). Some animals had previously received intraventricular injections of the 5-HT neurotoxin 5,7-dihydroxytryptamine (5,7-DHT, 100-200 μg free base).

Examination of ultrathin sections of the dorsal raphe prepared for EM autoradiography showed highly selective localization of radioactivity within nerve terminals. Labelled terminals contained both small agranular vesicles and larger dense core vesicles, characteristic of central adrenergic terminals. These terminals frequently participated in classical synaptic junctions. In contrast to the pattern of labelling observed with H^3-NE, nerve terminals forming specialized junctions were not labelled in similar autoradiographic studies with H^3-5-HT, even though prominent labelling of cell bodies, dendrites and axons was present. Hence, it is unlikely that H^3-NE produces non-specific labelling of 5-HT synaptic junctions. Furthermore, in animals whose 5-HT neurons had been destroyed by 5,7-DHT, H^3-NE was localized to intact axo-dendritic terminals of the type observed in controls. In addition, in the 5,7-DHT pretreated animals the dendritic elements post-synaptic to labelled terminals did not show degenerative changes. These studies suggest that adrenergic terminals innervate non-5-HT neurons in the dorsal raphe. Therefore, the adrenergic-serotonergic interaction in the dorsal raphe may be mediated indirectly via non-5-HT interneurons.

1086 DOPAMINE (DA) AUTORECEPTORS: RAPID DECREASE IN THE RESPONSE TO DA FOLLOWING AGONIST TREATMENT. M.D. Baring, J.R. Walters, NIH, NINCDS, Bethesda, MD 20205

Single unit recording studies have demonstrated that spontaneously firing DA cells in the substantia nigra pars compacta (SNpc) recovering from inhibition induced by a DA agonist such as apomorphine (APO) generally show a biphasic recovery pattern different from, for example, the response of the serotonergic raphe cells to LSD. After an i.v. dose of APO, 0.1 mg/kg, DA cells tend to be completely inhibited for up to 15 min and then recover rapidly to a plateau rate ≈ 40% of baseline, from which further recovery is gradual (Bunney et al, Nature 245:123, 1973). Each subsequent dose of APO is followed by an increasingly attenuated period of inhibition and recovery to the plateau rate until the cells are completely resistant to further injections of APO. At this point the cells are also resistant to the normally induced inhibition of other dopamimetic agents such as piribedil, amphetamine (AMP), and L-dopa (Walters et al, Adv. Neurol. 9:273, 1975). We have more recently observed that cells resistant to the effects of APO are also no longer inhibited by either lergotrile (.5-2.5 mg/kg) or lisuride (1.6 mg/kg), two dopamimetic ergot derivatives.

Previous studies showing that DA cells have normal responses to APO in rats with the striatonigral feedback pathway lesioned with kainic acid (Baring et al, Neurosci. Abst. 4:267, 1978) suggest that the events responsible for this rapid development of resistance might be occurring at the level of the DA autoreceptors on the DA cell body. To investigate this, the iontophoretic effects of DA on the single unit activity of DA cells in the SNpc of chloral hydrate-anesthetized rats were determined before, during and after a series of injections of i.v. APO at increasing doses. It was found that DA cells initially inhibited by iontophoresis of DA became resistant to the effects of this transmitter as the cells developed resistance to the effects of APO (cumulative dose, 0.4-0.8 mg/kg).

This agonist-induced resistance of DA autoreceptors might be a function of the partial antagonist properties of the drug. However, we have observed that cells recovering from i.v. administration of AMP, a drug which acts by releasing DA, (cumulative dose, 12 mg/kg) show diminished responses to APO, injected i.v. 15-45 min after max. inhibition by AMP, suggesting that DA itself may also induce changes in autoreceptor sensitivity. This observation together with the fact, as described above, that APO can initially inhibit DA cells completely before resistance develops, suggests that a rapid change may be occurring in sensitivity to the agonists or transmitter as a normal consequence of DA autoreceptor stimulation and/or subsequent membrane events leading to a change in firing rate.

1087 QUANTITATIVE IMMUNOCYTOCHEMICAL ANALYSIS OF THE INDUCTION OF TYROSINE HYDROXYLASE IN CATECHOLAMINE NEURONS IN RAT BRAIN FOLLOWING RESERPINE. R.H. Benno*, T.H. Joh, L.W. Tucker*, and D.J. Reis. (SPON: A.B. Judd). Lab. of Neurobiol., Dept. of Neurol., Cornell Univ. Med. Coll., New York, NY 10021.

We sought to determine by quantitative immunocytochemistry using the peroxidase-antiperoxidase (PAP) method: (a) if the enzyme tyrosine hydroxylase (TH) is uniformly distributed among all neurons within the nucleus locus ceruleus (LC) of rat brain; (b) if the increase in activity and accumulation of the enzyme (induction) elicited by reserpine (JPET 193:775, 1975) occurs in all or only a sub-population of LC neurons; (c) if reserpine will alter the amount of immunoreactive TH in dopaminergic neurons of the substantia nigra (SN) despite the absence of changes in TH activity (ibid). We first sought to determine the reaction conditions producing linearity of staining intensity (first order kinetics) with respect to the amount of immunoreactive protein; conditions necessary for quantitation. Untreated rats were perfused with 4% paraformaldehyde. Tissues were postfixed in picric acid - paraformaldehyde and embedded in paraffin. Five micron adjacent sagittal sections were taken through the LC and SN and immunostained. Staining intensity was measured by a TV image analysis system (B & L Omnicon) measuring integrated optical density in neurons of the LC and SN. Linearity of the reaction (pseudo first-order kinetics) was primarily dependent upon: (a) the concentration of the substrate diaminobenzidine (DAB); (b) the duration of incubation with DAB; and (c) the dilution of primary antibody. Incubation of sections with primary antibody and reaction with 0.01% w/v DAB and 0.003% v/v H_2O_2 resulted in increased staining directly proportional to incubation time up to 8 minutes. The optimal time for detecting differences in staining intensities was 3 min. In untreated rats, cells of the LC are heterogeneous with respect to TH content. Two cell groups differing in staining intensity are seen: large TH-positive cells located rostrally, ventrally, and dorsally, forming a shell around the nucleus and a central group with less enzyme. Both stain more intensely than the neuropil. Reserpine (10 mg/kg) resulted 3d later in an approximately 2-fold increase of TH staining in individual neurons of both cell groups and the neuropil. No change in the staining intensity for TH occurred in the SN. We conclude: (a) the PAP method can, under rigorous conditions, be utilized for quantitation of tissue antigens; (b) that neurons of the LC are heterogeneous with respect to the amount of immunoreactive enzyme; (c) the induction of TH elicited by reserpine occurs in all neurons in the LC; and (d) reserpine fails to increase TH enzyme protein in dopaminergic neurons of the SN.

(Supported by NIH Grants HL 07379, HL 18974, and MH 24285.)

1088 EFFECTS OF FREQUENCY AND PATTERN OF ELECTRICAL STIMULATION OF THE CERVICAL SYMPATHETIC TRUNK ON THE ACTIVITY OF THE ENZYME SEROTONIN:N-ACETYLTRANSFERASE IN THE RAT PINEAL GLAND. C.W. Bowers* and R.E. Zigmond (SPON: V. Chiappinelli). Dept. of Pharmacol., Harvard Med. Sch., Boston, MA 02115

Bilateral stimulation of the cervical sympathetic trunks (CST) of the rat at 10 Hz produces an increase in the activity of serotonin:N-acetyltransferase (NAT) in the pineal gland. The rate and magnitude of this increase are comparable to those observed during the normal nighttime rise in NAT activity in intact rats (Bowers and Zigmond, Soc. Neurosci. Abst. 4:268, 1978).

We have now studied the increase in NAT activity following stimulation at a number of different frequencies and with several different patterns of stimulation. In all experiments male albino rats were exposed to light during the dark part of their day/night cycle, and the CST were stimulated bilaterally at current levels twice those required to produce maximal exophthalmos of the ipsilateral eye. Pineals were removed and frozen immediately after the cessation of stimulation. Enzyme values are given in units of pmoles of product formed per μgm protein in 20 min ± S.E.M.

5 Hz stimulation for 0.5, 1.0 and 2.0 hours produced as large an increase in NAT activity as did stimulation at 10 Hz. For example, after one hour of stimulation at 10 Hz, the NAT activity was 27.2 ± 2.1 while after stimulation for the same length of time at 5 Hz the activity was 26.0 ± 2.1. The NAT activity of unstimulated animals was 2.0 ± 0.1. This suggests that stimulation of the CST at 5 Hz is sufficient to produce a maximal increase in NAT activity in the rat pineal gland. Stimulation at 2.5 Hz produces about 50% of this maximum response while stimulation at 1 Hz produces 10% of the maximum response.

In addition to its sensitivity to the frequency of stimulation of the CST, the NAT activity of the pineal gland is sensitive to the pattern of stimulation. For instance, stimulation of the CST with a repeating pattern of 5 Hz for 2 seconds followed by no stimulation for 8 seconds produced a 3-fold greater increase in NAT activity after one hour than did stimulation continuously at 1 Hz. This difference occurred in spite of the fact that both conditions of stimulation consisted of exactly the same number of stimuli. In contrast, stimulation at 5 Hz for 1 out of every 5 seconds for an hour produced an increase of the same magnitude as did continuous stimulation at 1 Hz. Thus, relatively subtle changes in the pattern of firing of the CST can produce large changes in the biochemical response of the pineal gland. (Supported by a Grant-in-Aid from the American Heart Association. CWB is a fellow of the Scottish Rite Schizophrenia Research Program.)

1089 EXAMINATION OF BLOOD PRESSURE CHANGES FOLLOWING DESTRUCTION OF ASCENDING SEROTONERGIC NEURONS IN SPONTANEOUSLY HYPERTENSIVE (SH) AND NORMOTENSIVE RATS. D. G. Bramlet,* R. A. Browning and J. H. Myers.* Southern Illinois University, School of Medicine, Carbondale, Ill. 62901.

Several laboratories have provided evidence that central serotonergic neurons play a role in the maintenance of hypertension in the SH rat. Recently, Smits et al. (Life Sci 23, 173-178, 1978) reported that electrical stimulation of the dorsal and median raphe nuclei produced an elevation in the blood pressure of normotensive rats. We have now investigated the role of ascending serotonergic neurons in the maintenance of hypertension in the SH and normotensive, Wistar-Kyoto (WKY) rat. The ascending serotonergic pathways of 11-12 week old SH and WKY rats were destroyed by electrolytic lesions of the dorsal and median raphe nuclei. Lesioned animals received a 2mA anodal current for 5 sec. In sham-operated animals, the electrode was lowered to a depth of 1mm above the raphe dorsalis and no current was passed. Nine blood pressure measurements (3 recordings per day for 3 days) were obtained on each rat before and after lesioning using the indirect tail cuff method. All animals were allowed 4 weeks to recover from surgery before obtaining post-lesion blood pressures. Rats were sacrificed 39-40 days post-lesion, at which time their brains were removed for both histological and neurochemical evaluation. As shown below, lesions of the ascending serotonergic pathways had no significant effect on the blood pressure of WKY rats despite an 80% reduction in forebrain serotonin (5-HT). Similarly, a raphe lesion in the SH rats did not significantly alter the further development of hypertension in spite of an 81% depletion of forebrain 5-HT. These findings suggest that the ascending serotonergic fibers emanating from the dorsal and median raphe nuclei are not involved in the maintenance of hypertension in the SH rat and play little role in the regulation of blood pressure in WKY rats.

Blood Presure ± SEM (mm Hg)

	Pre-Lesion		Post-Lesion	
	WKY	SHR*	WKY	SHR*
Sham Group	130 ± 3	168 ± 4	141 ± 4	199 ± 7

1090 EFFECT OF NEONATAL 6-HYDROXYDOPA TREATMENT ON α- AND β-ADRENERGIC RECEPTOR BINDING AND ON BEHAVIOR. David B. Bylund and Walid O. Shekim, Depts. of Pharmacology and Psychiatry, Sch. Med., Univ. Missouri, Columbia, MO 65212.

Treatment of neonatal rats with the neurotoxin 6-hydroxydopa is known to decrease adrenergic innervation and norepinephrine levels in the cerebral cortex while increasing innervation and norepinephrine levels in the cerebellum. Since the number of central β-adrenergic receptors, and perhaps α-adrenergic receptors, appear to be inversely related to changes in norepinephine levels (Bylund, Adv. Exp. Med. Biol. 116,133-162,1979),we studied the effects of 6-hydroxydopa on β-,α_1- and α_2- adrenergic receptor binding. In addition, we studied the effects of the treatment on behavior in order to evaluate it as an animal model of the childhood hyperactivity syndrome.

Neonatal rats were treated (s.c.)on days 1,3 and 5 with either 80 µg/g 6-hydroxydopa, or vehicle (ascorbic acid-saline).At 24-26 days their locomotor activity was measured. Subsequently, the adrenergic receptors were assayed in crude particulate fractions of cerebral cortex, cerebellum, midbrain and medulla-pons using ^{3}H-dihydroalprenolol, ^{3}H-WB-4101 and ^{3}H-clonidine. Norepinephine levels were determined using HPLC with electrochemical detection.

The 6-hydroxydopa treated animals were significantly hyperactive as compared to controls using both the activity box ($F(1,32)=5.4, p=0.027$) and the open field ($F(1,30)=12.4, p<0.001$) methods. As expected, the apparent number of β-adrenergic receptors (B_{max}) was significantly increased in the cerebral cortex (42%,See Table) with no change in the affinity (K_D).

Effect of Neonatal 6-Hydroxydopa Treatment on Adrenergic Receptor Binding in Rat Cerebral Cortex

	n	% of Control B_{max}	% of Control K_D
^{3}H-dihydroalprenolol	4	142± 9*	110±16
^{3}H-WB-4101	6	104±10	96± 9

Values given are means ±S.E.M. Control values (B_{max},K_D): for ^{3}H-DHA,9.1 pmol/g tissue, 0.88 nM; for ^{3}H-WB-4101,13.2pmol/g tissue; 0.80 nM. *$p<0.025$ by paired t test

However, no change was found in the number of cortical α-adrenergic receptors as measured by ^{3}H-WB-4101 binding. Similarly, β-receptor but not α-receptor binding was decreased in the cerebellum. Thus, at least in this model of hyperactivity, the β-adrenergic receptors,but not the α-adrenergic receptors appear to be regulated by the endogenous levels of norepinephrine.

1091 EVIDENCE OF CATECHOLAMINERGIC AND SEROTONINERGIC INNERVATION OF THE INTRAVENTRICULAR NEURONAL CLUSTER IN THE HAMSTER. J.P. Card*[1] and J.A. Mitchell. Department of Anatomy, Wayne State University School of Medicine, Detroit, Michigan 48201

Previous studies in our laboratory (JCN 180: 43, 1978) demonstrated the presence of a ganglion-like cluster of neurons and neuronal processes on the ependyma overlying the median eminence (ME) of the hamster. In the present study, the selective neurotoxic actions of 6-hydroxydopamine (6-OH-DA) and 5,7-dihydroxytryptamine (5,7-DHT) were employed to establish the catecholaminergic (CA) and serotoninergic (5-HT) character of the axons of extrinsic origin innervating the cluster.

Hamsters were assigned to 2 experimental and 2 control groups (5/group). Experimentals received 2 iv injections of 6-OH-DA (150 mg/kg bw, 24 hrs apart) or an intraventricular infusion of 5,7-DHT (100 ug; following blockade of noradrenergic terminals with desmethylimipramine). Controls received 2 iv injections or an intraventricular infusion of saline, respectively. At 48 hrs after initiation of treatments the ME-3rd ventricle region containing the neuronal cluster was prepared for transmission electron microscopy.

In controls, normal ultrastructure was exhibited by all neuronal perikarya, processes and glial-like supportive cells of the cluster. In contrast, administration of 6-OH-DA resulted in ultrastructural damage to a small number of axons within the cluster. Both early and advanced degenerative changes were evident: axons contained either dense accumulations of cellular debris and swollen vesicles with enhanced osmophilia or increased cytoplasmic density and swollen terminals, respectively. Supportive cells evidenced increased phagocytosis. Administration of 5,7-DHT also elicited axonal degeneration within the cluster. However, the number of terminals affected far exceeded that seen following 6-OH-DA treatment and the degenerative changes were accompanied by disruption of the cytoarchitectural organization of the cluster and adjacent periventricular neurophil. Degenerating axonal profiles were also apparent within the ventricle and ME. Phagocytosis was increased in supportive cells. In addition, perikarya of supportive cells were observed on the periphery of the cluster, an area normally occupied exclusively by nerve cell bodies in controls.

The results indicate that both catecholaminergic and serotoninergic systems are involved in the modulation of the neuronal activity of the supraependymal cluster. Studies are in progress to determine the location of the cell bodies from which the CA and 5-HT axons originate. (Supported by NIH RR-05387)

1092 DIFFERENTIAL RECOVERY OF REINFORCEMENT AND MOTORIC FUNCTION FOLLOWING UNILATERAL LOSS OF BRAIN DOPAMINE. Robert J. Carey. VAMC at Syracuse, Syracuse, NY 13210.

Rats with bilateral medial forebrain bundle electrodes which generated comparable rate-intensity functions for self-stimulation were administered intracerebral unilateral injections of 6-hydroxydopamine (4 µl of a 2 µg/µl sol.) into the substantia nigra. The nigral injections produced a virtual complete loss of forebrain dopamine in the injected hemisphere. Initially, this dopamine depletion was manifested behaviorally by a selective and severe decrease in self-stimulation in the dopamine deficient hemisphere as well as in ipsiversive circling and diminished locomotor activity. Over the course of a two month postoperative test period, however, self-stimulation obtained from the dopamine depleted hemisphere gradually recovered and became more sensitive to stimulation than the intact hemisphere. In contrast, the ipsiversive circling and reduced activity level persisted throughout testing. Furthermore, the motoric responses elicited by stimulation of the depleted and intact hemispheres became different. While the typical locomotor exploratory behavior was observed to accompany stimulation in the intact hemisphere stimulation of the depleted hemisphere produced ipsiversive circling. Additionally, giving the rats 2 mg/kg d-amphetamine produced reliable ipsiversive turning but at the same time facilitated self-stimulation equally for electrodes in the intact and dopamine depleted hemispheres. These studies show that dopamine depletion produces persistent motor but not reinforcement deficits.

1093 CONDITIONING OF STRESS-INDUCED ALTERATIONS OF NOREPINEPHRINE METABOLISM IN RAT BRAIN: STUDIES IN PROGRESS. Geraldine Cassens, Alvin Kuruc*, Paul J. Orsulak*, and Joseph J. Schildkraut*. Dept. Psychiat., Harvard Med. Sch., Boston, Mass. 02115.

The administration of single or multiple sessions of footshock increases levels of the sulfate conjugate of 3-methoxy-4-hydroxyphenylglycol (MHPG-SO_4), a major metabolite of norepinephrine in rat brain. In the present studies, we sought to determine whether these stress-induced increases in levels of MHPG-SO_4 in rat brain (UCR) could be elicited by environmental stimuli (CS) that had been previously paired with inescapable footshock (UCS). Male Sprague Dawley rats (200-220 g) were placed in an experimental chamber daily on Days 1-3 and one group received 80 trials of inescapable footshock (1.05 mA presented on a VI 60 schedule), while another group received no footshock. On Day 4, 24 hours after the last session, half of the shocked and half of the unshocked animals were again placed in the experimental chamber (CS), but received no footshock. The remaining halves of the shocked and unshocked groups were not placed in the chamber, but remained in their home cages (No CS). Immediately after the session on Day 4, animals were removed from the experimental chamber or home cage, sacrificed, and brains were assayed for levels of MHPG-SO_4.

Animals that had received footshock on Days 1-3 and were exposed to the CS on Day 4 showed significant increases in brain levels of MHPG-SO_4 ($p<.001$) when compared to: 1) unshocked animals that remained in their home cage on Day 4, 2) unshocked animals that were exposed to the CS on Day 4, or 3) previously shocked animals that remained in their home cage and were not exposed to the CS on Day 4. Further experiments have shown that increases in MHPG-SO_4 levels could be elicited by the CS after only a single pairing of the CS and UCS. Preliminary data suggest that these increases in MHPG-SO_4 are associated with increased defecation and crouching behavior, but not with increased locomotor activity. While these experiments have not differentiated between neuronal "sensitization" or "conditioning," we believe these studies are the first to show that increases in a naturally-occurring catecholamine metabolite in rat brain can be elicited by environmental stimuli that have been previously paired with stress. These findings will be discussed in relation to the deficits in escape behavior observed after exposure to inescapable shock ("learned helplessness").

1094 GUANOSINE 5'-TRIPHOSPHATE IS AN ENDOGENOUS COMPOUND IN THE RABBIT CEREBELLAR CORTEX WHICH "COUPLES" THE BETA-ADRENOCEPTOR TO ADENYLATE CYCLASE. Thomas E. Cote*, Tai C. Chen*, and John W. Kebabian
Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20205.

A beta-adrenoceptor regulates adenylate cyclase activity in cell-free homogenates of the rabbit cerebellum. The demonstration in vitro of the "coupling" between the beta-adrenoceptor and adenylate cyclase activity requires the presence of either guanosine 5'-triphosphate (GTP) or guanosine 5'-diphosphate (GDP). Thus, repeated washing of the particulate material in homogenates of the rabbit cerebellum abolishes the sensitivity of the adenylate cyclase activity to beta-adrenergic agonists. The addition to the particulate cerebellar material of either the soluble constituents of the cerebellar homogenate or the exogenous guanyl nucleotides, GTP or GDP, restores the sensitivity to beta-adrenergic agonists. Utilizing high pressure liquid chromatography (HPLC) the amount of GTP and GDP in the soluble components of the cerebellar homogenate can be measured; these two guanyl nucleotides can account for the restoration of the sensitivity to beta-adrenergic agonists. The endogenous nucleotides in the cerebellum were isolated with HPLC. Only the endogenous GTP and GDP were capable of restoring the coupling between the beta-adrenoceptor and adenylate cyclase activity; none of the other compounds isolated with HPLC were active. The effectiveness of GDP may reflect its conversion to GTP during the assay of adenylate cyclase activity. If ATP is used as substrate, approximately 75% of the exogenous [14-C]-GDP is recovered as [14-C]-GTP at the end of the assay of adenylate cyclase activity. However, if AMP-P(NH)P is the substrate such conversion is negligible; under these latter conditions GTP, but not GDP, can restore sensitivity to beta-adrenergic agonists. The beta-adrenergic antagonist, [3-H]-dihydroalprenolol (DHA) identifies specific binding sites similar to the beta-adrenoceptor which regulates adenylate cyclase activity. Exogenous GTP does not affect either the number of DHA binding sites or the affinity of these sites for l-isoproterenol. Furthermore, GTP does not cause a shift in the activation affinity of the adenylate cyclase activity for l-isoproterenol. In conclusion, the guanyl nucleotides GTP and GDP are endogenous constituents of the rabbit cerebellum which are essential for the functional "coupling" of the beta-adrenoceptor and adenylate cyclase but which do not affect the receptor per se: the activity of GDP occurs as a consequence of its conversion into GTP; the activity of GTP may reflect a direct effect of this compound.

1095 ALPHA- AND BETA-ADRENERGIC AGONIST ACTIVITIES OF 2-, 5-, AND 6-FLUORINE SUBSTITUTED NOREPINEPHRINES IN THE INTACT DOG. Cyrus R. Creveling, Kenneth L. Kirk*, Daniele Cantacuzene*, Jai D. Kohli*, and Leon I. Goldberg. NIAMDD, Bethesda, MD, 20205 and Dept. Pharmacol., Uni. Chicago, Chicago, IL 60637.

Previous investigations using isolated guinea pig aortic strips and atria demonstrated that substitution of fluorine (F) on the 2-, 5-, or 6-position of the aromatic ring of norepinephrine (NE) results in a marked alteration of the β1- and α-adrenergic agonist properties of NE (Fed. Proc. 38: 543, 1979). Similar agonist specificities with these NE derivatives were also observed in the amine-sensitive cyclic AMP generating system in slices of rat cortex and the displacement of α- and β-specific radioligands from isolated membrane preparations from rat brain (Fed. Proc. 38: 533, 1979).

In the present study we compared the effects of 2-, 5-, and 6-FNE, administered intravenously, on cardiac contractural force (CF) and arterial blood pressure (BP) and, after intraarterial administration, to femoral blood flow (FBF) to that of NE, in pentobarbital anesthesized dogs. 5-FNE was qualitatively similar but more potent than NE on CF, yielding an increase in both diastolic and systolic BP and a decrease in FBF. 2-FNE increased CF, diastolic BP, and FBF whereas 6-FNE had no effect on CF, increased diastolic BP and decreased FBF. Propranolol blocked the increase of CF with 2- and 5-FNE and the increase in FBF by 2-FNE. Thus 2-FNE acts on β1- and β2-adrenergic receptors; 5-FNE on both α- and β1-adrenergic receptors, and 6-FNE only on α-adrenergic receptors, confirming our earlier studies in the guinea pig. The present results, in addition, demonstrate the β2 action of 2-FNE. The marked effect of the site of F substitution on the specificity of these NE derivatives and the lack of effect of similar F substituents on dopamine (Fed. Proc. 38: 601, 1979) presumably reflect fluorine-hydroxyl interactions and/or F induced electronic effects which are manifested only in a chiral molecule. (Supported by NIH GM-22220.)

1096 HORSERADISH PEROXIDASE STUDIES OF AN AUTONOMIC GANGLION. William G. Dail, Celia Barraza*, Suzanne Khoudary*, and Heather Murray. Dept. Anat., Sch. Med., Univ. New Mexico, Albuquerque, NM 87131

To further characterize the organization of the superior cervical ganglion (SCG), target organs and an efferent nerve of the rabbit SCG have been treated with horseradish peroxidase (HRP). The superior cervical ganglion was studied by light microscopy 48 hrs after injection of the iris with HRP. Labeled ganglion cells seem to be evenly distributed throughout the SCG as seen with the o-dianisidine procedure for HRP. In contrast, injection of HRP into multiple sites in the submandibular salivary gland resulted in labeled neurons predominantly located in the caudal half of the SCG, near and below the origin of the external carotid nerve. With exposure of the salivary glands or the external carotid nerve to HRP, labeled neurons were found in the rostral portion of the cervical sympathetic trunk, 4cm from the SCG at the level of the accessory cervical sympathetic ganglion and in the stellate ganglion. Tissue was also treated with diaminobenzidine for study of the distribution of horseradish peroxidase with the electron microscope. Lysosomes filled with HRP were found in the soma of ganglion cells as well as in neurites at the periphery of labeled cells. Some of the HRP labeled neurites received adrenergic terminals (shown by 5-hydroxydopamine loading) and terminals containing small clear vesicles. In some cases nerve processes marked with HRP also contained scattered small dense core vesicles, although typical adrenergic terminals in the rabbit SCG have not been found to contain HRP.

These studies suggest that the superior cervical ganglion is not a homogeneous collection of neurons. Instead there is an apparent grouping within the SCG of neurons destined for a particular target organ. Neurons supplying the iris appear to be an exception to this pattern. The adrenergic fibers which are known to enter the caudal margin of the superior cervical ganglion arise from as far caudal as the stellate ganglion. The recognized target organs of the superior cervical ganglion are the destination of some of these fibers.

1097 EFFECTS OF SUPERIOR-COLLICULUS LESIONS ON APOMORPHINE-INDUCED ACTIVITY AND STEREOTYPY IN RATS. Paul Dean*, Peter Redgrave* and Sian G. Pope* (SPON: C. D. Jarvis). Dept. Psychology, Sheffield Univ., Sheffield, S10 2TN, U.K.

The efferent pathways by which alterations in striatal dopamine influence behaviour are poorly understood. Recent evidence has implicated the projection from caudate nucleus to substantia nigra (Marshall and Ungerstedt, Science, 198:62, 1977) and thence to superior colliculus (Wirtshafter et al., Neurosci. Abstr., 4:287, 1978; but see Crossman and Sambrook, Brain Res., 159:211, 1978) in the circling produced by apomorphine in rats with unilateral nigral lesions. The present experiment examined the effects of superior colliculus lesions on the stereotypy and activity changes produced by apomorphine in normal rats.

Rats with large bilateral electrolytic lesions of the superior colliculus (SC) were compared with non-lesioned controls in an open-field and a Skinner box following systemic injections of apomorphine (4-6 mg/kg). In the open-field, apomorphine produced a greater increase in locomotor activity in the SC than the control animals. The SC rats, however, showed much less stereotyped behaviour. All animals showed pronounced stereotypy when confined in the Skinner box, but in the SC group this was confined to sniffing and rearing; the intense stereotyped gnawing and licking that characterised the control group was not observed in rats with SC lesions.

These differences are consistent with the effects of high doses of amphetamine (12-24 mg/kg) on the behaviour of rats with SC lesions. Such doses produce extremely large increases in open-field activity, with little stereotypy (Pope, Dean and Redgrave, in press).

It appears that the stereotyped behaviour produced by systemic injection of dopamine agonists, which is thought to be associated with increased transmission within the nigro-striatal dopamine system, requires the integrity of the superior colliculus for its full expression, and may therefore be mediated in part by the striato-nigral and nigro-tectal pathways. In contrast, the increase in locomotor activity produced by such drugs, which is thought to involve the mesolimbic dopamine system, is probably mediated by pathways that do not pass through the superior colliculus.

1098 STANDARDIZATION OF THE SPG HISTOFLUORESCENCE METHOD FOR MONOAMINE TRANSMITTERS. J.C. de la Torre, Dept. of Neurosurgery, Univ. of Miami School of Medicine, Miami, Florida 33101.

The SPG histofluorescence method is a rapid, highly sensitive microscopic technique used to visualize tissue monoamine transmitters in cryostat sections. The SPG method differs from other histofluorescent microscopic procedures in 4 ways: 1.The reacting SPG solution sits at room temperature. 2.The tissue amine solution reaction takes 3 seconds. 3.The procedure from frozen tissue to microscopic examination is done in under 10 minutes. 4.No elaborate equipment, animal perfusion or personnel trained in histochemistry is required. Moreover, animal or human tissue biopsy can be wrapped in aluminum foil and buried in dry ice for transportation to the cryostat. One disadvantage in the original method (de la Torre & Surgeon, Histochemistry 49: 81, 1976) was the occasional variability in fluorescence intensity encountered after heating the tissue preparations on a hot plate during the final step in the procedure. The hot plate step has now been eliminated with the resulting effect of obtaining very consistent fluorescent preparations while still maintaining the high sensitivity of this procedure. The 7-step recommended method is as follows: (a) Prepare the SPG solution: 10.2 g sucrose, 4.8 g monobasic KH_2PO_4 and 1.5 g glyoxylic acid monohydride in 100 ml distilled water. (b) Stir until clear. (c) Titrate solution to pH 7.4 with 1 N NaOH and (d) top off with distilled water for a final volume of 150 ml. Prepare the tissue as follows: (1) Cut fresh tissue from body (brain, gut, muscle, etc.) into 5-10 mm slabs and immediately freeze on a pre-cooled chuck in cryostat at -30°C. (2) After tissue is frozen (about 10 min.), cut cryostat sections 16-32 μm thick, pick up section by pressing glass slide against cryostat knife. (3) Dip slide 3 times (1 sec./dip) in SPG solution. Quickly wipe off excess solution from bottom and edges of slide and immediately start drying step. (4) Slides are placed between 2 strong hairblowers set at maximum cool air for several minutes. Tissue must be completely dried (ground glass appearance). (5) After drying, place 1-2 drops of Light USP Mineral Oil to cover entire tissue on slide. (6) Place slides in pre-warmed 95°C oven for 2½ min. We recommend leaving a flat copper plate of any size or thickness in oven to hold slides so heat is more evenly distributed to tissue section. When placing slides in oven, do not keep oven door open longer than a few seconds since temperature will quickly drop from 95°C to below 90°C. Quick placement of slides in oven should not drop oven temperature below 90°C so that heat exposure time of 2½ minutes is satisfactory. (7) After oven exposure, excess or running oil is wiped off around tissue section and 1-2 fresh drops of mineral oil are placed on tissue, section is cover-slipped and examined in fluorescent microscope.

1099 ROLE OF BIOGENIC AMINES IN CEREBRAL ISCHEMIA OF THE MONGOLIAN GERBIL. G. Delbarre* and B. Delbarre (SPON: M. Cohn), Lab. Chir. Exp., Fac. de Med., 37032 Tours, France.

Studies in different animal models have established that cerebral ischemia profoundly alters the cerebral neurotransmitter functions of the monoamines. In our present investigation, our model for ischemia consisted of mongolian gerbils subjected to a unilateral surgical occlusion of the common carotid artery. Since many gerbils of this species lack a posterior communicating artery, the percentage of successfully induced ischemic subjects is directly related to the number of gerbils with this deficiency. Using a pharmacological approach, we studied here the effects of drugs known to interfere with monoaminergic metabolism. One hour before one of the common carotid arteries was ligated in the gerbils anesthetized with ketamine 40 mg kg^{-1}, imipramine 20 mg kg^{-1}, niamid 100 or 200 mg kg^{-1}, L.Dopa 300 mg kg^{-1}, HTP (DL) 37.5 or 75 mg kg^{-1} or saline was administered intraperitoneally. Neurological status was evaluated with the stroke index reported by McGraw et al (Stroke 7: 485-488, 1976) starting one hour after ligation and again at 4, 24, 48, 72 and 96 hours. Like saline, imipramine, niamid and L.Dopa did not affect the neurological status of the gerbils (Table 1). In contrast, HTP significantly improved the mean stroke index (Table 1). Our findings agree with those of Lhermitte and Degos (Neuropharmacol. 1: 666-672, 1978) who reported that 5 HTP improves the post anoxic syndrome of intention or action myoclonus described by Lance and Adams (Brain 86: 111-136, 1963).

TABLE 1

Saline 3.7 ± 1.3	Imipramine (20 mg/kg) 4.3 ± 1.8	
Saline 4.7 ± 1.8	Niamid (100 mg/kg) 9.8 ± 2.2

1100 MICROIONTOPHORETIC STUDIES ON DENERVATION SUPERSENSITIVITY TO MONOAMINES IN THE RAT HIPPOCAMPUS. C. de Montigny, R. Wang, T.A. Reader and G.K. Aghajanian. Centre de recherche en sciences neurologiques, Université de Montréal and Departments of Psychiatry and Pharmacology, Yale University.

The dorsal hippocampus receives serotonin (5HT) and norepinephrine (NE) inputs from the median raphé and locus coeruleus respectively. The present study was undertaken to assess the responsiveness of hippocampal pyramidal cells of the CA_3 region to putative neurotransmitters and analogs applied iontophoretically following 5HT and NE denervation. Sprague-Dawley rats received intraventricular injections (20 μl) of one of the following substances: 1) 200 μg (free base) of 5,7-dihydroxytryptamine (57DHT) one hour after desipramine administration (25 mg/kg, i.p.); 2) 200 μg (free base) of 6-hydroxydopamine (6OHDA); 3) NaCl 0.9%. In a fourth group of animals the locus coeruleus was destroyed bilaterally by electrolytic lesion. Iontophoretic experiments and biochemical determinations were performed two weeks to two months after these pretreatments. Hippocampal 5HT and NE content were determined with the radioenzymatic methods of Saavedra, and Coyle and Henry. 5HT 0.02 M in NaCl 0.02 M (pH 3.6), NE 0.1 M (pH 4.0), γ-aminobutyric acid (GABA) 0.05 M in NaCl 0.05 M (pH 4.0) and isoproterenol (ISO) 0.1 M (pH 4.0) were applied iontophoretically onto extracellularly recorded pyramidal cells.

Hippocampal 5HT and NE contents dropped to 11% and 37% of control values following 57DHT and 6OHDA respectively. In 57DHT pretreated animals, the responsiveness of pyramidal cells to all iontophoresized substances remained unchanged as compared with controls. In contrast, following 6OHDA pretreatment and locus coeruleus lesion responses to NE were markedly prolonged. However, the initial time course of the response to NE was not modified. Responses to ISO,5HT and GABA were not altered by 6OHDA pretreatment.

The prolongation of the effect of NE without any modification of initial responsiveness after both types of NE denervations suggests the presynaptic nature of this supersensitivity. This is corroborated by the unaltered responsiveness to ISO which is not a substrate for NE reuptake system. Furthermore, acute pharmacological blockade of NE reuptake with desipramine (5 mg/kg, i.p.) in intact animals induced the same phenomenon. The absence of a similar presynaptic type of supersensitivity to 5HT following 5,7-DHT may reflect the relatively minor role of reuptake in terminating the action of iontophorized 5HT in this region. The unmodified initial responsiveness to both 5HT and NE after denervation suggests that NE and 5HT receptors of pyramidal cell somata, in contrast to that of lateral geniculate and amygdala neurons (Wang et al., Brain Res., 1979), fail to develop postsynaptic type of supersensitivity.

1101 ALCOHOLIC METABOLITES OF CATECHOLAMINES AND RELATED AMINES IN BRAIN AND URINE: ANALYSIS BY GAS CHROMATOGRAPHY/MASS SPECTROMETRY AND THE EFFECTS OF L-DOPA. David J. Edwards and Marguerite Rizk*. Univ.of Pittsburgh Sch.Med.,Western Psychiatric Inst.&Clin., Pgh.PA.15261.

Although 3-methoxy-4-hydroxyphenylglycol(MHPG)is the major metabolite of norepinephrine(NE)in the CNS and its assay is often used as an index of NE metabolism, less attention has been paid to the alcoholic metabolites of other monoamines. They nevertheless appear to be quantitatively important metabolites of the parent amines,particularly the β-hydroxylated ones. We have developed a method using gas chromatography/mass spectrometry which permits the simultaneous assay of phenylethylene glycol, m- & p-hydroxyphenylethanol(mHPE & pHPE),p-hydroxyphenylglycol(pHPG), and 3-methoxy-4-hydroxyphenylethanol(MHPE),metabolites of phenylethanolamine,m- & p-tyramine, octopamine and dopamine(DA),respectively, and MHPG and 3,4-dihydroxyphenylglycol(DHPG),both metabolites of NE. Results obtained for the urinary excretion of free and total metabolites in control and L-DOPA(150mg/kg,i.p.) treated Sprague-Dawley rats (300-350g) were as follows:

	μg/24 hr (mean±S.E.)			
	Control (n=4)		+L-DOPA (n=5)	
Metabolite	free	total	free	total
mHPE	.53±.26	12±1	.36±.15	70±2**
pHPE	8.3±3.4	58±6	1.9±1.0*	37±9
pHPG	.12±.03	4.8±.9	.12±.06	4.9±1.8
MHPE	.18±.04	8.3±2.4	.96±.47	107±15**
MHPG	.95±.12	55±9	1.3±.17	80±6*

*p<.05, **p<.001: comparison vs controls, one-tailed t-tests.

Thus, this dose of L-DOPA produced 6- and 13-fold increases in total mHPE and MHPE,respectively, and a 47% increase in total MHPG. In a separate experiment,a high dose of L-DOPA(500 mg/kg) produced 15-,59- and 4-fold increases in the 24-hr excretion of total mHPE,MHPE, and MHPG,respectively. Whole brain concentrations of total MHPG and pHPG in control rats(160-200g)were 61±3 and 3.1 ±0.6ng/gm,respectively. MHPE was detected in only trace amounts (<2ng/g)in control rat brains and could not be quantitated. One hour following the i.p. injection of 100mg/kg of L-DOPA, brain levels of total MHPG,pHPG and MHPE were 93±4(an increase of 53% compared to controls,p<.001), 2.5±.3,and 14.3±2.1ng/gm. mHPE was not detected in either control or L-DOPA treated animals, and if present was <0.6ng/g. Our results suggest that L-DOPA is significantly metabolized in addition to DA to both NE and m-tyramine. These latter amines may therefore account for some of the effects of L-DOPA. However, since mHPE could not be detected in brain in either control or L-DOPA treated rats, it is unlikely that the formation of m-tyramine contributes to any CNS effects of L-DOPA.

Supported by grant MH-28340 from NIMH.

1102 SEROTONERGIC NEURONS IN THE GANGLION OF REMAK OF THE CHICK. Miles L. Epstein, Linda Hegstrand and Michael D. Gershon. Depts. of Anatomy and Psychiatry, Univ. of Wisconsin, Madison, WI 53706 and Dept. of Anatomy, Columbia Univ., Coll. Phys. and Surg., New York, NY 10032.

The ganglion of Remak is a neural structure, unique to avians, that extends from the cloaca to the bile duct on the dorsal surface of the gut. In recent studies, we have found this neural structure to contain axons that readily take up ^{3}H-serotonin (5HT). Pieces of hindgut from chick embryos of various ages were removed, incubated with ^{3}H-5HT (0.5μM), fixed, and processed for radioautography. Examination of the rectum from 7 and 8 day embryos showed the presence of some labeled cell bodies and axons inside Remak's ganglion. In older embryos the labeling of cell bodies is no longer seen and label is found only over axons. Biochemical analysis, using the method of Savedra et al. (J. Pharm, Exp. Ther. 186:508), of Remak's ganglion from newly hatched and from 4 week old chickens indicates the presence of endogenous serotonin. These observations suggest that there are serotonergic neurons in Remak's ganglion.

1103 FOURTH VENTRICULAR TANYCYTES IN THE RABBIT BRAIN STEM: A RELATIONSHIP WITH MONOAMINERGIC NUCLEI. David L. Felten, John P. Cummings, Suzanne Y. Felten* and Bruce Burnett*. Dept. Anat., Indiana Univ. Sch. Med., Indianapolis, IND 46227.

The ependyma of the fourth ventricle of adult and developing rabbit brains was examined with a Golgi-Cox method. Tanycytes with shafts extending into the rhombencephalon were found on the floor of the fourth ventricle. The somas of the tanycytes varied widely in shape, including cuboidal, polygonal, oval, and fusiform. Cilia frequently extended from the apical surface of the tanycyte somas into the fourth ventricle. Tanycyte necks tapered to both smooth and spiny shafts of varying lengths and widths. The widths ranged from less than 1 μm to more than 6 μm. The shafts extended into the brain stem to terminate in only 3 places: (1)Midline tanycytes on the floor of the fourth ventricle sent shafts into the midline region of the medullary raphe. These shafts entered a massive dendrite bundle and closely apposed cell bodies and dendrites of serotonergic nuclei raphe obscurus and pallidus, dendrites of the adjacent reticular formation which entered the bundle, and blood vessels of the midline. The shafts ran for 3000 μm or more in the adult rabbit medulla in a vertical orientation; (2) Paramedian tanycytes sent shafts into noradrenergic group A2 in nucleus intercalatus. The shafts abutted neurons in this region. A few shafts extended into the dorsal nucleus of X, just medial to group A2; and (3) Tanycytes at the lateral edge of the floor of the fourth ventricle sent shafts into the locus coeruleus, where they ended in apposition to cell bodies and dendrites of locus coeruleus, and local blood vessels. The shafts of the tanycytes traversed a zig-zag course through the rhombencephalon as they extended towards the monoaminergic nuclei. The tanycyte shafts extended into these nuclei as early as 18 days of fetal gestation. As the shafts reached the midline medullary raphe nuclei and locus coeruleus, the neurons showed a rapid expansion and maturation of dendritic arborizations. The tanycyte somas exhibited a very dull yellow fluorescence with the formaldehyde condensation technique. We suggest that (1) the tanycytes on the floor of the fourth ventricle send shafts almost exclusively into monoaminergic nuclei; (2) the tanycytes might serve as an anatomical communication channel between the fourth ventricle and the monoaminergic cells; and (3) the early appearance of these tanycytes in ontogeny may serve a trophic or permissive role on the dendritic sprouting of the monoaminergic nuclei in which they terminate, either directly or through a transported substance. 1104 REGULATION OF TYROSINE HYDROXYLASE ACTIVITY IN THE DOPAMINE NEURON AFTER SEVERE DOPAMINE DEPLETION. D.C. German, B.A. McMillen, M. Dalsass, and P.A. Shore. Univ. of Texas Health Science Center, Dallas, TX 75235.

Tyrosine hydroxylase (TH) in dopamine (DA) neurons is activated not only by enhancement of impulse flow, but also by cessation of impulse flow. Enhanced impulse flow is believed to result in TH activation via removal of end product (DA) inhibition of the enzyme as well as by kinetic changes in TH. Cessation of impulse flow is believed to result in TH activation because of the absence of released DA to act on presynaptic DA receptors.

To assist in an understanding of the relative contribution of enhancement or cessation of impulse flow to TH activity, we examined the consequences of severe DA depletion on in vivo TH activity in the rat corpus striatum (by 30 min. accumulation of striatal DOPA after decarboxylase blockade with NSD-1015). Accordingly, striatal TH activity was measured after a large dose of reserpine (2.5 mg/kg s.c.). One day later, TH activity had increased by about 3 fold. With no DA in the neuron to be released, it might be expected that the neuronal firing rate in nigro-striatal neurons would be compensatorily increased, yet no DA could be released to act on DA presynaptic receptors. Thus TH activation after severe DA depletion could arise by enhanced impulse flow, by a presynaptic mechanism, or by a combination of these. γ-Butyrolactone (GBL), which has been shown to cause a cessation of nigro-striatal impulse flow and to increase TH activity by a presynaptic mechanism, enhanced striatal TH activity about 3 fold. If reserpine's effect on TH were due solely to a lack of release of DA to act on presynaptic receptors, then GBL should not affect this action of reserpine. However, we found that GBL inhibited by over 50 percent the elevation of TH activity seen in one day reserpine rats. A similar degree of TH activation was observed in rats pretreated for 30 min. with the potent DA depleter, Ro 4-1284 (2.5 mg/kg i.p.), and GBL similarly inhibited this activation.

The marked inhibition by GBL of the elevation of TH activity seen after reserpine or Ro 4-1284 suggests that a significant portion of the enzyme activation is associated with enhancement of DA neuronal impulse flow. After the combination of reserpine-GBL (or Ro 4-1284-GBL), TH activity is actually lower than that seen following GBL administration to normal rats. This observation may be explained by the removal (by reserpine or Ro 4-1284) of DA storage function modulation of presynaptic regulation of TH activity as discussed elsewhere at this meeting (McMillen and Shore). Electrophysiological experiments are in progress studying the effects of DA depletion on DA neuronal impulse flow. (Supported by USPHS Grants MH-27574, MH-30546 and MH-05831).

1105 PROLIFERATION AND LACK OF SPECIES AND ORGAN SPECIFICITY IN THE TRANSIENT CATECHOLAMINERGIC CELLS OF DEVELOPING MAMMALS. Michael D. Gershon, Gladys Teitelman, Taube P. Rothman, Tong H. Joh and Donald J. Reis. Dept. of Anatomy, Columbia Univ. Coll. of P&S, New York, New York, 10032 and Dept. Neurol. Cornell Med. Coll., New York, New York, 10021.

Transient catecholaminergic (TCA) cells have been found in the mesenchyme of the developing rat gut (Cochard, Goldstein and Black, P.N.A.S. 75:2986, 1978; Teitelman, Joh and Reis, Brain Res. 156:229, 1978). These cells appear at 11 days' gestation and disappear before day 15. The TCA cells contain catecholamine and the biosynthetic enzymes, tyrosine hydroxylase (TH) and dopamine beta hydroxylase. In order to further evaluate the TCA cells we sought to determine if their appearance was specific for the rat gut or if they also appear in other species and in other organs. We also wanted to know if the cells are immature and still proliferating, or mature and postmitotic. The immunocytochemical demonstration of tyrosine hydroxylase (TH) with the unlabeled antibody, peroxidase-antiperoxidase method was used as a marker for TCA cells. A single injection of ^{3}H-thymidine (^{3}H-TdR), with a 2 hour survival period, was used to assess their proliferative ability. TCA cells were not limited to rat gut. They were also found in mouse gut where they were present by 10 days' gestation and disappeared before day 13. In addition, TCA cells appeared in rat kidney, sacral spinal cord, and dorsal mesentery. Several cells in the rat gut and other locations simultaneously displayed both markers. That is, they contained TH and were labeled by ^{3}H-TdR. We conclude that the TCA cells do not only occur in rats but occur in other mammalian species as well. Some of these ectopic and evanescent cells also colonize organs other than the gut. At least some of the TCA cells divide. These data suggest that migrating catecholaminergic precursor cells reach a variety of sites that do not, in adult mammals, contain adrenergic neuronal perikarya. It remains to be determined whether these immature dividing cells die or acquire non-adrenergic characteristics. 1106 SLOW BURSTING NEURONS IN THE PREOPTIC/ANTERIOR HYPOTHALAMUS OF UNANESTHETIZED RABBITS: EFFECT OF NOREPINEPHRINE, SEROTONIN, AND THERMAL STIMULATION. C. J. Gordon* and J. E. Heath. Dept. of Physiology and Biophysics, Univ. of Illinois, Urbana, IL 61801.

Rabbits were stereotaxically implanted with a guide tube to direct a microelectrode into the preoptic/anterior hypothalamus (POAH), a thermode and thermocouple reentrant tube to change and measure POAH temperature, respectively, and a cannula in the lateral ventricle to inject norepinephrine (NE) and serotonin (5-HT). A microdrive was secured to the head for lowering a tungsten microelectrode into the medial POAH. Firing rate of single units was recorded while the temperature of the POAH was clamped near 41°C and 34°C. When a neuron could be thermally classified, NE or 5-HT (30-100 µg) was infused into the lateral ventricle in concentrations of 1-3 µg/µl. Occasionally the single units were thermally stimulated both before and after the application of a neurotransmitter.

A total of 55 single units were isolated in the POAH with 30% displaying a rhythmic bursting activity. The time of bursting ranged from 9 to 67 seconds with a mean of 23±4 seconds. Three types of bursting neurons were isolated: (a) tonically firing cells induced into bursting by POAH thermal stimulation, (b) normally bursting units not influenced by POAH temperature but inhibited by NE (12% of bursting units) or 5-HT (19%), and (c) tonically firing cells induced into bursting by 5-HT (18% of bursting units) or NE (6%). In category "a" thermally induced bursting was inhibited by NE (12%) and 5-HT (19%).

Past investigations dealing with the measurement of thermally mediated motor responses have revealed rhythmic motor responses with frequencies similar to the neural bursting rhythms reported in this study. These monoamine and thermally sensitive bursting neurons may be important in the mediation of thermoregulatory reflexes.

1107 EXCITATORY EFFECTS OF GABA AGONISTS ON NIGRAL DOPAMINE CELLS: MEDIATION BY ACTION ON RETICULATA INHIBITORY NEURONS. Anthony A. Grace* and Benjamin S. Bunney. Depts. Pharmacol. & Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06510.

A number of investigators using biochemical and electrophysiological techniques have reported the apparent excitatory effects of indirectly applied GABA agonists on dopamine (DA) cells of the substantia nigra. We further investigated the effects of GABA on substantia nigra neurons using single unit recording techniques and microiontophoresis. Both DA neurons and non-DA zona reticulata neurons were found to be inhibited by microiontophoretically applied GABA. However, a population of non-DA cells in the zona reticulata (ZR) was found to be 20 times more sensitive to the inhibitory effects of GABA than were DA neurons. GABA applied microiontophoretically in the vicinity of the ZR neuron caused an increase in activity of nigral DA cells recorded simultaneously. This effect was blocked by i.v. picrotoxin. Conversely, the excitatory substance glutamic acid, when iontophoretically ejected into the ZR, caused an inhibition of DA neurons which was also blocked by i.v. picrotoxin. Dose response studies with the GABA agonist muscimol, administered parenterally (i.v.), revealed that incremental doses of muscimol increased the firing rate of DA neurons in a stepwise fashion which was directly proportional to the parallel inhibition this treatment induced in non-DA cells. Thus, GABA agonists appear to cause an increase in nigral DA cell firing rate by preferentially inhibiting GABA sensitive GABAergic reticulata neurons (i.e. through a process of disinhibition).

1109 THE SPINAL PROJECTION OF THE LOCUS COERULEUS (LC) = AN ELECTROPHYSIOLOGICAL STUDY. P. G. Guyenet, University of Virginia School of Medicine, Charlottesville, VA 22908.

It has been reported in one recent histofluorescence study that all the noradrenaline (NE)-containing neurons of the rat LC may send a collateral into the spinal cord (SC); using retrograde labelling techniques, others have suggested that only a fraction of LC cells, located in the posterior and deeper portions of the nucleus, send axons into the SC. In the present study, we confirm that even after multiple and massive pressure injections of HRP in the rat cervical SC (C_5 - C_7) only a subpopulation of LC cells, located as previously described, show evidence for the presence of the marker (2 - 3 µl total of 50% HRP, Hanker-Yates reaction). This result prompted us to perform a comparative electrophysiological study of SC and other LC projections. Single barrel or five barrel electrodes were used for recording single unit activity in rats anesthetized with chloral hydrate and bipolar concentric electrodes to stimulate the SC (C_6 - C_7) or the dorsal NE bundle (DB).

A small minority of LC cells only could be driven antidromically (AD) from the SC with latencies of 25 - 50 msec corresponding to conduction velocities of 0.5 to 1 m/sec. Prominent A-B break was observed with paired stimuli. The refractory periods of the A and B segments were respectively 2 - 2.5 msec and 12 - 100 msec. These cells were spontaneously firing at 0.2 to 2.5 spike/sec and could be totally inhibited by iontophoretic morphine and GABA. Their localization in the LC, as determined by the site of a spot of fast green iontophoresed after completion of recording, matched closely the topography of HRP labelled cells observed after SC injections.

Essentially in agreement with previous studies, most LC neurons could be AD-activated by stimulating the DB with latencies corresponding to conduction velocities of .6 to 0.8 m/sec. The refractory periods of the A and B components of the spikes were identical with that of neurons AD-activated from the SC. Three of these neurons (in 5) could be AD-activated both from the SC and the DB, although the current required to drive them from the DB was larger than that required to drive the majority of other LC cells.

It is concluded that the LC projection to the SC is composed of a subpopulation of neurons. These cells have an anteriorly directed collateral which presumably does not travel in the DB. Their electrophysiological and pharmacological properties are similar to those of the other cells in the nucleus.

1110 ALTERATIONS IN [^{3}H]CLONIDINE BINDING DUE TO 6-HYDROXYDOPAMINE AND MAO INHIBITORS. Margaret A. Hamburg*, Dorothy W. Gallager, Iain Campbell*, and John F. Tallman (SPON: W. E. Bunney, Jr.). Biological Psychiatry Br. and Clinical Neuropharmacology Br., NIMH, Bethesda, MD 20205

[^{3}H]Clonidine, an α-adrenergic agent, binds specifically to membranes prepared from rat cerebral cortex. Binding is rapid, reversible and saturable. Initial studies suggested two binding sites for clonidine; however, a ten-fold dilution of membranes led to the appearance of a single set of sites with properties like the higher affinity site. In addition, when incubations are carried out in the presence of guanyl nucleotides, GTP and analogues decrease steady-state binding by enhancing the dissociation rate ten fold due to the elimination of a slowly dissociating component of binding. Thus, only in the presence of GTP does both rapid and complete dissociation of bound clonidine occur. These experiments indicate that several factors might be responsible for the appearance of the two sites. The resolution of two sites into a single site depending upon assay conditions is supported by data showing the pharmacological profile of the apparent two sites to be identical: epinephrine > clonidine > norepinephrine > piperoxane > yohimbine > WB4101 > prazosin. This profile is different from that of the WB4101 binding site: prazosin > WB4101 > epinephrine > piperoxane > yohimbine > clonidine.

Lesions induced by intraventricular injection of 300 µg of 6-hydroxydopamine (6-OHDA) resulted in increases in the binding of [^{3}H]clonidine in cortex. Scatchard analysis over a full range of concentrations (0.25-40 nM) indicated a similar increase in binding at all points. WB4101 binding was also enhanced by 6-OHDA treatment.

Chronic (but not acute) treatment with the MAO inhibitor clorgyline (4 mg/kg, s.c. daily) resulted in a 25% decrease in the number of clonidine binding sites with no change in affinity. No changes in WB4101 binding sites were observed. These experiments indicate that [^{3}H]clonidine binds to a single population of high-affinity binding sites in brain which are distinct from binding sites for WB4101.

1111 LOCUS COERULEUS LESIONS: EFFECTS ON CEREBRAL OXIDATIVE METABOLISM IN VIVO: III-ACUTE AND CHRONIC CHANGES IN RELATION TO ADRENERGIC RECEPTORS. Sami I. Harik, Joseph C. LaManna, Myron Rosenthal and Shailesh P. Banerjee, Dept. Neurol., U. Miami Med. Sch., Miami, FL 33101 and Dept. Pharmacol., U. Rochester Med. Sch., Rochester, N.Y. 14642

Two weeks following unilateral locus coeruleus (LC) lesion produced by the local injection of 6-OH dopamine norepinephrine (NE) is depleted in the ipsilateral cerebral cortex of rats. NE levels in the cortical hemisphere contralateral to LC lesion are not different from those of control (sham lesioned) rats. NE depletion is associated with an increase in the density of β-NE receptors as measured by the specific binding of ^{3}H-dihydroalprenolol. No changes, however, in α-NE receptors are noted as measured by the specific binding of ^{3}H-WB-4101. NE depletion is also associated with loss of the normal blood volume increase when the cortical surface is stimulated to increased activity by electrical pulses. Also, re-reduction of cytochrome a,a_3, oxidized during the increased energy demand is slowed. The latter measurements were made from cortical tissues in situ by dual wavelength reflection spectrophotometry.

In order to determine if compensatory changes occur in NE-depleted hemispheres and to study the natural history of denervation supersensitivity, similar measurements were made 6 weeks following unilateral LC lesions. In these rats, marked NE depletion was again demonstrated in the cortical hemisphere ipsilateral to LC lesion. Despite the marked differences in NE levels between the two hemispheres, no differences were detected in the binding characteristics of α and β-NE receptors between the two sides. Likewise, increased energy demand produced by electrical stimulation was accompanied in both hemispheres by increased blood volume and transient oxidations and re-reduction of cytochrome a,a_3. The rates of each of these reactions did not differ in the two hemispheres.

The return of the density of β-NE receptor binding sites, as well as the metabolic events, to conditions similar to those of the control hemispheres, may be causally related or simply epi-phenomana of another event. In either case, it appears that the metabolic reactions described above may serve as an in vivo physiological index of β-NE receptor denervation supersensitivity. (Supported by Jack Wechter Memorial Fund)

1112 REGIONAL CHANGES IN CENTRAL NERVOUS SYSTEM CATECHOLAMINE METABOLISM DURING PERFORMANCE ON FIXED RATIO OR VARIABLE INTERVAL OPERANT SCHEDULES. Thomas G. Heffner, Daniel Luttinger*, John A. Hartman* and Lewis S. Seiden. University of Chicago, Chicago, IL 60637.

Previous studies have indicated that the performance of operant behavior is accompanied by changes in the metabolism of both norepinephrine (NE) and dopamine(DA) in the brains of rats. These experiments were designed to determine: 1) which central catecholamine (CA) projections are involved in this phenomenon and 2) if performance maintained by different operant schedule requirements is associated with differential alterations in CA metabolism. CA turnover rates in various brain regions were estimated from the decline of NE or DA levels from brain tissue following administration of the CA synthesis inhibitor α-methyltyrosine (αMT , 250 mg/kg, i.p.). Initial studies established that the decline of NE and DA from each brain region examined conformed to a single exponential function during a period of 1 hr after αMT injection. Water-deprived rats trained on either a fixed ratio 5 (FR-5) or a variable interval 5 second (VI-5) schedule of water reinforcement were placed in operant testing chambers after αMT injection. Water-deprived control rats were returned to single housing cages following αMT. All rats given αMT were sacrificed 37 min after injection. In rats performing on the FR or VI schedules, the apparent turnover rate of DA was increased relative to that in water-deprived control rats in the anterior striatum, the anterior hypothalamus, the amygdala and the spinal cord. No behavior-related changes in DA turnover rates were detected in the posterior striatum, posterior hypothalamus, nucleus accumbens, olfactory tubercle, septum, frontal cortex, ventral tegmental area or substantia nigra. Animals performing on the FR or VI schedules also showed an increased turnover of NE in the anterior hypothalamus relative to controls but showed no apparent changes in the relative rates of NE turnover in the posterior hypothalamus, nucleus accumbens, olfactory tubercle, amygdala, septum, substantia nigra, ventral tegmental area, hippocampus, cerebellum, frontal cortex or spinal cord. No schedule-dependent differences in the turnover rates of CA were observed between rats performing on the FR and VI schedules. These results indicate that the performance of operant behavior is associated with highly specific regional changes in the metabolism of catecholamines in brain. As such, these findings suggest that particular groups of central DA and NE neurons are involved in the mediation of conditioned behavior. (Supported by USPHS MH-11191-, MH-14274, MH-10562, and GM-07151).

1113 DECARBOXYLATION OF DOPA IN THE RAT STRIATUM AFTER COMPLETE AND PARTIAL UNILATERAL LESIONS OF THE NIGRO-STRIATAL SYSTEM. F. Hefti, E. Melamed, J. Liebman* and R.J. Wurtman. Lab. Neuroendocrine Regulation, MIT 56-245, Cambridge, Mass. 02139, USA.

The effects of L-DOPA were studied in animal models for early and end stage Parkinsonism using rats with partial and complete unilateral nigro-striatal lesions. 0.5 to 8ug 6-OH-DA injected in the substantia nigra (SN) produced a gradual decrease of striatal dopamine (DA) content. Complete lesions were obtained by injecting 8ug 6-OH-DA in the SN and additional 4ug in the medial forebrain bundle. After 2 weeks, the animals were injected with DOPA (100 mg/kg, 45min) and tyrosine hydroxylase (TH) and DOPA decarboxylase (DDC) activities were measured, as well as DA and its metabolites DOPAC and HVA (using HPLC with electrochemical detection).

In untreated animals with partial lesions, there was a linear correlation between TH activity and DA content in the lesioned striatum, indicating that TH activity can be used as a marker for the extent of the lesion. The DOPAC/DA and HVA/DA ratios were increased when the lesion reduced TH to more than 50%, suggesting increased DA release from the remaining neurons. Administration of DOPA produced increases in the striatal content of DA, DOPAC and HVA. In the lesioned side, DA levels did not reach the control side values whereas DOPAC and HVA were higher. After complete lesions (TH activity reduced to 5%, DDC to 20%, DA to 2%), DOPA administration increased DA concentration 4-fold to 8% in the lesioned striatum and 2-fold to 200% on the unlesioned side as compared to untreated and unlesioned controls. DOPAC and HVA levels were elevated far above control values on both sides. DOPA induced strong turning behavior away from the lesioned side, suggesting that the DA formed is functionally significant.

Animals with complete unilateral lesions and additional electrolytic lesions in the medial and dorsal raphe nuclei, which reduced striatal serotonin to 15%, also turned after DOPA and showed similar increases in striatal DA, DOPAC and HVA as rats with unilateral 6-OH-DA lesions alone after DOPA. In an additional experiment, different raphe lesions, which reduced striatal serotonin content ranging from 0 to 90%, failed to decrease striatal DDC activity. In order to test whether DOPA is decarboxylated in striatal blood vessels, animals with a complete cerebral hemisection were injected with DOPA and a peripheral decarboxylase inhibitor (which should inhibit DDC in blood vessel walls); DOPA still increased the very low DA content and markedly elevated DOPAC and HVA. In isolated bovine striatal microvessels, only a very low DDC activity was observed.

The data do not favor a major role of DDC contained in serotoninergic terminals or blood vessels in the decarboxylation of DOPA in the parkinsonian brain. This process may occur in residual DA neurons, but a role of other striatal cells is not excluded.

1114 CHANGES IN [H^3]-5-HYDROXYTRYPTAMINE RECEPTOR BINDING IN POST-MORTEM TISSUES: REGIONAL DISTRIBUTION OF [H^3]-5-HYDROXYTRYPTAMINE BINDING IN HUMAN BRAIN. J. A. Heltzel and W. H. Vogel, Dept. Pharmacology, Thomas Jefferson University, Philadelphia, PA 19107.

Membrane binding of [H^3]-5-hydroxytryptamine (5HT) was determined in crude homogenate preparations of whole rat brain minus cerebellum using the procedure of Bennett and Snyder (Molecular Pharmacol. 12: 373, 1976). Binding parameters of freshly dissected tissue and tissue frozen immediately following decapitation were evaluated by tissue linearity studies in the presence of 7 nM 5HT and by varying the ligand concentration in the incubation medium. 100 μM unlabelled 5HT served as a blank for non-specific binding.

	pmoles 5HT bound per gram tissue	K_D	B_{max}
Fresh Control	4.90 ± 1.34 (8)	1.4 nM	14.9
Frozen Control	4.34 ± 1.24 (4)	2.1 nM	17.4

No significant changes were noted in pmoles 5HT bound/g using 7 nM 5HT ligand, in the equilibrium dissociation constant (K_D), or in the number of receptor sites (B_{max}) between fresh and frozen tissue. Because specific 5HT binding represented a higher fraction of total binding at 3.5 nM ligand concentration, this level was used in the remaining studies. To simulate human post-mortem conditions, rats were killed by cervical dislocation, allowed to remain at room temperature for 3 hours, and refrigerated for 16 - 18 hours; brain tissue was removed on ice and stored at -70°C for 24 hours or longer.

	pmoles 5HT bound per gram tissue	K_D	B_{max}
Frozen Control	1.73 ± 0.67 (29)	2.1 nM	17.4
Frozen Post-mortem	2.76 ± 0.90 (31)	3.7 nM	10.6

Significant increases ($p < .001$) were observed in specific 5HT binding in post-mortem samples. An increase in the K_D was also seen in tissues from rats treated to reproduce human post-mortem conditions. 5HT receptor density appeared to be reduced.

Membrane receptor binding of 5HT in homogenates of human post-mortem brain samples showed the following preliminary profile of regional 5HT binding: pallidum > precentral cortex, hypothalamus > postcentral cortex, thalamus > substantia nigra, putamen. Regional distribution was estimated as a function of the pmoles 5HT specifically bound per gram tissue. Regional distribution determined by Scatchard analysis of subcellular fractions of human post-mortem brain samples are in progress.

1115 MULTIPLE ELECTROCONVULSIVE SHOCKS INCREASE AMPHETAMINE-INDUCED ROTATIONAL BEHAVIOR BUT REVERSE ITS PREFERRED DIRECTION IN RATS. Gordon K. Hodge and Thomas L. Hall*. Department of Psychology, University of New Mexico, Albuquerque, NM 87131.

Although the mechanism responsible for the therapeutic effect of electroconvulsive shock (ECS) remains obscure, biochemical, pharmacological, and some behavioral data suggest partial involvement of catecholamine (CA) systems. Manipulations of CA systems in rats affect a number of behaviors; if ECS treatment alters CA function, then it might be expected that ECS would produce commensurate behavioral changes in these animals.

To evaluate this possibility we compared effects of multiple ECS treatments (50 ma for 350 msec delivered across the ears; 1 treatment per day for 8 consecutive days; n = 14) with sham treatments (electrodes connected but no current; n = 14). 48 h before ECS treatments, all animals were administered d-amphetamine sulfate (2.0 mg/kg, i.p.), and rotational behavior was recorded for the following 3 h. 48 h after the last ECS treatment, all rats were again given amphetamine, and their rotational activity recorded for 3 h. Body weights were measured on days of amphetamine administration.

Amphetamine-induced rotational behavior increased following ECS treatments ($p < .05$). Moreover, the preferred sides of rotation, as assessed by pretreatment directions, were reversed by ECS ($p < .01$). Posttreatment body weights of ECS-treated rats were lower than those of sham controls ($p < .01$).

ECS treatment undoubtedly creates profound alterations in many neural systems. But because it is therapeutically efficacious in reducing depression, and since drugs which facilitate CA function are also effective in this regard, it is possible that at least one mechanism mediating ECS effects involves enhancement of CA systems. Our results are consistent with this interpretation. Insofar as increased rotational behavior is indicative of increased activity, the increased rotations of the ECS animals may have been due to higher activity of CA systems; this is consistent with pharmacological potentiation of these systems which results in hyperactivity and increased rotations. The cause of reversals in preferred direction of rotation is unknown, but such reversals may reflect a disparate effect of ECS on different systems or perhaps ECS exerts differential effects on functional components of the same system. While a number of factors may have accounted for the observed weight reductions in the ECS rats, it is known that facilitation of CA systems also promotes weight loss over the short term.

Supported by U.N.M. Research Allocations grant 020-812-402.

1116 LONG-TERM EFFECTS OF MULTIPLE DOSES OF METHAMPHETAMINE ON STRIATAL AND HIPPOCAMPAL TRYPTOPHAN HYDROXYLASE IN THE RAT. A.J. Hotchkiss* and J.W. Gibb, Dept. Biochem. Pharmacol. and Toxicol., University of Utah, Salt Lake City, Utah 84112.

Previous studies have shown that multiple sequential doses of methamphetamine (METH) cause a decrease in nigrostriatal tyrosine hydroxylase (TH) activity (Koda, L.Y. and Gibb, J.W., Pharmacologist 13 [1971] 253). Since there are many anatomical and biochemical similarities between the extrapyramidal dopaminergic system and the serotonergic projections from the raphe nuclei to the telencephalon, the activity of tryptophan hydroxylase (TPH), considered to be a marker for serotonergic neurons, was measured in the neostriatum and the hippocampus as well as in the pineal and midline raphe nuclei following multiple doses of METH.

Neostriatal TPH was reduced to 20% of control (35 mm/g/hr) at 24 hours following 4 doses of METH (15 mg/kg, s.c., every 6 hrs). In animals treated with a 5-dose regimen, TPH remained about 20% of control at 36 hours, 3.5 days and 8.5 days. At each time TH was also significantly reduced (40 to 50% of control).

The dose-effect of METH was evaluated using 4 sequential doses at 6-hour intervals and rats were sacrificed at midday, 5 days after the first METH dose. The doses studied were 5, 10, and 15 mg/kg. At this time, neostriatal TPH was 104%, 68% and 30% while TH was 96%, 91% and 56% respectively. A similar dosage schedule and time of sacrifice was used to evaluate three drugs for their ability to block METH effects on TPH; these drugs have been shown to block METH-induced depression of TH. Haloperidol (3 mg/kg i.p.), α-methyltyrosine methylester, (60 mg/kg, i.p.) or aminooxyacetic acid (30 mg/kg, i.p.) was given 4 times, concurrently with METH (15 mg/kg); in every case both neostriatal TH and TPH activities were not depressed when each of these drugs were coadministered with METH. This suggests that the mechanisms of action of METH and the drugs blocking the METH effect may be similar in both the dopaminergic and the serotonergic systems.

Other nuclei were also studied. Five days after 4 METH doses (15 mg/kg), hippocampal TPH was decreased to 28% of control while pineal TPH was not changed significantly. Midline raphe nuclei taken from a 1 mm slice (A 0.5 to P 0.5 mm, according to König and Klippel) also showed no change in TPH 5 days after 4 doses of METH. (Supported by USPHS grant 00869.)

1117 A SIMPLE TECHNIQUE TO DEMONSTRATE MONOAMINE CONNECTIONS UTILIZING AXONAL TRANSPORT OF A FLUORESCENT DYE IN COMBINATION WITH THE GLYOXYLIC ACID METHOD. Albert O. Humbertson, Jr. and Walter R. Buck, Dept. Anat., Sch. Med., The Ohio State University, Columbus, O., 43210.

Recently several investigators have combined the HRP technique with the glyoxylic acid method in order to determine if any of the neurons contributing to specific projections contain monoamines. This combined technique is useful, but somewhat laborious and time consuming. We have overcome some of the difficulty by utilizing a fluorescent dye, 4,6-diamino-2-phenylindole (DAPI), in place of HRP as a retrograde marker. This dye is retrogradely transported the same as HRP, but has the advantage that unfixed frozen sections can be used from the animal. The labelled neurons can be identified on slides with a fluorescence microscope equipped with a 360nm. filter system. We tested the feasibility of using this system with the glyoxylic acid method by injecting the fluorescent dye into the cervical spinal cord. Two days following the injection the animals were sacrificed and the brainstems and spinal cords were processed by the glyoxylic acid method. The sections were viewed with a 490nm. filter system in order to identify the monoamine containing neurons. The filter system was changed to 360nm. to identify the neurons containing the retrogradely transported DAPI. By merely switching the filter system back and forth, doubly labelled neurons can be identified. Details of the technique will be presented. (Supported by U.S.P.H.S. Grant NS-07410.)

1118 REGULATION OF RETINAL TYROSINE HYDROXYLASE: LONG-TERM EXPOSURE TO LIGHT INCREASED THE APPARENT Vmax WITHOUT A CONCOMITANT INCREASE OF ENZYME MOLECULES. P.M. Iuvone* and N.H. Neff. Dept. Pharmacol., Emory Univ. Sch. Med., Atlanta, GA 30322 and Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032

Continuous exposure of rats to light increased the rate of dopamine turnover in retinal amacrine neurons and gradually elevated the apparent Vmax of retinal tyrosine hydroxylase (TH) over a 4 day period. Three different immunotitration procedures were performed on retinal homogenates to determine if the change in apparent Vmax was caused by a change in the amount of enzyme protein or a change in the specific activity of the enzyme. Antibody directed against rat adrenal TH (donated by T.H. Joh) effectively inhibited retinal TH activity. All three immunotitration procedures indicate that the change in apparent Vmax was due to a change in TH specific activity rather than to a change in the amount of enzyme molecules. In addition, the change in apparent Vmax was found to be pH dependent, further supporting the notion of a change in specific activity.

Retinal amacrine neurons have dendritic processes but not axons. Our results suggest that changes in the specific activity of TH may be one of the mechanisms responsible for regulating catecholamine synthesis in dendrites.

1119 COMPARATIVE EFFECTS OF HALLUCINOGENIC DRUGS ON BEHAVIOR AND RAPHE UNIT ACTIVITY IN FREELY-MOVING CATS. Barry L. Jacobs and Michael E. Trulson. Program in Neurosci., Dept. Psychol., Princeton Univ. Princeton, NJ 08544.

The effect of hallucinogenic drugs is hypothesized to be mediated primarily through a depression of the activity of serotonin-containing neurons. This hypothesis was tested by recording single unit activity from the dorsal raphe nucleus of freely moving cats (see complete methodology in Brain Res. 163: 135-150, 1979), while concomitantly scoring the occurrence of hallucinogen-specific behaviors (e.g. limb flicking and abortive grooming). The following drugs were administed i.p.

Drug	Dose (µg/kg)	Raphe unit activity (change from baseline)	Limb flicks/hr
LSD	10	-18.0%	12.7
	50	-48.0%	25.8
DOM	50	- 9.5%	4.8
	250	-41.8%	32.2
Psilocin	100	-19.3%	5.0
	750	-54.5%	1.6
5-MeODMT	10	-14.2%	1.0
	50	-80.8%	5.8
	100	-87.6%	11.7
Amphetamine	5000	+64.0%	0

In general, these data confirm previous studies of the action of these drugs on raphe neurons in immobilized and/or anesthetized rats. These results also provide general support for the serotonin hypothesis of hallucinogenic drug action, since the four hallucinogens produced significant decreases in raphe unit activity, whereas amphetamine did not. However, since the potency of these various drugs in producing hallucinations in humans, and limb flicks in cats, i.e., LSD>DOM>5-MeODMT≅psilocin, does not correspond to their efficacy in depressing raphe unit activity, the latter effect apparently does not account for all of the important actions of hallucinogenic drugs. Aghajanian has shown that these drugs differ in their preferential action on raphe neurons as compared to their postsynaptic target neurons. Furthermore, several recent studies have shown that LSD and DOM have potent dopamine agonist effects, in addition to their effects on the brain serotonin system. Psilocin and 5-MeODMT, on the other hand, have little or no effect on the dopamine system. Therefore, we propose that inactivation of serotonergic neurotransmission is necessary and sufficient for hallucinogenesis, and that an additional dopamine agonist action greatly potentiates these effects.

1120 CHANGES IN CATECHOLAMINE CONCENTRATION-TIME PROFILES IN HEART. BRAIN AND PLASMA AFTER ACUTE ISCHEMIC STROKE. NADER S. JALLAD*, DONALD J. WEIDLER. Division Of Clinical Pharmacology Department of Pharmacology, University of Miami, Miami, Florida.

We have demonstrated previously that the onset of acute cerebral ischemia causes myocardial damage and cardiac arrhythmias. Since the alteration of tissue and plasma catecholamine concentrations may be important in effecting these cardiac changes, the concentrations of norepinephrine, epinephrine and dopamine in heart, brain, and plasma were studied as a function of time for 24 hr after the onset of acute ischemia stroke. Twenty-four anesthetized cats underwent ligation of the left middle cerebral artery, after which cats were permitted to awaken. Plasma samples were taken hourly and 4 cats each were killed at 4, 8, 12, 16, 20 and 24 hr. In brain tissue, norepinephrine and dopamine concentrations became significantly depleted in the ischemic cerebral hemisphere; but not in the non-ischemic hemisphere. The epinephrine concentrations in both ischemic and non-ischemic hemispheres did not change over the 24 hr. Plasma norepinephrine concentrations manifested two major peaks one at 8 hr and one at 20 hr. Plasma dopamine had a major peak at 8 hr and a minor peak at 18 hr, while plasma epinephrine peaked at 8 hr and 16 hr. In myocardial (left ventricular) tissue, the norepinephrine concentration was significantly elevated only in the 16-20 hr range; dopamine was elevated in the 4-8 hr range and peaked again at 16 hr. Myocardial epinephrine concentration had only one major peak, which occurred at 8 hr. The peak norepinephrine concentration in the heart (at 16 hr) was approximately 10 times the peak concentrations attained by epinephrine and dopamine. Based on these findings, we conclude that a period of increased susceptibility to cardiac arrhythmias may occur in the 16 -20 hr period after the onset of acute cerebral ischemia.

1121 CIRCADIAN RHYTHMS IN α- and β-ADRENERGIC RECEPTOR BINDING IN RAT BRAIN. Marian S. Kafka, Anna Wirz-Justice*, Dieter Naber*, and Alfred J. Lewy. National Institute of Mental Health, Bethesda, MD 20205

Psychoactive drugs such as antidepressants and neuroleptics alter specific binding to brain adrenergic receptors. In the pineal gland, a marked circadian rhythm in β-adrenergic sensitivity has been found in the absence of drug treatment. This study was designed to investigate whether under physiological conditions a circadian rhythm in α- and β-receptor binding was present in the brain.

Male Sprague-Dawley rats maintained for 3 weeks on a controlled light/dark cycle (lights on from 7 a.m. to 7 p.m.) were sacrificed in groups at 4-hour intervals, plasma prepared from the pooled blood, and hypothalami and forebrains (anterior to the cerebellum) dissected and frozen. Alpha- and β-adrenergic receptors in rat brain membranes were measured by the specific binding of [^{3}H]-WB4101 and [^{3}H]dihydroalprenolol, respectively. Plasma melatonin was measured by gas chromatography-mass spectrometry.

Melatonin showed the expected nocturnal rise, indicating the adequacy of the entraining light/dark cycle. Forebrain α-adrenergic receptor binding increased in the afternoon. The difference between minimum and maximum binding was 37% (analysis of variance, $F = 7.18$, $p < 0.001$). β-Adrenergic receptor binding increased in the morning. The difference between minimum and maximum binding was 39% (analysis of variance, $F = 5.48$, $p < 0.001$). Binding to α- and β-adrenergic receptors in the hypothalamus followed the same patterns as in the forebrain.

The circadian variation in α- and β-receptor binding suggests that circadian changes in the occupancy of adrenergic receptors by the neurotransmitters norepinephrine and epinephrine may modulate adrenergic function in the brain. The short-term physiological changes in adrenergic receptor binding are of the same order of magnitude as the changes observed after long-term drug treatments. While the time of day at which the rats are sacrificed (e.g., morning or afternoon) alters the magnitude of the receptor binding, it remains to be seen whether drug-induced changes in the number of adrenergic receptors are dependent on changes in the number of receptor sites, a shift in the timing (phase) of the circadian rhythm, or on both of these factors.

1122 RELEASE OF NOREPINEPHRINE AND DOPAMINE IN VITRO FROM BRAIN REGIONS OF AMYGDALOID KINDLED RATS. G. Jean Kant, James L. Meyerhoff, and Michael E. Corcoran. Dept. Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20012, and Dept. Psychology, Univ. of Victoria, Victoria, B.C., Canada.

Goddard et al. reported that brief bursts of subconvulsive non-polarizing electrical brain stimulation presented chronically to certain brain structures resulted eventually in a permanent change in the response of the animal to include localized seizure discharge, behavioral automatisms and generalized convulsions. This "kindling effect" has been shown to be trans-synaptic in nature, but the mechanism and specific neurons involved have not been identified. Considerable data indicate that brain catecholamine systems suppress various types of seizure susceptibility. It has been shown that drugs that potentiate norepinephrine and dopamine function suppress seizures while drugs that interfere with these monoamines can increase seizure susceptibility.

In our laboratory we have developed a sensitive model technique to measure small absolute amounts of endogenous norepinephrine and dopamine released in vitro. We decided to use this method to determine whether amygdaloid kindling involves permanent changes in the releasability of NE and/or DA from various brain regions.

Thirty-four male Long-Evans rats were stereotaxically implanted with bipolar electrodes into the basolateral amygdala. Seventeen animals were kindled beginning 10 days after surgery. Each day the rats received 1 sec of constant current 60 Hz square wave stimulation. The remaining rats served as yoked controls, receiving electrical stimulation at 3 Hz (a non-kindling frequency) for 1 sec. daily.

Three weeks after the last seizure, the animals were sacrificed by decapitation; the brain was removed and dissected into: amygdala-pyriform, frontal cortex, parietal cortex, caudate, accumbens-tubercle, thalamus, hippocampus, hypothalamus, and septal region. The brain tissue pieces were weighed, chopped (0.3mm x 0.3mm), and washed twice with cold Krebs-Ringer bicarbonate buffer. Each sample was then resuspended in 1.0 ml of 37°C buffer and incubated at 37°C for 10 minutes with or without added KCl to bring the final KCl concentration to 5,15 or 45 mM. Release was terminated by centrifugation and the supernatants were analyzed for NE and DA by radioenzymatic assay.

Spontaneous release of NE and DA was measurable in all regions studied. Added Potassium stimulated an increase in release of both transmitters with 45mM KCl having a greater effect than 15mM KCl.

Both spontaneous and KCl-stimulated release of NE and DA were similar for both kindled and control tissue in all tested regions.

1123 PHENYLACETIC ACID EXCRETION IN SCHIZOPHRENIA. F. Karoum, L. Chuang*, S. Potkin* and R. J. Wyatt. Lab. of Clinical Psychopharmacology and Lab. of Preclinical Pharmacology, DSMHR, Division of Special Mental Health Research, NIMH, Saint Elizabeths Hospital, Washington, D. C. 20032

Phenylethylamine (PEA) is hypothesized to be elevated in some schizophrenic patients. To further assess the role of PEA in this disorder, we measured the excretion of phenylacetic acid (PAA), the major metabolite of PEA, in 31 normal subjects and, 29 chronic schizophrenics.

The total and glutamine conjugate of PAA excretion was significantly ($p<0.01$) reduced in the chronic schizophrenic patient. It was unaltered in depressed patients. The total excretion of PAA (mean ± SEM) in controls, and schizophrenics was respectively, 161.87 ± 19.1 and 100.38 ± 12.5 mg/24 hr.

Further studies are needed to determine whether or not the altered PAA excretion is related to reduced monoamine oxidase activities in schizophrenics or to abnormal phenylalanine metabolism.

1124 STRESS-INDUCED INCREASE IN DIHYDROXYPHENYLACETIC ACID IN RAT FRONTAL CORTEX: MODIFICATION BY CHRONIC EXPOSURE TO COLD. Linda Kennedy*, Charles Saller*, and Michael Zigmond (SPON: B. N. Dixit). Department of Pharmacology, School of Pharmacy, and Departments of Psychology and Biological Sciences, University of Pittsburgh, Pittsburgh, PA. 15260.

Rats subjected to restraint showed a significant elevation in plasma catecholamines 15 minutes after the onset of the stress (6-8 ng/ml peak vs. basal level of less than 2 ng/ml). This was accompanied by a 41% increase in dopamine (DA) (control,.060 µg/g; restrained, .084 µg/g; $p<.05$), and a 29% increase in dihydroxyphenylacetic acid (DOPAC) (control, .047 µg/g; restrained, .060 µg/g; $p<.05$) in frontal cortex, suggesting an increase in DA turnover in that structure. No such change was observed in the striatum. The DOPAC concentration of frontal cortex was also increased 45% by a second stressor, 2-deoxy-D-glucose (750 mg/kg, i.p., administered 30 minutes prior to sacrifice). This apparent increase in DA turnover in frontal cortex was not accompanied by a change in cAMP content, although d-amphetamine (1.5 mg/kg, i.p.) did produce a 41% increase in cAMP which could be blocked by prior administration of fluphenazine (0.5 mg/kg, s.c.).

We next examined the ability of restraint to elevate DOPAC in animals subjected to chronic stress. Rats were maintained at 4°C for 15 days prior to sacrifice. Such treatment induced a 25% increase in tyrosine hydroxylase activity in frontal cortex (controls, 8.47 pmole/mg protein/min; chronic cold, 10.38 pmole/mg protein/min; $p<.05$), but no increase in DOPAC level. However, in cold-stressed rats, 15 minutes of restraint produced a 94% increase in DOPAC, a three-fold larger increase than that observed following restraint in naive animals.

These data thus support previous suggestions that stress increases DA turnover in rat frontal cortex. They further suggest that chronic stress enhances the biochemical response to subsequent acute stress.

1125 DIFFERENTIAL PROJECTION INTO THE DORSAL RAPHE COMPLEX BY BRAIN STEM AFFERENTS. R. E. Kingsley*, J. Strahlendorf, H. Strahlendorf and C. D. Barnes, Dept. Physiol., Texas Tech University School of Med., Lubbock, TX 79430, *Dept. Physiol. Indiana University School of Med., South Bend IN. 46556.

The Dorsal Raphe complex (DR) is a particularly complicated region of the reticular formation which receives afferent fibers from widely scattered and functionally dissimilar regions of the CNS (1). Because of the great deversity of these inputs, it is particularly appropriate to determine the degree of physiological convergence and divergence of the afferents within the Raphe.

In response to single shock stimuli delivered to the Locus Caeruleus (LC), Substantia Nigra (SN) and the Inferior Olive (IO), we recorded field potentials from within the DR. These recordings were made along a series of points from a set of electrode tracks which passed thru portions of the nucleus. After recording from a large number of points, we constructed a 4th dimensional matrix of data values which represented the rostral/caudal vs dorsal/ventral position vs voltage vs time response of the neurons within the DR to the corresponding stimulus. The voltage measurements were converted to relative current according to the method of Howland et. al. (2). Their algorithm eliminates the dominating effect which large somas and axon bundles have on ordinary field potential recordings. Finally, these data were plotted as a time-sequenced series of topographical contour maps with the peaks and valleys representing the sources and sinks of current respectively. Current sources are areas of net CNS depolarization.

Earch of the three nuclei which were stimulated evoked rapidly developing (<0.5 msec.) current sinks which persisted as long as 7 msec. after the stimulus. One of these sinks, in the center of the nuclear complex, was common to all three stimuli. Other current sinks developed later (1.5 to 5.0 msec.) for each of the stimuli. In general, the LC evoked these later sinks in the caudal region of the DR followed by a very late developing, but intense sink in the rostral portion. The SN evoked additional sinks in the caudal, dorsal and rostral portions of the DR. The dorsal and rostral sinks overlapped the large rostral LC sink, but was activated earlier by the SN. Late sinks associated with IO stimuli were very complex, but were in general confined to the rostral part of the DR.

1126 BLOCKADE OF DORSAL CENTRAL GRAY AREA FEARLIKE AVERSION BY DORSAL RAPHE NUCLEUS STIMULATION. R. Sanford Kiser, Cora A. Brown, Manjit K. Sanghera and Dwight C. German. Depts. Psychiat. and Physiol., Univ. Tex. Health Sci. Ctr., Dallas, TX 75235.

Stimulation of the dorsal central gray area (DCG) and adjacent tectum elicits aversive affective sensations of fear and apprehension in humans and "fearlike" behavior in animals. Previous pharmacological studies have suggested that a serotonin (5HT) mechanism inhibits DCG fearlike behavior. The present study tested whether the nearby 5HT-containing dorsal raphe nucleus (DRN) is involved.

Rats were implanted with two bipolar stimulating electrodes, in the DCG and the DRN. The animals were trained to escape DCG stimulation (100 msec trains of capacity coupled cathodal square wave pulses, 0.5 msec pulse duration, 60 Hz, 5 trains per second) by decremental bar pressing. In this paradigm, each bar press during a DCG stimulation period decrements the DCG current by 5% of its initial level. The animals received a baseline test run, consisting of twenty-five 120 second DCG stimulation trials (average initial DCG current = 20.4 ± 3.0 μA RMS) separated by 120 second time-out periods (with no brain stimulation). During the baseline test run, both the average number of decremental bar presses and the average latency to the first decremental bar press remained relatively constant. The following day, the animals received an identical test run, except that DRN stimulation (100 msec trains of capacity coupled cathodal square wave pulses, 0.5 msec pulse duration, 2 Hz, 5 trains per second) at 50.0 μA RMS was administered during the time-out periods preceding the first 15 DCG trials.

DRN stimulation caused a decrease in the average number of decremental bar presses, an increase in the average first bar press latency, and a profound reduction in the DCG fearlike behavior, yet did not cause somnolence or other signs of behavioral impairment. This "anti-aversive" effect had a long latency to onset and persisted long after the cessation of DRN stimulation. Six days later, a test run identical to the baseline test run revealed that bar pressing had returned to baseline.

These data indicate that stimulation of the DRN area reduces DCG fearlike behavior, possibly by influencing the DRN itself (or nearby endorphin-containing neurons). (Research supported by NIMH grant MH-26032.)

1127 DEVELOPMENT OF MONOAMINERGIC CIRCUITRY IN SOMATOSENSORY CORTEX OF NEONATAL RAT. Donald A. Kristt and James D. Silverman*. Dept. Path., Johns Hopkins Univ. Sch. Med., Baltimore, Md. 21205.

In the present study three aspects of developing MA synaptic organization in postnatal neocortex were evaluated: (i) the distribution and numerical density of MA synapses as a function of age and cortical depth, (ii) the structure of early formed MA synapses as compared to non-MA synapses, and (iii) differences among MA synapses themselves as a function of cortical depth. Forty Sprague-Dawley rat pups, ranging in age from newborn to 16 days of age were studied. MA synapses were identified using an ultrastructural cytochemical marker, 5-hydroxydopamine (5-OHDA), which results in the appearance of small granular vesicles (SGV) in their pre-synaptic terminals. From birth to 7 days of age, 20-30% of all synapses, sampled in somatosensory cortex, contain SGV's. However, few SGV synapses are seen in 8 day old cortex, and by 12 days of age, SGV's are no longer detectable in cortex. A specific distribution for these SGV synapses -- which is distinct from the overall synaptic distribution -- is first seen at 3 days of age and is essentially unchanged until 7 days postnatally. During this entire period, the SGV synapses predominate in the primordium of layer IV, where they account for 50-70% of all synapses. Morphometric analysis of SGV synapses indicates that there are differences in junctional symmetry, vesicle shape and configuration of the contact zone between SGV and non-SGV synapses, as well as between SGV synapses themselves in the various cortical layers. The laminar distribution and morphological characteristics of SGV synapses suggest that the MA projection to neocortex exhibits a high degree of spatial specificity during its ingrowth. Also, the relatively high proportion of SGV synapses in the first postnatal week may reflect a potent influence exerted by the MA inputs on immature neocortex. The decreased numerical density of SGV synapses after 7 days of age is probably due to the development of the blood-brain barrier to 5-OHDA.

Although the origins of the pre-synaptic elements are not definitely established there is evidence that they are derived from MA nuclei in brainstem, and that they arrive in cortex before birth. Since this has not been directly tested, somatosensory cortex of several neonatal rats have been injected with HRP. It was found that in the locus coeruleus numerous cells ipsilateral to the injection are retrogradely labeled before the SGV synapses become concentrated in primordial layer IV. No neurons in the raphe nuclei in midbrain were labeled. A few neurons located in the region of C.N. VII were retrogradely labeled and may represent catecholaminergic neurons from cell group A5.

1128 LOCUS COERULEUS LESIONS: EFFECTS ON CEREBRAL OXIDATIVE METABOLISM IN VIVO. II THE COUPLING BETWEEN OXYGEN DELIVERY AND ENERGY DEMAND. Joseph C. LaManna, Andrew I. Light,* Sami I. Harik and Myron Rosenthal, Dept. Neurol., U. Miami Med. Sch., Miami, FL 33101

When the cerebral cortex of rats is stimulated focally by trains of electrical square-wave pulses (2 sec trains, 20 Hz, 0.5 msec duration), there is a negative shift of extracellular potential, an increase in extracellular potassium ions and a proportional increase in local metabolic demands. The latter is measured in situ by dual wavelength reflection spectrophotometry of cytochrome a,a_3 or by NADH microfluorometry. The stimulus-induced transient oxidation of cytochrome a,a_3 is accompanied by an increase in local blood volume, as indicated by increased absorption at 590 nm. Re-reduction of cytochrome a,a_3, which occurs within approximately 5-10 sec following termination of stimulation, is accompanied by a decrease in blood volume back to baseline levels. Similar responses occur in the rat cerebral cortex contralateral to 6-OH-dopamine lesion of the nucleus locus coeruleus (LC). However, in the norepinephrine (NE) depleted hemisphere ipsilateral to LC lesion, blood volume responses to electrical stimulation are greatly diminished or absent and the rate of re-reduction of oxidized cytochrome a,a_3 is markedly slowed. The time to peak oxidation of cytochrome a,a_3 is amplitude-independent in normal control rats and this is unaltered in either cortical hemisphere of unilateral LC lesioned rats. The time to half recovery of the oxidized cytochrome is only slightly dependent upon amplitude. Ipsilateral to LC lesion, the recovery time is not only increased, but becomes strikingly amplitude-dependent; i.e. the effect of NE depletion becomes more pronounced at higher stimulus intensities or greater energy demands. Preliminary results indicate that the rate of NADH oxidation as well as the rate of NAD^+ re-reduction with stimulation is slowed in the cortical NE depleted hemisphere. The significance of the time to peak oxidation of NADH is that it is controlled by the rate of ADP availability and is ouabain sensitive. Thus, these results suggest that NA-K -ATPase is slowed in the cortical hemisphere depleted of NE by LC lesion and also indicate that the dynamic coupling between oxygen delivery and energy demand is altered when NE is unavailable. (Supported by PHS grants NS 14319 and NS 14325.)

1129 IN VIVO VOLTAMMETRIC RECORDING OF DOPAMINE AND 5-HYDROXYTRYPTAMINE RELEASE AND METABOLISM FROM DIFFERENT BRAIN REGIONS OF THE RAT. Ross F. Lane*, Arthur T. Hubbard* and Charles D. Blaha*. (SPON: M.L.Laudenslager, Jr.). Dept. Chem., Univ. Calif. Santa Barbara, CA 93106.

Voltammetric methods have been developed which allow continuous, simultaneous in vivo monitoring of the extracellular levels of dopamine (DA), homovanillic acid (HVA) and 5-hydroxytryptamine (5-HT) in brain tissue of the unanesthetized, unrestrained rat. A potential is applied to a carbon electrode (5-175 μm) stereotaxically implanted in a specific brain region and changes in current attending oxidation of DA, 5-HT and HVA are recorded. The potential at which oxidation occurs is indicative of which molecule is being oxidized. The methods are currently being used to study drug-induced release of DA and 5-HT from rat caudate nucleus (CN) and substantia nigra (SN). In the CN, amphetamine (AMP) administration evoked a rapid, temporary and dose-related release of DA, time-correlated with characteristic AMP-induced behavioral effects. Conversely, α-methyltyrosine (AMT, 250 mg/kg) induced a gradual and long lasting decrease in DA release and HVA formation. 5 hr after AMT treatment, release of DA elicited by AMP was completely prevented. Treatment with the DA receptor agonist apomorphine (2 mg/kg) caused a rapid and transitory decrease in DA release with time course in correlation with drug-induced stereotyped behavior. DA release and HVA synthesis were also stimulated by the antipsychotic neuroleptic DA antagonists pimozide, spiroperidol and haloperidol. Both DA and 5-HT were found to be rapidly released in CN by p-chloroamphetamine (PCA, 5 mg/kg). PCA-induced release of 5-HT was selectively prevented by pretreatment with p-chlorophenylalanine (300 mg/kg) and blocked by the 5-HT uptake inhibitor fluoxetine (20 mg/kg)(Lilly). Fluoxetine alone (20 mg/kg) produced a moderate increase in 5-HT, presumably due to inhibition of 5-HT reuptake.

AMP, AMT and apomorphine were also used to investigate release of DA from SN. Release of DA was stimulated by AMP (5 mg/kg) and decreased both by AMT (250 mg/kg) and apomorphine (2 mg/kg). Pretreatment with AMT (250 mg/kg) prevented AMP-stimulated release of DA.

These data indicate that in vivo voltammetry can be succussfully employed to probe the functional dynamics of DA and 5-HT neuronal systems. They provide support for currently held views that dendritic release of DA in SN may serve as an additional mechanism regulating the activity of the DA nigrostriatal pathway. (Supported by USPHS NIH Grant NS 13556).

1130 GENESIS OF CENTRAL MONOAMINE (MA) NEURONS IN THE RHESUS MONKEY. Pat Levitt and Pasko Rakic. Section of Neuroanatomy, Yale Univ. School of Medicine, New Haven, Ct.

Neurogenesis of the locus coeruleus (LC), substantia nigra (SN) and raphe complex (RC) was analyzed in autoradiograms from twenty-two 2-3 month old monkeys, each of which had been exposed to a pulse of ^{3}H-thymidine on selected embryonic (E) days. Heavily labeled neurons, representing cells that had undergone final division on the day of the ^{3}H-thymidine injection, were noted only in 8 monkeys exposed to the isotope between E27-43. LC neurons are generated between E27-36 with the major proliferation occurring between E30-33 and peaking around E32 (13% labeling index; heavily labeled neurons/total neurons). Neurogenesis in the LC occurs in a prominent mediolateral spatiotemporal gradient, such that the majority of neurons generated on E30 eventually become situated in the medial part of the nucleus, whereas most cells in the lateral portion are generated on E32 and E33. A sharp peak of proliferation of neurons destined for the compact portion of the LC occurs around E32. Cells that comprise the more diffuse areas of the LC are generated more evenly throughout the E30-33 period. SN neurons are generated between E36-43, with peak labeling in both pars compacta (12%) and pars reticulata (9%) occuring in specimens injected at E38 or E40. No appreciable spatiotemporal gradient was noted in either portion of the SN. Neurons of the ventral tegmental area are also generated between E38-43. Neurogenesis of the RC occurs between E28-43 with only a moderate rostrocaudal spatiotemporal gradient: Neurons of raphe dorsalis and centralis superior undergo final mitosis between E28-36, with the largest fraction of heavily labeled neurons (6 & 15% respectively) at E30, whereas cells of raphe magnus, pontis, obscurus and pallidus are generated between E28-43, with the highest labeling indices (27, 23, 19 & 17% respectively) in cases injected at E38 and E40. Thus, brainstem MA nuclei of rhesus monkey are generated during the first quarter of prenatal life. Histochemical studies in human embryos also indicate that MA neurons are present during the first quarter of gestation (Olson, et al., Z. Anat. Ent.-Gesch., 139, 1973). Thus, the timing of neurogenesis of MA systems in primates differs significantly from that in rodents, where genesis of these nuclei begins around midgestion and extends well into the last half of fetal life. (Lauder, et al., J. Comp. Neur., 155, 1974; Pierce, Prog. Br. Res., 40, 1973). However, although gestation in the rhesus monkey (165 days) is nearly 8 times longer than that in rodents (21 days in rat), and the number of MA cells several times greater, the majority of neurons of any single nucleus is generated within a similarly short period in the two species (3-4 days in rodent; 3-5 days in macaque), indicating that MA neuron systems in primates develop rapidly from a larger precursor pool. (Supported by NS 14841).

1131 NEOCORTICAL DEVELOPMENT AFTER PRENATAL LESIONS OF NORADRENERGIC PROJECTIONS. Hart G.W. Lidov and Mark E. Molliver, Departments of Cell Biology/Anatomy and Neurology, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

Monoaminergic axons are amongst the earliest extrinsic afferents to invade the developing telencephalon. Axons that synthesize catecholamines are present in the rat telencephalon as early as 13-14 days of gestation, while neurons of the cerebral neocortex are born later, between day 14 of gestation and the first post-natal day. Furthermore, in perinatal cerebral cortex, presumably monoaminergic synapses constitute a large proportion of the total synaptic population (70% in layer IV of SI). Combined with supporting biochemical data, these facts have led to the proposition that monoaminergic projections may exert a trophic influence on other elements of the neuropil in the immature nervous system. We are attempting to test this hypothesis by chemical destruction of the cortical noradrenergic afferents in fetal rats.

Fetuses were given intraperitoneal injections of the neurotoxin, 6-hydroxydopamine (200 mg/kg) on day 17 of gestation. The effectiveness of the lesions was confirmed in adults by glyoxylic acid histofluorescence and dopamine-β-hydroxylase immunofluorescence; vehicle injected animals were used as controls. In addition examination of the brains by Nissl and Golgi methods revealed the following findings: 1) The gross morphology, lamination, and cytoarchitecture of cortex appear normal. Dendritic arbors and spines are qualitatively normal. 2) The structure of the barrel field was examined in tangential sections as a measure of the thalamic influence on cortex. The barrels appeared normal in both form and size. 3) Histofluorescence reveals that the dopamine axons retain their normal distribution in frontal, cingulate, and perirhinal cortex and do not sprout into layers or regions normally occupied by noradrenergic fibers. 4) A large number (6/24) of animals had foci of ectopic neurons. These cells were found either adjacent to the ependymal layer or at the brain surface between the pia and the molecular layer. These results indicate that while cortex organization proceeds normally in the absence of noradrenergic afferents, these axons may influence either neuronal proliferation or migration. Further studies are in progress to assess the effects of similar lesions placed on days 13 and 15 of gestation. We conclude that no evidence for a trophic effect of noradrenergic axons upon the development of cortical neurons or layers has been demonstrated. {Antiserum to DBH was generously provided by Reinhard Grzanna. 1132 DOPAMINE MODULATORY ACTIONS AT NEUROMUSCULAR JUNCTIONS OF LOBSTER STOMATOGASTRIC SYSTEM. C. Lingle. (SPON: D.L. Barker). Dept. Biol., U.O., Eugene, OR 97403.

Striated muscles of the stomatogastric system of many decapod crustacea receive excitatory innervation from either cholinergic or glutamatergic-type motor neurons. The effects of dopamine on muscles and neuromuscular junctions of the spiny lobster, Panulirus interruptus, foregut were examined.

Dopamine produces prolonged enhancement of nerve-evoked contractions down to at least 50 nM at both types of junctions. In two muscles receiving cholinergic innervation, enhancement occurs at 5 nM or less. In these two muscles dopamine also produces a contracture and frequently elicits spontaneous rhythmic contractions that occur asynchronously in different fibers. The presence of such contractions just after removal of appropriate muscles from the animal suggests exposure to an endogenous agent able to elicit such activity, perhaps dopamine. That the mechanisms underlying rhythmic contraction are endogenous to the muscles, but require tonic activation, is suggested by 1.) asynchrony among adjacent fibers, 2.) lack of effect of cholinergic receptor blockade or TTX, and 3.) failure of 1/10 Ca^{+2} to reduce spontaneous activity while evoked contractions are reduced. Octopamine and serotonin do not elicit these contractions, but reduce and increase, respectively, the frequency of their occurrence.

Intracellular recording from sensitive muscles during dopamine application reveals a slow depolarization and a conductance decrease, consistent with the slow contracture. A potassium conductance decrease is likely. Additionally, during dopamine application spontaneous rhythmic conductance increases are observed which may be either hyperpolarizing, when contractions do not occur, or depolarizing. A chloride conductance increase is likely. In muscles in which dopamine only produces enhancement of evoked contractions, effects on membrane potential are less clear. Generally, small depolarizations are observed. Although effects on hyperpolarizing current pulses are small, dopamine produces an apparent conductance decrease when measured by depolarizing current pulses. The enhancement of ejps produced by dopamine can not be accounted for entirely by effects on membrane resistance, suggesting that both pre- and post-synaptic sites of action are likely. In addition, since the rate of relaxation of evoked contractions is increased during dopamine, a direct non-electrical effect on muscle is indicated. These effects of dopamine appear to be unique to neuromuscular junctions of the stomatogastric system, since no effects of dopamine on Panulirus opener muscle evoked contractions were observed at 10 uM or below.

1133 DISRUPTION OF THE CIRCADIAN RHYTHM OF EXCITABILITY IN THE MESOLIMBIC CATECHOLAMINE SYSTEM BY PERIPHERAL DEPRIVATION OF LATERAL EYE MOVEMENTS AND REM. A. Livermore, Jr.* and J. R. Stevens, Depts. Neurol. & Psychiat., Univ. Oregon Health Sci. Center, Portland, OR 97201, USA.

The rapid eye movements (REMs) of paradoxical sleep (PS) evoke light modulated potentials and multiple unit activity in the suprachiasmatic nucleus and in the ventral tegmentum of the mesencephalon, junction of dopamine cells of origin of the mesolimbic and nigrostriatal systems with the medial terminal nucleus of the accessory optic tract (Stevens & Livermore, Exp. Neurol. 60:541, 1978). Relationships observed between PS, photoperiod, maturation, and reproductive activities, led to the hypothesis that REMs may serve to transmit photic information to regions of the brain which modulate cerebromonoamine transmission in relation to daily and seasonal light changes.

To test this hypothesis, mesolimbic dopamine system excitability was examined in rats deprived of eye movements by peripheral muscle section. Injection of low-dose amphetamine in the rat induces a marked increase in locomotor activity which depends on the integrity of the mesolimbic dopamine system. This response displays a circadian cycle reaching a zenith around midnight and a nadir around noon in rats on a 12:12 light:dark cycle. Twenty-two Long Evans rats, 11 eye muscle resected and 11 sham controls, were injected with 1.2 mg/kg d-amphetamine i.p. at 0100, 0700, 1100, 1500, and 1900 hours at intervals of not less than 28 hours and placed in activity cylinders equipped with photocells which recorded locomotor activity. Twelve weeks postoperatively, the normal relationship of the amphetamine-induced hyperactivity response to the daily light:dark cycle of operated rats was grossly disrupted compared with sham-operated controls. In two animals inadvertantly blinded by the surgery, the circadian rhythm of the response was abolished. The data lend support to the hypothesis that lateral eye movements and REMs provide photic modulation to cerebral centers which regulate biologic rhythms of mesolimbic catecholamine activity.

1134 EVIDENCE THAT SEROTONIN IS A CIRCULATING NEUROHORMONE IN THE LOBSTER. Margaret S. Livingstone* and Edward A. Kravitz. Dept. Neurobiol., Harvard Med. Sch., Boston, MA 02115.

We have previously reported that serotonin is synthesized and stored in two locations in the lobster nervous system: the second thoracic roots and the pericardial organs. Both these structures are characterized by a cortex of nerve ending-like varicosities with an appearance typical of neurosecretory tissues. In this communication we report that serotonin can be released from these structures by depolarization and that physiologically effective levels of endogenous circulating serotonin are found in the hemolymph.

When second thoracic roots are incubated in ^{3}H-tryptophan they synthesize and store ^{3}H-serotonin. This serotonin can be released in a calcium dependent manner by potassium induced depolarization. A five minute depolarization with 100 mM potassium will release about two-thirds of the newly synthesized serotonin in the root (1-2 pmoles of radioactive serotonin). When roots are incubated in the presence of the decarboxylase inhibitor NSD-1055, 5-hydroxytryptophan, the precursor of serotonin, accumulates instead of serotonin. 5-Hydroxytryptophan is not released from these tissues with depolarization.

Serotonin levels in lobster hemolymph were measured using high-performance liquid chromatography with electrochemical detection. A peak in the hemolymph samples was observed that eluted with the same retention time as authentic serotonin. This peak was further identified as serotonin by measuring the peak height as a function of the applied voltage of the electrochemical detector. We thereby determined that the compound in the hemolymph eluting at the same time as serotonin had the same redox potential as authentic serotonin. The basal hemolymph levels of serotonin in lobsters maintained in circulating sea water in holding tanks or in seminatural environments ranged from 10^{-9} to 10^{-8} M. In lobster neuromuscular junction preparations, serotonin causes a facilitation of transmitter release from nerve endings and a direct contracture of muscle fiber. The threshold concentration of serotonin for both of these effects is about $5x10^{-9}$ M. Thus serotonin is present in lobster hemolymph at high enough concentrations to exert physiological actions on target tissues. We are currently measuring the serotonin levels of animals in different behavioral and environmental states. (Supported by NIH).

1135 FOREBRAIN NOREPINEPHRINE DEPLETION ATTENUATES THE BLOCKING EFFECT. Joan F. Lorden, Edward J. Rickert*, Ralph Dawson, Jr., and MaryAnn Pelleymounter*. Dept. Psychol., University of Alabama in Birmingham, Birmingham, AL 35294.

Lesions of the dorsal noradrenergic bundle (DB) retard the extinction of both runway and lever-press responses (Mason & Iverson, JCPP, 1977, 91, 165-73). DB lesions also impair the acquisition of a successive light-dark discrimination due to a tendency of DB rats to perseverate in responding to the negative stimulus. Rats with DB lesions are not hyperactive but do appear to be more distractable than normal animals. (Mason & Fibiger, Brain Res., 1978, 159, 421-6). On the base of this and related research, it has been proposed that a failure to filter out irrelevant stimuli could account for the behavioral effects of DB lesions. We have tested this hypothesis using Kamin's two-stage blocking paradigm.

Rats were pretrained to suppress operant responding in the presence of a light or tone (CS_A) that predicted footshock. This was followed by conditioning with a compound cue (CS_{AB}: light + tone) formed from the original cue (A) and a new stimulus (B). In normal rats pretraining to A blocks conditioning to B. That is, normal animals do not suppress operant responding when tested in the presence of only the redundant cue (B). Rats with 6-hydroxydopamine DB lesions were compared to rats with control lesions (5,7-dihydroxytryptamine lesions of the dorsal and median raphe nuclei) and vehicle-treated rats in the blocking paradigm. When vehicle or control lesion groups were tested for response suppression in the presence of the redundant stimulus, the blocking effect was observed. Rats with DB lesions showed an attenuation of the blocking effect and suppressed lever-press responding in the presence of the irrelevant cue. DB rats differed significantly from both the vehicle and raphe lesion groups. No significant differences were found among the three groups during either the pretraining or the conditioning to the compound cue. Nor were any differences obtained among DB, raphe or vehicle groups when pretraining was omitted and all animals were trained only on the compound cue.

Fluorometric assays of hippocampal norepinephrine (NE) and serotonin (5-HT) indicated that DB lesions reduced mean hippocampal NE by 83% and 5-HT by 3% in comparison with vehicle-treated controls. Rats with raphe lesions showed a 9% depletion of NE and a 78% depletion of 5-HT. Similar results were obtained in the remaining telencephalon. Telencephalic dopamine levels were unaffected by the lesions. The results provide support for the idea that depletion of forebrain NE impairs the ability of rats to exclude irrelevant stimulus information. (Supported by NSF grant BNS 77-15251 and a University Faculty Research Grant).

1136 TOPOGRAPHICAL ORGANIZATION OF LOCUS COERULEUS: EFFERENT PROJECTIONS OF CONSTITUENT NEURONS. S.E. Loughlin*, S.L. Foote, and F.E. Bloom. A.V. Davis Ctr. for Behav. Neurobiology, Salk Inst., La Jolla, CA 92037.

The nucleus locus coeruleus (LC) is known to have widely divergent efferent projections. The question of whether those neurons which project to a given terminal area are located within a defineable portion of LC has been answered for only a few cases (e.g., neurons projecting to spinal cord, Satoh et al., Exp.Br.Res.,30,'77, and others). In order to address this question in a systematic, quantified way, we have constructed computerized 3-dimensional maps of the spatial distribution of LC neurons in rat and used them to determine whether, and to what extent, these neurons are topographically organized with respect to their efferent projections. A computer-linked microscope is used to digitize LC cell positions and landmarks from serial sections. A computer graphics system is then used to realign these sections and re-create a 3-dimensional LC. Initially, 12μ, sagittally oriented, Nissl stained sections from a paraffin embedded brain were used to reconstruct a "normal" LC. The total numer of neurons digitized, approximately 1700, was in agreement with previous counts of the nucleus (Swanson, Br.Res.,110,'76). In addition, computerized "sectioning" of this digitized LC in the frontal and horizontal planes yielded LC profiles like those observed in similarly oriented histological sections from other brains. The accuracy of this reconstruction is also being quantitatively assessed using statistical analyses which compare the number and distribution of cells in 2 or more normal nuclei. In experimental animals, injections (.02-.2μl) of 30% Sigma Type VI HRP were placed stereotaxically in LC terminal areas and 40μ sections through LC and the injection site were reacted with TMB (Mesulam, J.Histo.Cyto.,26,'78). Following injections into hippocampus and spinal cord, relatively compact, identifiable subpopulations of cells within LC were preferentially labelled. While injections into hippocampus predominantly labelled dorsal LC, spinal cord injections yielded labelled cells only in the ventral third of LC. By contrast, injections into other terminal areas, such as hypothalamus, cerebellum, amygdala, and neocortex, produced more complex patterns of labelling. For example, amygdala injections resulted in several large, densely labelled cells scattered throughout LC and a greater number of lightly labelled neurons. The locations of labelled cells within LC following these HRP injections are also being mapped on the computer system. Distributions of labelled cells will be compared statistically with the normal cell distribution and with each other to determine possible topographical and density differences among these populations. USPHS Grant #AA03504.

1137 THE RAPHE NUCLEI IN THE 13-LINED GROUND SQUIRREL, A CYTO-ARCHITECTONIC STUDY. Cecilia Machin*, Carmen Rua*, Elizabeth Taber-Pierce and Charles P. Lyman*. Dept. Anat., Harvard Med. Sch., Boston, MA 02115

A detailed study of the cytoarchitecture of the raphe nuclei in the 13-lined ground squirrel, Citellus Tridecemlineatus, a hibernating animal, has been completed using classical neuroanatomical techniques at the light level. The eight semicontinuous, caudal to rostral, 5-HT nuclear groups are characterized by a distinctive cellular structure. (The interpeduncular nucleus, although present within the raphe was not included in the study, since it is believed to be functionally different from the 5-HT containing nuclei.) Data collected from four adult animals form the basis for the study. Sections were stained by the iron-hemotoxylin method of Loyez, by the Kluver-Barrera method and with cresyl violet. The cytoarchitecture of these nuclei was compared with previous descriptions of these nuclei in the cat, an animal upon which much of the sleep literature is based. A close relationship has been shown between 5-HT and slow-wave-sleep (SWS). Some research supports the conclusion that SWS and hibernation are physiologically homologous.

1138 INTERRELATIONSHIP BETWEEN CENTRAL NERVOUS SYSTEM β- AND α_2-ADRENERGIC RECEPTORS. A. Maggi*, D.C. U'Prichard and S.J. Enna.(SPON: S.J. Strada). Univ. Texas Med. Sch., Houston, Tx. and Northwestern Univ. Med. Sch., Chicago, Ill.

Dibner and Molinoff have reported that in vitro exposure of rat brain cortical slices to isoproterenol (ISO) causes a rapid and reversible decrease in β-receptor binding and activity. To further characterize this phenomenon, rat brain cortical slices were incubated at 37° in oxygenated Rall's buffer in the presence of 100μM ISO. Following incubation, the slices were thoroughly rinsed, then disrupted and membranes prepared to study neurotransmitter receptor binding using ^{3}H-ligand binding procedures. β-adrenergic receptors were assayed using ^{3}H-dihydroalprenolol as a ligand; α_1-adrenergic receptor binding was studies using ^{3}H-WB4104 as a ligand; and α_2-adrenergic receptor binding was studied using ^{3}H-clonidine as a ligand. As reported previously, in slices incubated with ISO there was a 50-60% decrease in the number of β-adrenergic receptor binding sites occuring within 30 min, with no change in receptor affinity. However, in the present study, a 50-60% increase in α_2-receptor binding was also found to occur in these membranes. The time-course of the α_2-receptor increase paralleled the time-course of the β-receptor decrease. No change was noted in ^{3}H-WB4101 receptor binding under these conditions. Co-incubation with sotalol, (20μM) a specific β-receptor antagonist, completely blocked both the β- and α_2-receptor changes induced by ISO. In contrast, incubation with clonidine, a specific α_2-receptor agonist, resulted in a decrease in α_2-receptor binding, with no change in α_1- or β-receptor binding. This clonidine-induced decrease in α_2-receptor binding was completely blocked by co-incubation with tolazoline (50μM), a specific α_2-receptor antagonist.

These results suggest that there may be an interrelationship between brain β- and α_2-adrenergic receptors such that overactivation of the former leads to desensitization of the β- and supersensitivity of the α_2-receptor. This increase in α_2-receptors may be a neuronal compensatory mechanism for overcoming excessive β-receptor discharge. (Supported in part by USPHS grants NS-13803, an RCDA NS-00335 (S.J.E.) and a Salk Institute-Texas Research Fnd. Award).

1139 NORADRENALINE AND SELECTIVE ATTENTION. Stephen T. Mason and Hans C. Fibiger. Div. Neurological Sciences, Dept. Psychiatry, Univ.British Columbia, Vancouver, B.C., Canada V6T 1W5

Depletion of forebrain noradrenaline (NA) to less than 10% of normal by intracerebral injection of 4μg of the selective neurotoxin 6-hydroxydopamine (6-OHDA) dissolved in 2μl saline produces resistance to extinction of a number of appetitively and aversively motivated tasks (for review see Mason, 1979). The most powerful explanation of this effect appears to be an alteration in the stimulus sampling of the animal as a result of the lesion-induced loss of a brain mechanism normally involved in the filtering out of irrelevant environmental stimuli (Mason and Iversen, 1978; Mason and Fibiger, 1979). This role for NA in selective attention was tested directly by examining the behaviour of NA-depleted rats in a latent inhibition paradigm and on a non-reversal shift. Latent inhibition involves pre-exposing animals in the absence of reinforcement to stimuli which will later be used as the discriminative stimuli in a successive discrimination operant task. Normal animals come to ignore these stimuli during the pre-exposure and so take longer to learn to use them in the discrimination task than do non-pre-exposed rats. 6-OHDA depletion of forebrain NA blocked the latent inhibition effect, suggesting an inability of the lesioned rats to learn to ignore stimuli during the pre-exposure phase. A further prediction of the attentional model is that the transfer from one stimulus dimension to a previously irrelevant one (non-reversal shift) should proceed more quickly in the lesioned rats since they, unlike controls, have not learned to ignore this initially irrelevant dimension. Such was observed in the non-reversal shift from a brightness relevant, spatial irrelevant to a brightness irrelevant, spatial relevant T-maze discrimination task. These two findings are interpreted as providing strong evidence in favour of a role for forebrain NA in stimulus sampling and selective attention.

1140 CHANGES IN TYROSINE HYDROXYLASE ACTIVITY IN THE BRAIN AND ADRENAL GLAND OF RATS FOLLOWING ACUTE AND CHRONIC ELECTROCONVULSIVE SHOCK. J. Masserano, G. Takimoto and N. Weiner. Dept. Pharmacology, Univ. Colorado Sch. Med., 4200 E. 9th Ave., Denver, CO. 80262.

In previous studies, we have demonstrated that various stresses (decapitation, pain, immobilization and cold) are associated with activation of rat adrenal tyrosine hydroxylase (TH). In the present study we have examined the effects of electroconvulsive shock (ECS) on adrenal and brain TH following both single and multiple (1 ECS/day for 7 days) applications. Rats were shocked with 300 mA applied transorbitally for 0.2 seconds. Five or sixty minutes following the single application, and 24 hours following the multiple administrations, of ECS the animals were injected with pentobarbital (60 mg/kg i.p.) and the adrenal glands were removed surgically. The animals were then decapitated and the following brain areas were removed; frontal cortex, caudate, hippocampus, hypothalamus, substantia nigra, locus coeruleus and nucleus solitarius. Five minutes following the single application of ECS, TH activity was significantly increased above control values in both the adrenal and caudate. Sixty minutes following acute ECS, adrenal and caudate TH activity had returned to control values. TH activity in the remaining 6 brain areas was unaffected by acute ECS treatment. Following repeated ECS treatment, TH activity was significantly increased in the adrenal gland, locus coeruleus and nucleus solitarius. Chronic ECS produced no change in TH activity in the remaining 5 brain areas.

Supported by USPHS grants NS 09199, NS 07927 and AA 03527.

1141 HALLUCINOGENS SENSITIZE SEROTONIN AND NOREPINEPHRINE RECEPTORS IN THE FACIAL MOTOR NUCLEUS. R.B. McCall & G.K. Aghajanian, Depts. Psychiat. & Pharmacol., Yale Univ. Sch. Med., New Haven, CT 06508

Our previous results indicate that serotonin (5-HT) and norepinephrine (NE) markedly facilitate excitatory inputs to the facial nucleus without directly exciting facial motoneurons (Brain Res., in press, 1979). In the present study the effects of hallucinogens on responses to 5-HT and NE in the facial nucleus were investigated by single-cell recording. Intravenous d-lysergic acid diethylamide (LSD, 10-100 μg/kg) had no effect by itself on glutamate-induced excitation of facial motoneurons. In contrast, the facilitation of facial neuron excitation by iontophoretic 5-HT and NE was greatly enhanced by low doses of LSD (5-10 μg/kg, iv.). The LSD-enhanced response continued for at least two hours. The iontophoresis of LSD at low currents which by themselves had no effect, also enhanced 5-HT facilitation; at higher currents LSD temporarily antagonized the response. Thus in small amounts LSD appears to sensitize 5-HT and NE receptors in the facial nucleus. The effects of two simple indoleamine hallucinogens, psilocin and N,N-dimethyltryptamine (DMT), were also tested. Like LSD, psilocin (0.5-2 mg/kg, iv.) markedly potentiated the effect of 5-HT and NE on motoneurons, but had no direct action when given alone. In contrast, DMT (0.5-2 mg/kg, iv.) facilitated glutamate-induced excitation of facial motoneurons by itself. This effect was blocked by the 5-HT antagonist metergoline indicating that DMT can act as a 5-HT agonist in the facial nucleus. In animals pretreated with metergoline, DMT markedly potentiated the facilitation of motoneuron excitation by NE. Thus DMT can also act to sensitize NE receptors in the facial nucleus. Like DMT, the hallucinogen mescaline (0.5-2 mg/kg, iv.) acted as a 5-HT agonist and potentiated the effect of NE. In contrast, a non-hallucinogenic ergot derivative, lisuride, had no effect on glutamate-induced excitation of motoneurons or on the facilitating effect of 5-HT and NE. In addition, the peripheral 5-HT antagonists methysergide, metergoline, cyproheptadine, and cinanserin blocked the action of 5-HT and failed to potentiate the effect of NE. These data suggest that enhancement of certain spinal reflexes by LSD and mescaline (Anden et al., Br. J. Pharmacol., 34, 1968; Maj et al., J. Pharm. Pharmacol., 29, 1977) may result from a sensitization of 5-HT and/or NE receptors in motor nuclei. In addition, if the sensitizing effects of hallucinogenic drugs observed in the facial nucleus occurs in other areas of the central nervous system, then the mechanism of receptor sensitization might contribute to the psychedelic effects of these drugs.

1142 THE TIME COURSE OF DISCHARGE ACTIVITY OF LOCUS COERULEUS AND MIDBRAIN RAPHE REM-OFF NEURONS DURING ENTIRE SLEEP-WAKING CYCLES. Robert W. McCarley, Andrew Strassman* and J. Allan Hobson. Laboratory of Neurophysiology, Department of Psychiatry, Harvard Medical School, Boston, MA 02115.

There is increasing evidence that neurons in locus coeruleus (LC) and midbrain raphe may play a regulatory role in mammalian behavioral state control. To test the hypothesis that these neurons participate in control of the cyclically occurring events of the sleep cycle it is essential to know the time course of their discharge activity over entire sleep cycles. Although previous studies had obtained samples of neuronal discharge activity during various states, none had obtained entire cycle recordings. Therefore we decided to examine extracellularly recorded discharge activity during unperturbed, entire sleep cycles in unanesthetized, head-restrained cats. A particular aim was to look at evidence that REM-off cells (waking/REM sleep discharge ratios < 0.5) in these biogenic-amine contining areas showed discharge time courses compatible with their playing an inhibitory role to REM-on pontine reticular cells, as postulated by the reciprocal interaction model of sleep cycle control. The time course of REM-off activity predicted by the mathematical equations of this model has four main characteristics: 1) A discharge peak as REM ends and waking begins; the model postulates that REM is terminated by increased inhibition of executive, excitatory neurons in the pontine reticular gigantocellular tegmental field (FTG). 2) A gradual, slow decline as REM-off activity is reduced by inhibitory self-feedback loops. 3) A low point of activity at REM onset corresponding to maximum disinhibition of REM executive cells. And 4) resumption of REM-off activity in the latter part of the REM period, as REM-off activity is recruited by the FTG activity.

We have recorded over 50 REM-off neurons in LC and raphe and thus far have examined unperturbed sleep-waking cycles in 6. Compared with the theoretical curve, the actual data show a slower decline from the peak at cycle beginning (associated with waking) and a shorter lead time of discharge activity increase anticipating REM-end (which marks the cycle end). Overall, however, there is agreement with the major features of the predicted curve: a peak at cycle onset, a long slow decline in activity associated with the behavioral state of slow wave sleep, a low point at REM onset, and a rise at cycle end. In particular the agreement between theory and fact on the characteristic slow decline in discharge activity during slow wave sleep deserves emphasis; the REM-off cells begin turning off long before REM onset. These findings are compatible with the hypothesis that REM-off cells may themselves be reponsible for some manifestations of the waking state and that their decrease in activity may disinhibit REM executive cells and so allow generation of a REM sleep episode.

1143 CORRELATION OF THE EFFECTS OF PARACHLOROAMPHETAMINE BY LIGHT AND HISTOFLUORESCENT MICROSCOPY. Robert E. McClung and Joe Wood. Dept. Neurobiology and Anatomy, University of Texas Medical School at Houston, Houston, Texas 77025.

Neurochemical and histofluorescent techniques have suggested that parachloroamphetamine (PCA) interacts with neurons to alter serotonergic mechanisms. The present study presents a correlation between light and fluorescent microscopic observations of the effects of PCA, aimed at clarifying the cellular and subcellular effects of the drug on a selected serotonergic neuronal population. Male rats were injected with saline or PCA (20 mg/kg I.P.) 12 hours prior to sacrifice. Behaviorally, at 12 hours post-injection, the animals demonstrated a hyper-reactivity as would be expected following administration of an amphetamine-like drug. Following decapitation, the brain was removed, frozen on dry ice, and 10-20 μ frozen sections were cut on a cryostat. Sequential sections were alternately treated with: 1) glyoxylic acid or 2) glutaraldehyde-dichromate-chromate followed by cresyl violet. In this manner the changes in histofluorescence could be correlated with the chrome-amine deposits present within the neurons. Neurons in the dorsal and medial raphe system showed decreased fluorescence and fewer chrome-amine granules which supports the concept that PCA is taken up in brainstem serotonergic neurons and alters their functional characteristics. At 12 hours post injection, some damage was apparent in the large serotonergic neurons of the brainstem. Histofluorescent sections also revealed a loss of serotonin in the forebrain projections of the raphe system. This suggests a dysfunction in the terminals of raphe neurons which have been reported previously to not show cell body alterations following PCA treatment. In contrast, catecholamine fluorescence and chrome deposits in nearby nuclei did not appear to differ between control and PCA treated animals. Thus, in the present study, PCA initially effects serotonergic neurons and terminals resulting in decreased levels of the indolamine while not visibly altering catecholamine stores.

1144 A NOVEL FLUORESCENT MARKER OF CNS VASCULATURE USED IN COMBINATION WITH MONOAMINE HISTOFLUORESCENCE. Jacqueline F. McGinty*, Leonard Y. Koda*, and Floyd E. Bloom. A.V. Davis Ctr. for Behav. Neurobiol., Salk Inst., La Jolla, CA 92037.

Pontamine sky blue (PSB) is routinely used to localize the placement of microelectrodes in brain tissue. One disadvantage of the technique is the difficulty of detecting small amounts of this dye with bright field microscopy. We have found that iontophoresed PSB fluoresces bright red under a rhodamine filter. This characteristic has enabled us to localize discrete microelectrode placements which are not detectable with bright field illumination. In addition, iontophoresed PSB is compatible with monoamine (MA) histofluorescence and fluorescein immunocytochemistry, and thus, provides an easy and sensitive method for the localization of electrode positions in histochemically-characterized brain regions (McGinty, et al., in preparation). PSB can also be used to fluoresce brain vasculature. In the present study, we combined PSB and glyoxylic acid-induced MA fluorescence to quantify capillary density in several monoamine-rich brain areas.

Six male Sprague-Dawley rats (200-300 g), with or without pargyline pretreatment (4 hours after 50mg/kg) were anesthetized and perfused with a chilled 0.5% paraformaldehyde-2% glyoxylic acid solution. The rats were then injected transcardially with 3-4 ml of chilled 0.2% PSB (Searle Diagnostic, Bucks, England) in Ringer's solution or 3-4 ml of India ink (Higgins, #4466). Twenty micron serial sections were then processed for MA histofluorescence (Bloom and Battenberg, J. Histochem. Cytochem. 74:561, 1976). Areas of interest were photographed with a 10x objective under epi-illuminated rhodamine and/or catecholamine filters. Since India ink was not compatible with histofluorescence, ink-injected tissues were Nissl-stained and photographed under bright field illumination. Blood vessels were counted on photographic enlargements (final mag. 225x). Data were compiled from 10-12 micrographs of each area per animal. Contrary to previous indications that the norepinephrine-rich locus coeruleus is highly vascularized (monkey-Finley and Cobb, J. Comp. Neurol. 73:49, 1940; rat-Shimizu and Imamoto, Arch. Histol. Jap. 31:229, 1970), our preliminary observations suggest that rat locus coeruleus is not highly vascular (3.3 ± 0.3 vessels/100μ^2) as compared with adjacent central grey (6.3 ± 0.5 vessels/100μ^2). Quantification and illustration of other brain regions will also be presented. PSB and India ink appear to be equally sensitive in revealing capillary networks. However, the advantage of using PSB is its compatibility with histofluorescence methods.

1145 SPINAL PROJECTIONS OF NOREPINEPHRINE-CONTAINING NEURONS IN THE RAT. S. McKellar and A.D. Loewy(SPON: S. Goldring). Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Although the noradrenergic innervation of the spinal cord has been well studied, the cells of origin of these pathways have not been fully identified. In order to study this problem, we have used the technique of Blessing et al. (Neurosci. Lett. 9:311, 1978) to demonstrate catecholamine fluorescence and horseradish peroxidase (HRP) in the same cells. Multiple 1 μl injections of a 50% HRP solution were made in the T1-T2 levels of the spinal cord of rats and after 2-3 days, the rats were perfused and serial sections of their brainstem were cut on a Vibratome and the sections examined with a fluorescence microscope. After the fluorescent cells were photographed, the sections were reacted with tetramethybenzidine, remounted, examined microscopically, and photographed.

Fluorescent cells were retrogradely labeled by HRP in the A7 group, which lies ventrolateral to the brachium conjunctivum, A6 group or locus coeruleus (especially its ventral portion), the subcoeruleus group, and the A5 group, which lies lateral and dorsal to the superior olive. No fluorescent cells appeared to be labeled by the HRP in the A1 cell group of the ventrolateral medulla or in the A2 group of the solitary complex. This lack of evidence may indicate that the HRP technique is not sufficiently sensitive. Alternatively, the fluorescence technique used here may demonstrate norepinephrine but not epinephrine due to the mild reaction conditions employed. We tentatively suggest that the spinal projections from these cell groups (Dahlström and Fuxe, 1965) arise from epinephrine-containing cells rather than from norepinephrine-containing cells.

1146 ROLE OF DOPAMINE STORAGE FUNCTION IN THE CONTROL OF TYROSINE HYDROXYLASE ACTIVITY IN THE DOPAMINE NEURON. B.A. McMillen and P.A. Shore. Dept. of Pharmacol., Univ. of Texas Health Science Center, Dallas, Tx. 75235.

Cessation of nigro-striatal dopaminergic neuronal impulse flow by axotomy or by administration of γ-butyrolactone (GBL) causes a marked increase in striatal tyrosine hydroxylase (TH) activity and in striatal dopamine (DA) content. Activation of TH is thought to arise as a consequence of the lack of DA release which normally allows stimulation of presynaptic DA receptors (autoreceptors) which inhibit TH activity. However, TH activation following cessation of impulse flow is short-lived compared with blockade of impulse flow or the elevation of DA. Thus there appears to be a mechanism which serves to modulate TH activity despite the continued absence of impulse flow. This could result from saturation of available intraneuronal DA storage sites, leading to an excess of intraneuronal DA free to bind to TH enzyme and inhibit its activity. DA storage function would thus play a role in the regulation of TH activity.

If this hypothesis is true, then reserpine might be expected to inhibit not only the usual GBL-induced rise in striatal DA, but should also inhibit GBL-induced activation of TH. Accordingly, the effect of reserpine (2.5 mg/kg s.c.) was tested in rats. Striatal TH activity (measured in vivo by 30 min. striatal DOPA accumulation after decarboxylase inhibition with NSD-1015) was greatly elevated one day after reserpine, but had returned to normal by 3 days despite continued depression of DA levels. GBL enhancement of striatal DOPA accumulation after NSD-1015 was markedly reduced in 3 day reserpine rats compared with normal rats (1.2 vs. 3.7 μg/g above NSD-1015 alone). This effect appeared to be due to a shorter-lived effect of GBL on TH activity. Analysis of DA after GBL alone showed that GBL-induced increase in DA levels peaked at a shorter time and at a lower content than in controls (4 vs. 11 μg/g DA increase).

Haloperidol also activates TH in part, at least, via DA autoreceptors. In 3 day reserpine rats, haloperidol enhancement of TH activity was also greatly depressed (1.6 vs. 4.4 μg/g DOPA above NSD-1015 alone) and the usual elevation of striatal DA metabolites seen after haloperidol was almost abolished. Thus inhibition of DA storage function by reserpine alters the coupling of DA autoreceptor activity with TH activity. It is suggested that DA storage function modulates TH activity by controlling the amount of DA available for attachment to and inhibition of TH enzyme. This hypothesis is consistent with recent immunocytochemical observations which suggest an association of TH enzyme with synaptic vesicles in DA neuronal terminal areas. (Supported by USPHS Grant MH-05831).

1147 **REGIONAL VARIATIONS IN RAT BRAIN EPINEPHRINE TURNOVER.** **Ivan Mefford* and Jack D. Barchas (SPON: R. N. Adams). Dept. Psychiatry, Sch. Med., Stanford Univ., Stanford, CA 94305.**

The turnover of epinephrine (E) and the major catecholamines, norepinephrine (NE) and dopamine (DA) were studied in the rat brain hypothalamus, midbrain, locus coeruleus and lower brainstem nuclei, nucleus tractus solitarii and vagal nuclei. Catecholamines were measured in these regions following pharmacological manipulation with the monoamine oxidase inhibitor, pargyline. Further studies are in progress using α-methyl-p-tyrosine and an inhibitor of phenylethanolamine N-methyl transferase, SK&F 64139. Animals were sacrificed at varying intervals after treatment, brains removed, dissected and analyzed for catecholamines by high pressure liquid chromatography (HPLC) with electrochemical detection. Preliminary evidence suggests turnover rates were highest in nucleus tractus solitarii and lower brainstem followed by locus coeruleus and hypothalamus respectively. On a relative basis, E turnover appears to be much greater than NE and/or DA in these regions. This high turnover rate in these brainstem areas suggests a possibly important role for E in the mechanism of a central response to stress.

1148 POTENTIATION OF MONOSYNAPTIC PURKINJE CELL EXCITATION AND INHIBITION FOLLOWING LOCUS COERULEUS ACTIVATION. Hylan C. Moises, Barry D. Waterhouse and Donald J. Woodward. Dept. Cell Biology, Univ. Tx. Health Sci. Ctr., Dallas, Tx. 75235.

Previous studies from our laboratory have demonstrated in the rat that iontophoretically applied norepinephrine (NE) exerts potent modulatory effects on the cerebellar synaptic circuitry, in addition to its well-known depressant influence on Purkinje (P) cell firing. Moreover, we recently reported that stimulation of the noradrenergic pathway from the locus coeruleus (LC) to cerebellum can enhance both excitatory and inhibitory responses of the P cell evoked by activation of multisynaptic afferent pathways from the sensorimotor cortex (Moises et al., 1978, Neurosci. Abst. 4:279). In this study, we examined whether LC conditioning stimulation could similarly facilitate responses of the P cell evoked by local stimulation of its monosynaptic afferent inputs.

Single shocks (0.2 msec duration at 0.5/sec) were applied to the cerebellar surface through bipolar electrodes, and the responses of P cells both on and off the local (LOC) beam of parallel fiber (PF) activation were recorded extracellularly in halothane-anesthetized rats. Poststimulus time histograms were used to quantitate responses to LOC stimulation when tested before and at various time intervals (50-1000 msec) after preconditioning LC stimulation, which in all cases was at current intensities subthreshold for directly affecting P cell discharge.

Excitatory spike responses and pure off-beam inhibitions were tested in 20 neurons following LOC stimulation. In 9 of 12 cells, inhibitory responses to LOC stimulation, mediated by basket-stellate cell input, were greatly enhanced in both magnitude and duration when preceded by LC conditioning stimulation (3 shocks of 0.1 msec duration at 50-100 Hz). In 3 of 4 neurons tested, excitatory spike responses evoked by direct PF input to the P cell were increased (from 0.55 to 0.83 spikes/stimulus) following LC activation. Post-excitatory inhibitions observed after the evoked spike excitation were also augmented by subthreshold LC stimulation in those 3 cells. Typically, this facilitatory noradrenergic influence on all synaptic inputs was most readily observed when LC conditioning was applied 100-500 msec prior to local PF stimulation. Stimulation in areas outside LC did not alter (3 cells) or reduced the off-beam inhibitory response (1 cell). These data suggest that tonic noradrenergic input may act to facilitate the transmission of afferent information to the cerebellar cortex by augmenting directly the actions of conventional monosynaptic afferent inputs that converge on the P neuron. (Supported by grants from NSF BNS77-00174, NIDA DA-02338 and the Biological humanics Foundation to DJW).

1149 THE EFFERENT PROJECTIONS OF THE DORSOLATERAL PONTINE TEGMENTUM IN THE CAT. Michele S. Moss* and Allan I. Basbaum. Dept. Anat., Sch. Med., UCSF, San Francisco, Ca. 94143.

The dorsolateral pontine tegmentum (DLPT) is a major catecholamine containing area which has been implicated in stimulation-produced and opiate analgesia. With a view towards determining the relationship of this region with other areas involved in pain control, we examined the efferent projections of the DLPT in the cat. Injections of 3H-leucine (0.1-0.3 ul) were made in the area of the locus coeruleus (LC), sub-coeruleus (SC) and parabrachial (PB) nuclei. After appropriate survival times, the brain and spinal cord were processed for autoradiography.

Ascending axons of the DLPT travel in a prominent bundle located just ventrolateral to periaqueductal grey. In the midbrain, the major terminal fields are located in the dorsal raphe and the ventrolateral periaqueductal grey. Projections are also seen in the rostral dorsolateral periaqueductal grey, the nucleus of Edinger Westphal and, via a descending branch of the ascending bundle, in the ventral tegmental area of Tsai and in the interpeduncular nucleus. In the diencephalon, the densest projections are located in the paraventricular thalamus and in the intralaminar thalamic nuclei (centralis medialis, paracentralis and centralis lateralis). Projections to the CM-PF complex resulted from injections into the reticular formation (RF) just medial to the LC/SC. A prominent terminal field in VPM was attributed to amino acid transport via "taste afferents" from the medial PB nucleus. The lateral hypothalamus, the zona incerta and the Fields of Forel are also densely innervated. Moderate projections were recorded in the paraventricular, periventricular and dorsomedial nuclei of the hypothalamus. Rostrally, there are dense projections to limbic structures including the bed nuclei of the stria terminalis, the diagonal band of Broca and the region in and around the central nuclei of the amygdala.

The descending projections seen to the dorsal motor nucleus of X, the solitary nucleus, the spinal trigeminal nucleus, the RF and the spinal cord are less pronounced than the ascending DLPT projections described above.

The projections of the DLPT show considerable overlap with both the distribution of 5HT and immunoreactive enkephalin in the cat. The functional significance of this overlap remains to be determined.

1150 CATECHOLAMINES IN DOG AND MOUSE OLFACTORY BULB: LAMINAR DISTRIBUTION AND RESPONSE TO DEAFFERENTATION. N. S. Nadi*, R. Head* and F.L. Margolis, Dept. Phys. Chem. & Pharm., Roche Institute of Molecular Biology, Nutley, NJ 07110.

Histochemical and immunocytochemical evidence in the literature has qualitatively indicated the presence and location of dopamine (DA) and norepinephrine (NE) in the mammalian olfactory bulb. The laminated structure of the olfactory bulb makes it possible to dissect it into layers enriched in known neuron types. Combining this with a very sensitive radioenzymatic assay for DA, NE and epinephrine (E) [a modification from da Prada & Zürcher, *Life Sci.* 19, 1161 (1976)], we have examined the distribution of these three catecholamines in the following layers of the dog olfactory bulb: the fiber layer (F) containing incoming olfactory nerve fibers; the glomerular layer (G) containing mitral cell dendrites, olfactory nerve endings and periglomerular cells; the mitral cell-granule cell layer (M-G) containing mitral cell perikarya, granule cells and tufted cells; and the white matter (W) containing afferent and efferent fibers of the olfactory bulb. The DA and NE exhibited distinctive patterns in the four layers of the dog bulb as shown below.

		Layer			
Catecholamine	Whole bulb	F	G	M-G	W
DA (ng/g wet wt.)	52	42	120	68	29
NE (ng/g wet wt.)	38	32	33	58	65

The levels of E were very low in the dog olfactory bulb (0.09 ng/wet wt.) and showed a uniform distribution across the four layers analyzed. In whole olfactory bulbs from mice, we have obtained the following preliminary results: DA, 73 ng/g wet wt.; NE, 117 ng/g wet wt.; and E, 1 ng/g wet wt. The effects of peripheral deafferentation by intranasal irrigation with zinc sulfate (Zn) [0.17 M] or vinblastine (Vb) [10 mM] on the levels of catecholamines in the mouse olfactory bulbs have also been investigated. At 3 weeks after treatment, when the majority of the peripheral input to the bulb had degenerated, the levels of DA in the mice treated with Zn or Vb were significantly lower (11 ng/g wet wt.) than those in saline-treated controls (73 ng/g wet wt.). In contrast, the levels of NE and E in the bulbs of Zn- and Vb-treated animals were not significantly different from the saline-treated controls. Since DA levels in the olfactory epithelium are below the limits of sensitivity of the assay, it is possible to conclude that the origin of the DA which is lost is intrabulbar. The cellular origin of the DA lost as a result of peripheral deafferentation and the influence of the peripheral neuronal input on its regulation will be discussed.

1151 OCTOPAMINE-SENSITIVE ADENYLATE CYCLASE: PROPERTIES AND PHARMACOLOGICAL CHARACTERIZATION. James A. Nathanson and Edw. J. Hunnicutt*. Dept. Neurol., Yale Medical School, New Haven, Ct. 06510.

A potent and highly specific octopamine (OCT)-sensitive adenylate cyclase has recently been identified in the firefly light organ (Nathanson, Science 203, 65). The characteristics of this enzyme support the hypothesis that OCT (or synephrine) is the neurotransmitter effecting neural control of lantern flashing, and that cyclic AMP (or pyrophosphate) mediates the intracellular action of the transmitter on light production. We now report some of the properties of OCT-sensitive adenylate cyclase. These data allow for the first time a detailed pharmacological characterization of an octopamine receptor.

Enzymatic activity was measured in washed particulate fractions prepared from isolated Photinus light organs. At optimal concentrations, OCT stimulated basal activity 50-fold. The pH optimum for OCT activation was between 7.4 and 7.9, and maximal stimulation occurred at 30-40°C. Hormone stimulation was supported by Mn^{++}, Co^{++} and Mg^{++} but not by Co^{++}, Ni^{++}, Fe^{++}, Ba^{++}, Cu^{++}, Zn^{++} or Cd^{++}. Calcium had complex effects on enzyme activity. The optimal Mg^{++}/ATP concentration was 8/2mM. GTP doubled maximal enzyme activity and slightly increased the K_a of the enzyme for OCT but was not essential for hormone activity.

Hormone activation was stereo-selective, D(-)OCT being 20-fold more potent than L(+)OCT. Among positional isomers, p-OCT was more than 30 times more potent than either m-OCT or o-OCT. Among beta-hydroxylated phenylethylamines, OCT was more potent than either norepinephrine (NE) or beta-hydroxy-phenylethylamine. Among the non-beta-hydroxylated amines, the OCT precursor, tyramine, was much more active than dopamine or phenylethylamine. Synephrine, the N-methylated derivative of OCT, was considerably more potent than N-methyl-NE (epinephrine). Both the alpha-adrenergic agonist, phenylephrine and the beta-adrenergic agonist, isoproterenol, were much less active than OCT, and the indolamine, serotonin, showed no activity. A number of additional compounds were tested for their ability to block the activation of OCT-sensitive adenylate cyclase.

These results support the presence of a phenylethylamine receptor distinct from those receptors known to be activated by the catecholamines, dopamine, norepinephrine and epinephrine.

1152 EFFECTS OF INTRA-HIPPOCAMPAL INJECTION OF KAINIC ACID ON BRAIN NOREPINEPHRINE. M.F. Nelson, R. Zaczek*, L. Oshida* and J.T. Coyle. Dept. Pharmacology, Johns Hopkins Univ. Balto, MD 21205

Our previous studies have demonstrated that injection of kainic acid (KA) into the rat hippocampus (HIP) acutely caused generalized tonic-clonic convulsions in association with degeneration of HIP intrinsic neurons and a profound reduction in HIP norepinephrine (NE) (Eur. J. Pharmacol. 50:209, 1978). Pretreatment of rats with anesthetics and anticonvulsants that block the seizures attenuated the HIP neuronal degeneration (Eur. J. Pharmacol. 52: 323, 1978). In the present study, the factors that mediate the fall in NE levels were examined.

Rats, briefly anesthetized with ether, received a stereotaxic injection of KA (0.5 µg in 0.5 µl) in the dentate gyrus; NE was measured in several brain regions at various times after injection. KA caused a rapid depletion of NE in all regions innervated by the locus coeruleus (LC) including the ipsilateral and contralateral HIP, lateral neocortex and cerebellum; notably, the hypothalamus and pons medulla were unaffected. The fall in NE was accompanied by an 80-110% increase in MHPG-SO_4 bilaterally in cortex and HIP. The reduction in NE was evident by 1 hr and maximal by 3-5 hr after injection (-50 to -70%). NE returned to normal over 3-5 days except in the injected HIP, which recovered slowly over two weeks. Neurochemical and immunocytochemical analysis of the injected HIP revealed the integrity of the NE-fibers in spite of loss of HIP intrinsic neurons.

To determine the dependency of NE depletion on impulse flow in the LC projection, an electrothermic lesion was placed in the midbrain immediately before the intra-HIP KA injection, and the rats were sacrificed 3 hr later for NE assay. The bundle lesion alone in sham injected rats resulted in a slight increase in NE levels in the cortex; however, prior bundle lesion did not prevent NE reduction in any area within 3 hr of injection of 0.5 µg of KA into the HIP.

To evaluate the possibility that KA might act at presynaptic sites on the NE terminal, HIP slices were preincubated with [^{3}H]-NE and the release of [^{3}H]NE was determined in a perfusion chamber. KA stimulated the release of [^{3}H]NE with an EC_{50} at 300 µM; release was blocked in Ca^{++} deficient medium. L-Glutamate was > 30-fold less potent than KA and did not exhibit additivity with KA. Addition of tetrodotoxin to the perfusion medium blocked KA induced release of [^{3}H]NE.

The data suggest that intracerebral injection of KA causes a marked release of NE that is regulated locally at the terminal level and is independent of impulse flow from the LC. This presynaptic mechanism of release becomes diffusely activated throughout the LC projection by injections in areas causing generalized seizures.

1153 MODULATION OF SPINAL MOTONEURON EXCITABILITY BY 5-HYDROXYTRYPTAMINE AND NOREPINEPHRINE. Richard S. Neuman and Susan R. White. Fac. Med., Memorial Univ. Nfld., St. John's, Nfld., A1B 3V6.

5-hydroxytryptamine (5-HT) and norepinephrine (NE), applied near lumbar spinal motoneurons by microiontophoresis, decreased the threshold for glutamate evoked motoneuron action potentials, increased the duration and frequency of motoneuron activity evoked by suprathreshold amounts of glutamate and increased the amplitude of ventral or dorsal root evoked motoneuron field potentials. These facilitatory effects of 5-HT and NE often lasted for several minutes after drug application ceased. Neither 5-HT nor NE directly elicited motoneuron action potentials in the absence of other excitatory input. The 5-HT antagonist, metergoline, prevented 5-HT but not NE facilitation of motoneuron excitability. These results indicate that, as has been reported for brainstem motoneurons (McCall & Aghajanian, Neurosci. Abs. 4 (1978) 447), 5-HT and NE enhance the effects of excitatory inputs to spinal motoneurons by actions on separate receptors.

Supported by MRC (Canada).

1154 SELECTIVITY OF NORADRENERGIC AXON SPROUTING FOLLOWING PERINATAL 6-OHDA TREATMENT. John A. Olschowka*, Hart G.W. Lidov, Reinhard Grzanna, and Mark E. Molliver, Departments of Cell Biology/Anatomy and Neurology, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

The administration of 6-hydroxydopamine (6-OHDA) or 6-hydroxydopa early in development results in a marked elevation of norepinephrine, of (^{3}H) norepinephrine uptake, and of dopamine-beta-hydroxylase (DBH) in brainstem and cerebellum. These neurochemical changes in brainstem and cerebellum have been attributed to an increased outgrowth (i.e. sprouting) of noradrenergic (NA) terminals innervating these areas. There has been no comprehensive detailed morphologic analysis of the altered pattern of NA innervation in the 6-OHDA treated animal. The present study uses an immunohistochemical method for the visualization of DBH to demonstrate the distribution and geometric patterns of NA axon terminals in the diencephalon, cerebellum and brainstem of treated animals.

Rats were given intraperitoneal injections of the neurotoxin, 6-OHDA (200-300 mg/kg) on day 17 of gestation or during the first 24 hr after birth. Vehicle injected animals served as controls. DBH immunofluorescence revelaed a total absence of NA axons in the telencephalon and a marked increase in the NA innervation of selective brainstem areas. The distribution of sprouted fibers was restricted to those areas which normally receive a NA innervation. A marked increase was seen in the paraventricular, anteroventral, and reticular nuclei of the thalamus, in the cerebellar cortex, and in the superior colliculi, motor and sensory nuclei of V, and cochlear nuclei of the brainstem. Within cerebellar cortex, lobules I-VIa are densely innervated in the normal and show the maximum degree of sprouting. The flocculo-nodular lobe, which is sparsely innervated in the normal, reveals very little sprouting. In both cerebellum and in superior colliculus, layers that normally receive a dense NA innervation show a greater increase in NA fiber density than do sparsely innervated layers. In those regions where the density of noradrenergic fibers was increased in 6-OHDA treated animals, the normal geometric pattern of NA axons was maintained. It can be concluded that the sprouting of noradrenergic fibers following 6-OHDA treatment is not random or diffuse, but exhibits some degree of neuronal specificity in that it conforms to the normal pattern of NA innervation. (Support: USPHS NS06117, NS08153, NS10290; H.G.W.L. supported by training grant GM-7309.)

1155 ACETALDEHYDE(AcH) CONDENSATION PRODUCTS OF DOPA OR DOPAMINE(DA): METABOLIC AND BEHAVIORAL ASPECTS. T.C. Origitano*, J. Hannigan*, P.D. Patel*, A. Kahn* and M.A. Collins. Dept. Biochem., Loyola Stritch Sch. Med. and Hines V.A. Hosp., Maywood, IL 60153.

Because of the possibility of their involvement in the acute or chronic aspects of alcoholism, certain tetrahydroisoquinolines (TIQs) derived from catecholamines(CAs) and the AcH produced in ethanol oxidation were examined with respect to their metabolism and effects on amines in brain and effects on alcohol preference after peripheral or central administration in rodents. Sensitive and specific assays--high performance liquid chromatography(HPLC) with electrochemical detection; capillary GC with electron capture--were utilized in the chemical studies, and a simple HPLC method for the separation of TIQ metabolites and endogenous amines was developed which employs Partisil CX columns. Carboxysalsolinol(cSAL), the TIQ from DOPA and AcH, present in rat brain following intraperitoneal injection, was decarboxylated to a limited extent to salsolinol(SAL), but the main metabolite appeared to be O-methylated. Striatal serotonin(5-HT)content was selectively raised by cSAL, but DA levels were decreased only if a decarboxylase (DC)inhibitor was pre-administered. Inclusion of cSAL in a diet containing DC inhibitor resulted in a statistically significant increase in alcohol solution preference after 3-4 wks in alcohol-avoiding mice, which is in accord with the results in rats by M. Hirst(unpubl.) and Myers & Melchior(Pharm. Biochem.Behav.7,381,1977). In further neurochemical studies, SAL, the TIQ from DA, also elevated 5-HT levels (like cSAL)when given intraventricularly in rats(200ng),but it also lowered striatal 5-hydroxyindoleacetate and CA levels; higher SAL doses tended to obscure these decreases. In general agreement with G.Cohen's studies (in press), 7-O-methylation of SAL seemed to be a prominant CNS route. We conclude that the simple TIQs derived from DOPA or CAs, and possibly their O-methylated metabolites, have significant interactions with the serotonergic system(perhaps via inhibition of 5-HT uptake and 5-HT specific monoamine oxidase analogous to β-carboline condensation products) which could be part of the neurochemical basis for their effects on alcohol preference and analgesia. Supported by USPHS AA00266 and V.A. Medical Research Service.

1156 SEROTONIN INNERVATION OF RAT FOREBRAIN: A RADIOAUTOGRAPHIC STUDY. A. Parent, L. Descarries and A. Beaudet*, Laboratoires de neurobiologie, Université Laval, Québec, and Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Canada.

Light microscope radioautography was used to study the organization of ascending serotonin (5-HT) systems in adult rat brain, following lateral ventricle perfusions of [^{3}H]5-HT. The cell bodies, axonal projections and terminal fields of 5-HT neurons were clearly visualized in paraventricular and basal forebrain areas. Labeled cell groups in midbrain raphe were seen to give rise to two major fiber systems. First, a prominent bundle, apparently originating from nucleus raphe dorsalis, ascends medially within the ventral half of periaqueductal gray, along with the dorsal longitudinal fasciculus. Ramifications of these fibers terminate in inferior and superior colliculi and subcommissural organ. At mesodiencephalic junction, the bulk of this bundle sweeps downward abruptly to innervate the entire periventricular gray of diencephalon. Second, a series of small fascicles, issued from nuclei raphe dorsalis (B-7 and B-6) and medianus (B-8) at various rostro-caudal levels, course directly ventralward through the tegmental and cerebellar peduncle decussations. These fascicles converge toward the medial forebrain bundle (MFB), arching beneath the red nucleus. Thence, some fibers enter fasciculus retroflexus to reach the medial habenula, others cross the midline within the supramammillary commissure, whereas most ascend in the MFB giving off numerous collaterals to hypothalamus. Part of the 5-HT innervation of the mammillary bodies seems to arise from labeled neurons in the medial lemniscus (B-9) whose axons travel in the mammillary peduncle. At thalamic levels, dense 5-HT terminal fields are present in the ventral portion of lateral geniculate nucleus and in midline and intralaminar nuclei. At rostral hypothalamic levels, labeled fibers leave the MFB, and enter the striae medullaris and terminalis to reach the lateral habenula and amygdaloid complex, respectively. Another contingent spreads more laterally to innervate the globus pallidus and neostriatum. At septal levels, many labeled axonal varicosities closely surround the cell bodies of the lateral nucleus, while ongoing fibers ascend through the diagonal band of Broca. Some of these continue dorso-caudally into the fornix and reach hippocampus, whereas others sweep around the corpus callosum, and course within the indusium griseum leaving collaterals to cingulate cortex. At the ventral surface of brain, patches of dense innervation are associated with the islands of Calleja. More rostrally, fascicles of labeled fibers pass through the anterior olfactory nucleus and arborize in the glomerular layer of olfactory bulb. In accordance with earlier data gathered by means of various neuroanatomical methods, this study emphasizes the complex and widespread distribution of 5-HT systems in rat forebrain.(Supported by MRC of Canada)

1157 DIFFERENTIATION OF MULTIPLE SEROTONIN RECEPTORS IN THE CENTRAL NERVOUS SYSTEM. Stephen J. Peroutka, Richard M. Lebovitz* and Solomon H. Snyder. Dept. Pharmacol., Johns Hopkins Univ., Sch. Med., Baltimore, MD 21205

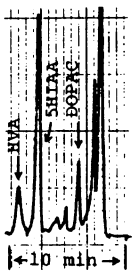
Serotonin receptors in the central nervous system of rats can be labeled by ^{3}H-5-hydroxytryptamine(5-HT), ^{3}H-lysergic acid diethylamide (LSD) and ^{3}H-spiroperidol. Binding data suggest ^{3}H-5-HT and ^{3}H-spiroperidol label distinct, non-interconverting populations of serotonin receptors while ^{3}H-LSD labels both sites. Evidence supporting this conclusion includes: (1) potencies of various drugs differ by factors up to a thousand-fold in competing differentially for ^{3}H-5-HT and ^{3}H-spiroperidol binding; (2) saturating doses of 5-HT do not affect the saturation kinetics of ^{3}H-spiroperidol binding. Conversely, ^{3}H-5-HT saturation is not affected by saturating concentrations of spiroperidol; (3) the number of specific ^{3}H-LSD binding sites is equal to the sum of ^{3}H-5-HT and ^{3}H-spiroperidol binding sites: (4) ^{3}H-LSD binding resembles ^{3}H-5-HT or ^{3}H-spiroperidol binding if the brain membranes are incubated in the presence of saturating amounts of spiroperidol or 5-HT, respectively; (5) guanine nucleotides affect agonist interactions with ^{3}H-5-HT binding but have no effect of ^{3}H-spiroperidol binding. ^{3}H-LSD binding is affected in an intermediate manner; (6) the potencies of antagonists in inhibiting 5-hydroxytryptophan induced head twitches correlate with relative drug potencies for ^{3}H-spiroperidol binding.

We conclude that both ^{3}H-5-HT and ^{3}H-spiroperidol label apparent serotonin receptors in the central nervous system. Under the assay conditions employed in this study, the ^{3}H-ligands label distinct, non-interconverting populations of serotonin receptors. ^{3}H-LSD labels both receptor populations to a similar extent. We suggest that the receptors labeled by ^{3}H-5-HT and ^{3}H-spiroperidol be designated as 5-HT$_1$ and 5-HT$_2$ receptors, respectively.

1158 ANALYSIS OF BIOGENIC AMINE METABOLITES IN RAT BRAIN HPLC WITH ELECTROCHEMICAL DETECTION. Kenneth W. Perry* and Ray W. Fuller. The Lilly Research Laboratories, Indianapolis, IN 46206.

The high sensitivity of electrochemical detection (EC) combined with the specificity of high performance liquid chromatography (HPLC) have provided an important new analytical tool in neurochemistry (R. N. Adams, Anal. Chem. 48, 1128A, 1976). We have developed an HPLC-EC method for determining catecholamine metabolites--homovanillic acid (HVA), 3,4-dihydroxyphenylacetic acid (DOPAC), and 3-methoxy-4-hydroxy-phenylethyleneglycol sulfate (MOPEG-SO_4)--and the serotonin metabolite 5-hydroxy-indoleacetic acid (5HIAA) in whole brain and in brain regions. Measurement of concentration of these metabolites can provide an index of the turnover of the neurotransmitter amines in brain.

Brain tissue is homogenized in acidified n-butanol. The homogenate is centrifuged, and heptane and 0.1 HCl are added. Following shaking and centrifugation, the butanol-heptane phase contains HVA, DOPAC and 5HIAA, and the aqueous phase contains MOPEG-SO_4 (and biogenic amines). The HVA, DOPAC and 5HIAA are then extracted with 0.1 M sodium acetate and are assayed simultaneously by HPLC-EC using a C_8 reverse phase column (4 mm x 25 cm) such as Dupont Zorbax with a mobile phase of 0.1 M Na_2HPO_4-0.05 M citric acid-10% methanol at pH 5. A typical chromatographic tracing is shown. The MOPEG-SO_4 is not electrochemically active and must first be hydrolyzed to free MOPEG by heating for 15 min at 85° in 0.2 N HCl. Free MOPEG is extracted into ethyl acetate, which is then evaporated. The MOPEG is dissolved in 400 µl of 0.1 N formic acid and subjected to HPLC-EC. Absolute sensitivity for these metabolites as pure standards is in the 0.1 pmole range, and the practical sensitivity for their assay in tissue is about 1 pmole per injection.



The metabolites were determined in six brain regions (cerebellum, cortex, corpus striatum, hypothalamus, midbrain and brain stem) to demonstrate the utility of the method and the localization of the metabolites. Typical concentrations (in pmoles/g) in whole brain were 610 ± 20 for DOPAC, 470 ± 20 for HVA, 2460 ± 60 for 5HIAA, and 710 ± 20 for MOPEG-SO_4. Pargyline (20-40 mg/kg i.p.) lowered DOPAC, HVA and 5HIAA at 48 hrs. The lowering of all three was antagonized by co-administration of harmaline (30 mg/kg i.p.). Harmaline had earlier been shown to antagonize selectively the inactivation of type A monoamine oxidase by pargyline. These findings indicate that the formation of all three metabolites occurred by type A monoamine oxidase.

1159 EFFECTS OF BIOGENIC AMINES IN RAT CEREBRAL CORTEX AFTER SEROTONINERGIC DEAFFERENTATION. MICROIONTOPHORETIC STUDIES. T.A. Reader, A. Ferron* and L. Descarries, Centre de recherche en sciences neurologiques (Département de physiologie), Université de Montréal, Montréal, Québec, H3C 3T8, Canada.

Various findings have recently reinforced the hypothesis that serotonin (5-HT), norepinephrine (NE) and dopamine (DA) afferents exert a modulatory influence on relatively large populations of cortical neurons. The present microiontophoretic studies were carried out to assess the responsiveness of cortical neurons to 5-HT, NE, DA and acetylcholine (ACh), after selective lesioning of the serotonin system. In normal adult Sprague-Dawley rats, DA, NE and 5-HT inhibited the majority of spontaneously active cortical neurons recorded in the fronto-parietal cortex. This effect, obtained with ejection currents of 50-100 nA during 20-30 s, was usually of prolonged duration (4-6 min) and often associated with a spike hyperpolarization. ACh-excitatory responses (to 40 nA for 10-15 s), which normally lasted for 60-90 s, were also blocked or reduced by the monoamines, for as long as the inhibition of spontaneous activity induced on the same cells. To produce a selective 5-HT deafferentation, 5,7-dihydroxytryptamine was administered by intraventricular injection after desmethylimipramine pretreatment. Biochemical determinations and iontophoretic experiments were performed two weeks later. The endogenous cortical 5-HT content, assayed with a radioenzymatic method, was reduced to less than 10% of controls. In such 5-HT-denervated animals, the initial phase of inhibitory responses to 5-HT as well as total duration of these responses were significantly enhanced in 70% of the cells recorded (mean duration: 14 min). The inhibition of ACh-excitatory responses by 5-HT was also found to be of longer duration in 75% of the units hypersensitive to 5-HT. Since the afferent serotoninergic component had been eliminated, the absence of reuptake mechanisms could account for prolongation of the responses to 5-HT. However, in a great proportion of neurons hypersensitive to 5-HT, the inhibitory responses to DA or NE were markedly reduced. It therefore seems likely that cortical aminergic systems exert their modulatory effects through distinct receptor sites. The elimination of one afferent component could induce enzymatic changes in the effector cells and/or increase receptor affinity or the number of receptor sites, thus giving rise to enhanced responses to 5-HT and its agonists. Furthermore, an increased number of 5-HT receptors might in turn alter receptor sites for other neuromodulators, thus explaining the lesser responsiveness to DA and NE.

1160 3-METHOXY 4-HYDROXY PHENETHYLENE GLYCOL (MHPG) IN MONKEY BRAIN, CSF, AND PLASMA DURING NALOXONE PRECIPITATED MORPHINE ABSTINENCE. D.E. Redmond, Jr., R.H. Roth, S.E. Hattox, J.M. Stogin* and J. Baulu* Depts. Psychiatry, Pharmacology, Yale, New Haven, Ct. 06510

The recent demonstration of the ability of clonidine to suppress the abstinence syndrome in humans[1] has focused attention on possible noradrenergic hyperactivity as a partial biological substrate of the syndrome. The recent electrophysiological observations made in rats demonstrating a dramatic increase in the firing rate of locus coeruleus cells during abstinence lend support to this hypothesis.[2] We now present preliminary data showing increases in brain and plasma of the major NE metabolite, MHPG, in morphine-tolerant primates after treatment with the opioid antagonist, naloxone.

Three groups of 3 Cercopithecus aethiops were treated as follows: Group 1 (G1) received morphine sulfate 3 mg/kg 3 x's daily for 10 days, and then 4 mg/kg 4 x's daily for 3 days, Group 2 (G2) received matching volumes of saline with each injection of Group 1. 30 minutes before sacrifice G1 and G2 monkeys each received three injections of 0.2 mg naloxone two hours after the last morphine or saline injection. Group 3 (G3) monkeys received one 4 mg/kg dose of morphine two hours before sacrifice. All animals were anesthetized with ketamine 5-10 mg/kg prior to venous blood and cisternal CSF sample collections and sacrificed by brain removal under deep pentobarbital anesthesia. The hypothalamus was rapidly dissected after immersion of the brain in an ice bath, while plasma was separated and prepared with NA metabisulfite. All specimens were stored immediately in liquid nitrogen prior to analysis of MHPG by the GC-MS method of Maas et al.[3]

Results confirmed increases in MHPG in hypothalamus during abstinence, accompanied by specific abstinence signs. G1 monkeys had 0.332 µg/g ± 0.036 (SEM) in hypothalamus, compared with 0.139 ±0.04 for G2 monkeys, or 0.142±0.016 for G3 monkeys. The plasma MHPG of morphine + naloxone monkeys was significantly greater than that of the two control groups. Plasma concentrations, in the same order, were 29.7±8.1 ng/ml, 14.7±1.6, and 9.7±0.5 ng/ml; and CSF concentrations were 47.3±9.7 ng/ml, 38/4±4.8, and 27.4±2.7.

We conclude that MHPG increases in hypothalamus and plasma following naloxone administration in morphine dependent monkeys. The correlation of hypothalamic and plasma MHPG ($r=0.91$, $p<0.01$) supports the utility of further studies of MHPG changes in the human opioid abstinence syndrome.

1161 THE NORADRENALINE CONTENT OF RAT BRAIN BLOOD VESSELS John F. Reinhard, Jr., Eldad Melamed, Sherman Elspas* and Michael A. Moskowitz
Laboratory of Neural & Endocrine Regulation, Dept. of Nutrition & Food Science, M.I.T., Cambridge, MA 02139

Brain extraparenchymal (pial) blood vessels and choroid plexus receive a histochemically defined adrenergic innervation from the superior cervical ganglion. Controversy exists as to the innervation of brain parenchymal blood vessels (microvessels), and to the relative distribution of noradrenergic neurons in parenchymal and extraparenchymal blood vessels of the brain. We therefore measured the catecholamine content of blood vessels taken from the leptomeninges, choroid plexus and brain parenchyma.

450-550 g male Sprague-Dawley rats were killed by decapitation and microvessels were isolated by a sucrose density gradient method after removal of the meninges and choroid plexus. Catecholamines were measured using high pressure-liquid chromatography and electrochemical detection after homogenizing the tissues in 0.1 M perchloric acid.

The noradrenaline content of microvessels, leptomeninges and choroid plexus was 528±17, 534± 122 and 277±154 ng/g, respectively; the catecholamines dopamine and adrenaline were not detected in these brain fractions. Right frontal cortical grey matter contained 640 ± 128 ng/g of noradrenaline. To test whether some of this amine was due to blood within the vessel lumen, animals were perfused in situ with isotonic saline. Levels of noradrenaline remained unchanged in microvessels and meninges but decreased by 34% in choroid plexus. Our results suggest that brain blood vessels contain measurable amounts of the catecholamine noradrenaline which does not derive from the luminal contents. Such an approach will be useful to determine the relative contributions of intrinsic (l. coeruleus) or extrinsic (superior cervical ganglia) noradrenaline-containing neurons to the innervation of the brain vasculature.

1162 MODULATION OF BRAIN ADRENERGIC RECEPTORS BY SPECIFIC LESIONS OF THE DORSAL NORADRENERGIC BUNDLE. T.D.Reisine, D.C.U'Prichard[1], S.T.Mason[2], H.C.Fibiger[2] and H.I.Yamamura. Department of Pharmacology, Univ. of Arizona Health Science Center, Tucson, AZ 85724, Department of Pharmacology, Northwestern Univ.[1] and Division of Neurol. Sci., University of British Columbia[2].

It has been suggested that the characteristics of central adrenergic receptors may be regulated by the levels of norepinephrine (NE) at the adrenergic synapse. To test this hypothesis as well as to better define the precise pre- or postsynaptic location of adrenergic receptors in the brain, lesions of the dorsal NE tract from the locus coeruleus were induced by bilateral intracerebral injections of the neurotoxin 6-hydroxydopamine (6-OHDA). In eight brain regions of control and lesioned rats, the levels of NE were measured and the characteristics of α_1, α_2 and β-adrenergic receptors were determined by the binding of the radiolabeled ligands ^{3}H-WB-4101, ^{3}H-clonidine and ^{3}H-dihydroalprenolol, respectively. In seven of the brain regions of the lesioned animals, NE levels were severely depleted. However, in the cerebellum, NE concentrations increased 54% over control values. Beta-receptor density was elevated in the lesioned amygdala, cortex, hippocampus, septum and thalamus but lowered in the cerebellum. Alpha$_1$-receptor binding increased significantly in the lesioned cortex, thalamus and septum, was below control levels in the cerebellum and unaltered in the other brain regions. Alpha$_2$-receptor binding was above control levels in the lesioned cortex but in contrast decreased in the lesioned septum and amygdala. Interestingly, intraventricular 6-OHDA lesions, while lowering cerebellar NE levels, elevated both α_1 and β-receptor binding. The sensitivity of α_1 and β-receptors in the lesioned brain regions changed in an opposing fashion to the levels of NE. These data suggest that α_1 and β-receptors are postsynaptic to NE-containing neurons and are significantly affected by the levels of NE at the adrenergic synapse. Alpha$_2$-receptors are mainly postsynaptic in the cortex. However, a substantial population of these receptors appear to be presynaptic to adrenergic innervation in the amygdala and septum. These presynaptic receptors might be similar to perpherial alpha$_2$-receptors and as such could function to regulate NE release. Supported in part by USPHS grants and RSCA to H.I.Y.

1163 ALCOHOL CONSUMPTION AND ACTIVITY LEVEL IN MALE RATS AFTER DORSAL TEGMENTAL BUNDLE LESIONS. Daniel L. Richardson* and Stanley A. Lorens. Dept. Pharm., Bldg. 135, Loyola U. Med. Center, Maywood, IL 60153.

Central norepinephrine (NE) pathways have been postulated to play a major role in determining the behavioral effects of ethanol (ETOH). Recently, Mason et al. (1979) reported that 6-hydroxydopamine (6-DA) lesions of the dorsal tegmental bundle (DTB) prevented the emergence of 15% v/v ETOH ingestion and blocked the reduction in locomotor behavior produced by 1.0 g/kg ETOH. In the present experiments the highest concentration (w/v) of ETOH preferred (at least 50% of 24 hr fluid intake) was established using the alternate day, free choice method. Beginning with 1%, each rat was exposed 3 times to 2% increments in ETOH concentration until they drank less than 40% of their daily fluid from the ETOH bottle. ETOH concentration then was reduced until a preferred concentration was reached. Between rats these varied from 2-12% resulting in 1.0 - 5.4 g/kg/day ETOH intakes. The animals were exposed to the preferred ETOH concentration for 7 consecutive alternate days before and 9 days after 6-DA (4 µg) DTB lesions (n=7) or control operations (n=6). Subsequently, the rats were exposed to decreasing concentrations (0.5 - 0.125 mg%) of quinine using the same procedure. Finally, open field activity and the effect of 1.0 g/kg ETOH on activity level in a LVE photocell chamber were examined. Regional forebrain NE levels were determined and the injection sites examined histologically.

The DTB lesions did not alter consumption of the preferred ETOH solution nor the quinine detection level. Likewise, the DTB lesions did not affect open field activity and failed to affect the sedative effect of ETOH. The DTB lesions reduced hippocampal and cortical NE levels by 79 and 72%, respectively.

DTB NE lesions do not affect the oral intake of a preferred ETOH solution not the sedative property of ETOH. That the failure of such lesions to affect these measures may depend on the animals having been exposed to ETOH preoperatively is currently under investigation. The present results, nevertheless, do not support the view that ascending DTB NE fibers play a significant role in mediating the behavioral effects of ethanol.

1164 SUBMAXILLARY SALIVARECTOMY ELEVATES PLASMA CATECHOLAMINES. S. Ritter, R.C. Ritter and C.R. Christianson*. College of Veterinary Medicine, Wash. State Univ., Pullman, WA 99164.

Persistence of significant amounts of plasma and tissue nerve growth factor (NGF) in adult mice suggest a possible role for NGF beyond its tropic and trophic developmental functions. The source of most NGF in the adult rodent is the submaxillary salivary glands. In order to determine whether removal of the main source of NGF affects sympathoadrenal function, we removed the submaxillary salivary glands from 18 adult male rats and subjected an additional 18 adult male littermates to sham salivarectomy. Fourteen days after surgery, these animals were deeply anesthetized with sodium pentobarbital, and the adrenal glands, vas deferens, spleen, heart and brain were removed for catecholamine (CA) assay. A blood sample was also taken by cardiac puncture after removal of the adrenal glands.

Our most striking finding was that plasma norepinephrine (NE) concentrations were 2.1 to 6.3 times higher in salivarectomized than in sham operated rats. Plasma epinephrine (E) concentrations were more variable but in some instances were 5.2 times greater than average concentrations in shams. Adrenal content of both NE and E was reduced to 50% of sham values. CA concentrations from other tissues did not reveal any significant differences between salivarectomized and sham operated rats. The above data suggest that salivarectomy caused increased basal CA release. We are also investigating the effects of salivarectomy upon the sympathoadrenal response to footshock stress. Preliminary data reveals significant differences in plasma and adrenal CA between salivarectomized and sham operated rats exposed to footshock.

If removal of the submaxillary glands was by itself a severe stress, then one might expect markedly elevated plasma CA in salivarectomized rats. However, the fact that salivarectomized rats gained weight at the same rate as shams, displayed no measurable changes in body temperature and did not drink prandially, suggests that severe stress was probably not a factor in generating the increased CA concentrations. Therefore, we suspect that elevated plasma CA in salivarectomized rats resulted from the absence of a sympathetic modulating hormone such as NGF. Experiments to determine the precise mechanism by which salivarectomy-induced CA alterations are brought about are in progress.

1165 LATERALIZATION OF BEHAVIORAL AND CATECHOLAMINERGIC RESPONSE TO EITHER INFARCTION OR 6-HYDROXYDOPAMINE LESIONS OF THE CEREBRAL CORTEX IN RATS. Robert G. Robinson. Dept. of Psychiat. Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

Right middle cerebral artery ligation in the rat leads to a 2 to 3 week period of spontaneous hyperactivity as compared with sham operated controls or preoperative baseline (Nature 255:322, 1975). Significant decreases in norepinephrine (NE) and dopamine (DA) concentrations in the cortex and brainstem occur concomitantly with this hyperactivity (Nature 255, 332, 1975). In marked contrast, left middle cerebral artery ligation, although producing a comparable lesion, does not lead to hyperactivity and these animals are behaviorally indistinguishable from controls. (Neurosci. Abst # 229, 1978). In addition, there are no significant postoperative changes in NE or DA concentrations in either the cortex or brain stem (Life Sci. 24: 943, 1979).

In an effort to compare the effects of focal ischemic lesions with the effects of focal lesions of catecholaminergic terminals, microinjections of the neurotoxin, 6-hydroxydopamine (6-OHDA) in a concentration of 2 ug/ul plus 1 mg/ml ascorbic acid were injected at a rate of 0.5 ul/min 1 mm below the surface of the cortex in approximately the same area where infarcts occur. Following injections into the right hemisphere, a dose response curve could be established with 2ug (N=6) producing a period of increased activity that was indistinguishable from post-ischemic hyperactivity. A 6ug dose (N=7) produced a period of increased activity which lasted 1 to 2 weeks longer than the 2ug dose, although the degree of hyperactivity was about the same for all doses (ie maximum activity 150-160% of control). In contrast to these findings, injections of either 2 ug or 4 ug of 6-OHDA into the symmetrical area of the left cerebral hemisphere did not lead to hyperactivity. These results cannot be attributed to a non-specific suppression of activity following left hemispheric injection because the left hemispheric injected animals were just as active as the controls and their food and water intake were not significantly different. These results clearly implicate the catecholaminergic pathways in the development of postinfarction hyperactivity and suggest that the underlying cerebral asymmetry in the rat may either be in the catecholaminergic pathways or in another postsynaptic neuron which is also involved in the development of hyperactivity.

1166 NOREPINEPHRINE ACTIVATES LATERAL GENICULATE NEURONS AND FACILITATES RETINAL INPUTS VIA AN α-ADRENOCEPTOR. Michael A. Rogawski and George K. Aghajanian. Depts. of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, Connecticut 06510.

The dorsal lateral geniculate nucleus (LGN) receives a dense noradrenergic innervation from the locus coeruleus (LC). It has previously been demonstrated that electrical stimulation of the LC enhances the responsiveness of principal LGN neurons possibly by depressing inhibitory interneurons (Y. Nakai and S. Takahori, Brain Res., 71:47-60, 1974). In the present study, the action of NE on LGN neurons was examined directly using microiontophoresis in the chloral hydrate anesthetized or unanesthetized cerveau isolé rat. Low iontophoretic currents of NE (1-15 nA) produced a delayed increase in the firing rate of most spontaneously active LGN neurons (latency 20-50 sec). This effect was mimicked by various sympathomimetic amines. The relative potency series of agonists was typical of postsynaptic α-adrenergic receptors: epinephrine > NE > phenylephrine > α-methylnorepinephrine > dopamine > isoproterenol. Prolonged (2-5 min) iontophoretic application of either d- or ℓ-amphetamine, which release NE from noradrenergic nerve terminals, also activated LGN neurons. The α-antagonists phentolamine, piperoxane and WB-4101 at low iontophoretic currents (<10 nA) produced a selective, dose-dependent and reversible blockade of the response to NE but not to glutamate. The β-antagonist sotalol had weak and variable effects at equivalent iontophoretic currents.

In order to examine the effects of NE on the response to afferent inputs, LGN neurons were orthodromically activated by electrical stimulation of the optic chiasm or with light flashes delivered above the eyes. The postsynaptic (r) component of the field response to optic chiasm stimulation, which represents the mass activity of principal LGN neurons, increased in amplitude during NE iontophoresis. With subthreshold shocks, iontophoretic NE markedly enhanced the probability of spike generation during both the early (∿2 msec) and late (100-300 msec) components of the evoked response. NE also enhanced the responsiveness of LGN units to light flash. The facilitation of the evoked activity was greater than the increase in spontaneous rate.

It is concluded that NE activates LGN neurons via a postsynaptic or α_1-type adrenergic receptor. Furthermore, these results suggest that NE released from axon terminals of coeruleo-geniculate neurons may serve to specifically enhance the transmission of visual information through the LGN.

1167 ACTIVITY OF STRIATAL NEURONS IN THE BEHAVING MONKEY: IMPLICATIONS FOR THE NEURAL BASIS OF SCHIZOPHRENIA AND PARKINSONISM

E.T.Rolls, D.I. Perrett*, S.J. Thorpe*, S. Maddison* and W. Caan*
Department of Exptl. Psychol., Univ. Oxford, Oxford, England.

In the tail of the rhesus monkey caudate nucleus, which receives a projection from temporal visual cortex, a population of single neurons has been found which respond with latencies of 90-140 ms to visual stimuli. The visual responses were selective, often on the basis of physical characteristics of the stimuli such as orientation, colour or size. However, unlike the responses of neurons in the inferotemporal visual cortex, the responses of many of these caudate neurons to a particular visual stimulus diminished rapidly over the first 1-5 trials. Eye movement recordings showed that this occurred even though the animal was still fixating the visual stimulus. The responses to a particular stimulus were in some cases partially restored after a delay, or by intervening visual stimuli, or by rotation of the stimulus, or by changing its color. Thus the habituation was often to specific features of the initially effective stimuli. The major responses of these neurons were to the first few presentations of completely novel stimuli which possessed the identified subset of physically effective features. Arousal could not account for the responses of these neurons, in that the neurons responded only to a subset of arousing and non-arousing visual stimuli, and were relatively uninfluenced when arousal (as shown by the GSR) was induced by touch or by auditory stimulation. In the head and body of the caudate nucleus, and in the nucleus accumbens, different populations of neurons were found which responded either unconditionally to sensory stimuli, or conditionally to environmental events which were cues to the animal to prepare for the initiation of behavior, or throughout performance of a task, or in relation to particular movements (Rolls et al., 1979). Together, these different populations of striatal neurons could be involved in orienting to significant environmental stimuli and then enabling performance. Two possibilities follow. First, reduced function of these neuronal systems produced by dopamine depletion leads to Parkinson's disease. Second, increased responsiveness or effectiveness of these neurons associated with over-effectiveness of the dopamine systems leads to such symptoms as distractability, failure to maintain attention, and orientation to the slightest or even non-existent environmental stimuli, found in schizophrenia, which can thus be alleviated by neuroleptic drugs which block dopamine receptors.

Rolls, E.T. et al (1979) In "The Neostriatum", eds. I. Divac and R.G.E. Oberg. Oxford: Pergamon.

1168 PIMOZIDE'S EFFECTS ON ICSS DEPEND ON THE INTERACTION OF REWARD AND EFFORT. William H. Rosenblatt*, Kim Hutchins*, and H. M. Sinnamon (SPON: D. Adams). Lab. of Neuropsychology, Wesleyan University, Middletown, CT 06457.

The maintenance of instrumental behavior is determined by the amount of work required as well as by the magnitude of reward. However the work factor has generally not been systematically varied in studies concerned with effects of neuroleptics on reward. This omission appears partly responsible for the question frequently raised about the drugs' behavioral specificity. This problem prompted the study of pimozide on performance of a progressive fixed ratio (FR) schedule in a situation where required work was varied by increasing the FR and reward value was varied by increasing the pulse frequency of 1-sec trains of stimulation to the ventral midbrain. Pimozide increased the latency to reinitiate responding after each reward but had minimal effects on the rate of barpressing after an FR sequence began. In general, the increase in latency occured only on FR sequences that were near the maximal supported by any one value of reward. Thus latencies increase at low FR's for low rewards and at high FR's for high rewards. Were simple motor debilitation produced by pimozide, the depression in performance would have appeared at all FR's beyond a certain value and be independent of reward value. At any given reward value, lower FR's are completed sooner than higher FR's and therefore are associated with higher stimulation densities and greater behavioral facilitatory afteraffects. The possibility that lower FR's were more resistant to pimozide because of density-related factors was eliminated by imposing a delay between the reward and the availability of the manipulandum. This delay was held constant for all FR's. Similar patterns of affects were found on progressive FR performance for varying amounts of water reward. The effects of pimozide suggest that dopaminergic systems are involved in the process by which memory of reward and anticipated effort interact to control the initiation of instrumental behavior.

1169 LOCUS COERULEUS LESIONS: EFFECTS ON CEREBRAL OXIDATIVE METABOLISM IN VIVO. I - CYTOCHROME OXIDASE IN THE STEADY STATE. Myron Rosenthal, Sami I. Harik, Joseph C. LaManna and Andrew I. Light,* Dept. Neurol., U. Miami Med. Sch., Miami, FL 33101.

The role of norepinephrine (NE) in oxidative energy metabolism of the cerebral cortex remains unknown. Since most NE supply of the neocortex emanates from the nucleus locus coeruleus (LC) discrete lesions produced by local stereotaxic microinjection of 6-OH-dopamine produce ipsilateral depletion, providing a means of assessing NE actions. Such lesions were made unilaterally in Wistar rats (250-300 gm). Two weeks later, these rats were anesthetized, tracheotomized, artificially ventilated and holes were drilled in the skull, bilaterally exposing the frontoparietal regions. Oxidative metabolic functioning was assessed by evaluation of changes in reduction/oxidation ratios of cytochrome a,a_3 measured through intact dura by dual wavelength reflection spectrophotometry. As in controls, hypoxia induced by changing the inspired gas mixture from normal (30% O_2/70% N_2) to 100% N_2 was accompanied by increased cytochrome reduction. Transition from 30% O_2 to 100% O_2 or 95% O_2/5% CO_2 produced increased oxidation, indicating that the cytochrome oxidase redox state in LC lesioned rats is also partially reduced as in cats, rabbits and human neocortex. When ratios of oxidation to reduction produced by hyperoxic and hypoxic transitions were calculated, no differences were apparent between hemispheres ipsilateral to LC lesion (NE depleted hemispheres) and contralateral hemispheres. This demonstrates that if NE does have an effect on cortical metabolism, this effect is not apparent under "resting" conditions of low energy utilization. Differences did become apparent, however, when these brains were stimulated by electrical pulses delivered directly to the cortical surface. Both sides responded to such stimulation with transient oxidation followed by re-reduction of cytochrome a,a_3 back to baseline. However, in NE depleted hemispheres, the rate of re-reduction of cytochrome a,a_3 was markedly slowed. These results indicate that NE plays a role in cortical energy metabolism under conditions of increased energy demand rather than under steady state conditions. (Supported by NS 14319, NS 14325 and the Rita Cohen Memorial Fund)

1170 CATECHOLAMINE INVOLVEMENT IN ABNORMAL CORTICAL EEG BURSTING IN DBA MICE. Lawrence J. Ryan* and Seth K. Sharpless. Dept. Psych., Univ. Colorado, Boulder, CO 80309.

Brief spindle episodes (BSE) have previously been observed in the cortical electroencephalogram of DBA/2 and rarely in C3H mice, but not in C57BL/6 or BALB/c mice. BSEs are characterized by 1-5 sec bursts, with rapid onset and completion, of 6-7Hz monomorphic waves which may attain amplitudes of 1200 μv or more. These episodes occur spontaneously and may be provoked by pentylenetetrazol.

Three lines of evidence suggest that the locus coeruleus norepinephrine (NE) system may be involved in modulating BSE activity.

1. Continuous recordings from 4 chronically implanted, freely moving DBA mice for a total of 168 hrs revealed that the average rate of BSE occurrence was 1.42 BSEs/hr. They primarily occur when the animal is awake and active, occasionally when drowsy and rarely during sleep. Catecholamine depletion by either reserpine (2.5 mg/kg, i.p.) or α-methyl-p-tyrosine (250 mg/kg, i.p.) produced a 6-50X increase in the rate of occurrence, beginning approximately 4 hrs after drug administration.

2. Eight chronically implanted DBA mice received 1.0 mg/kg mecamylamine, 2.0 mg/kg haloperidol and 10 mg/kg propranolol, presented in random order with 3 days between each drug presentation. During the 30 min recording after injection neither haloperidol nor mecamylamine affected BSE occurrence. After propranolol, BSEs occurred at a mean rate of 127/hr (13.2 SEM). In C57 mice, 10 mg/kg propranolol produced a few irregular 1 sec or less bursts of spike and polyspike activity which may or may not be homologous to BSEs in DBA mice.

3. Acute transection of the brain stem of DBA mice caudal to the locus coeruleus (LC) had no effect on the occurrence of BSEs, and they could still be elicited by 10 mg/kg propranolol. Transection immediately rostral to LC released BSEs. In 5 mice, 116.4 (21.6 SEM) BSEs were recorded in the period from 1-1.5 hrs after transection. Physostigmine (0.25 mg/kg), given 1.5 hrs after transection of 3 of these mice, had no effect on BSE occurrence in the next 30 min, although this dosage was sufficient to produce cortical activation.

Thus, a beta blocking agent, propranolol, greatly exacerbates the occurrence of an EEG abnormality characteristic of DBA mice, whereas a dopaminergic blocking agent, haloperidol, does not. Transection of the ascending LC adrenergic tract also exacerbates the abnormality. It is interesting that DBA mice show a deficiency in cortical NE during development. This suggests that a genetic defect in the LC noradrenergic system of DBA mice is responsible for the appearance of BSEs.

1171 POSSIBLE NORADRENERGIC MEDIATION OF THE GLYCOGENOLYTIC RESPONSE TO APOMORPHINE AND INSULIN IN RAT BRAIN. C.F. Saller* (SPON: R.J. Ertel). Psychobiology Program, Univ. of Pittsburgh, Pittsburgh, PA 15260

The effects of apomorphine (APO), a dopamine (DA) receptor agonist, on tissue glycogen levels were examined in the striatum, a brain region with a rich dopaminergic innervation, and in the hippocampus, a region with very low DA levels and few, if any, DA receptors. APO (5mg/kg, s.c., injected 20 min. before sacrifice) decreased glycogen levels in the striatum and in the hippocampus (see table). Fluphenazine (FLU), a DA receptor blocker prevented these decreases, suggesting a role for DA in promoting glycogenolysis. Pretreatment of rats with propranolol (PROP), a β-noradrenergic receptor antagonist, also prevented APO-induced glycogenolysis and, by itself, increased tissue glycogen levels. This result suggested a similar role for norepinephrine (NE). To determine if APO was acting by directly stimulating NE receptors or by indirectly activating NE-containing neurons, rats were depleted of NE and DA by administering reserpine (R) and α-methyltyrosine (AMT). This treatment elevated tissue glycogen levels and blocked APO-stimulated glycogenolysis. In contrast to the ability of all three pretreatments to block APO-induced glycogenolysis, only FLU blocked APO-induced stereotypy. Thus, APO may affect behavior by directly activating DA receptors, while its glycogenolytic effects may require the activation of NE-containing neurons.

The glycogenolytic response to insulin was examined in rats pretreated with FLU (0.5 mg/kg, s.c.) or PROP (5 mg/kg, s.c.) 30 min. prior to receiving insulin (4-24 units, s.c.). Rats were sacrificed 30 min. after the insulin injection. Insulin depleted striatal glycogen by 44%. This was unaffected by FLU, but completely blocked by PROP. Thus, the glycogenolytic response to insulin and to APO may be mediated by noradrenergic neurons.

PRETREATMENT	STRIATUM		HIPPOCAMPUS	
	Saline	APO	Saline	APO
Saline vehicle	-	-24*	-	-22*
FLU (0.5mg/kg, s.c., 30 min.[1])	-2	13*	4	8*
PROP (1mg/kg, s.c., 30 min.)	9*	19*	14*	18*
R (10 mg/kg, i.p., 24h) and AMT (250mg/kg, i.p., 4h)	20*	3	14*	14*

Data is expressed as the percent difference in glycogen levels between saline treated controls (striatum 1.93 ± 0.05 μmoles/g and hippocampus 2.51 ± 0.09 μmoles/g) and drug treated animals. (1) Times before saline or APO. *Significantly different from controls ($P < 0.05$).

1172 ALTERATIONS IN THE PERMEABILITY OF THE BLOOD-BRAIN BARRIER INDUCED BY AMPHETAMINE IN NORMOTENSIVE VS SPONTANEOUSLY HYPERTENSIVE RATS PRETREATED WITH HALOPERIDOL. Raman Sankar*, Floyd Domer, David Wellmeyer* and Perry Scallon*. Dept. of Pharmacology, Tulane University and College of Pharmacy, Xavier University, New Orleans, La. 70112.

Quantitative evaluation of the change in the permeability of the blood-brain barrier (BBB) to radioiodinated serum albumin (RISA) induced by amphetamine sulfate has been carried out in normotensive (WKY) and spontaneously hypertensive (SHR) rats. Approximately 50 μCi of RISA was administered intravenously 15 minutes after 2 mg/kg haloperidol to rats anesthetized with sodium pentobarbital. The mean femoral arterial blood pressure response to intravenous administration of saline or doses of amphetamine sulfate (2.5 and 5 mg/kg) i.v. given with the RISA was recorded. Fifteen minutes thereafter, the thoracic cavity was opened to permit the obtaining of a cardiac blood sample and the subsequent perfusion through the heart with 30 ml of saline to clear the cerebral vessels of radioactivity. The brain was dissected out and the blood and brain samples were weighed and counted for their content of radioactivity. The ratio of radioactivity in the brain to that in blood was then calculated as a measure of the permeability of the BBB. Administration of haloperidol caused a decrease in extrusion of RISA in both WKY and SHR rats. When given prior to amphetamine that had previously been found to increase the permeability of the BBB, there was a marked, significant decrease in permeability. This reversal of change in permeability of the BBB could be due to unmasking of action by amphetamine at a group of receptors not blocked by haloperidol. (Supported in part by USPHS Grant No. 5D18MB 160003-06A2 and 5T32 HL07299-02).

1173 EFFERENT CONNECTIONS OF THE SUBCOERULEUS REGION IN THE RAT. C.B. Saper and A.D. Loewy. Dept. of Anat./Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110 and Dept. of Neurology, Cornell Univ. Med. Ctr., New York, NY 10021

The subcoeruleus region (SC) in the rat is in ill-defined portion of the dorsolateral reticular formation of the pons and caudal midbrain, so named for its ventral relationship to the locus coeruleus. In the rat, the SC contains a subpopulation of catecholaminergic neurons. The connections of these neurons, which have been studied using fluorescence histochemistry, remain the only part of the SC to have been so studied (Olson & Fuxe, Brain Res., 43: 289, '72). We have traced the efferent connections of the SC in the rat using 20-30 nl of a 20-30 μCi/μl solution containing equal proportions of ^{3}H-proline, ^{3}H-leucine and ^{3}H-lysine into the SC, the *ascending* labeled projection, in contrast to earlier reports, was found to be rather sparse. Labeled fibers traveled rostrally primarily through the midbrain reticular formation and then into the medial forebrain bundle. Most fibers distributed to the midbrain reticular formation, the lateral hypothalamic and preoptic areas and the posterior hypothalamic area. A similar though more sparse projection was seen on the contralateral side of the brain. The major *descending* projection labeled after SC injections was a paramedian pathway. A large contingent of labeled fibers ran medially from the injection site into the dorsal paramedian reticular formation. These formed densely labeled fascicles which turned ventrally as they descended through the medulla, sweeping laterally over the dorsal surface of the inferior olivary complex, then into the spinal cord, where they formed a dense band of heavily labeled fascicles in the superficial part of the ventral and ventrolateral funiculi. The intensity of the labeling progressively diminished caudally as labeled fibers apparently turned into the gray matter where they ended in a light terminal field over the entire ventral horn and intermediate gray matter, with a few fibers innervating the dorsal horn. A few fibers were followed through the contralateral reticular formation where they collected at the ventral tip of the spinal trigeminal nucleus and were traced caudally into the medial part of the lateral funiculus of the spinal cord. These fibers contributed to the sparse labeling of the contralateral spinal gray matter in a distribution which mirrored the ipsilateral side. The SC has a massive input to the ventral horn of the spinal cord at all levels, which may be an anatomic substrate for the locomotor properties which certain physiological experiments have imputed to the region. Supported by USPHS grant NS12751 and American Heart Assocation Grant 77 797.

1174 DOPAMINE AGONIST EFFECTS ON CYCLIC NUCLEOTIDES IN RAT BRAIN. Michael J. Schmidt, Eli Lilly and Company, Indianapolis, IN 46206, and David J. Jones and William B. Stavinoha, Univ. Texas Health Sci. Ctr., San Antonio, TX 78284.

Conflicting data have been reported concerning the ability of dopaminergic stimulation to elevate cyclic AMP (cAMP) in the striatum. Failure to confirm early studies has been attributed to differing doses of agonists, variable treatment times or use of inadequate techniques for arresting brain metabolism at the time of sacrifice. The present studies were undertaken to repeat exactly some experiments in the literature with regard to dosage of dopamine agonists, animal strains and injection-sacrifice schedules. In addition, a newly developed microwave unit optimized for rats was used to arrest brain metabolism instantaneously and thereby prevent artifacts associated with sacrifice procedures. The temperature of the rat brain reaches 90°C within 0.5 sec with this unit (915 mHz, 17 kwatts).

Administration of L-DOPA (100 mg/kg), which increases dopamine in the brain, did not increase cAMP in the striatum or cerebellum. Cyclic GMP was increased 62% in the cerebellum, but no change was detected in the striatum. Amphetamine (2.5 mg/kg), which releases endogenous dopamine, did not consistently elevate cAMP in the striatum or cerebellum. Amphetamine elicited a rise in cGMP in the cerebellum but not in the striatum. Apomorphine (10 mg/kg), a direct dopamine receptor stimulant, did not change cAMP in the striatum or cerebellum, but enhanced cGMP accumulation in the cerebellum. Lergotrile (5 mg/kg), another direct-acting dopamine agonist, did not change cAMP levels in the striatum or cerebellum, but increased cGMP in the cerebellum. The lergotrile-induced elevation in cGMP was also detected in 7 other brain regions. The changes in cGMP produced by all dopamine agonists were prevented by pretreatment with haloperidol, indicating dopamine receptors were involved.

We conclude that measuring cAMP concentrations in the striatum is not a suitable means of assessing dopaminergic effects in vivo. Measuring cAMP synthesis in homogenates of striatum in vitro is also unsuitable, since apomorphine is only weakly active in this system and lergotrile and bromocryptine are inactive, despite the ability of these agents to compete for dopamine binding to receptors in vitro and to cause functional changes indicative of dopamine receptor stimulation in vivo.

1175 HUMAN BRAIN CORTEX MONOAMINE OXIDASE (MAO): ONE MOLECULAR ENTITY, TWO ACTIVE SITES. A. Schurr, B. T. Ho and B. M. Rigor* Department of Anesthesiology, University of Texas Medical School, Houston, TX 77030 and Department of Neurochemistry and Neuropharmacology, Texas Research Institute Mental Sciences, Houston, TX 77030.

Although it is generally accepted that monoamine oxidase (MAO) exist in two different forms, this conception was recently questioned by various investigators. Our findings with human brain cortex MAO indicating that this enzyme probably exists as a single molecular entity containing two different activities. This interpretation is based on the following findings:

A) The enzyme has similar sensitivities to the irreversible inhibitors clorgyline and deprenyl with type B substrates like 2-phenethylamine (PEA) and benzylamine (BA).
B) Deprenyl competes with these substrates for MAO while clorgyline behaves as a noncompetitive inhibitor.
C) Two Km values found for both PEA and BA which appear as two maxima on the Michaelis-Menten curves. The second maximum (high Km Value) was obolished upon applying low concentrations of clorgyline but not by deprenyl. 5-Hydroxytryptamine (5-HT) was able to mimic the effect of clorgyline.
D) 5-HT found to be a noncompetitive inhibitor of BA deamination when low concentrations of BA were applied and a competitive one with high concentrations of BA.
E) The MAO type A activity measured with 5-HT as a substrate, shows positive cooperativity, as indicated by the sigmoidity of the Michaelis-Menten Curve. The Hill coefficient caculated to be 2.25, pointing at the possibility that four (4) interacting binding sites for 5-HT are exist in human brain cortex MAO.
F) As for PEA and BA, the activity of 5-HT deamination has two Km Values. This activity is very sensitive to clorgyline but only partially sensitive to deprenyl. However, both inhibitors compete with the substrate for the enzyme.
G) The enzyme is affected differently by certain phospholipids and fatty acids depending on the substrate used, indicating the possible involvement of such molecules in the regulation of its activity.

1176 BEHAVIORALLY-DERIVED ESTIMATES OF CONDUCTION VELOCITY AND REFRACTORY PERIOD IN A REWARD-RELATED PATHWAY DIFFER FROM THE CHARACTERISTICS OF MONOAMINERGIC NEURONS. Peter Shizgal and Catherine Bielajew*, Dept. Psychol., Concordia U., Montreal, Que., H3G 1M8 and John Yeomans, Dept. Psychol., U. of Toronto, Toronto, Ont., H5S 1A1.

When an axon bundle is stimulated concurrently at two sites, the orthodromic action potential (a.p.) from the upstream electrode collides with the antidromic a.p. from the downstream electrode and only a single a.p. reaches the synaptic terminals. If the time between stimulations at the two sites is sufficiently long, then collision will be avoided and both orthodromic a.p.'s will reach the terminals. The critical interval at which collision is just avoided will depend on conduction velocity (c.v.) and refractory period (r.p.).

Such collision effects can be inferred from behavior if the vigor of stimulation-elicited performance is related to the frequency of firing in the stimulated pathway. (Collision reduces the frequency at which orthodromic a.p.'s arrive at the terminals.) Our study of the pathways mediating the rewarding and aversive effects of lateral hypothalamic (LH) and ventral tegmental (VTA) stimulation in the rat was based on this rationale. A frequency threshold scaling method (Yeomans, Physiol. Behav., 15: 593-602, 1975) was used.

The principal findings and implications were as follows: 1) The LH and VTA are directly linked by reward-related axons. 2) The estimated c.v. in these fibers ranged from 2.6 - 7.7 m/sec, values substantially higher than the reported c.v.'s of monoaminergic fibers. 3) Behaviorally-derived estimates of the r.p.'s of reward-related fibers were shorter than the reported r.p.'s of monoaminergic fibers. Findings 2) and 3) suggest that the directly-stimulated, reward-related fibers were non-monoaminergic. The c.v. data predict that these fibers were myelinated and from .47 - 1.4 μM in diameter, a range that includes the majority of myelinated LH axons. 4) In two subjects, we observed collision-like effects in a self-stimulation task but not in a stimulation-escape task. The same electrodes and current intensities were used for both behaviors. This result supports the idea that the rewarding and aversive effects of medial forebrain bundle stimulation are mediated by different fibers with different trajectories.

1177 MULTIPLE PITUITARY DOPAMINE RECEPTORS: EFFECTS OF GUANINE NUCLEOTIDES. David R. Sibley* and Ian Creese. Dept. Neurosciences, Sch. Med., UCSD, La Jolla, CA 92093.

A number of recent studies have suggested the existence of multiple dopamine receptors. One categorization is that "D1" receptors are linked to adenylate cyclase while "D2" receptors are not. The anterior pituitary mammotrophs have been suggested to possess prototype D2 receptors since the dopamine inhibition of prolactin release does not appear dependent on cAMP.

Guanine nucleotides have been shown to play a regulatory role in a variety of receptor-adenylate cyclase systems. They appear to facilitate coupling between receptors and adenylate cyclase and to selectively decrease receptor affinity for agonists but not antagonists. We now show that guanine nucleotides decrease dopamine agonist affinity for ^{3}H-spiroperidol binding sites in bovine anterior pituitary membranes suggesting the presence of D1 receptors.

At 0.1 mM the nucleotides GTP, GDP, GMP, ATP, ADP and AMP had no effect on total or nonspecific ^{3}H-spiroperidol binding. However, the ability of agonists to displace ^{3}H-spiroperidol binding was markedly influenced by GTP and GDP (0.1 mM) which increased the IC_{50}'s of dopamine, apomorphine, and ADTN by approximately 6-11 fold. GTP and GDP were maximally effective at 0.1 mM with EC_{50}'s of 10 μM. Other nucleotides were ineffective in reducing the potency of dopamine in displacing ^{3}H-spiroperidol binding. GTP did not influence the ability of antagonists haloperidol or chlorpromazine to displace ^{3}H-spiroperidol binding. Pituitary dopamine receptors have also been labeled by a new radioligand, the potent agonist, ^{3}H-N-propylnorapomorphine. These binding sites exhibit all the characteristics expected of dopamine receptors. Specific ^{3}H-N-propylnorapomorphine binding is more than 50% reduced by 0.1 mM GTP.

The finding of GTP regulation of agonist affinity for ^{3}H-spiroperidol binding sites in pituitary suggests that these binding sites are associated with adenylate cyclase. These dopamine receptors would appear not to be associated with the control of prolactin release as their agonist affinities are much lower than the concentrations required to inhibit prolactin release in vitro. Furthermore GTP does not regulate the affinity of bromocriptine for ^{3}H-spiroperidol binding sites in the pituitary although it is more potent than dopamine in inhibiting prolactin release. Bromocriptine is, however, an antagonist of the striatal dopamine-sensitive adenylate cyclase where its affinity for ^{3}H-spiroperidol binding sites is also insensitive to GTP.

These data suggest that bovine anterior pituitary contains two distinct dopamine receptors, one not associated with cyclase which controls prolactin release, the other adenylate cyclase linked and regulated by GTP with unknown physiological function.

1178 STIMULUS-DEPENDENT ANALGESIC ACTION OF MONOAMINE REUPTAKE INHIBITORS: RELATIONSHIP TO 5-HT AND NE FUNCTION IN CNS. K.J. Simansky* Dept. of Psychiatry, Cornell Univ. Med. College, White Plains, N.Y. and J.A. Harvey, Dept. of Psychol., Univ. Iowa, Iowa City, Iowa 52242 (SPON.: William T. Lhamon).

Neurotoxin-induced depletion of central nervous system serotonin (5-HT), but not norepinephrine (NE), lowers jump thresholds to shock in the flinch-jump test whereas NE, but not 5-HT, depletion decreases paw-lick latencies in the hot-plate test (Neuroscience Abstract 890, 1978). This stimulus-dependent hyperalgesia suggested that central 5-HT and NE systems modulate different aspects of nociception in the rat. The present study therefore examined the ability of four monoamine reuptake inhibitors, with different relative selectivity for the 5-HT and NE reuptake mechanisms, to produce analgesia to shock or heat in neurologically-intact rats. Animals were injected with 10 mg/kg (i.p.) of the hydrochloride salts of fluoxetine (FLU), a highly selective 5-HT reuptake inhibitor previously shown to increase jump thresholds (Messing et al., Psychopharm. Comm., 1975, 1, 511-521); nisoxetine (NIS) or desipramine (DMI), selective NE uptake inhibitors; or chlorimipramine (CMI), a mixed-acting uptake blocker. Vehicle -injected controls (VC) received saline i.p.

All four reuptake inhibitors produced analgesia, but the efficacy of each drug in altering pain sensitivity varied with the assessment technique employed. FLU (+47%), CMI (+38%), and DMI (+24%) significantly increased jump thresholds compared to VC while NIS (+14%) did not. In contrast, DMI (+130%), NIS (+53%) and CMI (+45%) increased mean overall paw-lick latencies during testing at 30, 60, 120, and 180 min after injection while FLU (+13%) and VC (+2%) failed to alter reaction times compared to preinjection baseline. It was also found that FLU failed to produce analgesia on the hot-plate during a single determination (without preinjection testing) made 4 hr after injection--when 5-HT reuptake inhibition is maximal. DMI increased latencies by 100% when tested only at 90 min after injection.

In a test of the neurochemical mechanism of action of DMI in increasing paw-lick latencies, rats were depleted of either NE and dopamine (DA) by the intraventricular injection of 6-OHDA, or of DA alone, by the injection of 6-OHDA after DMI pretreatment. NE + DA depletion, but not DA depletion alone, blocked the analgesic action of DMI in the hot-plate test 30 days after surgery.

The above data are consistent with the hypothesis that inhibition of NE, but not 5-HT, reuptake produces analgesia to noxious heat whereas 5-HT reuptake blockade is correlated with analgesia to shock. These studies therefore provide further evidence that both 5-HT and NE normally suppress the response to painful stimuli but that their functions in nociception are dissociable.
Supported by USPHS Grant No. MH16841 and MH10641.

1179 NORADRENERGIC NEURONS IN THE LOCUS COERULEUS AND CARDIOVASCULAR FUNCTION IN NORMAL AND SPONTANEOUSLY HYPERTENSIVE RATS. Torgny H. Svensson, Göran Engberg* and Peter Thorén*. Depts of Pharmacology and Physiology, University of Göteborg, S-400 33 Göteborg, Sweden.

The pontine noradrenergic nucleus locus coeruleus (LC) has been claimed to participate in maintenance of apprehensiveness and arousal as well as in regulation of autonomic, e.g. cardiovascular function, including various reflexes. Thus, electrical stimulation of the LC produces a pressor response and, recently, afferent stimulation of the vagus nerve was found to cause inhibition of LC neuronal activity. We have used single cell recording techniques to study the response of LC neurons in the chloral hydrate anesthetized rat to a physiologically relevant stimulus for cardiovascular reflexes, namely volume load. Intravenous injection of e.g. 1-4 ml blood caused a volume-dependent reduction in firing rate of LC neurons. Subsequent bleeding of the same amount of blood induced a prompt return to base line activity. Also bilateral vagotomy in the neck caused this reversal of the NA-cell inhibition. Thus, LC neurons respond reciprocally to moderate changes in blood volume, an effect probably mediated via vagal afferents. In spontaneously hypertensive rats (SHR) the average firing rate of randomly encountered NA neurons in the LC was progressively reduced with increased blood pressure of the animals when compared with normotensive, agematched Wistar Kyoto rats (WKR). Bilateral vagotomy did not increase the reduced LC neuronal firing rate in SHR. The α_2-receptor antagonist yohimbine produced greater activation of LC neurons in SHR than in WKR suggesting possibly altered autoreceptor function at LC neurons. The LC NA neurons appeared biochemically equally active in awake SHR and WKR in contrast to e.g. nigroneostriatal dopamine neurons, which seemed hyperactive in SHR. The LC NA cell activity may thus like heart rate and cardiac output in SHR be depressed below corresponding parameters of WKR controls after elimination of environmental stimuli by anesthesia.

1180 SEROTONIN AND GLUCOCORTICOID DEPLETION INDUCES RECEPTIVE FIELDS FOR GROOMING REFLEXES IN THE CAT. Richard M. Swenson & Walter Randall*. Dept. Anat., Sch. Med., & Dept. Psych., Univ. of Iowa, Iowa City, Iowa 52242.

Receptive fields for grooming reflexes (lick, bite, or scratch reflexes) are rarely seen in intact, adult cats or other species even though these reflexes can be elicited from newborns of some species (e.g., rats, dogs). Previous work has shown that lesions of the pons-midbrain tegmentum or of the frontal neocortex produce receptive fields for grooming reflexes in adult cats, and these lesions also cause a significant reduction in the activity of tryptophan hydroxylase, the "rate limiting" enzyme in the production of serotonin (5-HT), in the superior colliculus Randall, Pharm. Biochem. Beh., 1974, 2, 355-360). Also, inhibition of tryptophan hydroxylase activity by p-chlorophenylalanine (p-CPA) administration in conjunction with adrenalectomy (ADX) produces these grooming reflexes in adult cats although p-CPA or ADX alone is ineffective (Randall, Elbin, & Swenson, JCPP, 1974, 86, 747-750). P-CPA, however, is nonspecific in that it also affects catecholamine metabolism, and when administered systemically, depletes serotonin peripherally. The present study shows that when central 5-HT levels are reduced by lesions of the superior central and dorsal raphe nuclei or by injection of 5,7-dihydroxytryptamine (5,7-DHT) into the superior colliculus, in conjunction with ADX, receptive fields for grooming reflexes appear that are the same as those seen in cats after p-CPA and ADX or after CNS lesions. These receptive fields occur only after cortisol replacement is discontinued after ADX. Single, systemic injections of L-5-hydroxytryptophan (25mg/kg) or cortisol (100mg) significantly reduced receptive field size, whereas systemic administration of L-dihydroxyphenylalanine (50 mg/kg) was without effect. In cats with the single treatment of either raphe lesion or 5,7-DHT alone, small but significant receptive fields for grooming reflexes appeared only in the cats given 5,7-DHT. Raphe lesions led to significant reductions of 5-HT in hypothalamus(-71%), caudate(-68%), thalamus(-56%), and superior colliculus(-38%), whereas 5,7-DHT injection led to a significant reduction of 5-HT only in the superior colliculus (-70%). These data, in conjunction with our lesion and pharmacological work, indicate that serotonin in the superior colliculus and systemic glucocorticoids are involved in inducing grooming reflexes in cats. (Supported by NIH grant #5 RO1 MH15402-07).

1181 EFFECT OF ANTIDEPRESSANTS ON NORADRENERGIC AND SEROTONERGIC RECEPTORS. S.W. Tang* and P. Seeman. (SPON: F. Brawley), Pharmacology Department, University of Toronto, Toronto, CANADA.

In order to examine whether antidepressant drugs might act by inhibiting neurotransmitter receptors, the effects of these drugs were tested on noradrenergic and serotonergic receptors in vitro. The IC_{50} values or the concentrations of the antidepressants which 50% inhibited the binding of various ^{3}H-ligands to homogenates of calf brain regions are listed in the Table.

IC_{50} VALUES (nmoles/Liter) ± 10%						
^{3}H-ligand:	WB-4101	Clonidine	Dihydroalprenolol		Serotonin	LSD
nM ligand:	0.22	0.2	0.5	0.5	0.5	2
Region:	Frontal cortex	Frontal cortex	Frontal cortex	Cerebellum	Frontal cortex	Frontal cortex
Receptor:	alpha1	alpha2	beta1	beta2	serotonin	
Mianserin	56	12	11200	37000	90	100
Doxepin	24	2000	20500	7600	240	190
Amitriptyline	46	850	7000	4000	240	140
Clomipramine	130	7430	9300	21000	590	410
Imipramine	160	4930	13300	13500	1080	555
Trimipramine	67	1700	5300	13000	320	300
Nortriptyline	130	2980	5400	3600	380	350
Protriptyline	420	10360	8700	10000	1150	900
Desipramine	440	9400	14200	3000	3070	2000
Maprotiline	250	16770	7900	5400	220	1000
Nomifensin	980	2480	23300	66000	1370	2700
Iprindole	6150	16000	17000	9600	6000	5800

Since the therapeutic concentrations of these drugs in the patient's plasma water is known to be of the order of 50-150 nM we conclude that:

1. Mianserin and the tertiary amine tricyclic antidepressants may block alpha-adrenergic transmission by blocking the postsynaptic alpha1-receptors (data using ^{3}H-WB-4101).

2. Beta-adrenergic transmission is not inhibited by the drugs and thus may be enhanced by all antidepressants by either inhibition of noradrenaline re-uptake or by an increase in noradrenaline release (for the special case of mianserin which inhibited the pre-synaptic alpha2 receptor presumably labelled by ^{3}H-clonidine).

3. The weak but significant inhibition of serotonin receptors by some of the antidepressants may also contribute to the clinical antidepressant action.

(Supported by the Ontario Mental Health Foundation and the Medical Research Council of Canada).

1182 NEUROCHEMICAL RESPONSES TO 5-HYDROXYTRYPTOPHAN IN RATS TREATED DURING EARLY DEVELOPMENT WITH LITHIUM CHLORIDE. Hillel Taub* and David A.V. Peters* (SPON: L. Maler). Dept. of Pharmacol., Sch. Med., Univ. Ottawa, Ottawa, Ont., Canada.

We have recently reported that several psychoactive drugs as haloperidol and chlorpromazine affect the development of central 5-hydroxytryptamine-containing neurons in the rat when administered during early postnatal periods (Gen. Pharmac. 9: 97, 1978; Fed. Proc. 37: 858, 1978). We now present data on the effects of neonatal treatment of rats with lithium chloride. Newborn Sprague-Dawley rats were given once daily subcutaneous injections of lithium chloride (LiCl, 1 μEq/g) on day 1 through 6 after birth. Control animals received injections of saline (1 μl/g) on the same schedule. No other treatment was given until either 25 or 60 days of age when the rats were injected with L-5-hydroxytryptophan (5-HTP, 30 mg/kg, i.p.) or its vehicle and killed 60 min later. The rat brains were dissected into 10-12 regions and assayed for 5-hydroxytryptamine (5-HT) and 5-hydroxyindoleacetic acid (5-HIAA).

Neonatal lithium treatment alone produced small (15-30%) but statistically significant alterations in brain 5-hydroxyindole levels. At 25 days of age the 5-HT level was significantly elevated in the hippocampus, midbrain and thalamus and the 5-HIAA level significantly reduced in cerebral cortex, olfactory tubercle and thalamus. The increased 5-HT levels were no longer present at 60 days of age whereas the 5-HIAA levels were found to be significantly reduced in the cerebellum and corpus striatum in addition to the cerebral cortex, olfactory tubercle and thalamus.

As expected, 5-HTP injections at 25 and 60 days of age produced marked elevations in 5-HT (200-400%) and 5-HIAA levels (200-700%) in all brain regions studied. However, the magnitudes of the 5-hydroxyindole increases were significantly affected by the neonatal drug treatment. At 25 days of age the 5-HTP-induced elevations in both 5-HT and 5-HIAA were significantly greater (200-500%) in rats treated with LiCl during the neonatal period than in saline-treated controls in all brain regions except the hypothalamus. In contrast, the enhanced response to 5-HTP-injections was no longer apparent at 60 days of age and in several brain regions (cerebellum, motor and temporal cortices, hippocampus, olfactory tubercle, pons-medulla) and spinal cord the increases were significantly less in the LiCl group. These data suggest that exposure to lithium salts during the neonatal period may alter the development of 5-HT-containing neurons in the central nervous system. (Supported in part by OMHF).

1183 CHRONIC ADMINISTRATION OF AMPHETAMINE TO CATS: BEHAVIORAL AND NEUROCHEMICAL EVIDENCE OF DECREASED BRAIN SEROTONIN FUNCTION. Michael E. Trulson and Barry L. Jacobs. Program in Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

Amphetamine is thought to exert its psychobiological effect primarily through an action on brain catecholamines. In fact, the behavioral effects of chronic amphetamine administered in high doses to animals and humans (amphetamine psychosis) provides one of the important underpinnings for the catecholamine theory of schizophrenia. A recent report by Ellinwood (In: Animal Models in Psychiatry and Neurology, I. Hanin & E.Usdin (eds.) 1977, pp. 61-74), however, led us to examine the effects of chronic amphetamine administration on brain serotonin metabolism in cats. He reported that such treatments led to the emergence of several behaviors, such as limb flicking and abortive grooming, that we had previously shown to be elicited exclusively by hallucinogenic drugs and to be dependent on decreased brain serotonin function (Brain Res. 132, 301, 1977). In the present series of studies, groups of cats were administered amphetamine sulfate in a dose of 7.5 mg/kg i.p. twice daily for up to 10 consecutive days. Approximately 3-4 days following the onset of the injections, the cats began to display limb flicking and abortive grooming. The occurence of these behaviors reached their peak frequency (e.g., 15 limb flicks/hr) on days 7-10, and persisted at a level significantly above baseline for approximately 6 days following drug withdrawal. Paralleling these behavioral effects, brain serotonin and 5HIAA levels (measured in six different areas) were decreased by approximately 30-40% after 3-4 days of amphetamine treatment, reached a maximum decrease of 50-60% at 10 days, and then returned to within 30-40% of normal levels 5 days following drug withdrawal. By contrast, brain catecholamines and metabolites (NE, DA, HVA and DOPAC) showed a much more rapid (1-2 days) and dramatic (60-90%) decrease, which persisted for a much longer period of time (greater than 14 days following drug withdrawal). These data indicate that high dose levels of amphetamine to cats can produce significant reductions in brain serotonin and 5HIAA, and furthermore, that these changes are of behavioral significance. Since the onset of "amphetamine psychosis" in humans shows a closer temporal correlation with the changes in brain serotonin than with the changes in brain catecholamines, we suggest that a decrease in brain serotonin function may be of significance in the production of this form of psychosis.

1184 SELECTIVE MODULATION OF RAT CORTEX β_1-RECEPTORS AND RAT CEREBELLUM β_2-RECEPTORS AFTER CENTRAL NORADRENERGIC DENERVATION. David C. U'Prichard, Terry D. Reisine, Stephen T. Mason, Hans C. Fibiger and Henry I. Yamamura. Dept. Pharmacol., Northwestern Univ. Sch. Med., Chicago, IL 60611.

The dorsal bundle (DB) containing ascending norepinephrine (NE) fibers was lesioned in rats by bilateral stereotaxic injection of 6-hydroxydopamine (6-OHDA). DB lesion decreased NE levels by 97% in the frontal cortex after one month. β-Adrenergic receptor number, measured by ^{3}H-dihydroalprenolol (DHA) binding, increased 62% from 84.5 to 136.9 fmol/mg protein. The contribution of β_1-receptors and β_2-receptors to the total β-receptor population in the frontal cortex was assessed by examining inhibition of DHA binding by the selective β_1-antagonist practolol and the selective β_2-agonistsalbutamol. In control cortex, practolol and salbutamol inhibition curves were shallow (n_H = 0.8). Eadie-Hofstee plots were biphasic for both drugs, and true kinetic constants for each component of practolol and salbutamol binding were determined by iterative computer analysis using a NONLIN program (Upjohn Co.). Salbutamol bound with high affinity (K_D = 0.2 μM) to 20% of the DHA frontal cortex sites, which represented β_2-binding, and bound with low affinity (K_D = 4.0 μM) to the other 80% of sites, which represented β_1-receptor binding. Conversely, practolol bound with high affinity (K_D = 0.4 μM) to the majority (β_1) population, and with low affinity (K_D = 10 μM) to the minority (β_2) population of DHA cortex sites. Analysis of inhibition of DHA binding by either practolol or salbutamol showed that in DB lesioned frontal cortex the number of β_1-sites approximately doubled, whereas the number of β_2-sites was unaffected by the lesion. Rats were also given 6-OHDA i.c.v., which depleted NE levels by 96% in the cerebellum, and increased overall cerebellar DHA β-receptor binding by 39%. Eadie-Hofstee plots of practolol and salbutamol inhibition of cerebellar DHA binding were biphasic. However, contrary to the frontal cortex, the β_1-component of DHA binding accounted for only 20% of total DHA binding, and the β_2-component for 80%. Analysis of both practolol and salbutamol inhibition curves showed that the increase in cerebellar DHA binding was due to selective augmentation of the β_2-population, while β_1-receptor number was unchanged. Destruction of brain NE terminals thus causes a selective supersensitivity of β_1-receptors in the frontal cortex, and of β_2-receptors in the cerebellum. This suggests that functional neuronal postsynaptic β-receptors are of the β_1-type in the cortex and of the β_2-type in the cerebellum. The location and significance of cortical β_2-receptors and cerebellar β_1-receptors is as yet unclear.

1185 EFFECTS OF IONOPHORES ON TYROSINE 3-MONOOXYGENASE ACTIVITY IN PHEOCHROMOCYTOMA CELLS. Karen K. Vaccaro*, Bruce T. Liang* and Robert L. Perlman* (SPON: Thomas O. Fox). Dept. of Physiology, Harvard Medical School, Boston, MA 02115.

Catecholamine secretion from the adrenal medulla and from sympathetic neurons is accompanied by an acute increase in the rate of catecholamine biosynthesis in these tissues. This stimulation of catecholamine synthesis results from an increase in the activity of tyrosine 3-monooxygenase (TH). We have been studying the regulation of catecholamine synthesis and secretion in cell suspensions prepared from a transplantable rat pheochromocytoma. The carboxylic ionophores monensin, lasalocid and ionomycin (1-10 μM) all stimulate secretion of norepinephrine from these cells (Perlman, Fed. Proc. 38: 525, 1979). We have now studied the effects of these ionophores on TH activity in intact pheochromocytoma cells. TH activity was assayed by measuring the formation of ^3H_2O by cells which were incubated for 90 minutes at 37°C in the presence of L-(3,5-^{3}H)tyrosine.

TH activity in cells incubated in a control medium (123 mM Na^+) was 52.6±2.9 pmol/min/mg protein. Monensin, an ionophore for monovalent cations, caused a 40-75% reduction in TH activity in the cells. Lasalocid, an ionophore for both monovalent and divalent cations, stimulated TH activity by up to 100%. Incubation of the cells in a Na^+-free medium (choline chloride substituted for NaCl) increased TH activity by up to 85%. Monensin did not inhibit the TH activity of cells incubated in Na^+-free medium. Lasalocid stimulation of TH activity was the same in Na^+-free as in control medium. Ionomycin, a divalent cation ionophore, had no effect on TH activity in either medium. Thus, these carboxylic ionophores are useful for studying the coupling of catecholamine synthesis and secretion.

1186 Contrasting roles of dopamine and β-phenylethylamine in Type I behavior-related neocortical low voltage fast activity. C.H. Vanderwolf, T.E. Robinson and B.A. Pappas. Dept. Psychol. Univ. Western Ontario, London, Ont. Can., N6A 5C2; Neurosci. Lab., Univ. Mich., Ann Arbor 48109; Dept. Psychol., Carleton Univ., Ottawa, Can. K1S 5B6.

Following large doses of atropine SO_4 rats display large amplitude slow waves in the neocortex during immobility, tremor, tooth-chattering, and face-washing, (Type II behavior) but display atropine resistant low voltage fast activity (ARLVFA) during walking, struggling, postural changes, and head movement (Type I behavior). ARLVFA is abolished by prior treatment with reserpine but not by chlorpromazine, trifluoperazine, haloperidol, pimozide, α-methyl-p-tyrosine, p-chlorophenylalanine, methysergide, LSD or promethazine. However, since many of these drugs reduce the emission of Type I behavior, they produce a correlated reduction in the occurrence of ARLVFA. The effect of reserpine on ARLVFA is blocked by prior treatment with nialamide, suggesting the involvement of a monoamine. Replacement experiments showed that following reserpine, ARLVFA was not restored by l-dopa, apomorphine, clonidine or 5-hydroxytryptophan. However, β-phenylethylamine (PEA) appeared to restore normal ARLVFA, together with some active behavior. Restoration of ARLVFA was not affected by the addition of α-methyl-p-tyrosine, trifluoperazine or chlorpromazine, although these drugs eliminated most PEA-produced behavior. PEA may play a direct role in ARLVFA independent of catecholamines.

Although l-dopa and apomorphine were ineffective in restoring ARLVFA in reserpinized rats, they did produce: a) a sharp increase in Type I and other behavior, and b) an increase in atropine sensitive LVFA. Dopamine may play an indirect role in ARLVFA by stimulating the emission of Type I behavior and may also play some role in the atropine sensitive LVFA which is normally present during waking immobility.

1187 DORSAL RAPHE NUCLEUS PROJECTING TO THE SUPERIOR COLLICULUS AND THE LATERAL GENICULATE NUCLEUS IN THE RAT. Marcelo J. Villar*, Marcela Huerta* and Daniel A. Pasquier. (SPON: C. Avendaño) Instituto de Neurobiología, Serrano 665, 1414 Buenos Aires, Argentina.

The presence of aminergic fibers in both the superior colliculus and the lateral geniculate nucleus have been shown in the rat by using histofluorescence methods (Fuxe, Acta physiol. scand. 64 (suppl. 247): 37-84, 1965). Since then much effort has been done to demonstrate them with other techniques (Conrad et al., J.Comp. Neur. 156: 179-206, 1974; Moore et al. J.Comp. Neur. 180: 417-438, 1978), being the results controversial.

In this study the axonal transport of the horseradish peroxidase (HRP) was used to trace the afferents to the superior colliculus and the lateral geniculate nucleus. Injections up to 0.05 microliters of 30-50 % HRP saline solution were made through micropipettes. In addition iontophoretic deposit of HRP was also performed to avoid diffusion of the marker to neighbor regions. After 18-24 h of survival the animals were killed by perfusion through the heart with Karnowsky fixative; then the brains were removed and processed according to a routine method (Pasquier & Reinoso-Suárez, Brain Res. 120: 540-548, 1977).

Large HRP injections in the lateral geniculate nucleus labeled neurons in the rostral dorsal raphe nucleus. Most of these neurons were placed close to the midline, others, however, were in the lateral wings of the dorsal raphe nucleus. Very small iontophoretic deposit of HRP in the lateral geniculate nucleus also labeled dorsal raphe neurons primarily in its lateral wings. A few of these latter neurons appeared even after iontophoretic HRP deposit in the dorsal part of the lateral geniculate nucleus.

Large HRP injections in the superior colliculus labeled numerous neurons in the dorsal raphe nucleus, which were placed almost exclusively in its lateral wings. HRP deposit by iontophoresis labeled consistently some neurons in the lateral wings of the dorsal raphe nucleus.

These results suggest, 1) that an aminergic projection from the dorsal raphe nucleus reaches the superior colliculus and the lateral geniculate nucleus in the rat, and 2) that this projection is originated mainly from a lateral caudal extension of the dorsal raphe, which has remained largely ignored.

1188 TYROSINE HYDROXYLASE ACTIVATION AND INACTIVATION UNDER PROTEIN PHOSPHORYLATION CONDITIONS. Kent E. Vrana*, Carin L. Allhiser* and Robert Roskoski, Jr. Dept. Biochem., LSU Medical Center, New Orleans, Louisiana 70112.

Tyrosine hydroxylase, the rate-limiting enzyme in catecholamine biosynthesis, catalyzes the conversion of tyrosine to DOPA. Apparent enzyme activity is changed by altering its affinity for the reducing agent 6-MPH_4 (6-methyl-5,6,7,8-tetrahydrobiopterin) or the end-product feedback inhibitor dopamine. In agreement with other laboratories, when cAMP and Mg·ATP are included during activity measurements using rat corpus striatum homogenate, there is a decrease in 6-MPH_4 Km, an increase in the Ki for dopamine and no change in the apparent Vmax of the enzyme. At low 6-MPH_4 concentrations, therefore, the apparent enzyme activity is increased. Omission of ATP or Mg^{2+} abolishes the response; the response is markedly decreased by omitting cAMP. Enzyme activity was measured during a 15 minute incubation following pre-incubation of the homogenate under phosphorylating or control (no cAMP or Mg·ATP) conditions. After a 3 minute pre-incubation under phosphorylating conditions, there is a 2-fold increase in enzyme activity (11.0 vs 5.7 nmoles/mg·hr). A 30 minute pre-incubation, on the other hand, is associated with inactivation (3.1 experimental vs 5.1 nmoles/mg·hr control). Both phosphorylation activation and inactivation are enhanced by the addition of electrophoretically homogeneous bovine brain protein kinase catalytic subunit. The 6-MPH_4 Km's for control, activated and inactivated enzyme are 0.86, 0.32 and 0.38 mM, respectively. Inactivation, therefore, is not due to decreased affinity of the enzyme for cofactor. We also find that the Ki for dopamine is increased in both the phosphorylated activated and inactivated enzyme: control, 6.1 μM; activated, 37 μM; inactivated, 59 μM. Phosphorylation inactivation, therefore, is not due to an increased sensitivity of the enzyme to an end-product feedback inhibitor. Phosphorylation inactivation is associated with a decrease in the apparent Vmax. Additional experiments are required to determine whether this mode of inactivation has a counterpart in the physiological situation.

Concurrent with this work, we developed a new DOPA decarboxylase coupled assay, in which the labeled dopamine is resolved from the tyrosine substrate using low voltage paper electrophoresis.

This work was supported by USPHS Grant NS-11310.

1189 CHANGES IN THE SENSITIVITY OF β-ADRENERGIC RESPONSES IN THE RAT CEREBRAL CORTEX DURING THE ESTROUS CYCLE AND AFTER OVARIECTOMY. H. Ryan Wagner* and James N. Davis. (Spon: A. D. Roses), VA Medical Center and Duke University Medical Center, Durham, N. C.

We have previously reported a decrease in β-adrenergic receptor-mediated cyclic 3',5'-adenosine monophosphate (cAMP) response in the cerebral cortices of ovariectomized rats chronically exposed to 17α-ethynyl estradiol (Neurosci. Abstr. 4: 524 1978). Continuing with these studies, we now report differences between β-adrenergic receptor-mediated responses in the cerebral cortices of adult female rats during the four day ovarian cycle as well as between cycling females and adult male and ovariectomized female rats of the same age. Accumulation of cAMP (pmols/mg protein) elicited by the β-adrenergic agonist (-) isoproterenol (ISO) in slice preparations of cerebral cortex was lowest at proestrous (Vmax = 34), increased at estrous (Vmax = 38) and diestrous day-1 (Vmax = 38) and at a peak on diestrous day-2 (Vmax = 46). In contrast with values in cycling females, β-adrenergic cAMP accumulations were elevated in both male rats (Vmax = 70) and in ovariectomized female rats (Vmax = 53). The differences in β-adrenergic sensitivity to ISO appeared to be mediated in part by differences in the density of β-adrenergic receptor membrane binding sites. As measured with the β-adrenergic radioligand [^{3}H]-dihydroalprenolol (^{3}H-DHA), β-adrenergic receptor membrane binding (fmols ^{3}H-DHA bound/mg protein) was lowest at proestrous (Bmax = 77), slightly increased at estrous (Bmax = 91) and on diestrous day-1 (Bmax = 99) with a peak on diestrous day-2 (Bmax = 110). As with β-adrenergic cAMP responses, ^{3}H-DHA binding was elevated in both age-matched male rats (Bmax = 126) and ovariectomized females (Bmax = 150) relative to cycling females. No significant differences were seen in the EC_{50}'s for ISO stimulation of cAMP or in the apparent dissociation constants (K_d) for ^{3}H-DHA binding between any condition. Results suggest that estrogens may cause 1) a cyclical decrease of β-adrenergic responses during the ovarian cycle with the lowest values occuring at proestrous and 2) a general decrease in β-adrenergic sensitivity in adult female rats in comparison with both age-matched male and ovariectomized female rats. Receptor binding studies suggest at least part of the differences may be mediated by differences in the density of β-adrenergic membrane receptors.

1190 CHRONIC TREATMENT OF RATS WITH TRICYCLIC ANTIDEPRESSANTS INCREASES RESPONSIVENESS OF AMYGDALOID NEURONS TO SEROTONIN AND NOREPINEPHRINE. R.Y. Wang & G.K. Aghajanian, Depts. Psychiat. & Pharmacol., Yale Univ. Sch. Med., New Haven, CT 06508.

Recently deMontigny and Aghajanian reported (Science 202: 1303, 1978) that after 1-2 wks treatment of rats with tricyclic antidepressant drugs, there was a selective increase in the depressant response of hippocampal and lateral geniculate neurons to microiontophoretically applied serotonin (ionto-5-HT). The aim of the present study was to determine whether this finding holds for amygdaloid (AMYG) cells. In addition, the effect of chronic tricyclic antidepressants on the inhibition of AMYG cells by stimulation of the ascending 5-HT pathway was tested.

Drugs or saline were given ip for 2 wks. Chloral hydrate anesthetized rats were used for single-unit recording and microiontophoresis. Glutamate (Glu) was used to activate cells so that both spontaneously active and quiescent neurons could be studied. To standardize the activation level of cells, the maximum firing rate (prior to depolarization block) induced by ionto-Glu was determined for each cell. One half of the maximum firing rate was then maintained by adjusting the current of Glu. The sensitivity of AMYG neurons to 5-HT and other drugs was evaluated by the charge (the product of the current and the time) required to obtain a 50% decrease in the baseline firing rate.

The response of AMYG cells to 5-HT and lysergic acid diethylamide (LSD, a partial 5-HT agonist) was enhanced (1.5-3 fold) 24 hrs after 2 wks treatment with tricyclic antidepressant drugs (imipramine, desipramine or iprindole). However, the increased responsiveness of AMYG neurons was not specific for 5-HT; the response of cells to norepinephrine (NE) was also enhanced. AMYG neurons were more sensitive to endogenous 5-HT released by stimulation of the 5-HT pathway near the dorsal raphe nucleus (DRN). Compared to controls, the threshold for DRN-induced depressant effects on AMYG cells was significantly decreased. Chronic treatment with chloropromazine, a tricyclic antipsychotic drug, failed to alter the responsiveness of AMYG neurons to 5-HT or NE. Two or more days after discontinuation of chronic treatment with tricyclic antidepressants, the enhanced receptor sensitivity began to disappear; in some cases, subsensitivity was observed.

The results of the present study show that chronic treatment of rats with tricyclic antidepressant drugs increase responsiveness of AMYG neurons to 5-HT and NE. It is suggested that modulation of the sensitivity of postsynaptic 5-HT and NE receptors may be related to the delayed therapeutic actions of tricyclic antidepressant drugs (Supported by USPHS Grants MH-17871 and MH-14459).

1191 ALPHA, BETA PHARMACOLOGICAL CHARACTERIZATION OF NORADRENERGIC MODULATORY ACTIONS IN RAT SOMATOSENSORY CORTEX. Barry D. Waterhouse, Hylan C. Moises and Donald J. Woodward. Dept. Cell Biology, Univ. Tx. Health Sci. Ctr., Dallas, Tx. 75235

We previously reported that excitatory and inhibitory responses of rat somatosensory cortical neurons, produced either by natural stimulation of afferent synaptic pathways or microiontophoretic application of putative transmitters, are enhanced during norepinephrine (NE) iontophoresis. The issue considered in the present study was whether facilitatory effects of NE on cortical neuronal responses to putative transmitter substances could be defined in terms of classical alpha or beta adrenergic receptors. Extracellular activity of somatosensory cortical neurons was recorded from halothane-anesthetized albino rats using multibarrel micropipettes. Responses to iontophoretic pulses (10 sec duration at 45 sec intervals) of acetylcholine (ACH) and gamma-aminobutyric acid (GABA), putative cerebrocortical neurotransmitters, were examined before, during and after iontophoresis of NE, phenylephrine (PE) or isoproterenol (ISO) (4-30 nanoamps). Drug response histograms were used to quantitate effects of the adrenergic agonists on spontaneous and drug-induced activity.

In 15 of 24 (63%) cells, the alpha agonist PE exerted differential effects on spontaneous discharge and ACH-induced excitation which mimicked those exerted by NE. ACH responses of 7 cells were potentiated above control levels with doses of PE which produced no change or moderate depression of background discharge. In 8 neurons, ACH excitation was preserved relative to PE suppression of spontaneous firing rate such that signal to noise ratios were enhanced. In contrast, the beta agonist ISO had no effect or antagonized ACH-induced excitation in 17 of 19 (89%) cells tested. In 3 other cells, iontophoretically applied phentolamine, a specific alpha antagonist, reversibly blocked NE-induced enhancement of ACH excitatory responses. Unlike NE which consistently augments GABA-induced inhibition, PE and ISO at doses which suppressed spontaneous discharge produced no effect or antagonized the GABA response in 15 of 20 neurons.

In summary, these findings suggest that NE modulation of ACH responses in rat somatosensory cortex results from activation of an alpha type receptor, whereas NE augmentation of GABA inhibition occurs via a receptor interaction not easily categorized as an alpha or beta type. Furthermore, the pharmacological specificity demonstrated by NE, PE and ISO with respect to enhancement of GABA and ACH actions indicate that noradrenergic modulatory effects occur independent of a common depressant effect on spontaneous discharge. (Supported by grants from NSF BNS77-00174, NIDA DA-02338 and the Biological Humanics Foundation to DJW and NIH 5 F32 NS05699-02 to BDW)

1192 EFFECTS OF INTRACISTERNAL 6-HYDROXYDOPAMINE ADMINISTRATION ON THE ACQUISITION AND PERFORMANCE OF A SPECIFIC AND NOVEL LOCOMOTOR TASK IN RATS. Watson, M.* and McElligott, J.G. (SPON: S. McElligott). Department of Pharmacology, Temple University School of Medicine, Philadelphia, PA 19140.

Numerous investigators have proposed that catecholamines, notably norepinephrine (NE), are involved in learning processes. A method for evaluating the effect of central NE depletion on the acquisition and performance of a specific task requiring precise paw placement has been developed. Water-deprived rats were trained to traverse horizontally placed rods spaced at regular intervals (standard rod arrangement) for a water reward. Daily performance was assessed by determining average running time for approximately 25 trials using a photodetection system. In addition, foot placement was videotaped by focusing a T.V. camera on a full-length mirror angled beneath the runway. With 4 days of successive exposure to the task, rats ran 40% faster than on day one. The effect of central NE depletion on post acquisitional performance of this specific locomotor task was determined after rats were infused with 6-hydroxydopamine (in 0.1% ascorbate/saline vehicle). Three doses of 6-OHDA (25 µg in 25 µl) were administered intracisternally over a seven day period to enhance the preferential reduction of NE. Subsequent testing, which began 10-14 days following completion of treatment, showed no effect on post-acquisitional performance when compared to vehicle controls. A second group of rats was given 6-OHDA after 4 days on the standard rod arrangement and subsequently exposed to a similar but more difficult locomotor task. They were compelled to traverse an altered arrangement which consisted of irregularly spaced rods. Vehicle controls ran 44% faster by day four. 6-OHDA treated rats ran only 19% faster, showing impaired acquisition of this new task. Determination of intertrial intervals (latency between trials) showed no significant difference. In addition, no differences in open field behavior were noted between the two groups. Biochemical determinations were made using High Pressure Liquid Chromatography (HPLC) with electrochemical detection. Cerebellar NE was reduced by 73%, while limbic forebrain showed a reduction of 41% in NE and 29% in Dopamine (DA). While these data are consistent with a general neuromodulatory role for NE, the observed change in locomotor behavior may be the result of noradrenergic deafferentation of a specific brain region such as the cerebellum. Depletion of NE at cerebellar Purkinje cells may result in impaired acquisition of certain coordinated motor behaviors.

1193 IDENTIFICATION OF BULBOSPINAL SEROTONERGIC NEURONS ON THE BASIS OF CONDUCTION VELOCITY. M.W. Wessendorf*, E.G. Anderson, H.K. Proudfit. Depart. Pharmacol. U. of Illinois Col. of Med., Chicago Illinois 60612

The Nucleus Raphe Magnus (NRM) contains cell bodies of bulbospinal serotonergic neurons. The nucleus, however, contains cells of varied morphology, many of which may not be serotonergic. We have sought to establish criteria for identifying serotonergic cells on the basis of their conduction velocities.

Recordings from NRM cells were made using 4-barrel glass microelectrodes. Serial electrode drives along the rostral-caudal axis of the nucleus sampled bulbospinal units, which were identified by antidromic activation via ball electrodes placed on the dorsal lateral surfaces of the spinal cord between T_8 and T_{10}. Antidromic activation was assumed when observing invariance of latency in response to 3 Hz. stimulation, the ability of a cell to follow 60 Hz. stimulation, or collision between spikes simultaneously initiating at the soma and the spinal cord. Spikes were assumed to be of somatic origin if microiontophoretic application of d,l-homocysteic acid produced excitation.

In 160 bulbospinal cells recorded in the NRM, the conduction velocities were bimodally distributed. The conduction velocities of the majority of cells occurred in the range between 3.1 and 20 M/sec; however a large number of cells were also observed with conduction velocities between 0.7 and 1.0 M/sec. Very few cells had conduction velocities between 1.1 and 3.0 M/sec., or greater than 30 M/sec.

To determine the degree of representation of serotonergic cells in these ranges, conduction velocities were measured in rats injected intraventricularly with 150 mcg 5,7-dihydroxytryptamine (5,7-DHT), a serotonin neurotoxin. The treated animals were mixed with vehicle-injected controls in a blind experimental paradigm, and at 12 to 16 days a search was made for antidromically activated cells in the NRM. Data were normalized by expressing them as numbers of cells per electrode drive.

Treament with 5,7-DHT moderately reduced the number of cells encountered per drive through the NRM. On the basis of conduction velocity, cells in the 0.7-1.0 M/sec range were the most dramatically reduced, declining from 1.05 (± S.E. 0.32) cells per drive in controls to 0.16 (± S.E. 0.065) in treated rats. We therefore conclude that these cells are predominantly serotonergic. The units in the 3 to 6 M/sec range also declined significantly and may contain serotonergic cells. From the moderate decreases in other conduction velocity groups we cannot exclude the possibility that some faster conducting serotonin cells may exist.

Supported by USPHS NS Grant #12649

1194 DIFFERENTIAL DESCENDING PROJECTIONS FROM THE LOCUS COERULEUS AND THE SUBCOERULEUS/PARABRACHIAL NUCLEI IN MONKEY. K.N. Westlund and J.D. Coulter. Marine Biomedical Institute, Departments of Psychiatry & Behavioral Sciences and Physiology & Biophysics, University of Texas Medical Branch, Galveston, Texas 77550.

Descending projections from the locus coeruleus and the subcoeruleus/parabrachial region were examined using the anterograde autoradiographic tracing technique in monkey (*Macaca fascicularis*). Single injections of 0.1-0.3 µl of an equal parts mixture of [^{3}H] leucine and proline (50 µCi/µl) were made either into the region of the locus coeruleus or into the subcoeruleus/medial parabrachial nuclei. Labeled fibers descend ipsilaterally both medially, with the medial longitudinal fasciculus, and laterally beneath the trigeminal complex. Some fibers seen crossing the midline terminate in the contralateral locus coeruleus and subcoeruleus/parabrachial nuclei respectively. Common terminations in the brainstem include the raphe complex, the intermediate cell group of the facial nucleus, the nucleus prepositus hypoglossus, the spinal nucleus of the trigeminal and the medial reticular formation. Specific terminations of descending locus coeruleus fibers include the ventral portion of both the dorsal motor nucleus of the vagus and the nucleus of the solitary tract, as well as the subjacent reticular formation. Subcoeruleus/parabrachial specific terminations include the nucleus hypoglossus and the nucleus retroambiuus. Heavy fiber labeling from both regions continues into the spinal cord ipsilaterally in the ventrolateral white matter through cervical, thoracic, lumbar, and sacral cord levels. Fibers are seen crossing the midline at all levels of the medulla and spinal cord. At all cord levels both locus coeruleus and subcoeruleus/parabrachial terminations include heavy label ipsilaterally over the ventral horn in the region equivalent to Rexed's laminae VII-IX, particularly over the motor neurons. Laminae I and X contain fairly heavy terminations ipsilaterally while dorsal horn laminae III-VI are lightly labeled. Lighter label is also seen in the same general pattern contralaterally. The major descending termination of the subcoeruleus/parabrachial region is bilaterally at levels T_2-T_4 in association with the sympathetic intermediolateral cell column. The locus coeruleus, in contrast, projects heavily upon the parasympathetic lateral gray, bilaterally at levels S_2-S_4. Since localization of the terminal zones seen in this study corresponds closely with the pattern demonstrated histochemically for noradrenergic terminals, the locus coeruleus and the subjacent subcoeruleus/parabrachial regions appear to provide differential descending noradrenergic innervation of cranial and spinal somatic sensory, motor and visceromotor cell groups. (Supported by NS12481).

1195 HISTOCHEMICAL AND HISTOFLUORESCENT LOCALIZATION OF BIOGENIC AMINE DEPOSITS IN ALTERNATE SECTIONS. Joe Wood and Robert E. McClung. Department of Neurobiology & Anatomy, University of Texas Medical School, Houston, TX 77025.

Biogenic amines can be readily detected in the CNS by histofluorescent methods. These techniques are highly sensitive and yield striking photographs; however, the reaction products are sensitive to light and tend to fade. Moreover, histofluorescent techniques utilize dark field microscopy which reveals little of the non-fluorescent cytoarchitectural components. Electron microscopic localization of biogenic amines using glutaraldehyde-dichromate has been used successfully in the central nervous system, and there have been light microscopic observations made from small plastic embedded sections. Difficulties of correlation of histofluorescence with light and electron microscopy are now more apparent than real. Fresh brain material can be frozen on dry ice and sections made on a cryostat at approximately 10-20 microns. Tissue was obtained from rats, monkeys and cats, frozen, and sectioned on a cryostat. Sequential sections were alternated, with section A being used for histofluorescence, section B for a modified glutaraldehyde dichromate staining procedure, and section C as an untreated control. Glyoxylic acid histofluorescence shows norepinephrine and serotonin-containing cell bodies and processes, especially in the midbrain region. The next section was treated with a mixture of glutaraldehyde, sodium chromate and potassium dichromate at pH 4.1. Following incubation the tissue was stained with conventional histologic stains, i.e. cresyl violet and/or toluidine blue. Neurons correlative with histofluorescent areas were seen to contain catecholamine and/or indolamine chromium deposits in cell bodies and in some processes. Visualization of these deposits range anywhere from low-power light microscopy to oil immersion, and with care, pigments can be differentiated from amine deposits. In the unstained, untreated control sections, only pigment deposits are visible. This technique should lead to a better understanding of the cytoarchitecture of the central nervous system and the relation of amine-containing cells to other cell structures, i.e. glial cells and other neurons. The technique will be useful in localizing amine-positive areas for electron microscopy, and no doubt will serve as the bridge from mapping to electron microscopy. Supported by USPHS grant NS-10326.

1196 DEVELOPMENTAL CHANGES IN THE CEREBELLUM INVOLVING GRANULE CELLS, PURKINJE CELLS AND THE SEROTONIN INNERVATION INDUCED BY RAPHE TRANSPLANTS. Miyuki Yamamoto-Yoshida* and Victoria Chan-Palay (SPON: S.L. Palay). Depts. of Anatomy and Neurobiology, Harvard Medical School, Boston, MA 02115.

Serotonin neurons in several raphe nuclei contribute to the innervation of the cerebellar cortex and nuclei through mossy fibers, parallel fiber-like axons, and diffusely branching free endings. Whereas serotonin neurons and their processes develop early in prenatal ontogeny, the cerebellum develops late, postnatally. The aim of these investigations was to examine the effect of raphe transplants upon the subsequent development of the cerebellum in early postnatal rats. A series of experiments was conducted to determine the optimal ages of donor and host animals. Donor rats of ages 6 days to adult and host animals of 4 to 14 days postnatal age were used. The most consistent results were obtained with both donor and host animals of 6 postnatal days. The midline raphe structures of the medulla were carefully dissected from brains of donor animals. Host animals were anesthetized with ether and the IVth ventricle exposed to receive the transplant without mechanical traumatizing the overlying cerebellum. Post-transplantation survival was 4 weeks and longer.

The cerebellum and structures bounding the IVth ventricle were examined in one group of experimental animals following perfusion fixation with aldehydes and staining of the sections with thionin. Cerebellar structures close to the transplant consistently showed developmental anomalies. The cerebeller cortex displayed (1) folial malformation particularly in the vermis, (2) foci of arrested granule cells due to nondescent of the external granular layer, (3) foci of disruptions in the Purkinje cell layer. These foci of changes were directly related to the position of the transplant.

In a second group of transplanted animals, the serotonin innervation of the cerebellum was examined after three hour intracisternal or intraventricular infusions of ^{3}H-serotonin (50 µl, 10^{-6} M in saline, specific activity 10.8 Ci/mmol) followed by perfusion fixation with aldehydes. Light microscope autoradiograms revealed an unusual profusion of labeled serotonin axons in the foci with arrested granule cells and disrupted Purkinje cells, compared to normal and to control animals. Control experiments were performed using transplants of liver tissue or gelfoam sponges soaked in serotonin. These cases showed folial malformation but not the foci of neuronal changes, indicating that changes in folial pattern alone may be produced by transplants of various tissues. These results indicate that transplants of raphe can cause developmental changes in the cerebellum of the host. These anomalies may be due in part to a detectable increase in the serotonin innervation of the cerebellum, most probably originating from the transplant.

1197 COMPARISON OF NORADRENERGIC MODULATORY ACTIONS ON PURKINJE CELL RESPONSES TO IONTOPHORESIS OF γ-AMINOBUTYRIC ACID, β-ALANINE AND TAURINE. Hermes H. Yeh, Hylan C. Moises, Barry D. Waterhouse and Donald J. Woodward. Dept. Cell Biology, U. Tx. Health Science Center, Dallas, Tx. 75235

We have previously shown that both iontophoretically applied norepinephrine (NE) and stimulation of the locus coeruleus can potentiate γ-aminobutyric acid (GABA)-mediated inhibition of cerebellar Purkinje cells (PC). Glycine-induced inhibition was not enhanced and dopamine did not mimic the facilitatory effect of NE. The specificity of the observed NE modulation was studied further here in a series of iontophoretic experiments comparing depressant amino acids structurally related to GABA.

Multibarrel micropipettes were used to apply drugs and record extracellular PC unit responses in halothane-anesthetized rats. Inhibitory responses to iontophoretic pulses (10 sec duration at 30-35 sec intervals) of β-alanine, taurine and GABA were examined before, during and after NE iontophoresis (5-20 na). Drug response histograms were computed to quantitate NE effects on spontaneous and drug-induced neuronal activity.

Consistent with previous findings, NE at doses which had little or no effect on PC spontaneous activity produced marked augmentation in all 13 cells tested. In 3 cells, GABA applied continuously at low currents showed no ability to potentiate PC responses to superimposed GABA pulses. This suggests that the observed modulation with NE cannot be explained by summation of NE depressant effects with hyperpolarizations produced by GABA. NE interaction with β-alanine-induced inhibition, tested in 19 PC's, was clearly different from GABA, with a predominance of 10 cells showing no effect, 7 cells augmented and 2 cells antagonized. NE effects on taurine-induced inhibition was also dissimilar to GABA. In 14 cells tested, 6 showed no significant changes, 4 cells were potentiated and 4 cells were antagonized. NE facilitatory effects, when seen with β-alanine and taurine, were moderate in comparison to that of GABA. Picrotoxin reversibly blocked GABA (3 cells) and β-alanine (3 cells) inhibitions whereas taurine blockade (3 cells) appeared to be of distinctly longer duration. This preliminary result, in addition to the apparent specificity in NE modulation, would argue for a specificity residing within different amino acid receptors or, perhaps, reuptake processes.

In summary, these data confirm the previously reported NE modulation of GABA-mediated inhibition. Evidence is provided here that NE preferentially enhances the inhibition of PC's produced by iontophoretically applied GABA in contrast to that produced by other amino acid depressant agents. (Supported by grants from NSF BNS77-01174, NIDA DA-02338 and the Biological Humanics Foundation to DJW).

1198 ELECTROPHYSIOLOGICAL EVIDENCE OF INHIBITORY INPUTS TO THE VENTRAL TEGMENTAL AREA FROM THE PREOPTIC AREA AND THE NUCLEUS ACCUMBENS. C. Y. Yim*, H. Maeda* and G. J. Mogenson. Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

Previous anatomical studies have shown that limbic forebrain structures project to ventral tegmental area (VTA) of the midbrain (Nauta, Brain 1958, 81, 319). The present study investigated with electrophysiological recording techniques possible inputs to the VTA from the anterior hypothalamic-medial preoptic area (AHPO) as well as from the nucleus accumbens (NA).

Action potentials were recorded extracellularly from neurons in the VTA of urethane anesthetized rats using glass micropipettes filled with 4M NaCl. The effects of single pulse stimuli delivered to the NA and AHPO on the neuronal activity of the ipsilateral VTA were investigated. In some experiments, 7 barrel micropipettes were used for recording and iontophoretic application of picrotoxin (a GABA antagonist) and nipecotic acid (a GABA uptake inhibitor) to study the effect of these drugs on the response of VTA neurons to NA stimulation.

The electrophysiological characteristics of the population of units recorded suggested two types of VTA neurons: one type had long spike durations and slow rates of discharge and a second type shorter spike durations and fast rates of discharge. These observations confirm previous findings in which the two types were considered to be dopaminergic mesolimbic and non-dopaminergic neurons (Yim & Mogenson, Brain Research 1979, in press). Approximately 20% of VTA neurons were antidromically activated from the nucleus accumbens.

Both types of VTA neurons received convergent inputs from the AHPO and NA. Electrical stimulation of the AHPO inhibited the majority of the sample of VTA neurons tested with a relatively short latency(<10 ms). Stimulation of NA inhibited both types of VTA neurons tested but in addition, activated the first type of VTA neurons as well. Activations usually had longer latencies of > 10 ms. Inhibition of the VTA neurons by stimulation of NA was blocked by iontophoretically applied picrotoxin and prolonged by nipecotic acid with no change in latency.

These observations provided evidence of an inhibitory input from AHPO and NA of the limbic forebrain to dopaminergic and non-dopaminergic neurons in the VTA. The effects of the iontophoresis of picrotoxin and nipecotic acid suggest that the descending inhibitory pathway from the NA to the VTA is GABAergic. Nature of the transmitters that mediated the excitatory response from NA and the inhibitory response from AHPO stimulations remains unknown. The descending GABAergic projection from the NA to the VTA appeared to be similar to the feedback GABAergic pathway present in the nigral striatal dopaminergic system.

1199 PRENATAL PHENOBARBITAL EXPOSURE ALTERS MOUSE BRAIN NEUROTRANSMITTER UPTAKE. John W. Zemp, Thomas N. Thomas and Lawrence D. Middaugh, Department of Biochemistry and of Psychiatry and Behavioral Sciences, Medical University of South Carolina, Charleston, S.C. 29403.

We have previously reported that prenatal exposure to phenobarbital during the last third of pregnancy produces alterations in the brains of C57 BL/6J mice. These alterations include delays in some correlates of brain growth and development[1] changes in the circulating levels of corticosterone on the day of birth and at 21 days of age[2] and long lasting changes in behavior which may reflect a change in the arousal level of the exposed animals[3] . In this report we demonstrate that prenatal exposure to the barbiturate produces changes in the ability of crude synaptosomal preparations to accumulate several neurotransmitters. High affinity uptake of catecholamines, serotonin and γ amino butyrate(GABA) were estimated using crude synaptosomal preparations obtained from the brains of mice exposed to phenobarbital (20 or 40 mg/kg maternal body weight) (P_{20} and P_{40}) or to saline injections during the last week of gestation. The radioactive neurotransmitters was added to the crude synaptosomal preparation and incubated for five minutes at 37° C. Following filtration and washing, the filters were soaked overnight in sodium dodecyl sulfate and counted. Results were expressed as pmoles uptake/mg protein/5 minutes. Results indicated that for the P_{40} group there was a significant increase in the uptake of both dopamine and norepinephrine at low concentration (0.01μM) and a significant decrease in the uptake of GABA at low concentrations (0.01μM). No effect on the uptake of these neurotransmitters was observed in the P_{20}groups. By contrast the uptake of serotonin was significantly and substantially increased at all concentrations of serotonin studied with both the P_{20} and P_{40} groups. These results are consistent with a change in synaptic membrane function as a result of prenatal phenobarbital administration. (Supported by Grant # DA 06124 from ADAMHA)

MOTOR SYSTEMS

1200 FREQUENCY CHARACTERISTICS OF THE HUMAN ELECTRO-OCULOGRAPHIC RESPONSE Larry A. Abel*, A. Terry Bahill and B. Todd Troost Dept. Neurology, Univ. Pittsburgh School of Medicine and Biomedical Engineering Program, Carnegie-Mellon University, Pittsburgh, PA. 15261.

Human tissue is commonly modeled as a resistor in series with a parallel resistor-capacitor combination. This circuit should produce an inherent low-pass filtering of electro-oculographic (EOG) data, if the orbital structures involved are, in fact, adequately described by this model.

Using standard EOG electrodes and typical AC amplifiers we first found the EOG current to be 20 pA. We could not make our impedance measurements at currents this low, so we used 10 nA of current, which produced a current density of 3×10^{-4} mA/cm^2.

In an effort to find the cutoff frequency of the obligatory low-pass filtering we then measured the impedance of the head in a fixating subject and of the EOG electrodes as a function of frequency. The impedance of the head held constant at about 4 kohms over the entire frequency range. The impedance of the electrodes, however, showed a surprising increase in magnitude and phase angle at frequencies above 10 kHz. Electrode phase angle went from a 7 deg lag at lowest frequencies to zero at 100 Hz, then becoming an increasingly large lead at higher frequencies.

The lack of a pronounced attenuation at 25 Hz as predicted by a simple R-C tissue model indicates that the high frequency components of saccadic eye movements are not inherently eliminated by EOG recording. The presence, however, of concurrent EMG activity originating in the facial muscles still masks the fine structure of saccades, as can be seen by spectral analysis. Thus, other recording techniques are preferable when eye movements are to be studied in detail.

1201 THE NATURE AND DISTRIBUTION OF NECK MUSCLE AFFERENTS PROJECTING TO THE MEDULLA. V.C. Abrahams and T. Yokota, Department of Physiology, Queen's University, Kingston, Ont. Canada. K7L 3N6.

Electrical stimulation of muscle afferent nerves provides a convenient technique for studying central projection pathways. Afferent nerves serving the large dorsal neck muscles, unlike the more commonly studied hindleg nerves have a unimodal skewed distribution with a single peak at 3-4μ. Recordings have been made of conduction velocity and stimulus threshold from 238 neck muscle afferent fibres. Fibres activated by threshold (T) to 1.2T had conduction velocities of 20 m/sec and above. Increasing stimulus strength from 1.2T to 2T led to the appearance of a few (4 of 80) fibres conducting at velocities below 10 m/sec. All myelinated fibres were activated by stimulation at 10T. Spindle and Golgi tendon organs (GTO) afferents in neck muscle nerves conduct at velocities of 20 m/sec or more. Thus stimulation of the large dorsal neck muscle afferent nerves at strengths of T to 2T will lead mainly to excitation of spindles and GTO's. It is only when stimulus strengths from 2 to 10T are used that GPIII afferent fibres are activated. Stimuli of 10T and greater (and usually requiring longer pulse widths) are necessary for unmyelinated afferents to be excited.

These stimulation criteria were used to re-examine the nature of muscle afferent projections to the medulla just posterior to the obex. Fast green dye-filled glass micro-electrodes were used so that recording sites could be accurately noted. The largest group of units activated by neck muscle afferents at this level of the medulla were high threshold afferents and few spindle or GTO projections were found, and then in widely scattered regions. The largest population of units excited (43 of 63 examined) had muscle afferent thresholds mostly between 6 and 8T and never below 4T. The same units responded to mechanical stimulation of the ipsilateral cornea (usually light touch of cotton, but in 3 units needing a firm stroke), pinch of both pinnae with toothed forceps (but not light touch) and a sharp tap to the nose. These units were located deep to the trigeminal subnucleus caudalis in lamina V and VI. A few units with high thresholds (2.5 to 21T) and with large nociceptive cutaneous fields were found ventromedial to pars magnocellularis of trigeminal subnucleus caudalis. Low threshold units were found as previously described in the most lateral region of the cuneate nucleus and between the cuneate nucleus and trigeminal subnucleus caudalis.

1202 EFFECT OF VIBRATION ON THE ANKLE STRETCH REFLEX IN HUMAN. Gyan C. Agarwal and Gerald L. Gottlieb. Dept. of Physiology, Rush Presbyterian-St. Luke's Medical Center, Chicago, Illinois 60612 and College of Engineering, University of Illinois at Chicago Circle, Chicago, Illinois 60680.

Vibration applied to the tendon of the extensor muscles of the ankle joint produces the tonic vibration reflex (TVR) which increases when the vibration frequency is increased. The TVR produces changes in the mechanical properties about the joint as well as in the spinal reflexes associated with the vibrated muscle.

Torques were applied to dorsiflex the ankle of seated human subjects evoking a myotatic reflex and post-myotatic responses. Vibration inhibits the myotatic component of the stretch reflex in soleus. The degree of inhibition is proportional to the vibration frequency. This is in contrast to the facilitation of the myotatic reflex produced by tonic voluntary contraction.

Vibration does not influence the post-myotatic component of the stretch evoked response. This component is also not significantly influenced by the tonic voluntary contraction. These results indicate that the post-myotatic responses to limb perturbation are not only different from the myotatic reflex in their latency but also in their functional dependence to peripheral and central influences.

The mechanical effects of vibration were measured by applying sinusoidal or random torque inputs. Although the myotatic response to discrete stretches is suppressed by the TVR, the repeated stretches of sinusoidal oscillation produce an average EMG response which is not different in magnitude from the no vibration case with tonic voluntary contraction. The TVR affects a joint's response as measured in terms of mechanical parameters (mainly joint stiffness) in the same facilatory manner that is seen with tonic volunatry contraction.

1203 MULTIPLE UNIT ACTIVITY ASSOCIATED WITH VOLUNTARY HAND MOVEMENTS AND SOMATOSENSORY STIMULATION IN THE SENSORIMOTOR CORTEX OF THE MONKEY. Joseph Arezzo* and Herbert G. Vaughan, Jr. Dept. of Neuroscience, Albert Einstein Coll. of Med., Bronx, N.Y. 10461.

The firing patterns of cortical neurons associated with conditioned hand movements have been extensively studied in the monkey using single unit techniques. These studies are usually limited to recordings from a restricted region and are inherently biased toward sampling of larger neurons. In this investigation, we have examined digitally rectified and averaged multiple unit activity (MUA), recorded simultaneously from portions of the frontal and parietal cortex of monkeys trained to perform self-initiated hand movements. The timing and intracortical distribution of this activity has been compared with the MUA elicited by peripheral stimulation. Our recording methods provide a weighted sum of the neural firing within a sphere of tissue roughly 350 u in diameter, and thus, provide an index of net changes in neural population activity within a circumscribed cortical locus. These data are particularly useful in interpreting field potential recordings, which provide the sole available method for studying human sensorimotor processes.

Antecedent increases in MUA begin 90-100 msec before EMG monitored contractions and are recorded throughout the hand area of the precentral gyrus, including the anterior bank of the central sulcus. The antecedent activity is maximum in amplitude within the fifth lamina but can also be recorded in the fourth and fifth lamina. In the more superficial laminae of area 4, the initial increase in MUA is coincident with movement onset and continues for up to 200 msec following the end of EMG activity. Peripheral stimulation of the median nerve which is sufficient to produce a thumb twitch results in activation limited to the posterior portion of area 4. Within area 3a, a phasic burst of MUA begins 10-20 msec after movement and is followed by a second discharge which peaks 100 msec after movement onset. Area 3a receives the earliest somatosensory input with MUA beginning 6.0 msec following stimulation. Movement related MUA in areas 1 and 2 follows the onset of contraction and also peaks at 100 msec. Additional MUA which begins 150 msec after movement onset is recorded from area 5. No changes in MUA are found in area 7 associated with self-paced movements.

1204 GRADED EFFECTS OF STATIC FUSIMOTOR STIMULATION ON THE FREQUENCY RESPONSE OF MUSCLE SPINDLE PRIMARY ENDING. R.A. AURIEMMA*, G.P. MOORE, J.R.ROSENBERG‡ M. DUTIA* Dept.Biomed.Engr.,USC,Los Angeles Ca. 90007 and Institute of Physiology, Univ. Glasgow, Scotland.

The effect of gamma fusimotor innervation on the transducing properties of the spindle muscle receptor were studied in the tenuissimus muscle of the cat. Functionally single primary afferent axons and static gamma motor axons were isolated from dorsal and ventral rootlets at the L7-S1 level. Length perturbations having a Gaussian amplitude distribution of 10-100μ RMS level and a flat frequency spectrum from DC to 120 Hz were applied to the proximal half of the muscle and the Ia discharge recorded, with and without concurrent, independent Poisson pulse trains of 40-80 pulses/sec mean rate being delivered to one or more gamma axons. Crosscorrelation of the Ia spike train with the input length waveform allowed the calculation of the average prespike length epoch and an estimate of the impulse response function of the muscle receptor. The Fourier transform of the impulse response function provided an estimate of the receptor's frequency response.

In the absence of gamma stimulation the gain of the frequency response curve increased at 20db/decade, suggesting a system responding to the velocity of the applied perturbation When individual gamma axons were stimulated the relation was shifted by varying amounts for each axon, towards 40db/decade, a characteristic of an acceleration-sensitive system. When pairs of gamma axons were independently stimulated, the shift was generally greater than that seen from either axon alone, but was never greater than 40db/decade even for cases where one of the axons produced such a shift when stimulated alone. Increase in mean spike rate and an absolute decrease in the magnitude of the gain function at each frequency were observed to accompany the gamma effect on the slope of the gain curve (Supported in part by NIH grants NS 11298 & GM 23732.

1205 EFFECTS OF ALTERED GRAVITY ON A HUMAN OTOLITH-SPINAL REFLEX. S.B. Backman* and D.G.D. Watt. Dept. of Anaesthesia Res. and Aviation Med. Res. Unit, McGill Univ., Montreal, Canada H3G 1Y6.

The sensitivity of the vestibular otolith organs is lowered whenever the head is tipped out of its normal orientation. Recently, Melvill Jones & Young (1978) have demonstrated that "the threshold of sensitivity to saccular stimulation is significantly lower when in its normal orientation relative to gravity than when tilted 90° away from that orientation". This experiment extends this finding by replacing subjective assessment of linear movement with an objective test of otolith sensitivity.

Ten subjects were exposed to sudden, unexpected falls of 15cm (200 to 450 msec, depending on Δg) while surface emg activity was recorded from their left calf muscles. Step changes of .33, .67 and 1.0 g were employed, using counterweights to reduce acceleration below 1.0 g in the vertical direction. Subjects were also suspended horizontally, substituting for gravity with bungee cords running from the waist to the wall, and similar .33, .67 and 1.0 g step changes were used.

Emg activity consisted of 2 components, an early burst related to the onset of fall, and later activity concerned with landing. On average, emg activity began 74 msec after release for vertical Δgs of .67 and 1.0, and a horizontal Δg of 1.0. The early activity was reduced and sometimes absent for a vertical Δg of .33 and horizontal Δgs of .33 and .67, extending the average latency to as much as 116 msec in these cases. Later activity concerned with landing built up before contact and continued afterwards, its pattern being less consistent and of lesser amplitude when the subject was landing from a horizontal fall. Emg activity was rectified, all falls were averaged for each Δg and orientation, and the area under the resulting curve was measured from 50-150 msec after release. (This activity is considered to be predominantly otolith-spinal in origin, being of short and relatively invariant latency, time-locked to the acceleration stimulus, and too early for a voluntary response (Melvill Jones & Watt, 1971). It can also be selectively abolished by labyrinthectomy in cats (Watt, 1976) and is absent in labyrinth-defective human subjects (Greenwood & Hopkins, 1976)). The area of the early burst varied with the size of the acceleration stimulus when the subject was tested in either orientation. Furthermore, the gain of this otolith-spinal reflex was significantly reduced when the subject was horizontal. This confirms the findings of Melvill Jones & Young, and provides a means of quantitizing changes in otolith function in man during prolonged changes of gravity, as during space flight.

1206 THE SIZE PRINCIPLE: EFFECT OF INHIBITORY INPUTS TO MOTIONEURONES IN HUMAN SUBJECTS. P. Bawa, Dept. of Kinesiology, S.F.U., Burnaby, B.C., V5A 1S6.

In the decerebrate cat, Henneman and coworkers (1965, 1974) demonstrated that the effect of an inhibitory input to a motoneurone pool with an existing excitatory input is to reduce the effect of excitation, thus keeping the fixed order of recruitment of motoneurones. The following experiments were done to test the effects of inhibition in normal human subjects. The subject sat comfortably in a chair with his foot strapped to a plate carrying strain gauges so that the contractions of T A and triceps surae (G-S) muscles were isometric.

(i) Disynaptic spinal inhibition: The subject recruited a pair of distinct single motor units (SMUs) from T A and maintained their firing rate. Stimulus to the tibial nerve to elicit H-reflex in soleus resulted in inhibition of T A motor units. The high threshold (HT) SMU dropped out before the low threshold (LT) SMU for an interval up to 300 msec. No reversal in derecruitment observed.

(ii) Vibration of Achilles tendon: The subject recruited two distinct SMUs from T A and maintained their firing rate. Vibration of Achilles tendon at 60Hz, resulted in TVR in soleus and inhibition of T A-SMUs. The HT-SMU derecruited before LT-SMU without exception.

(iii) Descending inhibition: Achilles tendon was vibrated at 60Hz to recruit two distinct SMUs from soleus. The subject was asked to derecruit these units voluntarily while the vibration was still on. Out of the 50 pairs studied, 34 derecruited with HT-SMU before LT-SMU. In 12 pairs, LT unit dropped before HT unit while 5 pairs were "confused", the order of recruitment & derecruitment changed on rechecking.

The net excitability of a motoneurone is determined by the temporal and spatial relationships of excitatory and inhibitory synaptic inputs. In the first two cases, if there is only one inhibitory input which has a fixed spatial relationship to the excitatory input, a uniform reduction in the excitatory conductance change would result in a regular pattern of derecruitment. In the last case, in addition to the descending inhibition, inhibition from G.T.O.s (60Hz recruits G.T.O.s), Renshaw cells and PAD could interact in a more complicated way to result in the observed pattern of derecruitment. This implies that conductance changes are not the only determinants of decrecruitment, the interaction of IPSPs versus EPSPs have to be taken into account.

1207 DORSAL COLUMN NUCLEI LESION ELIMINATES DISUSE OF DORSAL RHIZOTOMIZED FORELIMB. A.J. Berman, D.E. Teodoru,* T.A. Tran,* and A. Blau.* Dept. of Neurosurgery, V.A. Hospital, Bronx, N.Y. 10468

After unilateral dorsal rhizotomy in the monkey, the forelimb is not used purposively unless the intact limb is restrained or incapacitated. This movement deficit has variously been attributed to learned non-use, cross-spinal inhibition, sensory inattention, or, most parsimoniously, preference for use of the fully innervated limb. Results of the present study indicate a further possibility, that dorsal column and dorsal column nuclei are implicated in the processes underlying loss of function after dorsal rhizotomy.

Eight monkeys underwent dorsal rhizotomy C2-T3 (DR) and/or dorsal column (DC) section and/or dorsal column nuclei (DCN) lesion. The time between procedures was four to six months. The lesions were: in three animals, bilateral DCN lesions and DC section followed by unilateral DR; in two, bilateral DCN followed by unilateral DR lesion; in two, unilateral DCN lesion followed by bilateral DR; and, in one, unilateral DC section followed by bilateral DR. Animals were maintained in a 14' x 9' x 8' cage with wire mesh walls and narrow beams affording opportunities for ambulating and climbing.

In every case in which DR was combined with DCN lesion or DC section, use of the DR limb was seen from the first postoperative day. This was true when DCN lesion or DC section preceded DR and was also the case when DCN lesion followed DR. The limbs with the combined lesions were used for support, climbing, ambulating, reaching for food placed on the floor or hanging from the ceiling, and for bimanual tasks. The animals with bilateral DR used combined-lesion limbs to the exclusion of contralateral DR-only limbs. The limb with both DR and DCN lesion was also often preferred over the limb with DCN lesion-only for performance of tasks requiring fine digital coordination. This presumably was due to the poor coordination of fingers in the hand ipsilateral to DCN lesion. This lack of coordination was significantly alleviated by superimposed dorsal rhizotomy.

It would appear that, after DR, the dorsal column, dorsal column nuclei system exerts inhibitory effects on movement. Lesions of these pathways remove this inhibition, allowing return of motor function.

1208 CONTROL OF NECK MUSCULATURE BY TECTAL EFFERENT PATHWAYS. G. Bilotto, K. Fukushima, J. H. Fuller and B. W. Peterson. The Rockefeller University, New York, N.Y. 10021.

Mechanisms underlying head movements elicited by activation of the superior colliculus have been investigated by recording activity of neck muscles and reticulospinal neurons in precollicular decerebrate cats during microstimulation of the intermediate to deep tectal layers. Trains (duration 30-400 msec, rate 300-400 Hz) of 100 μsec pulses with amplitudes of 5-100 μA produced saccadic eye movements and excitation of contralateral dorsal and ventral neck muscles plus inhibition of corresponding ipsilateral muscles. Excitatory EMG responses of neck muscles typically consisted of an initial burst at a latency of 5-13 msec (median 8 msec) followed by rebound depression and then by tonic excitation which lasted throughout the train. The strongest responses were produced by stimulation at posterior points. Muscles with upward pulling directions (rectus major, biventer, complexus) tended to be more strongly activated from medial tectal points which also produced oblique upward eye movements while longus capitis, which has a downward pulling direction, was best activated from lateral points which also produced oblique downward eye movements. Responses of muscles with primarily horizontal pulling directions (splenius, obliquus capitis inferior) were less sensitive to the medio-lateral position of the stimulus point. The pattern of tectally evoked neck muscle activity is therefore consistent with the retinotopic organization of the colliculus.

Extracellular recording revealed that 21/75 medial (MRST) and 8/34 lateral (LRST) reticulospinal neurons had reciprocal responses to stimulation of the ipsi- and contralateral tectum which resembled those of neck muscles. Most of the remaining neurons were silent and failed to respond to stimulation. Latencies of contralaterally evoked discharge ranged from 2.5 to 10 msec with a median of 5 msec. Some neurons were activated for the entire duration of the stimulus train, others responded only at train onset or exhibited a combination of the two patterns. Discharge of these neurons is therefore appropriate to contribute to the responses of neck muscles to tectal stimulation. Such neurons were most prevalent among MRST neurons located in the periabducens region which is consistent with the idea that this region is an important center for organization of both eye and head movement components of horizontal gaze shifts. The same MRST neurons may participate in vestibulo-neck reflexes since a number of tectally activated neurons also responded to stimulation of contralateral semicircular canal nerves.

1209 COMPRESSION EFFECTS ON THE COMPOUND ACTION POTENTIAL OF IN SITU SEVERED AND INTACT NERVES. L. Jack Bloom*, L. Donald Gilmore*, Carlo J. De Luca, (SPON: W. Bradley). Liberty Mutual Research Center, Hopkinton, MA, Children's Hospital Medical Center, Harvard Medical School, Boston, MA.

For the past six years our laboratory has been developing an implantable nerve electrode interface capable of recording neuroelectric signals from the surface of severed peripheral nerves. An investigation was undertaken to determine the extent of nerve injury resulting from compressive forces introduced in the surgical procedure and post-surgical trauma occurring when such an electrode is implanted.

Severed and intact peroneal nerves of New Zealand white rabbits were supermaximally stimulated and the compound action potential (CAP) was measured. The application of direct compressive force on a 3 mm length of nerve produced a corresponding decrease in CAP for both intact and severed nerves. The onset of these changes depended on the rate of force application. Experiments in which the force was rapidly applied exhibited a threshold value of 25 to 40 grams for both severed and intact nerve, above which further increases in force caused a rapid decrease in the amplitude of the CAP. The signal decreased to 50% initial value after application of 50 to 70 grams for the severed nerve and 90 to 100 grams for the intact nerve. Experiments in which a 20 gram sustained force was applied to severed and intact nerves produced similar decreases in the CAP during the initial 60 seconds of application. After that time a more pronounced decrease in CAP was observed in the severed nerve, with complete loss of the CAP observed at 25 minutes. A comparison of the 10 and 20 gram sustained force application showed a 50% decrease in CAP occurring at 2 minutes for the 20 gram weight and 60 minutes for the 10 gram weight. The initial positive phase of the CAP decreased in amplitude as a function of compressive force, indicating a decrease in the population of larger diameter fibers. The other phases of the CAP remain relatively unchanged throughout the course of the experiments. Control experiments indicate that ischemia and nutrient blockage seem to play a minor role in the decrease in the CAP during the observable period. The compressive force appears primarily to affect the structural integrity of the larger fibers. The rate and extent of the damage is dependent on the magnitude and duration of the compressive forces. The relatively low magnitude of the forces that cause injury requires that nerves be manipulated with care. These effects are more pronounced in a severed nerve.

1210 DISTURBANCES OF BOTH CONTROLLED PREHENSION AND GRASP RELEASE FOLLOWING UNILATERAL ABLATION OF THE SUPPLEMENTARY MOTOR AREA. Daniel Bourbonnais*, Allan M. Smith and Gilles Blanchette*. Centre de Recherche en Sciences Neurologiques, Université de Montréal, Montréal, Québec.

The effects of unilateral supplementary motor area (SMA) lesions on the performance of a learned precision grip of the contralateral hand was study in fascicularis monkeys. Animals were first trained to exert an isometric force between the thumb and forefinger for a one-second duration to obtain a fruit juice reward. Finger pressures were measured by a hand-held strain gauge and a tone signal indicated to the monkey that the exerted pressures were within an upper and a lower force limit. On both rewarded and unrewarded trials the animals were required to release the grasp on the transducer in order to initiate the next trial. Pre-operative surface recordings from the forearm flexor and extensor muscles of the wrist and fingers indicated that the maintained prehension was accomplished by a co-contraction of these muscles. Immediately following ablation of the SMA a grasp reflex appeared in the contralateral hand which persisted from 2 to 3 weeks. Grasping was easily elicited by cutaneous stimulation of the volar surface of the hand and could be augmented by stretch of the finger muscles. The most striking disturbance of the conditioned precision grip was the animals' inability to release the force transducer from its grasp with the contralateral hand. In contrast, release from the ipsilateral hand remained normal. During conditioned prehension a significant increase in the rectified EMG activity of the forearm flexor muscles and a significant decrease in the forearm extensor muscles was found to evolve post-operatively. A corresponding increase in the rate at which prehensile force was applied to the transducer developed during the three week post-operative observation period. Moreover, the mean finger pressures exerted by the hand were greater than the mean pre-operative levels. Repeated elicitation could habituate the grasp reflex and allow the monkeys to release objects from the contralateral grip under voluntary control. Frequently, release of the manipulandum was preceeded by a sudden violent increase in prehensile force as if this strategy enabled voluntary opening of the hand either by habituation of the grasp reflex or by the facilitation of opposing reflexes. The extent of the cortical lesions in both monkeys has been histologically confirmed by serial section.

1211 INTRAPPENDAGE EMG ANALYSIS OF SCORPION WALKING MOTOR PROGRAM. Robert Bowerman and Joel Butler*. Dept. of Zoology & Physiology, University of Wyoming, Laramie, WY 82071.

The neural control of arthropod locomotion has been extensively studied in insects and crustaceans, where considerable basic information about the structure and physiology of both nervous and muscular systems is available. A number of functional similarities between these arthropod walking control systems and those of vertebrates have been described. In contrast, little is known concerning arachnid systems. Even though the arachnid evolutionary line is distinct from that of the other arthropods, they face similar functional demands in terms of walking coordination, a similarity of functional solutions might be anticipated. With these thoughts in mind, the scorpion has been selected for study of the locomotory system, as a representative arachnid.

This report focuses on an EMG analysis of scorpion leg 4, from behaviorally important muscles during free-walking, forward motion. In addition to the EMG's the sensory discharge from two cuticular stress sensing elements, one in each tarsal claw, was recorded. These phasic receptors provide an accurate electrical record of timing of both swing phase initiation (tarsal claw burst cessation) and stance phase initiation (tarsal claw burst initiation). In this way, EMG's can be related to whole leg movements without the need for cinematographic analysis. The stepping relationship between legs,[1] and joint angle changes within legs[2] have been described previously.

The major EMG relationships between the elevator and depressor muscles of the trochanter-femur joint are described. These two muscles are primarily responsible for the movements of the swing and stance phases respectively. The following relationships will be reported. (1) EMG burst length vs. step cycle time, (2) integrated EMG burst vs. step cycle time, (3) phase relationships between elevator and depressor EMG bursts, (4) switching relationships between elevator and depressor EMG bursts, (5) timing between tarsal claw activity and elevator/depressor burst activity vs. step cycle time, and (6) tarsal claw burst length vs. step cycle time.

Also, during the stance phase the femur-patella and patella-tibia joints are extended by a single double extensor muscle but flexed by separate muscles.[3] The timing of motor outputs between these muscles will also be described.

1212 EFFECT OF HEMISECTION ON MOTOR DEVELOPMENT IN KITTEN HINDLIMB. Barbara S. Bregman and Michael E. Goldberger. The Medical College of Pennsylvania, Philadelphia, PA 19129.

At birth, immature proprioceptive placing is present in all directions, but is unreliable, high threshold and hypermetric. By 3 weeks, it is smooth and readily elicited. Tactile placing is seen at 22-23 days but is immature until 6 weeks when it is smooth, accurate and of small excursion. Monopedal hopping is present backward and lateral at birth, in all directions by 3 weeks. Vestibular response to drop is first seen at 3 days and is characterized by slight extension. By 24-26 days the mature response (extension, abduction and weight bearing) is present. Locomotor development reflects this reflex maturation. During week 1, the kitten pulls itself forward by the forelimbs. Weight bearing in the hindlimbs begins during week 2, when balance is poor; it improves by day 24. Locomotion is characterized by a wide based support with symmetrical abduction and external rotation at the hip. The foot's dorsum frequently drags along the surface at the beginning of swing until 21-23 days. Locomotion is wide based, ataxic, and over-deliberate until 6 to 7 weeks.

Kittens hemisected at T13/L1 on day 1 show initially (for 3-4 weeks) only a few, transient deficits. Ipsilateral proprioceptive placing and monopedal hopping are abolished or impaired for 1-3 days. These recover and then mature on schedule. Emergence of the immature vestibular reaction is delayed 3-6 days but its maturation is not delayed. During the first 3-4 weeks the hemisected kittens show a slight deficit in proximal fixation ipsilaterally. Then the kitten grows into some deficits, i.e. they don't appear until the 2nd month. They do not recover. Ipsilaterally, tactile placing is essentially abolished, although occasionally a gross placing response to tactile stimulus is elicited. Proprioceptive placing and hopping which had appeared to recover become abnormal (high threshold, hypermetric). As use of the hindlimb matures in the normal animal, locomotor deficits in the hemisected animal appear. Ipsilaterally, the dorsum of the foot always drags at the initiation of swing phase. The limb flexes hypermetrically and instability at the hip becomes even more severe. Reflex and locomotor development are integrated in both normal and hemisected kittens. Some reflexes are transiently impaired and then appear to recover. As the reflex normally becomes more dependent on higher control, recovery decompensates. Some reflexes and locomotor patterns are initially dependent on supraspinal control; they normally appear late in development. Hemisection arrests the development of these reflexes and locomotion reveals permanent immaturities.

1213 EFFECT OF UPPER CERVICAL AFFERENTS ON VESTIBULOSPINAL TRACT NEURONS. Emily Brink*, Naoki Hirai*, and Victor J. Wilson. Rockefeller Univ., New York, N.Y. 10021.

To study a possible site of interaction between vestibular and neck afferents, we have recorded extracellularly from identified vestibulospinal tract (VST) neurons in Deiters' nucleus and in the descending nucleus of decerebrate cats while stimulating the C_2 ganglion and dorsal rami bilaterally. Like the vestibulooculaf (VOC) neurons studied by Hikosaka & Maeda (Exp. Brain Res. 18:512, 1973) many VST neurons, in both nuclei, were excited by stimulation of the contralateral C_2 ganglion; this excitation often had a latency < 6 msec (early excitation). In contrast to VOC neurons, VST neurons were typically not inhibited from the ipsilateral ganglion. Early excitation could be followed by late excitation, which was sometimes the only effect seen. In some neurons, mainly in the descending nucleus, only inhibition (latency 5-10 msec) was observed. Early excitation was due to proximal, perhaps joint area, afferents because stimulation of the dorsal (or ventral) rami almost invariably caused only late excitation. Both early and late excitation were seen in lateral and medial VST neurons that project only to neck segments, as well as in others that were excited antidromically from the cervical enlargement. In many cases the same neurons were excited at short latency by stimulation of the contralateral C_2 ganglion, and monosynaptically from the vestibular nerve (usually whole nerve, but sometimes canal nerve stimulation). The results show that interaction between reflexes evoked by neck and vestibular afferents and acting on neck and limbs may take place in the vestibular nuclei.

Supported by N.I.H. grant NS 02619.

1214 SUPRASPINAL AND SEGMENTAL INFLUENCE ON MEDIAL AND LATERAL LONGISSIMUS NERVE ACTIVITY IN RATS. Emily Brink* and Donald W. Pfaff. The Rockefeller University, New York, NY.

Medial longissimus (ML) is a proximal tail muscle, innervated by L_6-S_2 nerve branches. Lateral longissimus (LL) is a lumbar back muscle, innervated by dorsal rami along its length. Inputs to these muscles were studied in urethane-anesthetized female rats by recording from ML and LL nerves while stimulating ipsilateral lumbosacral dorsal roots (DR), medial medullary reticular formation (RF), vestibular nuclei complex (VN), midbrain central gray and areas lateral and ventral (CG area), and ventromedial hypothalamus (VMH). Stimulation of appropriate DR evoked short-latency (probably monosynaptic) compound potentials in ML (ave. latency 2.2 msec, n=40) or in LL (2.1 msec, n=14)nerves. Stable short-latency responses were more consistently obtained for ML (40/40 cases) than LL (10/17 cases). Generally, ML response required double shock (1.2-2 msec interval); LL response required 3-4 shocks. Supraspinal influence was studied using a condition-test paradigm. Subthreshold pulse trains of variable length (cathodal pulses, .1 msec duration,≤100 μA, monopolar) preceded subthreshold DR single shocks. For ML nerves, conditioning stimulation of RF (n=14), VN (n=15) or CG area (n=20) facilitated occurrence of short-latency segmental responses to single DR shocks. Conditioning by RF (requiring 1-5 shocks) appeared with condition-test intervals (Cti) of 0.5-2 msec. VN conditioning (5-12 shocks): optimum Cti 2-4 msec. Conditioning by CG (9-20 shocks): optimum Cti 5-20 msec. In the fewer LL nerves where stable segmental responses were obtained, similar facilitation by VN (n=4) and CG area (n=2) conditioning was seen. Suprathreshold RF, VN or CG area stimulation could provoke sizeable potentials in ML (n=3,1,2) and LL (n=3,1,4) nerves. Stimulus trains of up to 50 shocks, 200 μA applied to VMH never facilitated ipsilateral ML or LL nerve activity. Results indicate that excitatory paths from RF, VN, CG area to ML and LL exist and suggest some difference in spinal organization of ML and LL.

ML motoneurons localized by antidromic stimulation were found in L_6-S_1 spinal cord, posterior to the lumbar enlargement, ventrolaterally in the ventral horn. LL motoneurons were found medially in the ventral horn of the lumbar enlargement.

1215 MODIFICATION OF MOVEMENT-RELATED EMG ACTIVITY BY PERTURBATIONS APPLIED BEFORE ONSET OF VOLUNTARY HUMAN ARM MOVEMENTS. S. H. C. Brown* and J. D. Cooke, Dept. of Physiology, Univ. of Western Ontario, London, Canada.

A triphasic pattern of EMG activity has long been recognized in association with voluntary movements. This pattern consists of an initial burst of agonist activity followed sequentially by a burst of activity in the antagonist and a final period of agonist activity. The experiments described here were designed to investigate the interaction between this common pattern of EMG activity and imposed perturbations in limb position.

Experiments were performed on normal human subjects performing a visual step-tracking task using flexion/extension movements about the elbow. Torque pulse perturbations were applied randomly during trials and were timed to occur following the change in target position but before the onset of movement. Perturbations both opposing and assisting flexion were applied (flexion load and flexion unload forces).

The response to the force opposing movement appeared as a second peak of biceps activity occurring in the later phase of the first biceps burst. This peak was present in some subjects in the absence of perturbation. Changes in delay time of the perturbation relative to movement onset did not alter the latency of the response. Little change was seen in the other movement-related EMG activity except for an increase in the amplitude of the triceps burst. No EMG responses were seen corresponding to the M1 or M2 reflex responses. These reflex responses were, however, present when perturbations were applied following movement onset or when the subject was required to maintain a fixed position. Application of perturbations assisting movement (flexion unload) produced a decrease in this later component of the initial biceps burst.

The results suggest that for some period prior to movement onset, reflex systems and the systems generating the initial burst of agonist activity are inaccessible to peripheral modification.

1216 EFFECTS OF VIBRATORY MUSCLE STIMULI APPLIED DURING VOLUNTARY HUMAN ARM MOVEMENT. C. Capaday* and J. D. Cooke, Dept. of Physiology, Univ. of Western Ontario, London, Canada.

Vibration of muscle tendons has been used by several investigators to study the "passive sense of position". In the present study the effect of such vibratory muscle stimulation on active arm movements has been investigated. Subjects performed a step-tracking task making alternate flexion/extension movements about the elbow. They were instructed to move 'briskly and accurately' between the target zones. All subjects were well practised at the task. No differences were seen in movement trajectories if the subjects performed the task with or without visual guidance.

A small DC eccentric motor enclosed in a plastic casing (weight approx 70 gm) was mounted on either the biceps or triceps tendon using adjustable Velcro straps. During continuous vibration of either tendon the amplitude and peak velocity of both flexion and extension movements were decreased. The changes were more marked in trials where the movements were performed without visual guidance (eyes closed). Similar changes in movement amplitude and velocity were seen when the vibration was applied just during the movements. Activity in reflex pathways was tested by application of torque pulse perturbations while the subject was required to maintain a fixed arm position. During vibration, of either tendon, short and long-latency reflex responses to the perturbation were markedly depressed in both biceps and triceps muscles.

The above results are consistent with activation of Ia muscle afferents by the vibration and with the results obtained from 'passive position sense' experiments. The results suggest that the effects of vibratory muscle stimulation on the parameters of active movements are produced by an action of muscle afferent input on supra-spinal structures.

1217 SPINAL PROJECTIONS FROM THE MEDULLA OF THE ALBINO RAT. A.J. Castiglioni, Jr. and J.D. Coulter. Marine Biomedical Institute, Departments of Psychiatry & Behavioral Sciences and Physiology & Biophysics, University of Texas Medical Branch, Galveston, Texas 77550.

Horseradish peroxidase (0.5-1.0 µl, 40% solution) was injected into various levels of the spinal cord of adult albino rats. The brainstems were cut into 50µm sections and the neurons containing HRP were visualized by reaction with tetramethylbenzidine (Hardy-Heimer method). At the level of the pyramidal decussation retrogradely labeled neurons were found in a dense band arching from the region dorsal to the lateral reticular nucleus toward the central canal ipsilaterally, and contralaterally in small numbers in the ventral reticular formation (R.F.) following injections of the thoracic cord. Injections of the cervical cord produced many labeled cells predominantly medially and dorsally in the R.F., while lumbar injections yielded small numbers of labeled neurons in the ventral reticular formation. In the medullary R.F. at levels of the inferior olive, lumbar injections produced large numbers of labeled cells in the ventral R.F. overlying the inferior olive contralateral to injections. Cells labeled from the thoracic cord were found latero-dorsal to lumbar projecting cells, and cells labeled from cervical injections were found medially and dorsally in the R.F. contralateral to injections. Injections in all spinal levels labeled cells throughout the medial reticular formation ipsilaterally at these medullary levels. Small cells in the marginal layer of the spinal nucleus of V were labeled in caudal portions of the nucleus from injections of the upper cervical cord (C_1-C_3). Rostrally many large neurons in deeper regions of the nucleus were seen after injection of either upper cervical cord or cervical enlargement. Many small labeled neurons were found just ventral to the lateral tip of the inferior olive following lumbosacral injections, as well as occasional labeled cells lying among fibers of the pyramid. At caudal levels of the inferior olive many labeled cells were seen in the nuclei of the raphe after lumbar injections. At slightly rostral levels many cells are seen ventrally in the raphe, between the inferior olives, but relatively few were seen dorsally. A similar pattern is seen after both thoracic and cervical injections, however, the number of labeled cells is reduced. Many cells of the nucleus parvocellularis of the medullary R.F. were labeled after cervical injections, mainly ipsilaterally, and reduced numbers of cells in this region were labeled from injections into lumbar levels. These results indicate that spinal projections from medullary reticular structures are less diffusely organized than previously thought. (Supported by NS12481).

1218 AN ANALYSIS OF PRE AND POST SYNAPTIC MECHANISMS FUNCTIONING TO CONTROL TRIGEMINAL MOTONEURON ACTIVITY DURING SLEEP STATES. Scott H. Chandler*, Yoshio Nakamura* and Michael Chase (SPON: R.E. Hall). Departments of Physiology and Anatomy, Sch. Med., UCLA, Los Angeles, Calif. 90024.

In a previous communication (Chandler et al., Neuroscience abstracts, p292, 1978.) we have shown that the antidromic field potential recorded in the motor nucleus of the trigeminal nerve is depressed during active sleep as compared to quiet sleep. Additionally, we demonstrated that intracellularly recorded antidromic spikes elicited by masseter nerve stimulation were specifically blocked during the transition from quiet to active sleep. This was correlated with the onset of muscular atonia and membrane hyperpolarization. In this report we will present data indicating that these events are due to a process of postsynaptic inhibition of trigeminal jaw closer motoneurons during active sleep.

Intracellular recording from trigeminal jaw closer motoneurons with 2M K citrate micropipettes (8-15mΩ) during quiet and active sleep was performed in unanesthetized, fully conscious, head restrained cats. Antidromic spike potentials in masseter motoneurons were elicited by stimulation of the masseter nerve. The antidromic spike showed a 7% decrease in spike peak potential, a 40% decrease in after-hyperpolarization amplitude and a 20% increase in time to peak (TTP) as measured from the foot of the action potential to its peak during active sleep as compared to quiet sleep. It was also found that the monosynaptic EPSP induced in jaw closer motoneurons by mesencephalic V stimulation decreased 12% in peak amplitude, 13% in TTP, and 17% in half width during active sleep as compared to quiet sleep. Additionally it was found that only the peak amplitude of the EPSP decreased during rapid eye movement periods of active sleep (AS-REM) as compared to non-rapid eye movment periods of active sleep.

These results provide the most direct evidence to date that the spontaneous hyperpolarization that occurs during active sleep in trigeminal motoneurons is due, at least in part, to active postsynaptic inhibition of these motoneurons. Furthermore, the data suggest that the phasic inhibition of the masseteric reflex during AS-REM is due to presynaptic inhibition of group Ia muscle afferents from the masseter muscle.

Supported by the USPHS (NS 09999), the NSF (77-22299) and the Japan Society for the Promotion of Science.

1219 SUBTHRESHOLD MEMBRANE ACTIVITY IN SPINAL CORD MOTONEURONS DURING ACTIVE SLEEP. Michael H. Chase and Francisco R. Morales*. Departments of Physiology and Anatomy and the Brain Research Institute, UCLA, Los Angeles, CA 90024.

During active sleep there is a decrease in the tone of the somatic musculature which occurs in conjunction with hyperpolarization of the membrane of α-motoneurons. Also, during this state, there are phasic increases and decreases in tone and reflex excitability. The present report describes lumbar α-motoneuron membrane potential changes which may provide the substrate for these phasic phenomena. A total of 35 antidromically identified motoneurons were examined throughout cycles of sleep and wakefulness, utilizing a technique for recording intracellularly in the chronic, undrugged, normally respiring cat (Morales and Chase, Intracellular Recording of Lumbar Motoneuron Membrane Potential during Sleep and Wakefulness, Exp. Neurol., 62:821-827, 1978). Records were obtained which satisfied the following criteria: (1) antidromic spike amplitudes greater than 60 mV (range 60-95 mV); (2) a stable membrane potential (greater than 50 mV) for more than 10 minutes; and (3) repetitive discharge following intracellular injection of depolarizing current. During active sleep the following three types of subthreshold membrane activity occurred which were predominant during bursts of rapid eye movements: (1) rapidly depolarizing potentials (3-5 mV; 10-30 msec); (2) slowly depolarizing potentials of large amplitude (4-8 mV, some 10 mV; 40-120 msec) occurring as rhythmic membrane potential oscillations; and (3) rapidly hyperpolarizing potentials (3-5 mV; 10-30 msec). Although rapidly and slowly depolarizing potentials were occasionally accompanied by bursts of spontaneous discharge, spike activity was rarely present. The fact that even large depolarizing potentials only occasionally promoted motoneuron spike discharge indicates the potency of the inhibitory influences acting on the final common pathway during active sleep. These data demonstrate the presence of considerable subthreshold membrane activity in spinal motoneurons during active sleep, especially in conjunction with rapid eye movement periods. We suggest that these subthreshold potentials may reflect the continuous descending excitatory and inhibitory influences that are responsible for the phasic motor events of active sleep.

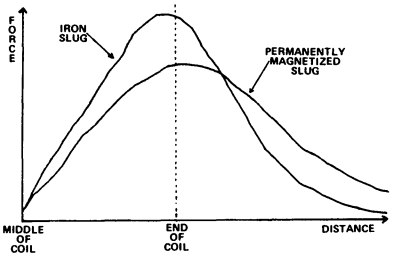
1220 ELECTROMAGNETIC MUSCLE STRETCH: TECHNICAL ASPECTS AND APPLICATIONS. T. R. Colburn*, J. R. Wolpaw, W. Vaughn*, and J. L. Christensen* (SPON: H. C. Lansdell). Res. Services Br., NIMH; Neurobiol. Dept., Armed Forces Radiobiol. Res. Inst.; Bethesda, MD 20014.

Use of an external solenoidal coil to apply force to a slug chronically implanted in the musculotendinous junction (Wolpaw & Colburn, Br. Res. 141:193, 1978) allows stretch of an individual muscle in an awake, intact animal without joint rotation or shortening of antagonist muscles. It is thus of value in studying the role of muscle stretch in performance (Wolpaw, Science 203:465, 1979). Coated iron slugs have been implanted for 3 mos in Rhesus monkey forearm muscles. The forearm passes through the center of the coil. The design goal is to maximize force on the slug and thus on the muscle and to minimize input power to the coil. Force exerted on a slug on the axis of a coil is dependent on slug length, cross-sectional area, material, and rate of change of the magnetic field. Rate of change of the magnetic field is determined by the location of the slug, by coil length, diameter, wire size, number of turns, and current. Force is always directed toward the middle of the coil. An iron slug gives a greater force peak, while a permanently magnetized slug gives a broader force peak. For the latter, slug orientation affects force amplitude. Slug location for peak force differs slightly, but for both slugs occurs near the end of the coil (Fig.). Coil inside diameter should be as small as practically possible, to maximize both force and frequency response. AC current can be used to deliver vibratory force, but should be rectified to reduce power consumption. An iron sleeve around the coil gives a 50% increase in force. Water cooling by means of copper tubing wrapped around the sleeve greatly reduces heating. Our coil measures 50 mm long, 42 mm i.d., 100 mm o.d., has 493 turns of #14 wire, an iron sleeve, water cooling (allowing a 5% duty cycle at maximum current for 1 hr), and a 40-amp, 25-volt power supply. It can exert a force of 420 gm (7-ms rise time) on a 2-gm, 20x5x3-mm iron slug which is easily implanted in any of several monkey forearm muscles.



Force vs distance from middle of coil for a soft iron (Armco) slug and a permanently magnetized (Alnico) slug.

1221 QUANTITATIVE SUBCORTICAL DISTRIBUTION OF EFFERENT PROJECTIONS FROM MOTOR CORTEX IN RAT. Robert C. Collins and Terry Der*. Dept. of Neurology, Wash. Univ. Med. Sch., St. Louis, Mo. 63110

Subcortical projection sites from motor cortex have been identified in many animals using electrophysiological or anatomical techniques. The relative distribution of efferent projections among all the different terminal fields has not been established. As part of an on-going study of the use of motor pathways during focal seizures it became important to know the site and relative density of first order projections from motor cortex.

^{14}C-proline alone, or mixed with ^{14}C-leucine (0.03 to 0.1 µl; 1µCi/µl) was injected through a 20 µm tip micropipette into the forelimb area of motor cortex of rat, 2-3 mm lateral and anterior to bregma. Animals were killed 24 hours later, perfused fixed with 3.3% paraformaldehyde buffered to pH 7.3 with 0.2 M cacodylate. Serial coronal or horizontal sections were cut at 20 µm at -15°C, picked up on cover slips and mounted on cardboard for exposure to Kodak SB-5 film. These were developed at 10-20 days to study major projections, then re-exposed for 1-3 months to enhance faint projections. Sections were subsequently stained with thionin to match autoradiographic densities with nuclear groups. A Leitz MPV microdensitometer was used to measure optical densities (OD). Cross sectional areas of terminal fields were measured planimetrically after enlargement and the volume of terminal fields computed. The quantity of projection to each subcortical nucleus was calculated as mean OD x mm^3.

The injection sites measured 1-3 mm in diameter, involved all cortical layers, and were confined to motor cortex. Over 50% of the total amount of subcortical projections ended in VA (26.5%) - VL (30.1%) complex. Ipsilateral (16.1%) and contralateral (2.9%) caudate/putamen terminal field densities occurred in a bi-laminar pattern in dorsolateral quadrants. The ventral medial n. (VM) received 11.5%, and the central lateral n. (CL) 8.5%. 1-2% of the total was found in reticularis, zona incerta, pretectal, and the posterior nuclear group each. Less than 0.5% appeared in central medial n. (CE), subthalamic n., the parafascicularis n. and the peri-rubral field each. In addition to caudate there were very faint projections across midline in CE, CL and VM.

1222 EYE MOVEMENT CONTROL: THE EFFECTS OF PAIRED SUPERIOR COLLICULUS AND FRONTAL EYE FIELD ABLATIONS. Janet Conway*, Peter H. Schiller*, and Sean True* (SPON: S. Corkin) Dept. Psyc., MIT Cambridge, MA 02139.

Ablation of either the superior colliculi (SC) or the frontal eye fields (FEF) produces relatively small deficits on eye movements. In both of these structures, however, single units discharge in association with saccadic eye movements and stimulation triggers saccades at low current levels and with short latencies. Recently it has also been shown that ablation of the SC does not interfere with stimulation elicited saccades from the FEF (Schiller, P.H. Brain Res 122: 154, 1977.). This finding suggests that these two structures form a parallel pathway to the brainstem for the control of saccadic eye movements.

To test this hypothesis, we removed, in successive stages, both the SC and the FEF in 10 rhesus monkeys, the majority of which had a search coil implanted for monitoring eye movements. The animals were trained to pick apple pieces out of randomly oriented slits in various locations in a plexiglass "apple board" which faced them. A minicomputer was used to measure saccadic and fixation parameters. Normal monkeys performed well on this task and the subsequent analysis disclosed a clustering of fixations at positions corresponding to the locations of the apple pieces on the board.

Removal of either the FEF or the SC alone produced only small deficits on the apple board task. FEF ablation yielded a temporary neglect of peripheral targets which completely disappeared 1-4 weeks after surgery. SC ablation alone reduced saccade frequency and target acquisition accuracy to some extent. By contrast, paired ablation of the FEF and the SC produced a dramatic deficit: monkeys made very few visually triggered saccades. The deficit was still profound more than a year after the operations. In spite of the fact that the animals were unable to direct their eyes appropriately, they attended to visual targets without looking, and cleared the apple board in the experimental situation.

The results suggest that the FEF and the SC form two relatively independent channels for the control of visually triggered saccades. Either pathway can subserve this function. A severe, non-recoverable deficit ensues only when both channels are disrupted. (Supported by NSF grant #BNS 76-82543 and NIH grants #5 R01 EY00676 and #1 T31 GM07484)

1223 ELECTROMYOGRAPHIC CONTRIBUTIONS TO REFLEX REGULATION OF MUSCLE PROPERTIES IN THE DECEREBRATE CAT. P. J. Cordo* and W. Z. Rymer (SPON: G. H. Collins). Dept. Physiol., SUNY Upstate, Syracuse, NY.

The stretch reflex response of the soleus (SOL) (n=4) and medial gastrocnemius (MG) (n=18) muscles was observed by recording tension and EMG from whole muscle and single motor units during imposed 5 mm/sec stretches. Whole muscle EMG was recorded intramuscularly, fully rectified, filtered and integrated; single unit EMG was also intramuscularly recorded, with fine-wire bipolar electrodes. During stretch responses, muscle force increased linearly while integrated EMG increased abruptly and then leveled off. We observed a rapid divergence of the force-EMG relations of isometric from that of lengthening muscle, indicating a transient reduction in the net capacity for force production shortly after stretch onset. This increase in activation is generated by reflexively induced motor unit recruitment and rate modulation.

Recruitment in order of increasing size and the sharp decline in numbers of newly recruited units with increasing force appear to be preserved in dynamically lengthening muscle. Force thresholds of motor units are increased in lengthening, compared to isometric muscle suggesting an overall broadening of the force range of the recruitment mechanism. In dynamically lengthening muscle, recruitment was observed throughout the force range obtained with MG stretch reflexes and at forces above 1 kg in SOL.

Rate modulation was observed to occur with three basic patterns during stretch reflex activation: 1) step increases in rate just after stretch onset, in motor units activated prior to stretch initiation, 2) doublets, in units activated both prior to and during stretch and 3) smooth increases in firing rate in units recruited during stretch. The mean slope of the force versus firing rate relation obtained for dynamically recruited units (smooth rate changes) in MG (n=102) was 2.0 pps/100 g increase in muscle force and in SOL (n=22) 0.2 pps/100 g. The mean±s.d. step increase in rate observed for previously active units was 3.7±1.8 pps in SOL (n=22) and 6.1±2.4 pps in MG (n=18). Motor units were observed to fire with doublets more frequently at higher initial forces, but the overall probability of doublet occurrence in all trials of all MG units (n=102) was 18%.

Although the lengthening SOL possesses a smaller dynamic range of recruitment and rate modulation than MG, it appears to be significantly greater than that previously reported (1). Additional EMG observed with lengthening, compared to isometric contractions is thought to represent reflex compensation for intrinsic nonlinear muscle properties. The most prominent compensatory mechanism is likely to be motor unit recruitment, a proposition supported by previously reported electrical stimulation studies (2).

1224 THE DEPENDENCE OF MUSCLE TENSION ON STIMULUS INTERPULSE INTERVAL AND MUSCLE LENGTH. Patrick E. Crago. Case Western Reserve University, Cleveland, Ohio 44106.

Quantitative assessment of the contribution of temporal summation to total muscle force would be improved by the availability of an analytical model relating firing rate to force. Models that are linear in the frequency domain (Milner-Brown, Stein and Yemm, J. Physiol. 230, 371, 1973) are only applicable over restricted ranges of modulation because of the non-linear, sigmoidal relationship between force and firing rate. An analytical model has been developed that relates steady-state force to firing rate over a wide frequency range and that has an explicit dependence on muscle length.

The model was derived empirically from plots of steady-state force as a function of stimulus interpulse interval (IPI) at different muscle lengths. The data were from isometrically constrained cat soleus muscles activated by synchronous electrical stimulation of the whole muscle nerve or by distributed stimulation of ventral root filaments. Some data published previously by other investigators was also used.

The following analytical model describes the results:

$$F = FO\ (1+(a+bL)IPI)$$

where F is muscle force and L is length. FO, a and b are empirically derived constants.

At a fixed muscle length, force increases linearly with decreasing IPI, and the linearity is good from about 10% to 90% of the maximal force regardless of muscle length. The slope of the linear region (calculated as the linear regression of force on IPI) decreases approximately linearly with increasing muscle length. The intercept of the linear regression line on the zero IPI axis remains constant as length changes, expect near maximal physiological length. Maximal force, which is achieved at a small but non-zero value of IPI, varies only about 10% over a wide range of lengths (-20 to -4 mm with respect to maximum).

In practice, limits must be placed on the calculated value of F to insure that it does not exceed the maximal force (at short IPI's and long lengths) or go below zero (at long IPI's and short lengths). With these restrictions the model is reasonably accurate over a large portion of the physiological ranges of length and firing rate.

This model is currently being used in studies of force modulation under physiological conditions and in the design of control systems for orthoses employing electrically stimulated muscles. (Funded by NIH, NINCDS Contract Number NO1-NS-2-2314).

1225 DIFFERENCES IN THE REFLEX EFFECTS OF DIGITAL NERVE STIMULATION ON THE FIRING OF LOW AND HIGH THRESHOLD MOTOR UNITS IN HUMAN FIRST DORSAL INTEROSSEOUS MUSCLE. A.K. Datta* and J.A. Stephens* (SPON: A. Taylor) Sherrington School of Physiology, St. Thomas's Hospital Medical School, London, ENGLAND.

Previous observations in both cat and man indicate that the pattern of recruitment of motor units can be altered by cutaneous stimulation (1,2). During controlled ramp contractions of 1st dorsal interosseous muscle (1DI), for example, continuous stimulation of the digital nerves of the index finger raises the recruitment threshold of units normally recruited at contraction strengths <1.5N (6% maximum) and lowers the threshold of those normally recruited at strengths >1.5N. One explanation for this finding would be that cutaneous stimulation has an overall excitatory effect on high threshold units but an inhibitory effect on low threshold units. To investigate this hypothesis we have performed the following experiment.

Subjects were required to maintain a contraction of 1DI such that the motor unit under study fired steadily at 10pps. 80ms after every third unit action potential the digital nerves of the index finger were stimulated using single shocks at 3x threshold for perception. Histograms were then constructed of the interval between the two motor unit spikes following each stimulus. Given an afferent plus efferent conduction delay of 30ms the reflex effects of the stimulus begin some 10ms after the start of each measured interval. We can assume that if the overall reflex effect of the stimulus is excitatory then this will cause a shortening of the measured interspike interval. Conversely if the effect is inhibitory then we can expect the measured interval to be prolonged.

All units recruited at contraction strengths >1.5N had their measured interspike interval shortened by digital nerve stimulation. All these units had fast twitch contraction times (30-62ms). The excitatory drive to these motoneurones had been increased by the stimulus. The net reflex effect of cutaneous stimulation for these units was excitatory. In contrast all but two slow twitch (>75ms) low threshold units (<1.5N) had their intervals lengthened. The overall reflex effect of the cutaneous stimulus for these units was inhibitory. The behaviour of low threshold (<1.5N) fast twitch (<75ms) units was more mixed. 5 were excited and 8 were inhibited.

We conclude that the changes in the pattern of recruitment produced by cutaneous stimulation in man as in cat can be attributed to differences in the reflex connections of motoneurones which are related to motor unit mechanical properties (3).

1226 [^{14}C]-2-DEOXYGLUCOSE UPTAKE IN MONKEYS WITH HYPOTONIC HEMIPLEGIA AFTER PRECENTRAL CORTICAL ABLATION. George Dauth, Sid Gilman, Kirk Frey*, John Penney*, Bernard Agranoff. Depts. of Neurol. and Biochem., Sch. Med., The Univ. of Mich., Ann Arbor, MI 48109.

Lesions of the precentral cortex in humans and infrahuman primates result in a contralateral hemiparesis, initially hypotonic and subsequently hypertonic. The anatomical substrates and mechanisms underlying these effects are unknown. We have investigated this problem in monkeys with ablations of the precentral cortex using the [^{14}C]-2-deoxyglucose (2-DG) autoradiographic technique of Sokoloff. The hypothesis is that uptake of 2-DG will reflect alterations in the metabolic activity in brain structures important in the genesis of hypotonia and hypertonia. M. fascicularis monkeys were rendered hemiplegic by ablation of areas 4 and 6. One week later, when the contralateral limbs were hypotonic and paretic, the animals were given 100 μCi/kg of 2-DG intravenously. Forty-five minutes later the animals were sacrificed; the brains were removed and sectioned for autoradiography and histology. The results show a marked depression in uptake of 2-DG in structures receiving projections from areas 4 and 6. This is evidenced in the autoradiographs by decreased grain density in the following nuclei ipsilateral to the lesions as compared to the same nuclei contralaterally: caudate nucleus, putamen, red nucleus, pontine nuclei, and thalamus. The findings implicate these nuclei in the pathogenesis of hypotonic hemiplegia after cerebral cortical ablation.

1227 ULTRASTRUCTURAL CHARACTERIZATION OF CEREBELLAR TERMINALS ON RUBROSPINAL NEURONS IN RAT. A COMBINED ELECTRONMICROSCOPIC STUDY USING ANTEROGRADE AND RETROGRADE AXOPLASMIC TRANSPORT, Jan J. Dekker, Section of Neuroanatomy, Yale University School of Medicine, New Haven, Ct. 06510.

Although the ultrastructural morphology of the rat red nucleus has been described (Reid et al., J. Comp. Neur. 162, 1975), no data is available on the site of termination and synaptoarchitecture of cerebellar input to this nucleus. In the present ultrastructural study, the synaptic terminals of the cerebellar nucleus interpositus and their postsynaptic targets in the red nucleus were identified by means of anterograde axoplasmic transport of ^{3}H-leucine and retrograde transport of horseradish peroxidase (HRP).

In four 6 week old albino rats ^{3}H-leucine was injected into the left nucleus interpositus and in the same animals HRP was injected into the left rubrospinal tract at a level posterior to the obex. After a one day survival the animals were perfused and the contralateral red nucleus was dissected out and cut in slabs 250 microns thick. The slabs were then incubated in a 3,3'-diaminobenzidine solution and subsequently osmicated, dehydrated and embedded in Araldite. One micron thick sections were cut from the polymerized blocks and processed for light microscopic (LM) autoradiography. The silver grain distribution and the position of the HRP-labeled neurons in these sections were used to guide the trimming of the blocks into pyramids. Subsequently, ultrathin sections were cut from these pyramids and processed for electron microscopic (EM) autoradiography.

In the sections prepared for LM autoradiography the majority of the silver grains were located above the caudal part of the red nucleus, which also contained many densely packed giant and large neurons with HRP granules in their cytoplasm. In the rostral, parvocellular part, a few HRP-labeled neurons, but almost no silver grains, were present. EM examination of the ultrathin autoradiographic sections cut through the magnocellular part of the red nucleus revealed that the bulk of the silver grains were located above myelinated axons and synaptic terminals, whereas only a few grains were present over other profiles such as glial and neuronal perikarya. The labeled terminals were almost exclusively large, elongated and electronlucent, and contained dispersed aggregations of round vesicles. They usually established multiple asymmetrical synaptic junctions with smooth parts of giant and large cell somas as well as with smooth parts of proximal dendrites. Furthermore, HRP granules were present in most of the giant and large neuronal perikarya and in many proximal dendrites which were in synaptic contact with labeled terminals. This indicates that axonal terminals from the cerebellar nucleus interpositus establish direct axo-somatic and axo-dendritic contact with both large and giant rubrospinal neurons. (Supported by NS 14841).

1228 EFFECTS OF SPINAL CORD STIMULATION ON SEGMENTAL REFLEXES IN MAN
Milan R. Dimitrijevic, L. Donald Lehmkuhl* and Arthur M. Sherwood*
The Institute for Rehabilitation and Research, Houston, Tx. 77030

Neurophysiological follow-up studies are in progress in 15 patients with implanted systems for epidural spinal cord stimulation. These studies are based on evoked spinal cord potentials, somatosensory evoked potentials, tendon jerks, vibratory reflexes and polyelectromyographic recordings of spinal reflexes and their dependence on brain influence. The procedures, done initially in all patients, were repeated at approximately 3, 6 and 12 month intervals post-implant. Evaluation of the evoked spinal cord and somatosensory potentials, and the interaction of tendon jerks and vibration revealed no significant changes in the neurophysiological characteristics of the four patients re-evaluated by the time of this writing. However, there was a noticeable decrease in the electromyographic features of spasticity and evidence of improved suprasegmental control in these patients.

1229 FICTIVE LOCOMOTION IN THE STINGRAY, *DASYATIS SABINA*.
M.H. Droge and R.B. Leonard. Marine Biomed. Inst. and Dept. of Physiol. & Biophys., UTMB, Galveston, TX 77550.

Electromyograms (EMG's) show that stingrays locomote with a rostral to caudal wave of elevation and depression of the pectoral fins. At each segmental level the activity in dorsal and ventral musculature alternates. Increased swimming velocity, due to exteroceptive stimulation, produces decreased cycle times and increased EMG activity. Although the overall cycle changes, the duration of bursts retains similar phase relationships.

Animals restrained by chronically implanted vertebral clamps swim with the same cycle times and EMG patterns as freely swimming animals. Unlike dogfish sharks, stingrays decerebrated at the mesencephalic/diencephalic junction locomote spontaneously while animals with high spinal transections do not. The EMG pattern recorded from decerebrate stingrays is the same as that recorded from intact animals.

In this report, compound neuronal activity was investigated in the restrained, decerebrate preparation. A cuff electrode was attached to the peripheral nerve innervating the dorsal fin muscles. Simultaneous recordings were made from the cuff and from bipolar EMG electrodes in muscle of the same segmental level. Rhythmic bursts of neural activity were recorded corresponding to the EMG bursts during spontaneous locomotion. The cycle times measured from either neurograms or EMG's were approximately 0.9 s. This is within the range observed in different types of preparations. The animals were then immobilized with curare and artificially respired. The dose was sufficient to block both spontaneous EMG activity and EMG evoked by stimulation of the nerve in the cuff electrode. Following immobilization, spontaneous rhythmic discharges continued in the neurogram. If the discharges stopped, they could be elicited by exteroceptive stimulation or electrical stimulation of the rostral midbrain tegmentum. In all cases the rhythmic activity showed the same cycle times and durations as observed before paralysis. Stimulation of the midbrain with a continuous 50-60 Hz train was particularly reliable in eliciting rhythmic activity. Such stimulation also evokes normal locomotor movements in nonparalyzed, decerebrated animals. Rhythmic EMG or neurogram bursts often continued for several cycles after cessation of the stimulus.

The observation that normal locomotor rhythms can be recorded from the motor nerve after immobilization establishes fictive locomotion in this preparation. The decerebrated, immobilized stingray thus provides a good experimental model for further investigation of vertebrate locomotion.

1230 REFLEX EMG ACTIVITY IN PARKINSONIAN PATIENTS.
Joel R. Dufresne and John F. Soechting. Laboratory of Neurophysiology, University of Minnesota, Minneapolis, MN 55455

The myotatic reflexes of Parkinsonian patients were tested by applying pseudo-random torques about their elbow joints. Rectified, surface EMG activity was obtained from the biceps and triceps muscles. A description of the reflex motor output was provided by impulse response functions giving the average EMG response to a 20 ms pulse of torque.

Two populations of Parkinsonian subjects could be distinguished on the basis of these impulse response functions. The first group yielded responses similar to those for normal adult subjects. Subjects in this group were observed to have little rigidity. In general, their data could be fit by a simple linear model relating EMG activity to forearm position, velocity, and acceleration.

The EMG impulse response functions for patients in the second group were significantly different, in that they contained a large damped oscillation at a frequency of 10-12 Hz. This oscillation was not present in normal subjects or in the first group of Parkinsonian patients. Moreover, their frequency was much higher than that for typical Parkinsonian tremor (3-5 Hz). They were also observed to outlast any large transients in the impulse response functions for forearm velocity and acceleration. Patients in this group had a significant level of rigidity in their "off" state. However, the oscillations were actually greater during the "on" state, when rigidity had been effectively suppressed by L-Dopa.

These results confirm and extend previous work showing that patients with rigidity had exaggerated M2 responses. They suggest that: (1) While oscillations in the EMG impulse response functions could be correlated with the clinical observation of "off" state rigidity, rigidity itself was not directly responsible for them. (2) The oscillations appear to be triggered, rather than sustained, by kinematic feedback from peripheral receptors.

1231 RECRUITMENT ORDER OF MOTOR UNITS IN THE FLEXION REFLEX OF THE ACUTE AND CHRONIC SPINAL CAT.
R.G. Durkovic and K.E. Misulis*. Dept. Physiology, Upstate Medical Center, Syracuse, NY 13210.

As part of an investigation of the physiology and behavior of the flexion reflex in spinal cat the present study was designed to test motor unit recruitment order in the tibialis anterior (TA) muscle. The experimental preparation was the unanesthetized decerebrate cat with a T-10 spinal transection made either two weeks before or immediately before decerebration. Single motor unit EMG was recorded by means of a fine needle electrode inserted into the belly of the TA muscle. Electrical stimulation of the cutaneous superficial peroneal or saphenous nerves was used to evoke reflex TA muscle activation. Cutaneous nerve stimulus intensities were below those required to activate cutaneous C fibers.

The reflex discharges of pairs of motor units were monitored simultaneously and recruitment order was determined either as a function of varying stimulus intensity or by determining the probability of firing at a constant stimulus intensity. In the flexion reflex of acute spinal cats recruitment order was generally in order of increasing EMG spike amplitude. Such a relationship was observed in over 75% of motor unit pairs with reversal in about 20% of the cases. These results are significantly different from chance. In contrast, recruitment in chronic spinal cats was very different with large EMG spikes often being recruited with a greater probability and at stimulus intensities lower than units with small EMG spikes (in over 55% of motor unit pairs). Recruitment orders for pairs of units determined using superficial peroneal nerve stimulation were, with few exceptions, the same as those determined using saphenous nerve stimulation for both acute and chronic spinal cats.

Studies from other laboratories indicate that a direct relationship exists between motoneuron size and EMG spike amplitude. If this relationship applies to the present experiments, the results suggest that the majority of TA alpha motoneurons are recruited in an orderly fashion (from small to large) in the flexion reflex of the acute but not the 2-week chronic spinal cat.

1232 MUSCLE AND MOTOR UNIT PROPERTIES OF EXERCISED AND NON-EXERCISED CHRONIC SPINAL CATS. V.R. Edgerton, L.A. Smith*, and E.Eldred. Dept. Kinesiology, Anat. and Brain Res. Inst., UCLA, Los Angeles, CA. 90024.

The role played by motor unit activity in determining the biochemical and physiological properties of muscle is thought to be critical. Lower spinal transections have resulted in a transformation of both the histochemical profile of some fibers in soleus (SOL) muscle of guinea pigs (Karpati and Engel, Arch. Neurol. 17:542, 1967) and the contractile properties of the whole SOL in cats (Buller, et al, J. Physiol. 150:399, 1960). It has also been hypothesized that the shorter contraction time (CT) of the SOL, after cord transection, is due to a virtual elimination of motoneuron discharge (Gallego, et al, J. Physiol. 281:253, 1978).

To study the role of neuromuscular activity, eight 2-week old kittens and eight 12-week old cats were completely spinalized at approximately T_{12}. Four of the 2-week and five of the 12-week cats were exercised 20 min daily on a treadmill for a period of 3 mo. These cats were situated so that only the hind limbs touched the treadmill belt and locomoted at speeds ranging from 0.15 to 0.75 m/s. The transected cats differed greatly in the ability to bear the weight of their hindquarters, but all exhibited contraction of ankle muscles (Smith, et al, Neurosc. Abst., 1979).

The mean muscle to body weight ratio for the gastrocnemius of the exercised 12-week (12-EX) cats was 90% of normal cats, while it was 60% for the other groups. The SOL muscle to body weight ratio was 60% of normal in the 12-EX and 40% of normal in the other cats. Mean whole muscle CT of the SOL for the 2-week non-exercised (2-NE), 2-week exercised (2-EX), 12-NE and 12-EX was 60, 30, and 44 ms, respectively. For the medial gastrocnemius (MG), mean CT for the same groups was 31, 31, 52 and 43 ms. Mean CT for motor units of the SOL were 46 and 47 ms for the 12-NE and 12-EX cats (N=81). MG mean CTs were 33, 28 and 25 ms (N=88) for the 2-NE, 2-EX and 12-EX cats. Mean motor unit tetanic tensions were 21, 10 and 24g for the 2-NE, 2-EX and 12-EX cats, respectively. Some conversion of histochemically identified fiber types from a slow-to-fast twitch profile occurred in the SOL, but the percentage was not consistent and did not have the degree of conversion seen in the physiological properties. Fatigue properties of the SOL and MG motor units remained within normal ranges for all groups tested.

This data suggests that absence of activity cannot explain the shorter CT for the SOL after transection, since this occurs even when the motor units are involved in considerable amounts of activity during locomotion.

Supported by a grant from the Easter Seal Foundation.

1233 STRUCTURAL, HISTOCHEMICAL AND ELECTROMYOGRAPHIC ANALYSIS OF INDIVIDUAL COMPONENTS OF THE CALF MUSCLE COMPLEX IN CATS. Arthur Wm. English* (SPON: S. L. Wolf). Dept. Anat., Emory Univ., Atlanta, GA 30322.

The calf muscle complex of cats consists of five anatomically distinct components. Medial gastrocnemius (MG) and soleus (SOL) are both unipennate muscles which insert onto the medial and ventral parts of the tendocalcaneus, respectively. Lateral gastrocnemius consists of at least three unipennate components. Its lateral head (LG_l) is readily distinguished from an intermediate head (LG_i) by their fiber orientation and insertion. Its medial head (LG_m) shares a separate tendon of insertion with plantaris and is thus a single mechanical component supplied by two nerves. At the middle of the leg, myosin ATPase staining at pH 4.55 reveals that the components can also be differentiated histochemically. LG_l and MG consist primarily of fast twitch, glycolytic fibers (FG). Slow twitch oxidative (SO) and fast twitch oxidative-glycolytic (FOG) fibers are found less frequently. Soleus contains almost exclusively SO fibers and those fast twitch fibers found are FOG. LG_m and LG_i lie intermediate; both contain 30-50% SO fibers and 10-20% FOG fibers. To begin to determine whether these individual components may subserve different functions, electromyograms were recorded from each of the components during repeated overground stepping trials in each of six adult cats. The onset, duration and intensity of EMG activity was analyzed for each with respect to individual step cycle elements, as determined from synchronous high speed cinematography. All of the muscular components examined showed a similar pattern of temporal spacing of EMG activity. Activity begins during the first extension epoch (E_1), prior to foot placement, continues throughout the yield or E_2 epoch and most of the following E_3 epoch, and terminates just prior to the removal of the foot from the ground. Modulation of the temporal patterns of activity of each of the components with changes in stepping frequency was similar. EMG intensity during each epoch, in each muscular component, as determined from rectified and integrated signals, generally increased with increases in stepping frequency. Differential increases in these intensity measures were noted, but not of the same order as has been reported for peak EMG amplitudes (E. G. Smith et al, J. Neurophys. 40:503-513, 1977). It is concluded that the individual muscular components may make differentail contributions to the overall force at the tendocalcaneus which reflect a division of labor in the complex. Supported by Grant AM19916-02.

1234 AXON COLLATERALS OF CAT MEDIAL AND INFERIOR RECTUS MOTONEURONS. C. Evinger*, R. Baker and R.A. McCrea (SPON: J.A. Zadunaisky). Dept. Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Avenue, New York, NY 10016

Unlike the findings in the mammalian spinal cord, there has been neither anatomical nor physiological evidence supporting the presence of axon collaterals from cranial motoneurons. In particular, extensive electrophysiological investigations of extraocular motoneurons have failed to detect recurrent synaptic effects. Nevertheless, intracellular injections of horseradish peroxidase into ten medial and six inferior rectus motoneurons has demonstrated the existence of axon collaterals in every case. In seven cats, both the dorsal and ventral, as well as rostral and caudal subgroups, of these motoneurons were examined. Identification was based on antidromic activation from the isolated medial and inferior rectus nerves and the neurons' response to vestibular nerve stimulation. Reconstruction of stained motoneurons showed that each cell had somadendritic trees in excess of 1 mm in diameter with inferior rectus being slightly larger. The dendrites of these cells always extended into the periaqueductal gray and often into the MLF, but seldom crossed the midline. One or more collaterals emanated from the parent axon of every injected motoneuron. Even though these collaterals exhibited extensive branching, they all terminated within the ipsilateral oculomotor nucleus less than 1 mm from the parent soma. The terminals of the axon collaterals were large, averaging 3.5 μ (± 1.5, n = 114 medial rectus terminals; major and minor terminal diameter/2). Despite their extensive branching and termination within the oculomotor nucleus, there was neither morphological nor electrophysiological evidence for recurrent synaptic contact with any extraocular motoneuron. These results suggest that the collaterals of medial and inferior rectus motoneurons terminate on oculomotor internuclear neruons. This suggestion is supported by the observation that non-motoneurons within the oculomotor nuclei exhibit recurrent synaptic activation following IIIrd nerve stimulation. Thus, the efferent signals to other brainstem nuclei from the oculomotor internuclear neurons could, in part, be similar to that arriving at the extraocular muscle. This organization contrasts with that of the abducens nucleus where motoneurons and internuclear neurons exhibit qualitatively identical discharge patterns, but in which neither the motoneurons nor internuclear neurons have recurrent axon collaterals. Supported by USPHS Grants EY-02007, NS-13742 and Fellowships NS-05857 and NS-06163.

1235 **SHORT TIME SCALE CORRELATIONS BETWEEN DISCHARGES OF MEDULLARY RESPIRATORY NEURONS.** J.L. Feldman, D. Sommer* and M.I. Cohen. Dept. of Physiology, Albert Einstein College of Medicine, Bronx, N.Y. 10461 and Depts. of Physiology and Anesthesia, Northwestern Univ.,Chicago, Ill. 60611

The interactions on a short time scale among inspiratory (I) neurons and among expiratory (E) neurons of the cat medulla have been studied by analyzing simultaneous recordings of spike activity from two or more neurons. Microelectrodes were used to record activity in three regions: a) the ventrolateral nucleus of the solitary tract (vlNTS), containing I neurons almost exclusively; b) the rostral portion of the ventral respiratory group (rVRG), in the ventrolateral medulla rostral to the obex containing mostly I neurons; and c) the caudal portion of the VRG (cVRG), containing mainly E neurons. Crosscorrelation histograms (CCHs) between activites of two I neurons or two E neurons were used to ascertain the existence of correlated discharges on a short time scale (ca. 1 msec), as indicated by a sharp peak near zero lag in the CCH. Adjacent neuron pairs (recorded with the same electrode) have a high incidence of such correlated discharge: they were present in 16/26 pairs of I neurons and 28/45 pairs of E neurons. In contrast, such correlations were extremely rare for pairs of distant neurons (recorded with two microelectrodes on opposite sides of the medulla): only 1/43 I neuron distant pairs had a clear cut peak in the CCH and none of the 97 (0/97) E neurons distant pairs had such a peak. However, 18/43 I neuron distant pairs had common high-frequency oscillations (HFOs), with period 9-17 msec. These results indicate that: a) within local clusters of I or E neurons there is a high incidence of local interactions and/or locally shared inputs; b) only a small fraction of distant neuron pairs are oligosynaptically connected. Since respiratory neurons of a particular discharge type are ultimately connected, as indicated by synchronization of firing on a time scale of seconds or tens of milliseconds (HFOs), the coordination of activity between distinct regions is probably produced by limited and specific connections between specialized subpopulations. (Supported by N.I.H. Grant HL-20800).

1236 NEURONS INVOLVED IN PEDAL WAVE GENERATION IN APLYSIA. Steven M. Fredman and Behrus Jahan-Parwar. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

In our previous work on pedal locomotion in Aplysia californica, we have found that the motor program is centrally generated and that the neuronal circuitry for the pedal waves which drive locomotion appears to reside in the pedal ganglia. In the present study, we have examined pedal ganglia neurons using a semi-intact preparation. Simultaneous intracellular and extracellular recordings have permitted identification of neurons with axons in the pedal nerves. Two different classes of presumptive motor neurons have thus far been identified: i) neurons which fired bursts of spikes during the rising phase of the pedal contraction wave; ii) neurons which were inhibited during the rising phase of the wave, but fired during the falling phase of the wave. Physiological stimuli which elicit locomotion such as seaweed extract applied to the anterior tentacles increased the frequency of the pedal waves. Correlated with this was a change in the timing of the motor program with neurons in both classes exhibiting an increase in burst frequency and increased spike frequencies within each burst. The timing of neurons within each class relative to each other remained essentially constant. For neurons with axons in the same nerve, no synaptic connections have been observed either among neurons of the same class or between neurons in the different classes. Some neurons which fired during opposite phases of the pedal wave had common synaptic input, but of opposite signs. These data suggest that the coordination of the motor neurons is maintained by interneurons rather than by interconnections among themselves.

1237 VESTIBULAR AND NECK REFLEXES IN CONSCIOUS RABBITS. James H. Fuller. Biol. Sci. Grp., U-42, Univ. Connecticut, Storrs, CT 06268

Rabbits were chronically prepared with head holders and DC oculogram electrodes and rotated about the vertical axis. Three reflexes were examined. First, during sinusoidal rotation in the horizontal plane without vision and with the head fixed to the platform, a torque produced in that plane mimics the eyes nearly perfectly, with counterrotating and resetting occurring consistently and in coordination with the eyes. If the animal's head is freed to move in the same plane, the resulting head movements (vestibulo-collic reflex, VCR) partially null the platform rotation (gain of 0.2 to 0.9). Second, if the head is mechanically (passively) stabilized in space and the body rotated beneath it, the collico-ocular (neck-eye) reflex (COR) results: a rotation of the body to the animal's left (i.e., a rightward deviation of the animal's neck) is accompanied by rightward eye movements (gain of about 0.1); thus, a self-initiated rightward movement of a free head on a stationary trunk would be accompanied by a rightward eye movement—or, opposite the vestibulo-ocular reflex (VOR)—as noted by Gresty (Acta Otolaryngol. 81: 386, 1976). Third, during rotation with a free head, all three reflexes ought to interact: a leftward platform movement results in a rightward head movement (VCR), a rightward eye movement due to neck deviation (COR), and a vestibularly-induced rightward eye movement (VOR)—the amount of eye movement is determined by the gain of the VCR, with the COR proportional and the VOR inverse to the magnitude of the VCR. If the animal's head is suddenly fixed to the rotating platform by an electronic brake (eliminating neck deviation), in principle, the COR is also eliminated. The vestibular component of gaze is not altered; rather, it is shifted wholly to the VOR. Elimination of the COR ought to bias the gaze towards platform movement: no such change was seen. Furthermore, during continuous rotation, the VCR may vary in gain between 0.2 to 0.8 over 1/2 min; this variation in neck deviation should affect the gaze by varying the COR. It does not.

In conclusion: 1) measurement of the COR by passively fixing the head in space is an artificial paradigm since neck muscles actively shorten and lengthen to stabilize the head in space and can only rarely be accomplished by the animal; 2) fixing the head to a rotating platform may not measure the VOR alone since the animal is isometrically contracting its neck muscles (revealed by head torque measurements), which may co-vary with the COR; 3) whatever the origin of the COR, it cannot be viewed as an universal reflex that assists or resists the VOR—it can do either, contingent on whether the animal's head movement is independent of or dependent on body movement. Its importance in intact animals is moot.

1238 SYNAPTIC EVENTS IN THE MEDIAL RECTUS MOTONEURONS DURING VESTIBULAR NYSTAGMUS IN THE CAT. Nobuhiko Furuya*, Yoshikazu Shinoda* and Jun-Ichi Suzuki*. (SPON: M. Maeda). Dept. of Otolaryngology, Teikyo Univ. Sch. of Med., Tokyo Japan

Intracellular recordings from the medial rectus motoneurons were made during vestibular nystagmus in encéphale isolé cats under local anesthesia. Repetitive electrical stimulation of the ipsilateral vestibular nerve produced slowly increasing nerve discharges followed by abrupt cessation of activity in the medial rectus nerve. In accord with the rhythmic change of the medial rectus nerve discharges, the membrane potential of medial rectus motoneurons showed a slowly increasing depolarization followed by a fast and then a slow hyperpolarization. The onset of the hyperpolarization coincided with that of the abrupt cessation of the nerve activity. After electrophoretic injection of Cl^- ions into the cell, the earlier fast hyperpolarization was not affected, but the later slow hyperpolarization was reversed to a depolarization. Mean rising slopes of the earlier fast hyperpolarizations before and after Cl^- ion injection were not significantly different in the motoneurons whose resting membrane potentials and frequencies during nystagmus were stable. Application of depolarizing current through the recording electrode filled with 2M K-citrate revealed a reduction of amplitude in the fast hyperpolarization; application of hyperpolarizing current resulted in an increase in amplitude.

These results indicate that disfacilitation is primarily responsible for the quick cessation of the medial rectus nerve activity; contributions of IPSPs to the fast hyperpolarization must be very small, if present at all. This pattern of activity differs from the synaptic events in the abducens motoneurons during vestibular nystagmus in which not only disfacilitation but also IPSPs are involved in the fast hyperpolarization. Clear evidence of IPSPs during the later slow hyperpolarization of medial rectus motoneurons indicates that post-synaptic inhibition does contribute to this phase of activity, however.

1239 INPUT RESISTANCE OF SPINAL MOTONEURONS DURING SLEEP. L.L. Glenn and W. C. Dement. Dept. Psychiatry, Sch. Med., Stanford Univ., Stanford, CA. 94305

During wakefulness and non-rapid-eye-movement (NREM) sleep, a background of continuous muscle tone exists in postural muscles. During REM sleep, all postural tone and electromyographic activity ceases except for occasional myoclonic jerks. After an analysis of central root recurrent discharge in combination with spinal cord sections, Gassel, Marchiafava and Pompeiano (1965) proposed that motoneurons are inactivated because of an increase in postsynaptic inhibition. In the present communication, we report the first confirmation of this hypothesis based upon measurements of motoneuron input resistance during wakefulness and the two phases of sleep. Seven cats were implanted for the recording of cortical, geniculate, ocular, and dorsal neck muscle potentials. The vertebrae over the lumbosacral cord were fused and prepared for later ventral horn microelectrode penetrations. After recovery from surgery, sleep deprivation, in combination with gradual adaptation to combined cranial and lumbar restraint, enabled the intracellular recording of motoneurons in restrained, but naturally sleeping and waking cats. Input resistance was measured by the passage of constant current pulses (-25nA to +25nA) through one barrel of a double micropipette (1-2 micrometers, potassium acetate) while recording voltage with the other. The input resistance of 11 motoneurons during NREM sleep ranged from 0.42 to 8.7 megaohms. Using NREM sleep as the baseline state, motoneuron resistance decreased a mean 67% ($p<0.01$) upon entering REM sleep. Wakefulness resistance averaged 106% of NREM levels (N.S.). Hyperpolarizing currents were passed through the microelectrode during the transition between NREM and REM sleep. In most motoneurons, the membrane depolarized towards an inhibitory equilibrium potential as the cat entered REM sleep. The diminished input resistance and reversal of the REM sleep hyperpolarization directly confirms the hypothesis that motoneurons are inactivated as a result of increased postsynaptic inhibition. Furthermore, this suggests that the synapses responsible for the inhibition terminate upon the motoneuron soma.

Gassel, M.M., Marchiafava, P.L., and O. Pompeiano. Arch. Ital. Biol. 103:25-44, 1965.

1240 ORIGINS OF CORTICAL AND CEREBELLAR PROJECTIONS TO THE RED NUCLEUS IN THE CAT. R. Gold, D.J. Reed*, M. Rowinski and D.R. Humphrey, Lab. of Neurophysiol., Emory Univ. Sch. Med., Atlanta, GA 30322.

The projections to the feline red nucleus (RN) were defined with retrograde labeling techniques. Injections of horseradish peroxidase (Sigma VI, 30-50 % solution, 0.05-0.2 µL) were made bilaterally into the RN of 9 animals. After a survival time of 48 hr, the brains were perfused, removed and reacted either with DAB, preceded by cobalt chloride (N=8; cf. Adams, Neurosci., 2: 141), or with TMB (N=1).

Labeled corticorubral (CR) cells were found in areas 4 and 6, with a smaller but consistent population in area 5. Very few labeled neurons were found in areas 3a, 3b, 1, 2 and 7. Cells within the distal forelimb region of area 4 were labeled only by injections into the rostral one-third of the RN. In contrast, cells were labeled in the proximal forelimb region of area 4 and in area 6 by injections in all parts of the nucleus; these areas included regions on the medial wall of the hemisphere and in both banks of the presylvian sulcus, which are thought to correspond, respectively, to the supplementary motor area and the frontal eye field. Injections into the caudal one-third of the RN also labeled cells within the hindlimb region of area 4. All labeled cells were pyramidal in shape, with the modal transverse soma diameter being 15 µm in areas 4 and 6, and 17-20 µm in area 5.

Injections into the caudal two-thirds of the RN labeled cerebellar cells principally within the contralateral nuc. interpositus (IP). In contrast, rostral RN injections labeled cells principally in the contralateral dentate nuc., although they were much fewer in number than the labeled IP neurons seen following more caudal injections. Labeled neurons were also seen in the entopeduncular nuc., in or near the VL nuc., and in the dorsal column nuclei.

These results indicate that the input to the RN originates principally from cortical areas 4 and 6, and from the IP and dentate nuclei of the cerebellum. Previous studies in this laboratory have defined similar origins for cortical and cerebellar projections to the RN in the monkey. CR neurons in the monkey are, however, smaller and more superficially located than is the case in the cat. The receptive field properties of corticorubral neurons are currently under investigation. (Supported by NIH Grant NS-10183).

1241 SPECIFICATIONS FOR THE VESTIBULOOCULAR TRANSFER FUNCTION: PHASE DATA FROM IDENTIFIED OCULAR MOTONEURONS IN CAT. Jefim Goldberg* and Edward L. Keller. Dept. of Electrical Eng. and Computer Sci., Univ. of California, Berkeley, CA 94720.

The frequency response of the vestibuloocular reflex (VOR) pathways has been studied in the decerebrate or anesthetized cat and monkey, and more recently, in the alert, intact monkey. These pathways include the vestibular end organ, primary vestibular neurons, pools of central, brain stem neurons, ocular motoneurons, and the oculomotor plant (globe, eye muscles, and other orbital tissues). During head rotations these pathways must provide a total of 180° of phase lag with respect to head accelerations in order to produce compensatory eye movements. Part of this phase lag, particularly at higher rotational frequencies, is generated by the dynamics of the oculomotor plant.

In the decerebrate cat the phase lag of vestibular nucleus neurons during sinusoidal rotations of the head (at frequencies above 0.1 Hz) is similar to that observed in the monkey. On the other hand, the response of abducens motoneurons (ABN) in the decerebrate cat lags head acceleration by a significantly smaller amount than in the alert monkey. Thus at a representative frequency of 0.25 Hz, it has been reported that ABN in the cat lead compensatory eye movements by about 70°. In the alert monkey discharges of presumed ABN show a phase lead of about 18°. To explain the large difference one would have to postulate an oculomotor plant in cat that is an order of magnitude slower than that in the monkey. This does not seem reasonable. Another alternative is that the units previously recorded in the monkey abducens nucleus, and not antidromically identified, are not all motoneurons and the sample is biased toward shorter phase-lead neurons.

To answer this question, we made phase measurements of neural discharge in alert, chronically implanted cats. Discharges of antidromically identified ABN were recorded while the animals were being rotated at frequencies of 0.1-1.5 Hz. At 0.25 Hz, motoneurons lead eye position by 24° on the average. Abducens nucleus units that are not driven antidromically from the 6th nerve exhibit an average lead of about 33°. Both types of neurons increase these phase leads during states of lowered alertness.

The 24° average phase lead for the alert cat ABN approximates the reported 18° monkey phase lead. The 70° lead reported for decerebrate cat motoneurons is most likely due to the preparation and its state of alertness.

1242 HIERARCHICAL CONTROL OF LOCOMOTOR RECOVERY FROM THE EFFECTS OF DORSAL ROOT LESIONS. Michael E. Goldberger. Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Recovery of motor function may be due not to the mass action of all undamaged pathways but to a controlled process in which the contribution of each pathway is somehow ranked or weighted; i.e. the recovery is regulated hierarchically. If this explanation were correct, one should be able to demonstrate that one pathway is more important than another in recovery after a particular lesion. The role of descending systems in recovery was assessed (using hemisections) after ipsilateral lumbosacral (l-s) deafferentation in which: 1) all l-s roots were cut, or 2) the L6 root was spared (spared root preparation) and were also compared with the effects of hemisection alone. Cats performed several food-rewarded locomotor tasks involving timed traverse of 9 ft. long runways. These included an obstacle course, boards with randomly placed holes of various sizes, pairs of one-inch wide bars with variable distance between them, 2" wide runways and 12" wide boards which were used as controls for locomotor speed. The more difficult tasks lengthened the time of a traverse in normal and lesioned animals by increasing the number of 'mistakes' the animals made (i.e. by requiring greater accuracy). Therefore, measurements of speed were used to indicate degree of impairment and course of recovery from it. L-S rhizotomies sparing L6 produced a mild deficit on all runways except the 12" wide board on which no deficit was seen. Recovery began when tactile placing returned at 7 days and was "complete" by 6 weeks. In another group of cats, L1 hemisection produced a severe deficit which began to show recovery on the 12" board on d2 and on the other runways on d8. Recovery was "complete" by 6 weeks. When ipsilateral hemisection was added in the recovered spared-root animals, a severe deficit resulted which also showed recovery on the 12" board beginning d2 and on the other runways beginning on d8 when proprioceptive placing returned. Recovery was "complete" by 6 weeks. In contrast, hemisection made in completely deafferented cats abolishes all recovery permanently. The recovery in deafferented cats is therefore dependent on the ipsilateral descending systems, but recovery in spared root cats may be independent of these systems. Since sparing a root (Goldberger and Murray 1978) also: 1) blocks sprouting of descending systems and 2) prevents the development of hyperactivity of descending (e.g. vestibulospinal) reflexes both of which are seen in deafferented cats, the results suggest: a) an inequality in importance of the spared root and descending systems in mediation of recovery and that b) recovery and sprouting show similar responses to a particular combination of lesions.

1243 ABSENCE OF CROSS-AXIS PLASTICITY IN THE VESTIBULO-OCULAR REFLEX. Lionel O. Greene, Jr.* and Laurence R. Young. MIT, Department of Aero/Astro, Center for Space Research, Cambridge, MA 02139.

The vestibulo-ocular reflex (VOR) plasticity shown following the wearing of optically reversing prisms represents a change in gain in afferents originating in semicircular canals lying in the same anatomical planes, but not a transfer of innervation to the extra-ocular musculature from canals situated in differing orientations. The vestibular response to visual inputs requiring compensatory ocular movements across the semicircular canal planes was monitored in the present experiment by fitting two rhesus monkeys with dove prism spectacles that caused vertical visual field movements for horizontal head motion and horizontal visual field motion with vertical head movements. VOR gains (eye velocity/head velocity) in the horizontal and sagittal planes were assessed during passive trapezoidal oscillations (accelerations to 30,45,60 and 90°/s, 25 s constant angular velocity) about yaw (G_z, earth vertical) and pitch (G_y, aural) axes. Tests were conducted in both the light and dark.

OPTOKINETIC NYSTAGMUS. Compensatory eye movements were generated during G_y and G_z accelerations to 30 and 45°/s following 10 days of testing. Visual suppression of vestibular cues was incomplete during accelerations to 60 and 90°/s, as the gain was always less than 1.0 (range: 0.0-0.9); nor was the direction of ocular motion always orthogonal to the rotational plane. There were no differences for G_y or G_z accelerations.

VESTIBULAR NYSTAGMUS. The inability of the oculomotor apparatus to evoke saccades across the planes of semicircular canal orientation has been demonstrated, thus delineating a limit of VOR plasticity. After 15 weeks of 90° rotated vision:

GAIN PER ACCELERATION			POST ACCELERATION	
Rotation	HORIZONTAL	VERTICAL	HORIZONTAL	VERTICAL
yaw	0.3 of normal	none	0.5 of normal	none
pitch	none	0.4 of normal	none	0.6 of normal

To show that these results were valid and not due to an abnormal subject population, reversing prisms were fitted to the test animals and the horizontal and vertical VOR's monitored. Trapezoidal accelerations were used as test stimuli in addition to sinusoidal accelerations at 0.1 Hz, ± 140°.

GAIN/PHASE PER ACCELERATION			POST ACCELERATION	
	HORIZONTAL	VERTICAL	HORIZONTAL	VERTICAL
yaw	non-reversed; 0.4 of normal 25-45° phase lag	-	reversed;	-
pitch	-	non-reversed; 0.7 of normal 20-40° phase lag	-	non-reversed; 0.7 of normal

These results imply asymmetries in central nervous responses to accelerations about the horizontal and sagittal planes, the bias possibly originating in the otolith end-organ/macular structures.

1244 VIBRATORY DECREMENT IN THE STRETCH REFLEX. Z. I. San and W. Z. Rymer. Upstate Med. Cent.,Syracuse,NY 13210 and Nortwestern Univ. Sch. Med.,Chicago,Ill. 60611.

The stretch reflex is known to be weaker in the presence of vibration superimposed upon the stretch than in its absence. The vibratory decrement in the stretch reflex is attributed to the occlusion of the stretch response of the primary endings in the presence of vibration. We have examined the question of whether the vibratory occlusion of the primary ending can explain the dynamics of the decrement in the stretch reflex. Ten experiments were carried out on decerebrate cats; the force, the EMG and the discharge of a primary ending pertaining to either the soleus or the medial gastrocnemius were monitored. Applying the same ramp stretch repetitively, a control series of averaged responses (force and EMG) was recorded for different values of pre-stretch force. (The latter was varied via the crossed extensor reflex.) Low amplitude vibration selected in order to synchronize the discharge of the primary ending was applied either (a)before and during the stretch, or (b)only for a period ending prior to the stretch. The force and EMG responses were compared with those interpolated from the control series according to pre-stretch force. We found that the responses in the presence and also in the aftermath of vibration were smaller compared to the appropriate controls. The decrement could not be explained simply by the occlusion of the primary endings' discharge. For instance, in paradigm (b) the decrement could be pronounced even though there was no occlusion of the primary ending's response. The time course of the development (or cessation) of the decrement in the stretch reflex was of the order of hundreds of milliseconds after initiation (or termination) of vibration. We found no comparable effect of preceding vibration upon the monosynaptic reflex evoked by tendon jerks. This is evidence against the involvement of presynaptic inhibition. The results point toward the possibility of polysynaptic circuits at the spinal level that respond with considerable lag to the Ia afferent signals.

1245 Skeletal Muscle Electrolyte, Water, and Lipid Concentrations in an Inherited Canine Neuromuscular Disorder. G.A.Hegreberg and M. J. Hamilton*, Dept. Veterinary Microbiology and Pathology, Washington State University, Pullman, WA 99164.

An inherited canine neuromuscular disorder is characterized by general muscular weakness, muscular atrophy, and an intolerance to cold and exercise stress. The disorder is inherited as an autosomal recessive trait and is clinically apparent at 3-4 months of age. The clinical course is slow and progressive in the maturing dogs but stabilizes after maturity. Urinary creatine excretion is elevated and urinary creatinine/creatine ratios are depressed in affected dogs. Serum electrolytes and serum creatine kinase activity are within normal limits in the affected dogs.

Pathologic changes in the skeletal muscle observed in the affected dogs are consistent, generalized, and severe and involve the distribution and size of the muscle fiber subtypes I and II. The affected dogs have a marked deficiency of type II fibers and an increase in the diameter size variation of both type I and II fibers. Other pathologic changes include centralization of nuclei, nuclear rowing, and an increase in interstitial connective tissue.

We have demonstrated that plasma aldosterone levels are significantly elevated in the affected dogs. Plasma renin activity is not significantly increased and plasma cortisol levels are comparable to levels found in nonaffected dogs.

Because of the alteration in electrolyte control mechanisms, intracellular electrolytes, C^{14} inulin space, and total lipid and water concentrations were measured in skeletal muscle from 4 adult affected and 4 adult nonaffected dogs. Electrolytes were measured using atomic absorption spectrophotometric methods and data expressed as meq/kg fat-free wet weight. Results indicate an increase in intracellular sodium and chloride concentrations and a decrease in intracellular potassium concentration in the affected dog skeletal muscle (Na- affected 71.6 ± 11.0, nonaffected 50.3 ± 12.5; K- affected 69.5 ± 5.6, nonaffected 93.4 ± 10.0). There was a significant increase in the lipid content of the affected dog muscle and a decrease in the water content. No significant change was observed in the C^{14} inulin space.

This disorder will provide a useful model to study electrolyte control mechanisms, muscle electrolyte shifts in disease, and to compare with similar changes which occur in aged muscle. (Supported by NIH grants RR00515, FR5465, GM07125, and the Muscular Dystrophy Associations of America, Inc.)

1246 SEGREGATED ORIGINS FOR SUPERIOR COLLICULAR PROJECTIONS BASED ON THEIR INTENDED TARGET STRUCTURES. [1] C. K. Henkel, [2] S. B. Edwards and [3] K. S. Kersey*, [1] Dept. Anat., Bowman Gray Sch. Med., Winston-Salem, NC 27103 and [2], [3] Dept. Anat., Univ. of Va. Sch. Med., Charlottesville, VA 22901.

In search for a general principle governing the anatomical organization of the deeper or motor layers of the superior colliculus, we analyzed the distribution of collicular cells which give rise to several functionally distinct projections and compared their laminar and spatial arrangements. The histochemical method of de Olmos ('77) for labeling the retrogradely transported HRP enzyme was used, and the position of labeled cells was recorded with the aid of an x-y plotter. In five cats iontophoretic HRP deposits were made in the cervical spinal gray to study the origin of the direct tectospinal projection controlling head movements. The data indicated that about 80% of the cervically-projecting collicular cells was found in stratum griseum intermedium (SGI). Most of them were found at an intermediate depth within SGI, and many were giant cells 40-70μ in diameter. Both the SGI and deeper cells projecting to the cervical cord were found predominantly in the caudal and lateral portions of the colliculus. In several additional animals HRP deposits in cervically-projecting areas of the reticular formation labeled collicular cells in a similar distribution, indicating that the indirect tecto-spinal pathway has a collicular origin similar in many respects to that of the direct pathway. In six cats HRP deposits were made in a paralemniscal zone of the ipsilateral, caudal midbrain reticular formation in order to compare the origin of an indirect tecto-facial pathway related to control of pinna movements (Henkel and Edwards, '78) to the above data. In striking contrast to the distribution of head movement-related collicular cells, 75% of the pinna movement-related collicular cells was found in stratum griseum profundum (SGP). Over 60% of these was present in the rostral half of SGP. Those cells labeled in SGI were located in its deepest portion (88%) and were seldom larger than 40μ in diameter. This information suggests that the laminar organization of cells in the motor layers of the superior colliculus reflects a functional segregation based on the peripheral target structure of collicular projections.

1247 COMPARATIVE MORPHOLOGY OF CAT ABDUCENS INTERNUCLEAR NEURONS AND MOTONEURONS. S.M. Highstein, A. Karabelis*, R. Baker and R.A. McCrea (SPON: Morris B. Bender). Dept. Neurosci., Kennedy Ctr. for Res., Albert Einstein Coll. of Med., Bronx, N.Y. 10461; Dept. Physiol., New York Univ. Med. Ctr., New York, N.Y. 10016

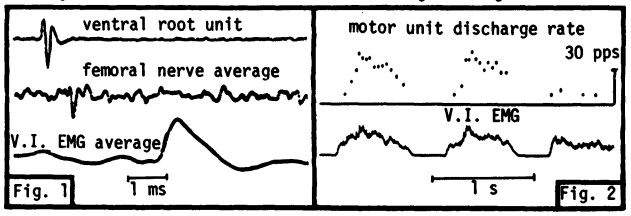
In anesthetized cats the abducens (Abd) nucleus was explored with microelectrodes containing 4% HRP. The purpose was to antidromically identify and stain Abd motoneurons (Mns) and internuclear (Int) neurons (Ns) in order to characterize their soma-dendritic trees and axonal trajectories. All neurons received disynaptic IPSPs and EPSPs following ipsi- and contralateral vestibular nerve stimulation. Abd Mns generally were larger and tended to lie more caudal in the nucleus than Int Ns, but both exhibited soma shapes extending from small fusiform to large multipolar. The axon hillocks of Abd Mns were directed toward all parts of the nucleus except laterally, yet all axons eventually turned ventrally to form the VIth nerve without any sign of collateralization either in the Abd nucleus or in the brainstem (n=24 Mns). Axon hillocks of Int Ns (n=22) were nearly always directed dorsally and axons left the Abd nucleus in a coronal trajectory spanning the entire dorsal-ventral extent of its medial border. Every Int axon headed toward the contralateral MLF before curving rostrally towards the IIIrd nucleus; but 30% exhibited a caudal collateral that coursed in the contralateral MLF towards the prepositus. The dendritic trees of all Abd Mns branched more extensively than those of Int Ns, especially at secondary and tertiary levels. Dendrites of Abd Mns often spanned the entire Abd nucleus. Abd Mns exhibited 6 to 8 primary dendrites as compared to 4-6 for Int Ns. Characteristically Abd Mns and Int Ns had long ventral dendrites which often extended into the reticular formation below the nucleus. In addition, dendrites of both populations curved around the facial genu, especially laterally toward, but not entering, the medial vestibular nucleus. The dendrites of Abd Mns were always extended more dorsomedially toward the MLF. We suggest that the morphological differences in soma-dendritic profiles (i.e. size) are responsible, in part, for the quantitatively different physiological responses in Abd Mns and Int Ns. We conclude that the absence of any recurrent axon collaterals within the Abd nucleus demonstrates that horizontal conjugate gaze signals are determined individually by all neurons within the nucleus and are not the result of intrinsic neural circuits. In fact, it is likely that the massive dendritic tree of Abd Mns might result from the necessity for receiving all information concerning vergence and conjugate gaze signals, much of which is shared by the comparatively smaller dendritic trees of Int Ns and medial rectus Mns. Supported by Grants EY-02007 and EY-01670.

1248 A METHOD FOR RECORDING AND IDENTIFYING SINGLE MOTOR UNITS IN INTACT CATS DURING WALKING. J.A. Hoffer, M.J. O'Donovan* & G.E. Loeb. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

A combination of three recently developed techniques has enabled us to obtain stable records from single motor neurons in normal cats during walking, and to characterize motor units by fiber type. Fine flexible wires (Loeb & Duysens, J. Neurophysiol. 42:420, 1979) are introduced through the dorsal root ganglion into the L5 ventral root. A recording cuff (Davis, Gordon, Hoffer, Jhamandas & Stein, J. Physiol. 285:543, 1978) is placed around the femoral nerve, and bipolar EMG probes sample each of the five muscles supplied by it (rectus, sartorius, and the vasti: medialis, lateralis and intermedius). Active ventral root electrodes generally sample one or more discriminable units. By spike-triggered averaging from the ventral root into the nerve and muscle electrodes, the orthodromic neural and EMG spikes can be extracted to obtain the conduction velocity, muscle of destination, and EMG signature of each unit (Fig. 1).

On occasion a recorded motor axon can be microstimulated in isolation through the ventral root electrode, and the mechanical properties of its muscle unit obtained under anesthesia. A heavy suture fixed to the patellar tendon, emerging through the skin, is attached to a myograph for measurement of twitch parameters, sag, and fatigue index. Further procedures could in principle include glycogen depletion and histochemical identification from muscle biopsy material (Garnett, O'Donovan, Stephens & Taylor, J. Physiol. 287:33, 1979). Criteria used to verify that the recorded and stimulated units are identical include replication of conduction velocity and EMG signature, and occlusion of the muscle response to spike-triggered microstimulation if the stimulus is delivered within the refractory period of the muscle, but outside that of the nerve.

Fig. 2 shows the normal firing pattern of the vastus intermedius (V.I.) unit from Fig. 1 (slow twitch contraction time; 90 ms). The motor neuron was recruited as the rectified/smoothed muscle EMG crossed a reproducible level, and its firing rate closely followed the whole muscle EMG during walking.



1249 A BASIS FOR PATHOLOGIC FIXATION EYE MOVEMENTS EXISTS IN NORMAL SUBJECTS. John R. Hotson, Dept. Neurol., Stanford Univ. Sch. Med., Stanford, CA. 94305.

Some patients with impaired supranuclear oculomotor control have pathologic large amplitude eye movements when fixating on a target. Small amplitude saccades and slow drifts are widely known to occur in normal subjects in similar test situations. The fixation eye movements in 12 control subjects were recorded using a purkinje image eyetracker and in addition to saccades and slow drift, small amplitude square waves, polyphasic square waves, flutter movements, and vertical nystagmus occurred.

Square waves consisted of an initial disruptive saccade which, after an intersaccade interval less than 350 msec., was followed by a second corrective saccade returning the eye toward the intended position. The mean amplitude of square waves (19.7', SD 10.4) and polyphasic square waves (40.0', SD 16.7) was significantly greater (p=0.001) than horizontal fixation saccades (9.2', SD 3.3).

Intersaccade intervals of square wave varied from 50 msec. to 350 msec. Square waves with an interval less than 200 msec. were greater in amplitude (p=0.004) than match paired square waves with 200-350 msec. intervals, suggesting that the corrective saccade occurred sooner when the initial saccade produced a large gaze deviation. The mean amplitude of the first saccade of polyphasic square waves (25.8', SD 9.9) was similar to the mean square wave amplitude, however the mean amplitude of the second saccade (48.6', SD 18.4) was significantly greater (p=0.016). The mean duration of the first intersaccade interval of polyphasics was also shorter than square waves (p=0.016), while the last polyphasic interval was the same. Polyphasics may be produced by a coupling mechanism similar to square waves, however the second corrective saccade occurs earlier and overshoots the position of intended gaze, requiring additional corrective saccades.

Four patients with diffuse cerebellar disorders had fixation eye movements qualitatively similar to control subjects, however the amplitude and/or frequency of saccades, slow drift, square waves and polyphasic square waves were increased. It is possible that defective supranuclear control of small fixation eye movements may lead to the development of large amplitude fixation instability. (Supported by NASA grant NGR 05-020-634 and Inst. Med. Res., San Jose, Ca.)

1250 A COMPARISON OF THE DISCHARGE PATTERNS OF MOTOR CORTEX AND SPINAL MOTORNEURONS IN THE MONKEY DURING THE 'VOLUNTARY' CONTROL OF WRIST POSITION. D. R. Humphrey and D. J. Reed*, Lab. of Neurophysiology, Emory Univ. Sch. of Med., Atlanta, GA 30322.

When monkeys are trained to grasp a small handle and to maintain a constant wrist position in the presence of perturbing forces, they employ two modes of operation, depending upon perturbation frequency. At low frequencies (0.1-0.5 Hz) and moderate force levels (100-200 gm), the position of the wrist is controlled principally by a smooth modulation in the firing rates of small motor units in the wrist flexor and extensor muscles. Spike-triggered averaging reveals that these units generate low twitch tensions (0.1-0.5 gm), and their discharge rates correlate highly with the time course of the force perturbation. At higher perturbation frequencies (0.6-2.0 Hz), these small units discharge at near constant rates, which appear to be near maximal levels (40-50 imp./sec). This occurs in both flexors and extensors, so that the wrist is partially 'clamped' by co-contraction, a manuever that is effective because of the increased mechanical impedance of tonically active muscle. Over this same frequency range, however, the control of wrist position is further aided by a progressive 'recruitment' into activity of larger motor units, which have larger twitch tensions; their firing rates are increasingly modulated as the perturbation frequency increases, despite a constant peak-to-peak force level.

Recordings from cells within the forearm area of the contralateral motor cortex reveal a similar pattern of behavior. Small (slowly conducting) pyramidal tract (PT) and corticorubral cells also exhibit a modulated firing rate during the tracking of low frequency perturbations, and tend to fire at a more constant rate during rapid perturbations. In contrast, rapidly conducting PT cells, as well as unidentified neurons in more superficial layers, tend to fire most intensely during higher frequency perturbations.

It is our hypothesis that these results reflect (a) a similar order of recruitment from small to larger cells at both cortical and spinal levels, and (b) an interaction of changing central and increased peripheral inputs to both cortical cells and segmental motorneurons. During the voluntary tracking of low frequency perturbations, the task is performed principally by small cells at both levels, which are the first to be recruited by central command structures. At higher perturbation frequencies, the central command changes to a 'clamping' effort, which is associated with a facilitation of input pathways from receptors in the wrist and hand. This input is increasingly effective in modulating the firing rates of large PT cells and motorneurons, but is not reflected in the firing rates of the smaller cells, because they are at saturation levels. (Supported by NIH Grant NS-10183).

1251 ALTERATION OF PHYSIOLOGICAL ACTION TREMOR BY FATIGUE. Paul A. Iaizzo*, Robert S. Pozos, Roger W. Petry*, (SPON: D.J. Forbes) Department of Physiology, University of Minnesota, Duluth, School of Medicine.

An action tremor which accompanies voluntary motion in normal subjects has been called Physiologic Action Tremor (PAT). Since it has been noted that large involuntary oscillations of the limbs can be observed, in extremely fatigued subjects, the present study was undertaken to see if fatigue altered the frequency and/or amplitude of PAT. If so, then PAT might be considered the physiological substrate for the tremors produced by fatigue.

PAT of the ankle was recorded before and after the subject was fatigued by using an AVR-250 accelerometer taped to the patella and biopotential surface electrodes placed on the tibialis anterior and soleus muscles. Acceleration and EMG signals were recorded on a tape recorder and later analyzed for frequency and amplitude changes using a PDP-12 digital computer. The fatigue state was produced by asking the subject to run a distance which the subject considered moderately fatiguing.

Analysis of the data shows that the frequency range of PAT in the non-fatigued subject versus the tremor seen when a subject was fatigued, fall in the same frequency range of 3-8 hz. There was a significant difference ($p < .05$) in the amplitude of the acceleration record as well as the EMG signals in the fatigued states. The mean pooled RMS acceleration values for PAT was 12.0 cm/sec^2 whereas for fatigue altered tremor was 16.4 cm/sec^2.

The data suggests that fatigue induced by running alters significantly the amplitude of PAT. Since PAT, fatigue altered tremor, and clonus have a similar frequency range but varied amplitudes, the alteration of the mechanism for PAT may be an explanation of the other two tremors.

1252 LIMB MUSCLE ACTIVITY IN CHICK DURING LOCOMOTION. Richard Jacobson* (Spon: Paul Grobstein). Dept. of Pharmacolog. and Physiolog. Sci., Univ. Chicago, Chicago, IL 60637.

The intralimb pattern of leg muscle activity during locomotion was determined in recently-hatched chicks. EMG's were recorded from as many as four muscles simultaneously while the animals were walking unrestrained or on a treadmill at various speeds. Some animals were also videotaped in order to relate muscle activity to footfall and joint angle changes. Records have been made from nearly all major muscle groups controlling the hip, knee and ankle joints. The data from 28 chicks provide the following generalizations: (1) No significant differences in the temporal pattern of muscle activity can be observed when free and treadmill walking are compared. (2) Each leg muscle falls into one of two principle categories: those active chiefly during stance, the period when the limb supports and propels the body mass; and those active chiefly during swing, when the limb is lifted off the ground and brought forward. (3) The swing muscles can be further subdivided according to their activity during the flexion or extension of the swinging limb.

We have also correlated this physiological picture of leg muscle activity with the anatomical map of leg motor neuron pools in the lumbosacral spinal cord (Hollyday, unpublished). Perikarya of cells which innervate stance muscles lie in two main regions: a large medial cluster and a smaller dorso-lateral cluster. Perikarya of cells which innervate swing muscles are in motor nuclei which lie between the two main stance clusters.

Two main generalizations arise from this anatomical data. (1) Every segment of the lumbosacral cord has motor pools innervating stance muscles and motor pools innervating swing muscles; thus, the entire step cycle is represented in each segment. (2) There is a longitudinal continuity of motor nuclei that innervate muscles with a similar activity pattern.

1254 EFFERENT PROJECTIONS OF THE PONTINE OCULOMOTOR PAUSER REGION IN THE CAT. C.R.S. Kaneko, T. P. Langer* and A.M. Graybiel, Dept. of Psychol., MIT, Cambridge, MA 02139 and Dept. of Physiol. and Biophysics, Univ. of Washington, Seattle, WA 98105.

Two zones in the pontine tegmentum have been identified with distinct oculomotor functions in cats and monkeys on the basis of recordings from single units during eye movements: 1)a paramedian zone containing "burst" and "burst-tonic" units that increase their firing rates shortly before eye movements, and 2) a more medial zone near the level of the VIth nerve rootlets containing "omnipause" units that cease firing before a saccade occurs. We have attempted to distinguish between the efferent connections of these two pre-oculomotor regions by means of the autoradiographic technique. In 3 cats the "pauser region" was identified electrophysiologically and injections of labelled amino acids were made in the vicinity of omnipause neurons. In 3 other cats labelled amino acids were deposited stereotaxically into the paramedian reticular formation near the abducens nucleus.

In all cats labelling could be traced through a broad central expanse of the reticular formation including the nuclei gigantocellularis, pontis caudalis and pontis oralis and extending rostrally into the mesencephalic tegmentum. Regions of the central gray substance,particularly near the IIIrd and IVth nerve nuclei, were variably labelled, somewhat more so in cases of midline than paramedian injection. Labelling of the abducens-periabducens region also appeared but could not be interpreted adequately because the deposits were too close by.

Cases of midline injection were distinguished by a sharp focus of labelling in the medial part of the medial accessory nucleus of the inferior olive. In 1 case the flocculus was labelled. At mesencephalic levels these cases showed denser labelling of the reticular formation, including the nucleus of the posterior commissure and perirubral fields. A striking difference in labelling between the 2 sets of cases appeared at the mesodiencephalic border: all midline injections, but not more lateral deposits, elicited dense labelling of the nucleus of the fields of Forel (NcF), a region known to project directly to the oculomotor complex and implicated in vertical gaze control.

While the anatomical findings cannot definitively establish the projections of functionally defined cell groups, these differences suggest that medial "pauser region" and paramedian tegmentum indeed have distinct efferent connections. In particular, the findings suggest that the medial pauser region of the pons may have direct efferent connections with both vertical and horizontal saccade-generating mechanisms and with cerebellar-precerebellar circuitry as well.

1255 ORGANIZATION OF REFLEX RESPONSES TO ANKLE DISPLACEMENT IN HUMAN LEG AND ARM MUSCLES. R.E. Kearney and C.W.Y. Chan, Biomedical Engineering Unit and Aviation Medical Research Unit, McGill University, Montreal, Quebec, Canada.

In a previous study (1) we demonstrated that cutaneous stimulation of the human foot evokes systematic reflex changes in muscles of both the ankle and arm. The present study extends this work to consider the nature of the responses elicited by ankle displacement.

Step displacements (0.1 rad in amplitude, 40 ms rise time) of ankle position were applied in either the dorsiflexing or plantarflexing direction by means of a servocontrolled electro-hydraulic actuator. Subjects lay supine and were instructed to maintain a tonic contraction of the relevant muscle (tibialis anterior (TA), gastrocnemius (G), triceps brachii (TB), or biceps brachii (BB)), aided by visual feedback of the smoothed and rectified surface EMG, and not to react to the stimuli. Stimulus-related changes in the tonic EMG activity were detected by means of averaging and Wiener filtering, as a means of assessing reflex activity. Examination of five normal subjects has revealed two principal findings.

First, the responses of the ankle muscles are distinctly asymmetric. Dorsiflexion of the ankle evoked a strong, short latency (40 ms) excitation of G, attributable to the monosynaptic Ia pathway. This was followed by a period of reduced activity, and then a return to normal. The TA displayed an exactly reciprocal pattern of response, in which an early decrease in activity was followed by a period of excitation. In contrast, plantarflexion of the ankle evoked a weaker, short latency excitation of TA followed by a second, often larger, period of excitation lasting from about 80 - 100 ms. Furthermore, the G response did not display any significant reciprocal inhibition. It is possible that the asymmetry of the response reflects differences in the relative importance of cutaneous and muscle afferents in the two muscles. The functional implications of these differences remain to be determined.

The second major finding was that ankle displacement evoked large and systematic reflex responses in TB but not BB. Thus dorsiflexing displacements in the ankle result in a decreased TB activity at a latency of about 70 ms while there was no significant change in BB activity. In contrast, plantarflexing displacements of the ankle evoked a short latency (40 ms) excitation of TB followed by a decrease in activity. Occasionally, small increases in BB activity were also noted. The large size and short latency of the TB responses indicate that they may have important functional roles to play - perhaps in the control of locomotion.

1256 PONTINE CONTROL OF SACCADIC TRAJECTORIES: MICROSTIMULATION AND SINGLE UNIT STUDIES. W.M.King, A.F.Fuchs, W.Becker,and G.Johanson
University of Washington, Seattle,WA 98195 & Universität ULM/FRG

Although it has long been thought that saccadic eye movements are preprogrammed, Robinson (1) has recently suggested that the saccadic trajectory is under continual control by pontine circuits. To both test this hypothesis and to determine the neural elements involved in such circuitry, we attempted to interrupt saccades transiently in mid-flight by delivering stimulus trains to various brain stem loci between the abducens and oculomotor nuclei. Cathodal stimulus trains (0.1 msec bipolar pulses at 300 Hz with 10-35 msec train durations) were triggered to occur as early as 3 msec after the onset of randomly selected saccades elicited in the trained monkey. At certain sites near the midline, currents as low as 10-20 μa caused saccades to decelerate within 11 msec of the train onset. Within 11 msec after the train ended, the saccade either resumed its course (perturbed saccade) or was terminated (truncated saccade). A perturbed saccade appeared to be a single eye movement, and in most cases was as accurate as a control saccade to the same target. In contrast, the truncated saccade always fell well short of the target and was followed by a second saccade, often after latencies of less than 50 msec. For long stimulus trains, the second saccade overshot the target necessitating a corrective third saccade. Perturbed saccades occurred if the stimulus train ended during what would have been the acceleratory phase of the eye movement had the stimulus not occurred (computed as the mean acceleratory phase of control saccades to the same target). If the stimulus train ended after the estimated acceleratory phase, the saccade was truncated.

Preliminary reconstructions of successful penetrations indicate that sites where weak stimulation caused saccade interruptions were invariably confined to within ± 1 mm of the midline throughout a core of brain stem which extended from the rostral pole of abducens to a point about 5 to 7 mm ventral to the trochlear nucleus. Single unit recordings obtained through the stimulating microelectrode indicated that sites where omnipause neurons (which ceased firing for saccades in all directions) were encountered always produced saccade interruption at low currents, but interruption was obtained also at sites without omnipause neurons. However, at virtually every effective site some form of saccade related activity was found.

Generally, these results seem consistent with Robinson's "bang-bang" model although modifications will be necessary to account for certain characteristics of interrupted saccades.

1257 EFFECTS OF DENTATE LESION ON DISCHARGE PATTERNS OF MOTOR CORTEX NEURONS AND REACTION TIME IN MONKEYS. Yves Lamarre, Giuseppe Spidalieri* and Liliane Busby*. Centre de recherche en sciences neurologiques, Faculté de médecine, Université de Montréal, C.P. 6128, succursale A, Montréal (Québec) Canada H3C 3J7.

There is experimental evidence in favor of a role played by the cerebellum in the initiation of some fast movements. It is not known, however, whether dentate provides a true phasic motor command or only a nonspecific tonic facilitation to supraspinal motor centers. In an attempt to answer this question, we examined the effect of electrolytic lesion of the dentate nucleus on the initiation of ballistic flexion and extension of the arm triggered by sensory cues of different modalities. Two monkeys were trained to perform in response to randomly presented light signals, pure tones or small elbow displacements. Unit activity in precentral cortex, angular displacement of the elbow, arm and neck muscle activity, as well as eye movements, were recorded and processed on-line with a PDP-9 computer.

Three average values were calculated: 1) time from onset of stimulus to onset of elbow displacement (RT), 2) time from onset of stimulus to onset of cortical neural changes (RS) and 3) time from onset of cortical neural changes to onset of elbow displacement (RM). The pattern of discharge of each neuron was the same whether the movement was triggered by visual, auditory or somesthetic signals. After dentate lesions, RT and RS increased by about 60 msec for light and sound in the two monkeys, the increase being the same for both flexion and extension movements. The reaction time to elbow displacement was not changed in one animal and was increased by only 20 msec in the other. In both animals, movement parameters, RM values, spontaneous activity and sensory responses to sound and elbow displacement were not changed. These data are in favor of the hypothesis that the lateral cerebellum participates in the phasic motor command for some fast ballistic arm movements, particularly those triggered by teleceptive input signals. 1258 PROJECTIONS FROM MESENCEPHALON TO THE INFERIOR OLIVARY COMPLEX IN CATS AND MONKEYS. Pierre Langelier*, Raymond Marchand*, René Boucher and Louis J. Poirier, Laboratoires de neurobiologie, Pav. Notre-Dame, 2075 ave de Vitré, Québec, Qué. G1J 5B3.

The autoradiographic method was used to study the fiber projections from the tectum and the mesencephalic tegmentum to differents parts of the inferior olivary complex. Twelve adult cats and four monkeys (Macaca fascicularis and squirrel monkeys) were used in the present analysis. In order to further map the efferents of this area, tritiated leucine was injected unilaterally in the red nucleus, the adjacent tegmentum and different parts of the tectum.

Following injections in the lateral part of the midbrain tegmentum, the labeled material was found in the ipsilateral dorsal accessory inferior olivary nucleus (DAO). In the light of our preliminary results it appears, more specifically in cats, that the neurons of this part of the midbrain tegmentum send a topographically organized projections to the ipsilateral DAO.

In three other cats and one monkey, ^{3}H leucine was injected into the medial portion of the superior colliculus. In agreement with Weber J.T. et al (Brain Research, 144 (1978) 369-377) we found the labeled amino acid into the dorsal part of contralateral caudal medial accessory olive (MAO). However we did not observe any labeled material in the contraleteral MAO with injections in the lateral portion of the superior colliculus.

On the other hand, after injections of tritiated leucine into the rostal red nucleus in cats and monkeys we could observe the distribution of silver grains in the ipsilateral dorsal lamella of the principal nucleus of the olivary complex, as well as along the course of the dorsally situated rubro-olivary pathway.

No evidence was found for a projection to the olivary nucleus with injections in the vicinity of the periaqueductal gray.

1259 MOVEMENT AND THE MECHANICAL PROPERTIES OF THE INTACT HUMAN ELBOW. J. M. Lanman*and T. A. Zeffiro (SPON: N. Geschwind)
Dept. Psych., M.I.T., Cambridge, Ma. 02139.

Recent studies of motor coordination have emphasized the importance of the mechanical properties of muscle in the control of movement. In the present study, we investigated short term changes in muscle properties by measuring the response of the intact human elbow joint to mechanical perturbations. The resistance of the intact joint to such displacements reflects contributions from the muscles and passive tissues spanning the elbow joint. In order to explore the effects of both muscular activation and movement on joint properties we studied three conditions: (1) voluntary isometric contraction,(2) passive movement, and (3) voluntary movement.

In the isometric condition, the subject maintained a constant arm position against various loads. In the passive movement condition the subject's arm was moved at a constant velocity. Finally, the voluntary movement condition combined muscular activation with movement. During all three conditions a small amplitude, high frequency (3-30 Hz) sinusoidal perturbation was applied about the elbow joint. Joint impedance was derived from the resistance of the elbow to this superimposed displacement. We obtained continuous measures of joint impedance, joint angle, and the biceps and triceps EMG's.

During isometric contraction, joint impedance increased monotonically with increasing muscular activation (estimated by EMG). In contrast, during passive arm movements joint impedance decreased markedly. This was true even for very slow passive movements when no change in muscular activation could be detected. Finally, voluntary movements resulted in changes in joint impedance which were consistent with the combined effects of muscular activation and movement.

We attribute these changes in joint impedance to variations in the properties of the muscles acting about the joint. We conclude that length changes (whether active or passive) and neural activation have opposing effects on the mechanical properties of muscle. These results will be discussed in relation to the well-characterized effects of length change and activation on the mechanical properties of isolated muscle.

1260 LONG LATENCY VERSUS LONG LOOP REFLEXES: DEPENDENCE ON THE TEMPORAL CHARACTERISTICS OF THE IMPOSED DISPLACEMENT. R.G. Lee and W.G. Tatton. Neurosc. Research Group, Univ. of Calgary, Calgary, Alberta and Playfair Neurosc. Unit, Univ. of Toronto.

The reflex EMG response to perturbation of an extremity consists of an early component (M1) and one or more late components (M2, M3). The origins of the late components have been the subject of much recent controversy. Several lines of evidence, including their long latencies, support the concept that the late components are at least partially mediated by a transcortical feedback loop. However, assigning specific latencies to these responses requires the assumption that the effective input occurs over a limited time interval at or near the onset of the displacement. The mechanical properties of the torque motor systems used to study these responses in humans are such that the displacement continues for 100 msec. or longer even when a step-change in load is applied. The present study was designed to examine the late components of the EMG response when the displacement was arrested at varying times following the onset of the perturbation. Recordings were carried out on 12 normal human subjects using a computer controlled torque motor to generate randomly timed displacements of the wrist joint. EMG responses from the wrist flexors were rectified and averaged and the integrated EMG activity was measured over the M1 interval (30-55 msec. following onset of the imposed load) and over the M2-M3 interval, (55-90 msec.). When the displacement was stopped prior to 45 msec. there was a well defined M1 response but the late EMG components beyond 55 msec. were absent. As the duration of the displacement was increased beyond a critical interval between 50-55 msec. there was a rapid increase in the size of the late responses. Further, the duration of the late components was monotonically related to the duration of the imposed displacement beyond the critical period.

These results raise the possibility that the late EMG components are entirely independent of long loop mechanisms activated near the onset of the perturbation but rather result from segmental reflexes activated later in the course of the displacement. Yet the timing of the critical interval (50-55 msec.) and the dependence of the duration of the late components on the time course of the displacement makes two other possibilities more likely: 1) The abrupt termination of the handle displacement introduces inhibitory influences on motoneurons which prevent them from responding to descending excitatory inputs from long loop pathways. 2) Continued stretch or displacement provides an essential convergent input to motoneurons or to interposed interneurons in polysynaptic pathways which is required for the motoneurons to respond to long loop inputs.

1261 DISCHARGE PATTERNS OF CONCURRENTLY ACTIVE MOTOR UNITS. Ronald S. Le Fever* and Carlo J. De Luca. Dept. of Orth. Surg., Children's Hosp. Med. Ctr., Harvard Med. Sch., and M.I.T., Boston, Ma..

The discharge patterns of concurrently active motor units have been investigated in three muscles of four normal adult subjects. Both constant-force and force-varying isometric contractions have been studied in the deltoid, biceps and first dorsal interosseous (FDI) muscles, at levels up to 80% of the maximal voluntary contraction. These firing patterns have been obtained through the use of an expanded version of the technique for the separation of superimposed action potential trains reported at the 8th Annual Meeting of the Society for Neuroscience.

Three channels of EMG signal, one bipolar and two monopolar, are recorded from a modified DISA bipolar needle electrode. Analog and digital filtering of the EMG signal is employed to reduce the duration of the action potentials, and consequently the degree of superposition. The EMG signal is decomposed into its constituent action potential trains using a visually assisted computer algorithm. Using this technique, the firing patterns of typically three to six motor units can be obtained throughout an entire contraction with usually less than 2% error.

Statistical analysis performed on these firing patterns indicates that concurrently-active motor units tend to rapidly modulate their firing rates in unison with corresponding small force fluctuations. The magnitude of these rapid firing rate changes compared to the small fluctuations in force is considerably larger than the overall change in firing rate due to an overall change in the force level. This analysis also indicates that motor units in the FDI increase their firing rates to a greater extent than motor units in deltoid or biceps when the overall force level is increased. Also, in the FDI of one subject, three motor units were observed to lock into exact synchronization for a period greater than 1.5 seconds during an isometric contraction at 60% of maximal voluntary contraction. When these motor units were not firing synchronously, however, both their firing rates and modulation of these rates were similar.

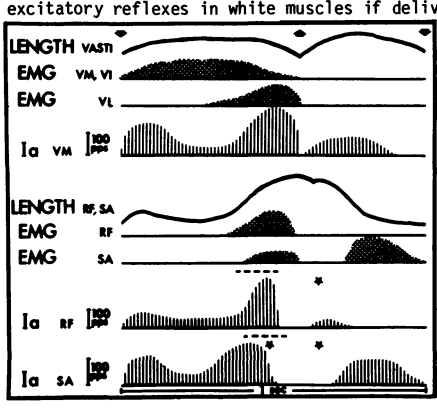
Quite often the motor units recruited at the lowest force levels exhibit the greatest amount of firing rate modulation at high force levels. This discharge behavior of motor units suggests that the number of motor units recruited and their overall firing rates supply the bias of a contraction level; and that small fluctuations about this force are achieved through the simultaneous changes in the firing rates of all active motor units. This scheme has great appeal from a systems control viewpoint. (Supported in part by NIAMDD grant #AM 19665, and by a joint grant from the United Cerebral Palsy Res. and Ed., the C.A. Dana and the Hearst Foundations.)

1262 MODIFICATIONS UNDERLYING ADAPTIVE PLASTICITY OF THE PRIMATE VESTIBULO-OCULAR REFLEX ARE POST-SYNAPTIC TO THE MEDIAL VESTIBULAR NUCLEUS. S. G. Lisberger and F. A. Miles. Lab. Neurophysiol., NIMH, Bethesda, MD 20205.

We have been attempting to localize the site(s) in the vestibulo-ocular reflex (VOR) pathways where changes underlying long-term adaptive plasticity of the VOR might occur. Recordings were made in the medial vestibular nucleus (MVN), which contains the secondary neurons in the horizontal VOR pathways. Half of the sample ("high-gain") was recorded in monkeys adapted to 2.0X telescopic spectacles: VOR gain measured in darkness was greater than 1.5. The rest of the sample ("low-gain") was recorded in monkeys adapted to goggles providing a visual field fixed with respect to the head: VOR gain was less than 0.4. For pure-vestibular and vestibular-plus-saccade cells, sensitivity to vestibular inputs was measured from sinusoidal whole-body rotation with the animal's head in the normal stereotaxic plane. Pitch tilting of the whole animal was used to identify vertical canal inputs. Most cells (96%) having increased firing rates during ipsilateral head rotation (VI) received inputs from the horizontal canals. On average, cells in the high-gain sample had slightly greater sensitivity to head velocity (0.78 spikes/s/°/s, n=130) than cells in the low-gain sample (0.64 spikes/s/°/s, n=129). Most cells (82%) having increased firing rate during contralateral head rotation (VII) received inputs from the vertical canals. Again, cells in the high-gain sample had slightly greater sensitivity (0.51 spikes/s/°/s, n=129) than those in the low-gain sample (0.44 spikes/s/°/s, n=146). Grouping individual cells according to various response properties (sensitivity, phase shift, discharge during saccades) failed to reveal any sub-population displaying large changes that would have been obscured by a large, unchanged fraction of our sample. In addition, there were no differences in phase shift and only small differences in resting rate. For a small sample of vestibular-plus-position cells (VI,EII), sensitivity to vestibular inputs was estimated as the value of K_2 obtained by fitting firing rate during rotation in the dark with the equation FR = DC + K_1 x (eye position) + K_2 x (head velocity). Again, cells in the high-gain sample had slightly greater sensitivity (0.97 spikes/s/°/s, n=22) than those in the low-gain sample (0.78 spikes/s/°/s, n=15). The differences we have found in the sensitivity of MVN cells are much too small to account for the 4-fold difference in VOR gain. We conclude that the changes underlying plasticity occur either at the terminals of MVN cells or in other VOR pathways post-synaptic to the MVN.

1263 UNIT ACTIVITY OF CAT KNEE EXTENSOR SPINDLE AFFERENTS DURING NORMAL AND PERTURBED WALKING. G.E. Loeb and J.A. Hoffer. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Floating microelectrode wires (Loeb and Duysens, J. Neurophysiol. 42:420, 1979) were used to record from cells in the L5 dorsal root ganglion which innervate the five anterior thigh muscles (quadriceps plus sartorius). The unit records were used to spike-trigger average the delayed signal from a femoral nerve cuff electrode to obtain conduction velocity. Stimulation through implanted bipolar EMG electrodes identified spindle afferents and their muscles of origin. Two implanted length gauges recorded the length of the pure knee extensors, vastus medialis (VM), intermedius (VI), and lateralis (VL), and the hip-flexing knee extensors, rectus femoris (RF) and sartorius (SA). Representative activity patterns during slow walking are shown schematically. VM and VI (mainly red muscles) were active throughout stance whereas VL and RF (white) contributed mainly to push-off. SA (white) also provided some late stance thrust but was used mainly as a flexor. Three spindle Ia's shown were active during stance, with onset bursts reflecting dynamic stretch sensitivity and/or fusimotor activity coincident with the onset of quadriceps activation as a whole. The late stance bursts might reflect similar dynamic sensitivity for RF and SA Ia's, but not for VM, where shortening must be overcome by γ-static activity coincident with the white muscle burst (not seen in VM). We interpret swing phase activity in the VM Ia as due to passive stretch; in SA Ia, to α-γ coactivation. Single 0.1 msec shocks to sural nerve or foot dorsum skin elicited excitatory reflexes in white muscles if delivered just before foot lift (dotted lines). Brisk spindle discharge then followed but only when the muscle was elongating (at *'s), suggesting γ-dynamic activation. Light taps to various skin areas of the limb during quiet standing elicited brief (~50 msec) bursts (~200 pps) of Ia firing at 30-50 msec latency without EMG activation of these muscles, a pattern not produced by electrical stimuli during walking.



1264 ACTIVITY OF MULTIPLE INDIVIDUAL MOTOR UNITS IN CATS DURING LOCOMOTION. W.B. Marks. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Arrays of wires are implanted in the medial gastrocnemius muscle of the cat's hindlimb. Recording tips are spaced closely enough that any unit impulse is seen in several leads, and far enough apart such that, for different units, the ratios of amplitudes in the leads differ. The number of active units is held within a resolvable range by limiting the speed of locomotion. A ring of uninsulated probes forms a cylinder around the recording leads in order to attenuate invading fields from remote units and to provide a common indifferent signal for the recording channels. Motor unit waveforms are distinguished by their pattern of amplitudes across several leads as well as by their time courses in each lead. Recording multiple units with multiple leads appears to be less sensitive to muscle movement than differential recording from pairs of leads. In the former, the recording points are spaced farther apart and the multichannel unit patterns are distinguishable in spite of changes in their waveform in a few channels caused by movement. In addition, the lead array is stabilized by attaching it to the surface tendon; the leads terminate just below the surface, the origin of the fibers. When two or more unit waveforms overlap in time and superimpose, they are resolved using a digital multichannel filter (Roberts & Hartline, Brain Res. 94:141, 1975) which forms linear combinations at multiple delays from all the channels, each combination orthogonal to all but a chosen multichannel unit waveform. Multi-lead recording appears to be functional at high levels of muscle activation, since the extra channels enable the filter to resolve more overlapping impulses.

Thusfar we have followed the activity of up to five motor units of the medial gastrocnemius muscle during walking, using 8 leads spaced about 300 microns apart and implanted in the dorsal margin of the muscle where high oxidative (S & FR) fibers, used during walking, are sparse (Burke et al., J. Neurophysiol. 40:667, 1977). We will attempt to derive from such multiunit data the number of different signals impinging on the motor neuron pool. If for example the firing rate of some units is rising while that of others is falling, or if in general all the recorded firing rates or recruitment order cannot be explained from the time variation of a single number, the 'muscle activation', then additional influences on the pool must be present and can be calculated.

1265 INTERACTION OF SACCADES INDUCED BY VISUAL STIMULI AND ELECTRICAL STIMULATION OF THE SUPERIOR COLLICULUS. Lawrence Mays and David Sparks. Neurosciences Prgm. & Dept. of Psychology, Univ. of Al. in Birmingham, Birmingham, AL 35294.

It has often been assumed that saccades elicited by visual stimuli are retinocentrically organized ballistic eye movements. This view implies that a retinal error signal is translated into a command to the saccadic system to move the eyes in a certain direction for a certain distance. In contrast, another model of the saccadic system states that saccades are spatially organized and not ballistic (Zee et al., Arch Neurol. 33, 1976). A spatially organized system requires that the eyes be driven to a particular position in the orbit rather than be preprogrammed for a certain vector.

These two models predict different effects of saccades induced by electrical stimulation of the superior colliculus upon visually elicited saccades. Electrical stimulation of the deeper layers of the monkey superior colliculus produces short latency (e.g., 25 msec) saccades of an amplitude and direction determined primarily by the stimulation site. Macaques were trained to make accurate saccades to briefly presented visual targets for a water reward. Eye position was measured using the electromagnetic search coil technique. Between the signal to make a saccade to a target and the beginning of the saccade, the target was turned off and a brief (40 msec) electrical stimulus train was delivered to a site in the superior colliculus through a microelectrode. Thus, after the signal to look to the target, but before a saccade could be made, the eyes were driven to another position. The electrically induced saccades were usually followed by another short (or zero) latency saccade. This second saccade was an attempt to acquire the recently presented visual target. If saccades are preprogrammed in a retinocentric coordinate system then this second saccade should have the same vector as if no electrical stimulation occurred. Since the eyes were forced to move by the electrical stimulation, the final eye position should miss the actual target position by an amplitude and direction equal to that produced by the electrical stimulation. If, on the other hand, saccades are programmed to take the eyes to a specific location in the orbit (or look to a specific location in space) then the amplitude and direction of the visually elicited saccade should compensate for the intervening electrically-induced saccade. This latter result, consistent with the spatial model of saccade generation, was reliably observed. Even if the electrical stimulation was timed to interrupt the visually elicited saccade, the stimulation-induced movement was followed by a short (or zero) latency saccade to direct the eyes to the location of the recently extinguished visual stimulus.

1266 INTERCONNECTIONS BETWEEN VESTIBULAR NUCLEI AND THE NUCLEUS PREPOSITUS HYPOGLOSSI. R.A. McCrea and R. Baker. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., New York, N.Y. 10016.

Previous studies have shown that neurons in the nucleus prepositus hypoglossi receive monosynaptic inputs bilaterally from the vestibular nuclei (Baker and Berthoz, 1975) and that prepositus neurons in turn project back to the vestibular nuclei (Pompeiano, Corvaja and Mergner, 1978). The aim of the present study was to examine in detail the specific morphological and physiological characteristics of these pathways. When ^{3}H Leucine was injected into the region of the prepositus, the medial and descending vestibular nuclei were heavily labeled bilaterally. Intracellular injections of HRP into single prepositus neurons revealed that axons of medium sized, 'principal', cells sent collaterals to both the medial and descending vestibular nuclei. These prepositus neurons terminated exclusively on either the ipsi- or contralateral side of the brainstem. The latter pattern appeared to be correlated with the vestibular input because collateralization usually occurred on the side from which vestibular excitation was received. When HRP was injected extracellularly into the prepositus, many neurons were labeled throughout the medial and descending vestibular nuclei and to a lesser extent in the superior and ventral lateral vestibular nuclei. On the other hand, intracellular injection of HRP into axons of single secondary vestibular neurons in the descending and medial vestibular nuclei in acute and alert cats revealed that neurons which terminated in the prepositus also sent collaterals towards the spinal cord in the medial vestibulospinal tract. In many cases, the same vestibular neuron also terminated in the abducens nucleus. Similar collateralization may also exist for other secondary vestibulo-ocular neurons because many were antidromically activated following stimulation of both the prepositus and oculomotor nuclei. Those vestibular neurons that sent collaterals to the spinal cord, prepositus and abducens nucleus did so either ipsi- or contralaterally, exclusively. These data indicate that prepositus neurons receive some of the same vestibular signals as extraocular and neck motoneurons. We conclude that the above connections suggest the prepositus nucleus is intimately involved with both eye and head movement. The extensive reciprocal connections between prepositus and vestibular neurons may be important for the generation of both eye and head position and, in fact they may be necessary for providing gaze signals to other neurons, including motoneurons. Supported by USPHS Grants NS-13742, EY-02007 and Fellowship NS-05857.

1267 TWO MACRO-REPRESENTATIONS OF THE FACIAL MUSCLES IN THE PRECENTRAL GYRUS OF MACAQUE MONKEYS. EveLynn McGuinness*, Dave W. Sivertsen*, and John Allman. Vanderbilt University, Nashville, TN 37240 and California Institute of Technology, Pasadena, CA 91125.

Using a chronic preparation we stimulated with microelectrodes approximately 2000 responsive sites in the face region of motor cortex in 6 macaque monkeys (4 Macaca mulatta, 2 Macaca fascicularis). Current levels used were always less than 25 μA. The modal threshold for mimetic muscles was between 2.5 and 5 μA. Responses were extremely discrete, the usual response at threshold current levels was a small focus of movement in part of a muscle. Facial muscles cluster together into two macro-representations or domains in the posterior and anterior portions of the face region of the precentral gyrus with tongue movements represented in the intervening portion and along the lateral extent. Eyelid movements are represented at the medial edge of the face representation adjoining the representation of shoulder muscles. There is a diagonal band of jaw responses which begins laterally at the central sulcus and cuts across the surface of the gyrus in the anteromedial direction. Within both anterior and posterior domains there is local re-representation of muscle movements. This microrepresentation has been described previously (McGuinness and Allman, 1977, Neuroscience Abstracts; Kwan et al., 1978, J. Neurophysiol.). Although the domains cannot be characterized as distinct topographical representations of the entire face on the basis of the data we now have, there is a tendency for adjacent muscles to occur together and the representations may be roughly topographical within the limits set by the morphological structure of the muscles themselves. We feel that the basic microorganization is columnar; however, the columns could be either roughly cylindrical or take the form of narrow curving bands, running medio-laterally across cortex. On the basis of microstimulation alone it is difficult to differentiate between patterns produced by stimulation of frequently repeated non-contiguous zones devoted to the same muscle or narrow bands which are intersected by electrode penetrations at different points in cortex. Our results might best be characterized as two complete but not strictly topographical representations of the facial muscles which are roughly mirror-symmetrical around the tongue and possibly the eyelid. Strick (Brain Res., 1978) has reported a dual representation in the hand region of motor cortex in the squirrel monkey. Although the pattern he finds differs from ours in detail (alternation rather than reversal) the basic principle is similar.

1268 ELECTROPHYSIOLOGY OF MYOTONIC DYSTROPHY IN CULTURE. Michael Merickel, Richard Gray*, Priscilla Chauvin*, and Stanley Appel. Dept. of Neurology, Baylor Col. Medicine, Houston, TX 77030

Myotonic muscular dystrophy (MyD) is an inherited disease (autosomal dominant) which involves progressive muscular weakness and muscle degeneration. An inborn error of metabolism is expected to underly MyD. However, the specific defect has not been identified in this disorder or in any of the dystrophies. We have approached the study of MyD by utilizing electrophysiological techniques to investigate the membrane properties of muscle fibers from normal and MyD patient biopsies which are grown in a primary tissue culture system. Other investigators have attempted unsuccessfully to find morphological abnormalities in cultured MyD muscle at the EM or light microscope level which makes the investigation of possible electrical abnormalities particularly important. The cultures were prepared from muscle biopsy specimens which were trypsin dissociated using previously reported techniques (Yasin et al, J. Neurol. Sci.32:347-360 1977). Cultures were chosen for electrophysiology on the basis of morphological criteria, such as the appearance of striations, and were studied between three to five weeks after plating.

Our results have demonstrated that myotubes cultured from MyD patient biopsies have abnormalities in some of their fundamental electrical properties compared to myotubes from normal, control biopsies. However, no morphological abnormalities were observed at the light microscope level. Abnormalities in the electrical properties of MyD myotubes include: 1) significantly decreased average resting potential (-32.4 ± 2.1 mV for myotonic vs -45.2 ± 2.2 mV for control); 2) repetitive firing of action potentials when slowly released from membrane potentials hyperpolarized with respect to rest (eg., slow depolarizing ramp) while control myotubes fire only a single action potential; 3) significantly decreased outward-going, delayed rectification compared to control myotubes based on observations of steady-state current voltage plots. The decreased delayed rectification is being investigated as a cause of the repetitive firing behavior described in 2). A decreased resting potential has also been observed in intact muscle preparations by other investigators. This information in consort with our observations described above suggest that the MyD disease process is propagated in primary culture, even though it may be modified by the culturing process to some extent. Propagation of the MyD disease process in culture is particularly important because it will permit detailed electrophysiological studies to be carried out to further characterize the abnormality (ie., determination of ionic basis of resting potential decrease) as well as being an excellent system for future biochemical studies of the specific inborn error of metabolism.

1269 EFFECT OF LONG-TERM ADAPTATION TO ORAL RESPIRATION ON ELECTROMYOGRAPHIC DISCHARGE OF CRANIOFACIAL MUSCLES. Arthur J. Miller and Karin Vargervik*. Ctr.Craniofacial Anomalies, UCSF, San Francisco, California 94143.

Bilateral blocking of the nasal airway in rhesus monkeys altered the neuromuscular activity of several craniofacial muscles. Electromyographic (EMG) activity was recorded from 16 craniofacial muscles in 26 paired animals (13 experimental) during the first 6 months of adaptation to oral respiration. The craniofacial muscles demonstrated two types of EMG patterns: 1)rhythmicity with respiratory pattern; and 2) an increase in spontaneous, uninterrupted discharge (i.e., tonic).

The presence of a rhythmic discharge, its sequence within the respiratory cycle and its mode of developing its maximum discharge were assessed by rectifying and averaging the mean voltage for each craniofacial muscle and a primary respiratory muscle. Five craniofacial muscles were rhythmically active in the normal monkeys: genioglossus (5% of recorded time), dorsal fibers of the tongue (3%), levator labii superioris proprius (10%), elevator of the upper lip (13%), and dilator naris (68%). The experimental animals showed significant increase in the rhythmicity in the tongue and lip elevator muscles (non-parametric Sign Test: $\alpha < .05$). Oral respiration induced rhythmic activity in several other craniofacial muscles: geniohyoid (14%), digastric (7%), anterior temporalis (14%), and lateral pterygoid (10%). The medial pterygoid, zygomaticus and caninus were rhythmically active in 1-2 experimental animals.

Tonicity was determined by rectifying and integrating EMG activity with automatic resetting of the integrator for 10 trials over 2 hours. The intervals between resets were averaged by a digital counter for 1000 intervals, displayed on a scope raster, and computed for a first order histogram. In the control animals, tonicity was present in seven muscles: geniohyoid (45%), digastric (19%), genioglossus (57%), lip elevator (26%), caninus (37%), mentalis (63%), and anterior temporalis (53%). In the experimental animals tonicity in these muscles was not changed significantly but tonicity was induced in several other craniofacial muscles: dorsal fibers of the tongue (35%), superior orbicularis oris (25%), inferior orbicularis oris (32%), medial pterygoid (19%), and lateral pterygoid (14%). The platysma, zygomaticus and buccinator were tonically active in 1-2 experimental animals. (Supported by NIH Grant # DEO 2739).

1270 CLASSICAL CONDITIONING AND SENSITIZATION OF FLEXOR MOTOR UNIT ACTIVITY IN THE SPINAL CAT. K.E. Misulis* and R.G. Durkovic, Dept. Physiol., Upstate Med. Ctr., Syracuse, NY 13210

Decerebrate cats were made spinal by a T10 cord transection. Classically conditioned flexion reflex facilitation was elicited in the manner of Durkovic (Physiol. and Behav. 14:297, 1975). The conditioned stimulus (CS) was electrical stimulation of the cutaneous saphenous nerve at 10/sec for 1.5 sec. The unconditioned stimulus (US) was electrical stimulation of the cutaneous portion of the superficial peroneal nerve at 30/sec for 0.5 sec. Nerve stimuli recruited Aα and Aδ fibers but were below C fiber threshold. Conditioned and unconditioned responses were flexion reflexes measured by an isometric tension transducer attached to the tibialis anterior (TA) muscle tendon. In addition, single motor unit EMG was recorded by means of fine needle electrodes inserted into the free belly of the TA muscle. For conditioning animals, the US was presented during the last 0.5 sec of the CS train. For sensitization animals, the US followed the CS onset by 30 sec. In both paradigms the interval between CS presentations was 60 sec. Five pre-acquisition CS alone trials were presented initially and used as a baseline for comparison of behavior during 15 acquisition trials for both conditioning and sensitization groups. Selection of a motor unit for recording during conditioning or sensitization was based upon the discharge characteristics of the unit in response to the CS before acquisition. The criteria were such that each unit must have fired at least once during the five pre-acquisition trials, in response to any of the first 10 pulses of the CS train. Also, each unit must not have fired to more than about 50% of these stimuli. One unit was examined in each of the 20 conditioning and 20 sensitization animals.

During conditioning, tension in response to the first 10 CS pulses increased an average of 33% compared to pre-acquisition levels. The increase in tension during CS presentations for sensitization animals was 5%. Motor unit activity in response to the CS increased an average of 48% during conditioning and 8% for sensitization animals. The difference between conditioning and sensitization results was highly significant for both tension and unit recordings. For individual motor units there was no evidence of the occurrence of multiple discharges in response to any pulse of the CS train. Thus, a variation in inter-spike interval of doublets or triplets does not appear to play a role in conditioned facilitation in this preparation.

The results indicate that during classically conditioned facilitation of the flexion reflex in the spinal cat, TA alpha motoneurons have an increased probability of firing single action potentials in response to each CS pulse.

1271 MORPHOPHYSIOLOGY OF THE SUPERIOR VESTIBULAR NUCLEUS IN THE CAT AND RABBIT. AN INTRACELLULAR HRP STUDY. A. Mitsakos*, H. Reisine, and S.M. Highstein.Dept.Neurosci. Albert Einstein Col. Med.,Bronx, N.Y. 10461.

The superior vestibular nucleus (SVN) was explored with HRP loaded microelectrodes in anesthesized, paralyzed cats and rabbits. Stim. electrodes were placed in IIIrd nucleus,and on ipsilateral(Vi) and contralateral(Vc) vestibular nerves.Intracellular responses to the above stims. were obtained, HRP was injected.Animals were perfused, frozen sections reacted with $CoCl^3$-diaminobenzidine, and neurons reconstructed with the aid of a drawing tube.

Neurons responding antidromically to IIIrd nucleus stim. are central or dorsal in SVN.They receive monosynaptic EPSPs from Vi and are either unresponsive to Vc or receive disynaptic IPSPs.Axons of these cells ascend, without collaterals, in the MLF or brachium conjunctivum. These are presumably the relay neurons to IIIrd nucleus subserving vestibulo-ocular reflexes. We hypothesize that neurons receiving monosynaptic EPSPs from Vi are functionally Type 1 but should not be as deeply modulated by natural stimuli as are Type 1 cells receiving Vi-EPSPs and Vc-IPSPs.

Presumed vestibular commissural neurons are central or ventral in SVN and send their axons,without collaterals, across the midline toward the contralateral vestibular nuclei. These neurons receive Vi-EPSPs.

Central SVN neurons also project their axons, without collaterals,to the cerebellum via the brachium pontis.These neurons receive Vi-EPSPs and Vc-IPSPs.

Some neurons, ventral in SVN send their axons ventrally to collateralize in the reticular formation. These neurons receive IPSPs from Vi and Vc and are presumed to be functionally Type IV.

To date, no SVN neuron monosynaptically activated from Vi has an axon collateral within the SVN.This suprising finding implies that the SVN components of the vestibulo-ocular reflexes are organized by descrete pathways straight through the nucleus and shifts the presumptive sites for the integration of information from different planes of space to sites other than the SVN.

1272 THE MOTONEURON AS AN ENSEMBLE AVERAGER OF SPINDLE PRIMARY AFFERENT SPIKE TRAINS. G.P. Moore, R.A. Auriemma and D.G. Stuart
Dept. Biomed. Eng., USC, Los Angeles, CA 90007 and Dept. Physiology, Univ. Arizona, Tucson, AZ 85724.

The intracellular potential of medial gastrocnemius (MG) motoneurons of deeply anesthetized cats was recorded while the MG muscle itself was subjected to continuous band-limited (0-100 Hz) random passive stretches by a servo-puller connected to its tendon. Stretch amplitude had a Gaussian distribution whose rms value was approximately 100 μ. A time-averaged relationship (cross-correlation function) between the imposed length change and the afferent spike train was computed for several different spindle primaries. This function is proportional to the averaged length signal preceding a spike and invariably includes a shortening-lengthening sequence. Its transform in the frequency domain is suggestive of a system sensitive to rate of change of muscle length. Since MG motoneurons are known to receive monosynaptic input from a large percentage of MG primary spindle afferents, the motoneuron potential might be expected to reflect the instantaneous behavior of the ensemble of primary afferent discharge. When the transmembrane potential of MG motoneurons was correlated with the random length signal the resulting functions were nearly identical in waveform to the correlation functions obtained from individual afferents using the same input. Given the characteristics of the input signal, the correlation function provides an estimate of the average change in afferent firing probability and in motoneuron membrane potential which would follow an impulse change in MG length, an input roughly equivalent to a tendon tap. Under these particular experimental conditions, therefore, the motoneuron appears to act as a constant gain element whose input-output gain characteristics are largely derived from the frequency characteristics of spindle primary afferent discharge (a contribution from spindle secondaries with similar characteristics cannot be excluded). We have demonstrated, therefore, that the response of a single motoneuron averaging an ensemble of spindle primary afferent spike trains from its own muscle can be almost indistinguishable from the time average of the response of a single primary afferent.

1273 EXCITABILITY CHANGES IN SPINAL CORD MOTONEURONS DURING ACTIVE SLEEP. Francisco R. Morales* and Michael H. Chase. Departments of Physiology and Anatomy and the Brain Research Institute, UCLA, Los Angeles, CA 90024.

During active sleep there is suppression of the tone of the somatic musculature. We have observed that this hypotonia (or atonia) is accompanied by sustained membrane hyperpolarization in antidromically identified lumbar motoneurons. In the present study we examined changes in excitability of these motoneurons during active sleep as compared to quiet sleep. Experiments were carried out in undrugged, normally respiring cats employing the technique described by Morales and Chase (Intracellular Recording of Lumbar Motoneuron Membrane Potential during Sleep and Wakefulness, Exp. Neurol., 62:821-827, 1978). The excitability of lumbar α-motoneurons was evaluated (1) by studying the degree of soma-dendritic invasion of antidromically propagated action potentials, and (2) by examining the response of these cells when depolarizing currents were passed through the intracellular microelectrode. Antidromic invasion was studied in 15 cells by delivering short duration, low intensity stimuli to a hind limb peripheral nerve. Intrasomatic records showed that the B (soma-dendritic) spike was either delayed or completely blocked during active sleep. The A (initial segment) spike occasionally exhibited phasic reductions in amplitude. In 11 cells there was an average increase in rheobasic current of 255% (range: 160 to 380%) when active sleep was compared to quiet sleep. This elevation in threshold for unitary spike generation was paralleled by a corresponding increase in threshold for repetitive discharge. These findings indicate the presence of potent postsynaptic inhibition of final common pathway motoneurons during active sleep.

1274 CHANGES IN SHORT AND LONG LOOP REFLEXES BEFORE VOLUNTARY MOVEMENTS IN MAN. James A. Mortimer, David D. Webster* and Thomas G. Dukich*. Geriatr. Res. Educ. Clin. Ctr., VA Med. Ctr., and Dept. Neurol., Univ. of MN, Minneapolis, MN 55417.

Changes in the magnitudes of short and long latency EMG responses to step increases in load prior to the initiation of a ballistic flexion movement were studied in 8 persons with normal motor function (23-35 yrs). Torques were applied to subjects' forearms through a horizontal support coupled to a pair of DC torque motors. EMG was recorded from bipolar surface electrodes over the biceps and triceps muscles. Subjects were asked to maintain a 90° elbow flexion against a steady 2 Nm load tending to extend the forearm, and instructed to respond to a 2.9 KHZ tone by flexing the forearm as quickly as possible. Torque pulses of 2 Nm amplitude and 500 ms duration tending to extend the forearm were presented at 8 different "delays" relative to the tone (50 and 25 ms prior, at the same time, and 25, 50, 75, 100 and 125 ms following tone onset). For each delay 20 torque pulses were given, and the tone was presented without torque perturbation on 20 trials. EMG responses corresponding to the 9 modes of stimulus presentation were sorted and averaged by computer with torque and position. The average EMG response to the tone in the absence of torque pulses was subtracted from the average EMG responses for each time delay to obtain the response to the torque pulse at that delay. Motor response indices were then calculated by integrating the rectified EMG waveforms from 25 to 50 ms and 50 to 75 ms following the onset of the torque pulse. The two indices thus obtained correspond approximately in time to the M1 and M2 components described by Tatton and Lee.

Reaction times measured from the onset of the tone to the earliest change in the EMG averaged 110 ms. No substantial change was seen in the biceps M1 or M2 index for delays prior to 50 ms following the tone. A large increase in the M2 index occurred at a torque pulse delay of 50 ms and persisted approximately 75 ms. Since the M2 index is computed on the basis of activity beginning at 50 ms, the increase in its magnitude occurs 100 ms following the tone or approximately 10 ms preceding the EMG response to the tone. By contrast, the earliest average change in the M1 index was not seen until 125 ms following the tone or approximately 15 ms after the beginning of the voluntary EMG response. This difference in latency for changes in the M2 and M1 indices was evident in 6 of 8 subjects. In the other 2 subjects, no increase in the M1 or M2 indices occurred before 150 ms following the tone.

The results are consistent with modification of the gain of a pathway mediating the M2 response at a level higher than the spinal cord. Changes in the M1 index may be related to motoneuronal facilitation accompanying the voluntary EMG response.

1275 FRONTAL LOBE INPUT TO PRIMATE MOTOR CORTEX. Kamel F. Muakkassa* and Peter L. Strick. V.A. Med. Ctr. and Depts. of Neurosurg. and Physiol., SUNY-Upstate, Syracuse, NY 13210.

There is both controversy and confusion concerning the location of "premotor" areas in the frontal lobe which have direct access to the motor cortex. Our experiments sought to define more clearly the origin of frontal lobe inputs to face, arm and leg areas of the primate motor cortex (area 4). Small single or multiple injections of 30% HRP were made into the face, arm or leg areas in the motor cortex in 11 monkeys (M. mulatta and fascicularis). In 5 of these animals the injections were placed after arm, face or leg areas were mapped using intracortical microstimulation.

HRP injections into area 4 (face, arm or leg) resulted in retrograde labeling of neurons in four spatially separate regions of the frontal lobe. For example, HRP injections into the leg area of motor cortex resulted in labeling of neurons in: 1) the superior limb of the arcuate sulcus (caudal bank), 2) the medial bank of the superior precentral sulcus, 3) the supplementary motor area (SMA), caudally, and 4) the ventral bank of the cingulate sulcus, caudally. Labeled neurons were found in both deep and superficial cortical layers. The size of labeled neurons in layer III, where the highest density of labeled neurons was found, varied considerably and included small and large pyramidal cells.

Each of the four "premotor" areas in the frontal lobe is somatotopically organized. HRP injections into the face area of motor cortex resulted in labeling of neurons in: 1) the inferior limb of the arcuate sulcus (caudal bank), 2) the lateral bank of the inferior precentral sulcus, 3) the SMA, rostrally, and 4) the ventral bank of the cingulate sulcus, rostrally. HRP injections into the arm area of the motor cortex resulted in labeling of neurons in the four "premotor" areas between the regions labeled following the face and leg area injections.

Of the four "premotor" areas the greatest density of labeled neurons was always found in the arcuate and SMA regions. Labeled neurons were also seen in the motor cortex and the four "premotor" areas contralateral to the injection sites.

Thus, our results demonstrate four somatotopically organized "premotor" areas in the frontal lobe which project directly to the motor cortex of both hemispheres.

1276 ABNORMAL SPINAL REFLEXES CONTRASTED IN CEREBRAL PALSY AND ADULT CNS INJURIES. Barbara M. Myklebust*, Richard D. Penn, Gerald L. Gottlieb, Gyan C. Agarwal*. (SPON: RD Penn). Dept. Neurosurg., Rush Med. Coll., Chicago, IL 60612.

The EMG activity evoked by sudden perturbations at the ankle differ in normal subjects, cerebral palsy (CP) patients, and patients with adult-onset damage to the CNS. In the normal adult, dorsiflexion produces a stable myotatic reflex in the stretched triceps surae (TS) muscle at 40-45 ms, while the anterior tibial (AT) muscle remains electrically silent. Plantarflexion evokes a much more variable response in the stretched AT muscle at 80-120 ms, while the TS group is silent.[1]

Thirteen of 14 patients (ages 7 to 27 years) with spastic CP with or without athetosis showed simultaneous responses, at the latency of the myotatic reflex, in the antagonistic AT and TS muscles following forced dorsiflexion. Plantarflexion evoked an abnormally early response (40-45 ms) in the AT muscle. The one patient who did not show this pattern was the only subject who was independent in ambulation and able to participate in sports.

Eight patients (ages 18 to 57 years) were tested who had adult-onset injuries to the CNS, including multiple sclerosis, stroke, incomplete spinal cord transsection, and head trauma. As with the CP patients, clinical evaluations demonstrated hyperreflexia and increased tone in all cases; clonus was frequently present. Seven patients demonstrated an abnormally early response in the AT muscle with plantar stretch, but they did not have co-activation of AT and TS muscle following dorsal stretch. In one patient who had several strokes during the 25 years prior to testing, dorsiflexion elicited coactivation of antagonists.

These results confirm that patients with spasticity have abnormal spinal reflexes; while the clinical signs may be similar in patients with cerebral palsy and adult-onset CNS injuries, the evoked spinal reflexes are different in these two types of patients. The time of onset of injury with respect to the maturation of the CNS may be a significant factor in the development of coactivation of antagonistic muscle groups. Finally, cerebral palsy is a disorder of the brain and of the spinal cord, which may involve abnormal spinal circuitry resulting from a CNS insult during the perinatal period.

Supported by United Cerebral Palsy Education and Research Foundation.

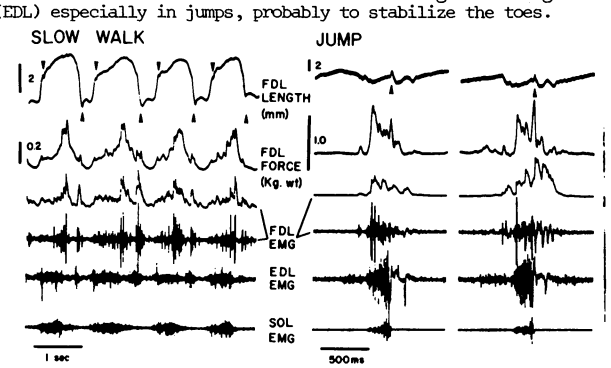
1277 THE INTEGRATION OF BALANCE POSTURAL ADJUSTMENTS INTO THE WALKING ACTIVITIES OF NORMAL HUMAN SUBJECTS. Lewis M. Nashner. Neuro. Sci. Inst., Good Samaritan Hosp. & Med. Cntr., Portland, OR 97209.

This experiment is the first of a series which will examine the neural processes integrating stabilizing postural adjustments into the locomotor activities of human subjects. The six degree-of-freedom platform (used previously for stance postural studies) has been incorporated into a walkway so that the trajectory of the support leg could be perturbed unexpectedly in a number of different ways and at different phases of the step cycle. The EMG adjustments occurring within the interval 100-175 ms after the onset of perturbations were found by calculating the difference between the EMG waveforms of perturbed and unperturbed trials.

The patterns of EMG adjustments of four leg muscles, gastrocnemius and tibialis anterior of both legs, were statistically consistent among six subjects tested. The organizational characteristics of them can be summarized as follows: Stabilizing adjustments elicited by perturbing the support leg during the mid-stance phases of the step cycle (the leg carries the full vertical load) were organizationally similar to those elicited by the imposition of comparable platform perturbations during quiet stance. In contrast, only perturbations imposed upon the leading leg elicited EMG adjustments during the double-support phases of the step cycle, and the adaptive characteristics of those adjustments were quite different than those evident during quiet stance or the mid-stance phases of locomotion.

1278 FORCE PRODUCTION, LENGTH CHANGES AND EMG ACTIVITY IN FLEXOR DIGITORUM LONGUS (FDL) MUSCLE DURING WALKING AND JUMPING IN UNRESTRAINED CATS. M. J. O'Donovan*, R. P. Dum and R. E. Burke. (Spon: K. Frank) Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205. The FDL muscle in cat acts on the distal phalanx to plantar flex the toes and protrude the claws. Since its motor unit organization (Dum et al., Neuroscience Abstr. 4:294, 1978) differs somewhat from the ankle extensors for which force data have been reported (Walmsley et al., J. Neurophysiol.41:1203, 1978), we used similar methods to study FDL output in intact cats. In addition to force and EMG recordings (ibid.), we measured length of the FDL proper with a mercury-in-silastic transducer attached to the tibia near the origin of FDL fibers, with the distal end sewn onto the FDL tendon of insertion. All leads came to a connector on the cat's back and data was recorded on FM magnetic tape synchronized to videotape records of the animal's movements. Gauges were calibrated in situ under anaesthesia. During walking (below left), FDL force peaks at less than 20% of maximum tetanic output (1.5 - 2 kg) during the last 1/3 of stance, after a period of active lengthening. A 2nd burst of EMG activity often occurs at the end of stance as FDL rapidly shortens,producing positive work around toe liftoff (upward arrow; downward arrow denotes toe touchdown). Jumping involves both larger force peaks from FDL (1 kg; below right) and smaller length changes than during treadmill walking. FDL force suddenly rises as the foot begins to extend (start of soleus(SOL) burst) and peaks again as the toes lift off (arrow). There is co-contraction of FDL and extensor digitorum longus (EDL) especially in jumps, probably to stabilize the toes.



1279 VISUALLY INDUCED ADAPTIVE CHANGES IN OCULOMOTOR CONTROL SIGNALS. L. M. Optican* and F. A. Miles. Lab. Neurophysiol., NIMH, Bethesda, MD 20205.

The neural commands underlying saccadic eye movements have two components: a dynamic component, or pulse (p), which rapidly moves the eye to a new orbital position, and a static component, or step (s), which then holds it there. If these two components are not appropriately matched the eye drifts away from the new fixation point. Such post-saccadic drift is evident in patients with VIth nerve palsies of recent origin (Kommerell et al., Invest. Ophth., '76) and in monkeys recovering from surgical detachment of the extraocular muscles (Optican & Robinson, Soc. Neurosci., '77), but is corrected over a period of days. This has led to the suggestion that an appropriate match between the pulse and step components is maintained by an adaptive mechanism which responds to the post-saccadic slip of the retinal image. We sought to determine whether post-saccadic retinal slip alone was sufficient to elicit this adaptation. Experimental subjects were two rhesus monkeys. Each was seated, with its head fixed, before a translucent screen (subtending 100° x 100°) on which a densely featured image was back-projected. A servo-controlled mirror galvanometer in the projector's light path allowed the scene to be moved horizontally under computer control. The animals' eye movements were monitored with the Robinson search coil method and fed into the computer. Immediately after each saccade, the computer caused the scene to drift horizontally, with an exponential time course (40 ms time constant), by an amount equivalent to 45% of the amplitude of the horizontal component of the saccade. In some experiments the scene was made to drift in the same direction as the saccade and, in others, in the opposite direction. After several hours of this optically-imposed post-saccadic slip, both monkeys developed post-saccadic ocular drift which was always in the same direction as the imposed visual drift and was evident both in the dark and when the animals viewed a stationary visual scene. The pulse-step mismatch (psm), defined as $[(p-s)/p]100\%$, was used to provide an estimate of the animals' post-saccadic drift: positive values indicate backward drift, negative values, forward drift. Before exposure to the stimulus, the mean psm was -0.3 $\pm$ 1.9% (N=48). After 8 hours of exposure to opposite-direction slips the mean psm was 5.5 $\pm$ 2.3% (N=58, range 0.6 to 10.3%) and the mean psm following same-direction slips was -10.0 $\pm$ 4.6% (N=60, range -2.8 to -23.1%). The time constant of the ocular drift was similar in both situations, with a mean of 69 $\pm$ 25 ms (N=39). We conclude that the step components of saccadic eye movements are matched to the pulse components by adaptive mechanisms which, at least in part, sense post-saccadic retinal image slip.

1280 VESTIBULO-OCULAR REFLEX (VOR) IN THE SQUIRREL MONKEY: EFFECTS OF HORIZONTAL CANAL (HC) INACTIVATION. G. Paige* (Spon: J.M. Goldberg.) Dept. Pharmacolog. & Physiolog. Sci., Univ. Chicago, Chicago, IL 60637.

Eye movements in squirrel monkeys were recorded, in darkness, before and after unilateral HC inactivation, obtained by a plugging procedure (Money & Scott, 1962). Monkeys were rotated sinusoidally in the HC plane, within a bandwidth of .01-4.0 hz, and at constant amplitude (40^o/sec). Amplitude intensity series ($40-360^o$/sec) were presented at .02 and .2 Hz.

In normal monkeys, VOR gain is relatively flat and averages .8 over the recorded bandwidth. Phase lead (re velocity) is near 0^o from 4. to .1 Hz, increasing to near 45^o at .01 Hz. The effective time constant (T_e) of 17 sec is 2-3 times greater than that typical of peripheral vestibular afferents (Goldberg and Fernandez, 1971). Intensity series data display gain and phase linearity at .2 Hz. Phase lead at .02 Hz decreases from ~25^o at 40^o/sec to ~12^o at 120^o/sec, with little further change at higher amplitude. No gain change accompanies this effect.

Recordings made within 2 days of HC plugging indicate that VOR gain is near 50% of normal. Gain and phase linearity is normal. Spontaneous nystagmus (SN), with slow phase ~10^o/sec to the plugged side, is always present.

During the month following HC plug, three signficiant modifications of the VOR are observed: a) generalized gain recovery (to ~75% of normal); b) increased low frequency phase lead (.01-.05 Hz), usually accompanied by gain reduction, such that T_e is reduced to near that of peripheral afferents; and c) SN is greatly reduced.

Animals recovering from HC plug in a normal cage environment display most of the observed modifications during the first week. If either vision or head movement is prevented during this time, gain remains virtually fixed. However, reduction in T_e is always observed. SN is still present and is often enhanced or erratic.

Recordings from peripheral afferents of HC-plugged monkeys are consistent with the notion that the canal plug effectively eliminates canal function, leaving tonic vestibular input intact.

1281 STABLE SIMULTANEOUS SINGLE UNIT RECORDINGS FROM GROUPS OF MOTOR CORTICAL NEURONS IN THE UNANAESTHETIZED AND UNRESTRAINED CAT. C. Palmer*, M.J. Bak, G.M. Dold* and E.M. Schmidt. Lab. of Neural Control, NIH, Bethesda, MD 20205.

Simultaneous recordings of nearby single neurons in the forelimb area of cat motor cortex have been obtained on closely spaced microelectrodes in the freely moving animal during a variety of movements and manipulations. The microelectrodes, modified from a previous chronic electrode design in use in this laboratory (Salcman, M., Bak, M.J. Med. Biol. Eng. 14:42-50), consisted of prefabricated groups of 2 or 3 electrodes with intershank distances of from 200 μ to 75 μ and lengths of 1.1 to 1.5 mm to record in laminar V. The location of the forearm area was established during surgery using cortical surface stimulation. Stimulating electrodes were implanted in the pyramidal tract to identify PT neurons. All the electrode locations were later histologically confirmed. Unit activity was monitored with muscle electrical activity (EMG) from four forelimb muscles, biceps brachi (BIC), triceps brachi (TRI) palmaris (PAL) and extensor digitorum communis (EDC), the elbow angle was recorded with a saline filled length gauge. The data was recorded on tape synchronized with videotape records of movements. The animals were also implanted with indwelling intra-jugular cannulas, so that each unit's sensory field could be confirmed under light barbiturate anaesthesia. Fig. 1 shows 2 units recorded on microelectrodes 120 μ apart, during free fall from a height of 40 cm. Foot contact was obtained with a plate containing a piezoelectric crystal. Both units had cutaneous input from the lateral margin and dorsum of the foot pad yet the units were relatively silent during foot contact indicating that in certain movements there may be gating of sensory input to the motor cortex.

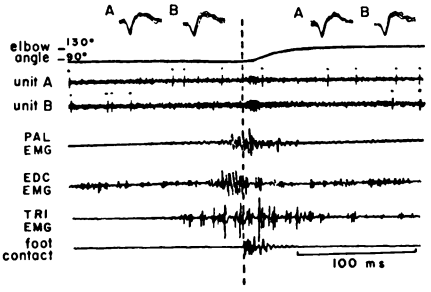

Fig. 1. 2 cortical units A and B, at the top of each section shown unit shape is before and after foot contact (----).

1282 EFFECT OF MIDBRAIN LESIONS ON VESTIBULO-NECK REFLEXES. Costas Pappas* and John H. Anderson. Depts. Phsl., and Otolaryngol., Sch. Med., Univ. of Minn., Minneapolis, MN 55455.

The control of head posture is important for stabilizing gaze and whole body posture relative to gravity. For this, vestibular reflexes which are dependent upon stimulation of the vertical semicircular canals and otolith organs play a major role. In order to quantitate the vestibular contributions, one can define the relation between input accelerations and the neck muscle (EMG) responses in restrained animals. Recently, Anderson and Pappas (Soc. Neuro. Abst., 1978) have attempted this, more specifically to characterize the overall reflex dynamics in alert, restrained cats during sinusoidal roll and pitch rotations. The results indicated a) both vertical canal and otolith inputs make significant contributions to the motor responses and b) both "direct" and "indirect" pathways must be involved. Regarding the latter, it should be noted that after chronically sectioning the descending MLF (2-8 day prior to recording), it has been found that there is a profound disturbance of the reflex dynamics: For low frequency (less than 0.15 Hz) pitch rotations the phase of the muscle response regarding angular acceleration shows much less of a lag, approaching that of the canal afferents themselves (Anderson and Pappas, European Neuro. Soc. Abst., 1979). Compared to normal, this indicates that a response to the otolith inputs and to a neural integration of the canal inputs was reduced.

To account for this we postulate that the midbrain reticular formation, i.e., the region of the interstitial nucleus of Cajal (INC) and the rostral interstitial nucleus of the MLF, is necessary for the proper convergence of otolith and canal inputs and for the neural integration of vertical canal inputs (Pola and Robinson, J. Neurophysiol. 41:245-259, 1978). The processed signals could possibly then be carried over the interstitial-spinal or MVST pathways in the MLF. As a first test of this, we made bilateral, electrolytic lesions in the region of INC in 4 cats. 2-8 days thereafter we recorded the neck EMG responses of the biventus cervicus muscle when that cats (alert, restrained, and blindfolded) were subjected to sinusoidal pitch rotations. The results from all these animals (throughout the 8 day period) were similar to that of the MLF lesioned cats: For low frequency the EMG showed much less of a lag, e.g., 80-110 deg at 0.15 Hz instead of 130-140 deg in the normal. At the higher frequency (1.0-3.0 Hz), the phases were approximately normal. These data thus do provide some support for the proposed role of the midbrain nuclei. To further test this, experiments are now in progress whereby we are attempting to selectively destroy only the neuron populations, leaving fibers in passage undisturbed, by using the neurotoxic agent, kainic acid.

1283 DOUBLE REPRESENTATION OF THE DISTAL FORELIMB IN CAT MOTOR CORTEX: ANATOMICAL AND PHYSIOLOGICAL DEMONSTRATION, C.L. Pappas* and P.L. Strick, (SPON: J.B. Preston) Depts. of Physiol. and Neurosurg., SUNY-Upstate and V.A. Med. Ctr., Syracuse, N.Y. 13210

The representation of body parts in the motor cortex has been traditionally expressed as a distorted map of the body displayed on the cortical surface. In this map, each body part is represented only once. The results of recent experiments have questioned the concept of a single representation of body parts.

Using intracortical microstimulation (ICMS), we have found two spatially separate representations of the distal forelimb in area 4γ of the cat motor cortex. The two representations were most clearly seen in maps of digit responses. Two "digit zones", where ICMS at threshold evoked contractions limited to digit musculature, were seen in all animals tested. Although their absolute location varied, the two "digit zones" were always separated by a field from which responses of more proximal musculature were evoked. In some animals separate wrist zones also could be demonstrated adjacent to each "digit zone". Shoulder representation tended to surround the areas where more distal responses were evoked. EMG monitoring during ICMS demonstrated that the same digit muscles could be represented in both "digit zones".

We next sought to anatomically demonstrate the two digit representations. A number of anatomical studies have demonstrated that callosal connections originate from all areas of the motor cortex except those which contain the representation of distal musculature. We reasoned that the shape and location of distal forelimb representation in area 4γ ought to be revealed by the absence of callosal connections. We reexamined the origin of callosal connections in area 4γ of the cat motor cortex using retrograde transport of HRP. Two spatially separate "callosal holes", where labeled neurons were either absent or of markedly low density, were found within the forelimb region of area 4γ. While the absolute location of the "callosal holes" varied among animals, the holes were consistently separated and surrounded by areas with many labeled neurons.

To provide direct evidence that the "digit zones" fall within "callosal holes", we combined ICMS and EMG recording with retrograde transport of HRP in 3 animals. A small lesion was made in each physiologically defined "digit zone" in cats previously injected with HRP into the contralateral motor cortex. The lesions were found within the anatomically defined "callosal holes".

In summary, a double representation of the distal forelimb can be defined in area 4γ of the cat motor cortex using both anatomical and physiological methods.

1284 MOTOR UNIT PROFILE OF MOUSE SOLEUS. David J. Parry* and Donald M. Lewis* (SPON: K. C. Marshall). Dept. Physiol. Univ. of Bristol, England.

Studies on single motor units have revealed a rather good correlation between mechanical properties and histochemical fibre type. (Edstrom & Kugelberg, 1968; Burke et al., 1973) The mouse soleus does not show the fibre type composition characteristic of this postural muscle in other species. It contains only about 40% of fibres exhibiting staining properties of type I fibres i.e. low alkali-stable myofibrillar ATPase coupled with high oxidative enzyme activity. The remaining fibres are also high in oxidative capacity but stain darkly for ATPase. These latter fibres have variously been labelled red, C, IIA, FOG, or II_{ox}, and appear at least in the cat, to be relatively fatigue resistant, fast-twitch fibres. (FR type of Burke et al., 1973.) We have examined the motor unit profile of soleus muscles of normal mice of the strain C57 Bl/6J, employing conventional ventral root splitting techniques. Mean motor unit size, expressed as a % of whole muscle twitch tension was about 5% (range 2.2 to 10.5%), suggesting that the muscle contains about 20 motor units. No correlation was found between the size of units and their times to peak tension. The time to peak tension of whole soleus muscles range from 13.1 to 21.6 msec and in 45 motor units a flat distribution with range of 7 to 37 msec was obtained. No evidence of a division into two groups of fast and slow units as observed by Close (1967) in rat soleus was observed. 32 of the 45 units (i.e. about 70%) had times to peak of less than 20 msec, the upper limit of the faster group of units seen by Close in rat soleus.

1285 SOMATOTOPY IN DEEP CEREBELLAR NUCLEI REVEALED BY ACTIVE MOVEMENT OF INDIVIDUAL JOINTS. J. Gavin Perry* and W. Thomas Thach. Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

A method was developed for examining somatic representation in motor systems. Monkeys were trained to make rapid alternating movements of the lower leg and each of four joints of the arm. Every eight alternations, the monkey was rewarded with juice and his mouth would perform a sixth (licking) movement. Colored lights informed the monkey as to which joint to move and when. Monkeys were over-trained (10 months) and therefore made the minimum movement (as determined by EMG) necessary to obtain a reward. EMGs were recorded from 30 muscles over one side of the body while the monkey performed the task. This was done before and after a three month period of unit recording. The EMG data showed that the different movements involved different muscles and that the movements were constant from day to day except for a slight slowing towards the end of the experiment.

Single units of both the dentate and interpositus nuclei were recorded while the monkey performed the task. Over a three month period nearly 640 units were recorded in 63 penetrations in one monkey. Discharge from every unit large enough to isolate was recorded on tape along with electrical signals representing flexion and extension timing for each movement.

Of 22 penetrations through the dentate nucleus, 9 contained units related to mouth movements. These were all clustered in the posterior half of the nucleus. Two penetrations in the anterior third of dentate contained only leg related units. Another 5 penetrations in the anterior third contained some units related to leg only, and others to arm and leg movements. The remaining penetrations across the middle third of the nucleus contained units related to the various arm movements. Although clusters of units relating to a specific joint were seen, there was no obvious somatotopic mapping of the proximo-distal dimension in this experiment.

Interpositus was similar to dentate, with mouth units posterior and leg and arm units anterior. Further experiments with better control of movements may reveal finer grain somatotopic representation in these nuclei.

1286 INTERACTION OF VESTIBULAR AND NECK REFLEXES IN CONTROL OF NECK MUSCLE ACTIVITY. B. W. Peterson, J. H. Fuller, G. Bilotto and V. J. Wilson. The Rockefeller University, New York, N.Y. 10021.

Reflex stabilization of the head during angular rotations in the horizontal plane was studied in precollicular decerebrate cats with their heads tilted 28° forward from the stereotaxic plane in a holder that allowed rotation of the head about a vertical axis passing through the C_1-C_2 joint. Head angular rotation or torque about this axis was measured together with EMG activity of neck muscles that produce horizontal head movement (obliquus capitis inferior, splenius, complexus). Rotational movements were modulated either by single sinusoids or by sums of 8 sinusoids with frequencies ranging from 0.01-2 Hz.

Two reflexes were found to contribute to stabilization of the head in the horizontal plane: the vestibulocollic reflex (VCR) and a neck-neck reflex (NNR) in which neck rotation induced compensatory contraction of neck muscles. When the VCR was elicited alone by whole body rotation with the head fixed, it caused EMG activity like that observed by earlier workers (eg: 114° lag between leftward angular acceleration and peak activity of right muscles at 0.2 Hz) while head torque lagged 10° behind EMG. When the head was allowed to move during body rotation, compensatory head rotations occurred which lagged 162° behind acceleration at 0.2 Hz. Although the amplitude of head rotation was always less than half that of the turntable stimulus, EMG amplitude decreased by as much as 80%.

The NNR, measured in isolation by rotating the body upon a stationary head, behaved as a first order lead system. At 0.2 Hz and below, maximum activity of right neck muscles was in phase with peak leftward deviation of the neck (ie: rotation that lengthened the right neck muscles). Above this frequency phase advanced and gain increased. The NNR therefore acts as a "neck stretch reflex" which in the present situation counters movement of the head relative to the body. A stretch reflex of the neck musculature has been described by Bizzi et al. (J. Neurophysiol. 41:542-56, 1978) in the alert monkey where, however, it made only a minor contribution to compensation for loads applied to the moving head. In our preparation the NNR was an important factor in the large decrease seen in neck muscle activity during body rotation with the head free. It also appears to contribute significantly to opposing movement of the head on a fixed body where the NNR and VCR work together. The high reflex resistance to movement in this latter situation suggests that the combined action of the NNR and VCR may be important to compensate for inertial and mechanical instability of the head-neck system.

1287 PATTERNS OF POSTURAL SUPPORT DURING LIMB MOVEMENT. A. Polit* and J. Massion*(SPON: E. Bizzi)C.N.R.S. I.N.P. Marseille, France

When a standing quadruped makes a limb movement, a change in posture occurs which permits the execution of the movement without loss of balance. Previous work has shown that when the limb movement is triggered by a tactile/proprioceptive stimulus on a leg the weight supported by both the stimulated forelimb and the contralateral hindlimb decreases while that in the other diagonal pair increases. This pattern has also been observed in dogs making hindlimb or forelimb movements[1] and has been observed during stimulation of motor cortex in cats.[2] Several lines of reasoning suggest that this pattern is organized at bulbo-spinal levels as are those for locomotion.

Five cats were used in these experiments. The animals were trained to stand quietly with their paws on platforms which measured vertical force. Moveable platforms, right and left, were used to elicit a placing reaction by a forelimb. The animals were also conditioned to lift either forelimb on command using a preparatory tone followed by a beeping tone and flashing light to trigger the movement. The pattern of postural adjustment during this type of movement was different from that during placement: weight transfer was primarily between the forelimbs, although there was sometimes a symmetrical increase in weight under the hindlimbs. Placement movements elicited after training the cats to lift on command tended to be less diagonal and approached the pattern observed for conditioned movements.

In 3 cats the motor cortex was electrically stimulated shortly after the signal eliciting a movement was presented. Cortical points in the forelimb area were used. The pattern of postural support accompanying the stimulation-induced movement was less diagonal when the lifted limb was the one that was to be used in the conditioned movement than when the stimulation-elicited lift involved the contralateral limb. This response asymmetry disappeared during control sessions in which the cat was required only to stand quietly.

These experiments suggest that postural commands accompanying movement target final positions not only for the cat's center of gravity, but also the torsion on the vertebral column, and that a "tuning" of the output circuits preceeds overt movement. In addition, the use of conditioned movements in a postural context provides an interesting approach to the study of mechanisms by which new patterns of postural support are acquired.

1288 CONTRIBUTION OF INTRAFUSAL VISCOELASTICITY TO MUSCLE SPINDLE ADAPTATION. R. E. Poppele, D. Quick*, and W. R. Kennedy. Lab. of neurophysiology and Dept. of Neurology, University of Minnesota, Minneapolis, MN 55455

Adaptation of muscle spindles to stretch is thought to be largely due to a viscoelastic relaxation of the intrafusal muscle bundle. Indeed, it has been shown that dynamic bag fibers (bag_1) in particular do exhibit such viscoelastic relaxation following a quick stretch. This is a mechanical adaptation which will result in a phase lead in the response of the receptor to sinusiodal stretches, a fact which provides an opportunity to determine whether the mechanical adaptation is quantitatively adequate to account for receptor adaptation. Measurements of the phase lead of responses to small amplitude sinusiodal stretches were made in isolated cat tenussimus spindles. Strain (or the change in length per unit length) across the primary sensory area of bag fibers was plotted as a function of time along with the primary afferent discharge rate for applied stretch frequencies from 0.05 to 2 Hz. The results suggest that only a portion of the phase lead exhibited by the primary afferent can be accounted for by muscle viscoelasticity. The maximum phase lead of sensory strain occurs in the neighborhood of 0.2 Hz where it is still approximately 30^{o} less than the phase lead exhibited by the primary output. At 1.0 Hz, the sensory strain is in phase with the applied stretch, whereas the primary ending output has a phase lead of 90^{o} (at 25^{o} C). Therefore if adaptation in spindle receptors is to be quantitatively accounted for by mechanical factors, these must be associated with structures within the sensory area and not with the viscoelasticity of intrafusal muscle poles.

1289 EVIDENCE FOR SKELETOFUSIMOTOR (BETA) EFFECTS DURING CHANGES IN MUSCLE LENGTH AND FORCE IN THE DECEREBRATE CAT. E.M. Post*, W.Z. Rymer, Z. Hasan*, (SPON: J. Horel). Dept. Neurosurgery, SUNY-Upstate, Syracuse, N.Y. 13210.

Last year we presented evidence that reflexively-induced increases in isometric spindle receptor discharge rate occurring after extrafusal threshold was reached could be attributed to beta fibers. To better appreciate the nature of beta effects, an understanding of their action during changing muscle length and force is necessary. The purpose of this present study was to identify possible beta influence on spindle receptor discharge during constant velocity stretch and isotonic shortening and to correlate these results with those isometric responses presumed to be of beta origin.

We recorded from triceps surae spindle receptor afferents in isolated dorsal root filaments of 13 decerebrate cats. Decerebrates were used so that variations in initial muscle force could be induced in a quasi-physiological manner via crossed extensor stimulation (CES). The receptor-bearing muscles were subjected to stretch with and without CES, and to reflexively-induced isotonic shortening with the muscle stretcher providing an electronically simulated load.

Of the 60 units examined with ramp stretch, 36 showed additional increases in discharge during CES. 3 response patterns could be discerned: 1) an increase in discharge during the ramp (11/36) termed dynamic type, 2) an increase in discharge during the pre- and post-ramp periods only (16/36) termed static type and 3) a combination of 1 and 2 (9/36), static-dynamic type. 10 of these 36 units showed a late rate acceleration during stretch not paralleling the unstimulated response. Since gamma fibers are relatively unresponsive to stretch, these units seemed to be the most likely candidates for beta activity. Supportive evidence for a beta contribution was provided in that 7 of these 10 units showed isometric acceleration.

Isotonic shortening was studied in 28 units. The isometric responses of these units proved to be an accurate predictor of their behavior during shortening; 6 of the 7 units that decreased their rate with increases in isometric force also showed a diminution in rate (x=8.65 ips/mm, 3.4-20.9) with shortening while 8 of the 11 units that isometrically accelerated increased their rate (x=9.38 ips/mm, 1.1-32.4) with shortening. Because beta action should induce parallel activation of intra-and extrafusal fibers, a limited decline or even an acceleration in rate during shortening would be anticipated.

It appears that identification of beta fibers may be possible by discerning a constellation of response patterns during isometric and dynamic states.

1290 RESPONSES OF ASCENDING TRACT OF DEITERS' (ATD) NEURONS TO NATURAL AND ELECTRICAL STIMULI. H. Reisine and S.M. Highstein. Dept.Neurosci.,Albert Einstein College of Medicine, Bronx, New York,10461.

The ventro-lateral vestibular nucleus (VLV) was explored with intra- and extracellular microelectrodes in anesthesized, paralyzed cats. Stimulating electrodes were placed in the IIIrd nucleus and on the ipsi-(Vi) and contralateral (Vc) vestibular nerves. The MLF and brachium conjunctivum (BC) were acutely severed in the pontine tegmentum. Neurons in the VLV,antidromically activated by IIIrd nucleus stimulation received monosynaptic EPSPs from Vi and disynaptic IPSPs from Vc. Neurons with the above profile of responses were injected with HRP and subsequently were invariably found to lie in the VLV.

Antidromic activation of VLV neurons was signalled by an antidromic field potential in VLV. This potential was abolished by lesions 1 mm wide between the MLF and BC in the pontine tegmentum indicating the course of the ATD.

In a second set of experiments decerebrate cats were rotated about a vertical axis in the plane of the horizontal semicircular canal. Stimulating electrodes were implanted as above. VLV neurons were isolated extracellularly and identified as ATD neurons by their antidromic responses to IIIrd nucleus and orthodromic (monosynaptic) responses to Vi stimulation. Responses of these neurons are in phase with table (head) velocity in the range of $\pm$ 30^{o}/sec. at 0.4 - 0.65 Hz increasing to ipsilateral and decreasing to contralateral rotation (Type 1 responses). This head velocity signal should be transmitted directly to medial rectus motoneurons by the ATD and undoubtedly contributes to the horizontal vestibulo-ocular reflex in intact cats. The remaining reflex following bilateral MLF lesions may be accounted for, in part, by the head velocity signal carried by the intact ATD.

1291 AVOIDANCE TRAINING OF A SUSTAINED RESPONSE AFTER DORSAL RHIZOTOMY IN RATS. Barbara E. Rodin* and Doreen Berman. Dept. Psych., Queens College of CUNY, Flushing, N.Y. 11367

It has been suggested that acquisition of movement, without sensory feedback, may occur by pairing efferent commands with feedback from environmental contingencies. However, the types of instrumental movements previously reported in dorsal rhizotomized (DR) limbs have been discrete and of short duration. Although the efferent command system alone may be adequate for the acquisition of any number of discrete movements, it is hypothesized that it would be insufficient for the acquisition of sustained responses. These presumably require a mechanism for detection of passive return of the limb to resting position. To test this, rats were trained in a shock avoidance task requiring sustained alteration in baseline limb position. Performance of unilateral DR limbs was compared with that of contralateral intact limbs.

Two groups, each consisting of eight surgically treated (T13-L6, left) rats, were used. One group was trained preoperatively with both limbs and retested a month after surgery; the other group, without preoperative experience, received initial training a month postoperatively. Half the animals in each group were trained first with the left and half with the right limb. During training, animals were suspended over an electrolyte solution, without vision of the hind limbs. An electrode for monitoring limb position was attached to one hind-foot. Whenever the electrode entered the solution, escapable shock was delivered to the trunk. Avoidance could be achieved by maintaining the position of the monitoring electrode above the surface of the solution. Number of insertions and time in solution were recorded, and animals were run to a predetermined criterion. Training sessions were twenty minutes long.

With sensate limbs, sustained alteration in limb position was acquired rapidly both before and after surgery. With DR limbs, however, acquisition of the sustained response failed to occur under all conditions but one. The appropriate response was achieved in DR limbs only when order of postoperative testing or training (to criterion) was intact limb: DR limb. Acquisition was more rapid when there had been preoperative experience in addition to contralateral limb training. However, comparing the DR with the intact limb, many more sessions were required for acquisition, and a different response topography was found. When avoidance was not achieved, animals escaped shock with the DR limb via a series of rapid discrete movements.

Sensory feedback is apparently necessary for the acquisition of sustained movements of this type in rats, unless there has been recent performance of the response by the contralateral intact limb.

1292 THE ACTIVITY OF RETICULO-SPINAL CELLS DURING LOCOMOTION IN CATS. S. Rossignol and J. Parent*. Centre de Recherche en Sciences Neurologiques, Département de physiologie, Université de Montréal Montréal, Québec, CANADA, H3C 3T8.

Reticulo-spinal cells were recorded extracellularly at the medullary and pontine levels during treadmill locomotion in precollicularly decerebrated cats. Cells were identified by high frequency antidromic stimulation through a thin silver strip inserted under the spinal cord at the level of L1. EMGs of the Quadriceps and the Triceps Radialis were recorded on both sides. The cervical vertebrae were solidly fixed and all 4 limbs were allowed to move. A good number of cells were kept for several hundred cycles allowing to record their activity at different walking speeds (walk and trot) as well as during manual blockade of one or more limbs. Of the 31 cells recorded, 27 (87%) were modulated while 4 (13%) remained silent or were silenced during locomotion. Cells discharging in distinct bursts showed a positive correlation between the burst duration and the duration of the step cycle at various speeds, indicating a relation to a component of the step cycle which changes with speed namely the stance phase, the swing phase being considered practically constant at various speeds. The peak firing of different cells in relation to the step cycle was found to vary. The stability of the firing pattern of a given cell was tested by varying the walking speed which in a number of cases changed the phase relationship between fore- and hindlimbs as well as by blocking the limbs manually. In some cells carefully analyzed by computer it was possible to show, when triggering the analysis on the EMG of one forelimb, that the firing pattern was invariant when the forelimbs were walking alone or with the right or the left hindlimb and even when the coupling changed between fore- and hindlimbs. This strong dependence of the cell discharge on the forelimbs could be seen even more clearly in some cells when blocking the forelimbs which stopped the firing although the hindlimbs continued walking. At times when the animal initiated a period of locomotion with the hindlimbs, the cells started firing only later when the forelimbs also walked. Although cells could discharge with only the forelimbs walking, the frequency of discharge often changed when one or both hindlimbs walked. The strong dependence on forelimbs of the discharge of reticulospinal cells with axons identified in the lumbar cord might suggest that they play a role in the coordination of fore- and hindlimbs during locomotion.

(Supported by a group grant of the MRC. J.P. received a fellowship from the Ministry of Education, Quebec)

1293 **Absence of Force-Feedback Contributions to the Stretch Reflex of the Decerebrate Cat.** W.Z.Rymer, Northwestern University Medical School,Chicago, Ill. and Z.Hasan, SUNY-Upstate, Syracuse, N.Y.

The reflex force evoked by stretch of the soleus muscle in the decerebrate cat is proportional to the length increment, and is largely independent of stretch velocity. It has been suggested that this spring-like behaviour arises from the combined effects of force and length feedback, derived largely from tendon organ and spindle receptor input respectively[1].

We examined the contributions of force-feedback to stretch reflex action with the help of Dantrolene sodium, an agent known to reduce contractile force via excitation-contraction decoupling. Experiments were performed in the soleus muscle of 12 decerebrate cats. The calcaneal insertion was severed, and attached to a servo-regulated muscle stretcher. Emg signals were recorded differentially using fine wires immplanted in the muscle, and the emg was rectified and filtered with 25 msec. time constant. Force and length were also measured.

In each animal, a series of stretches of constant amplitude and velocity were used to record force amd emg responses, over a range of initial forces. Initial force variations were induced via the crossed extensor reflex. The animal was then given successive 1.0 mg doses of Dantrolene intravenously, until peak twitch tension was reduced by at least 30%. The stretch reflex responses were then reexamined, again using crossed extensor stimulation to vary initial force levels. In every case, reflex stiffness was markedly reduced, yet there was no significant increase in the emg incremental response. Moreover, the lack of emg change was not a result of Dantrolene effects on muscle spindles-- the monitored response of single spindle receptor afferents showed no significant alteration until much larger cumulative doses of Dantrolene were achieved (typically greater than 5mg/kg). Were force-feedback to contribute to the spring-like behaviour, a reduction in contractile force should have been followed by an increase in emg. Since no such increase occurred, it is concluded that force-feedback contributions are insignificant in this preparation.

1294 EFFECT OF TOPICAL ANESTHESIA TO VARIOUS SKIN AREAS ON THE H-REFLEX. Mohamed A. Sabbahi*, Whitney R. Powers*, and Carlo J. De Luca (SPON: J.V. Basmajian) Dept. of Health Sciences, Sargent College, Boston University, Boston, Ma.

The H-reflex was recorded every 5 seconds with surface electrodes located over the soleus muscle, using the method of Sabbahi Awadalla (1976). The achilles tendon reflex (ATR) was elicited by an electrically activated solenoid plunger which produced strikes of equal force to the tendon, and the reflex response was recorded every 10 seconds via the same electrodes. Topical anesthetic (20% Benzocaine) was sprayed to the appropriate skin areas for 10-20 sec. and recordings were taken at time intervals for a total of 40 minutes. Anesthetic was applied to the skin overlying the calf, tibial, quadriceps and hamstring group of muscles in twelve normal subjects, and to the skin of the whole lower limb in three other subjects. The H-reflex response was recorded before (control) and after the application of the anesthetic.

The H-reflex was significantly increased in amplitude after application of the anesthetic to the skin overlying the calf, hamstring and quadriceps muscles. This reflex facilitation continued to increase for the duration of the experiment. Thirty minutes after the anesthetic was applied to the skin overlying the calf muscles the peak-to-peak amplitude of the H-reflex increased by 76%; when applied over the hamstring muscles, by 200%; and when applied over the quadriceps muscles, by 167%. The degree of reflex facilitation varied from one subject to another; in one subject it was more than 600% of the control value after 40 min. of the application of the anesthetic.

When the anesthetic was applied to the skin overlying the anterior tibial muscle, reflex inhibition was recorded. After 30 minutes, the peak-to-peak amplitude of the H-reflex was 60% of the control value. However, the degree of inhibition was less significant in the first 15 min. after application of the anesthetic.

When the whole lower limb was sprayed with anesthetic, the reflex facilitation occurred. The amplitude of the H-reflex increased by 111% after 30 minutes.

Neither the M-response nor the ATR showed significant changes after the application of the anesthetic. These results do not support the findings of Hagberth et al., 1963, but are consistent with our previous work (Sabbahi Awadalla, 1976). These results in association with the results of other studies of the H-reflex recovery curves currently in progress in our laboratory, indicate that the skin receptors modulate the H-reflex via a central mechanism. All of the skin areas of the lower limb except that directly over the antagonist muscle (Tibialis anterior), supply inhibitory inputs to the motorneurons of the calf muscles.

(Supported by a Project Hope fellowship. The anesthetic was supplied by ARNAR-STONE Lab).

1295 MOTOR CORTICAL UNIT ACTIVITY RELATED TO SEVERAL CONDITIONED HINDLIMB FORCES IN THE MONKEY. S.A. Sahrmann, M.H. Clare, and W.M. Landau. Dept. Neurol., Sch. Med., Washington U., St. Louis, Mo. 63110

Rhesus monkeys were conditioned with light signals to perform four randomly selected tasks with the hindfeet. Force was exerted bilaterally on fixed bars with attached strain gauges. The tasks were: (1) to exert a strong plantarflexion force, hold it a random time, on cue exert a strong, brief, rapid dorsiflexion force and return to rest (rapid-relax); (2) to do the converse; (3) to plantarflex into a small force window, holding until signalled to return to rest; and (4) to perform the converse of (3).

Preliminary analysis of 86 cortical cells is presented. Based on data for 200 msec. before (pre-Cn) and after (post-Cn) the achievement of force criterion, six types of cortical neurons have been identified: Plantarflexor cells (1) maximal activity occurred preceding the achievement of the required force (phasic cells, 27%), and (2) those with strong activity continuing during the hold period (tonic cells, 20%); (3) dorsiflexor phasic cells, 22%; (4) dorsiflexor tonic cells, 20%; (5) cells whose major activity related to the time of initiation of and maintenance of small plantarflexion hold, 8%; and (6) cells whose greatest firing occurred during the return to rest at the end of each task, 3%.

Average resting discharge frequency (ADF) was calculated for the 500 msec. preceding the presentation of the first signal of each task. Among plantarflexor cells, most phasic cells had low ADFs (56% less than 13/sec.) while only a few of the tonic cells had low ADFs (21%). There were higher ADFs for the majority of dorsiflexor cells (64% tonic, 73% phasic).

Phasic cells (69% plantarflexor and 87% dorsiflexor) fired faster in the initiation of the rapid-relax action than in the initiation of the hold action. During the 200 msec. post-Cn discharges continued at a faster rate (greater than 10% difference) after rapid-relax action than with hold action (64% of all cells). Less than 50% of the cells showed greater activity with a strong hold force than with a small hold force.

1296 COMPARISON OF MORPHOLOGICAL FEATURES OF FAST AND SLOW PT CELLS REVEALED BY INTRACELLULAR PRESSURE INJECTION OF HRP. H. Sakai* and C.D. Woody. (SPON: E. Eldred) UCLA Medical Center, Los Angeles, CA. 90024.

Recordings were obtained from the motor cortex of 14 awake cats using 4% HRP-1M KCl filled electrodes. Morphological features of 19 PT cells were analyzed. Eight of the cells were also injected with 1mM cGMP. Intracellular injections were made with a pressure of 60-90 psi applied for 0.5-2 sec following assessment of the response of each cell to antidromic stimulation. The cells were recovered by core biopsy. The pyramidal tract was stimulated ipsilaterally at the level of the facial nucleus (P. 8.0; L. 1.3; V. -10) using concentric, bipolar electrodes (two, 300 Hz pulses of 0.03 msec duration delivered every sec). Distance from the recording site in the coronal-pericruciate cortex to the locus of antidromic stimulation was between 4 and 5 cm. Cells which were activated antidromically with latencies shorter than 2 msec were classified as fast PT cells (N=11) with conduction velocities of at least 20m/sec. Cells activated with latencies longer than 2.5 msec were classified as slow PT cells (N=6). Two cells with latencies between 2.0 and 2.5 msec could not be classified into either group.

The following observations were made:

1) The diameters of axons measured at a level 10-20μm beyond the axon hillock were larger in the fast conducting PT cells (correlation coefficient, r=0.738 between axon diameter and conduction velocity).
2) All PT cells with somas recovered (N=17) were pyramidal cells located in layer V. Fast PT cells had larger somas (30-70μm) than did slow PT cells (18-30μm). This confirms the result of Naito et al. (Brain Res. 1969) obtained by methyl blue staining.
3) The lateral extent of the dendritic field within layer V was greater in fast PT cells than in slow PT cells.
4) Slow PT cells had high densities of spines on dendrites in layer III in agreement with Labelle and Deschenes (Brain Res. 1979), but counterstaining revealed that one-third of the fast PT cells injected with HRP without cGMP did also. Thus the density of spines in layer III was not as reliable an index for separating fast and slow PT cells as soma size and axon diameter.
5) Electron microscopic examination done collaboratively with C. Ribak, U.C. Irvine, showed dense amounts of HRP reaction product within neurons without spread of HRP into the extracellular space. Although the internal structures were obscured by reaction product, the membranes and synaptic junctions were well preserved. (Supp. by HD 05958 & E. Gruen)

1297 VOLUNTARY MOVEMENT AND EXCITABILITY OF HUMAN EYEBLINK REFLEXES. Jerome N. Sanes* and James R. Ison. Dept. Psychology, University of Rochester, Rochester, NY 14627.

This study reports on changes in eyeblink reflexes when humans perform voluntary phasic and sustained movements with either the reflex agonist or remote muscle groups. In response to a reaction stimulus subjects either briefly blinked or contracted forearm muscles or began sustained contractions of orbicularis oculi or forearm muscles. Eyeblink reflexes were elicited before and after movement. Surface electromyographic activity (EMG) was recorded from orbicularis oculi muscle and eyeblink reflexes were elicited by percutaneous shocks to the supraorbital branch of the trigeminal nerve. The reflex consists of a 12 msec latency ipsilateral response (R1) and a 30-50 msec latency consensual response (R2). A disynaptic trigemino-facial path mediates R1, a polysynaptic path through ponto-medullary reticular formation mediates R2.

Prior to both movements, at the onset of reaction stimuli R1 increased, then increased further beginning 75 msec before the reaction, peaking at 25-10 msec before voluntary EMG onset. During this period R2 was moderately suppressed. Nearly immediately following onset of phasic voluntary movement R1 was maximally enhanced and then declined almost to normal after about 400 msec. R2 was further suppressed, with a trough at 50-100 msec, and recovered by about 400 msec after movement onset. Tonic movements produced the initial R1 enhancement and also a final but considerably reduced stable facilitation; the R2 function nearly approximated that found with brisk movements. However, for tonic eyelid activity only, R2 showed a secondary potentiation peaking about 1500 msec following EMG onset.

These findings (1) partially substantiate the claim that reflex excitability is a sensitive and specific measure of pyramidal tract and other supraspinal influences on motoneuronal pools before and after voluntary movement; (2) further elucidate characteristics of reflex recovery after onset of movement; and (3) reveal differential influences of voluntary action on separable neuronal pathways. Enhancement of R1 in relation to agonist muscle activity is understandable in light of findings of pyramidal tract neuronal activity, presumed to influence the final common motoneurons, before and during voluntary movement. Changes accompanying remote muscle activity possibly reflect activity in collateral pathways or action of a more generalized motor readiness system. Reflex suppression was the predominant effect on R2, even though its final common path was potentiated, as shown by increased R1 strength. The locus of this net inhibition must lie in the longer associative pathways for R2 elaboration. Thus these data illustrate net facilitative and inhibitory effects by the same behavior on reflexes with identical afferent and efferent limbs but distinctive central pathways.

1298 FACILITATION AND SUPPRESSION OF FORELIMB MUSCLE ACTIVITY FROM SINGLE INTRACORTICAL MICROSTIMULI IN BEHAVING MONKEYS. S. Sawyer*, P.D. Cheney, R.F. Martin and E.E. Fetz, Dept. of Physiol. and Reg. Primate Res. Ctr., Univ. of Wash., Seattle, WA 98195

The effects of single precentral microstimuli on activity of 12 identified forearm muscles were documented in monkeys making active wrist movements. Stimulus-triggered averages (StTA's) of rectified EMG activity detected subthreshold facilitation and suppression of muscle activity produced by intracortical stimuli (.2 ms, biphasic), using stimulus intensities too weak to evoke overt responses (5-10 μa) and repetition rates too low to involve temporal summation (≤15/s). When applied at cortical sites of cells producing post-spike facilitation in spike-triggered averages of EMG activity, stimulus pulses evoked a pattern of post-stimulus facilitation (PStF) identical to, but more intense than the pattern of post-spike facilitation.[1] As stimulus intensities increased from lowest effective levels (ca. 1 μa) up to 10 μa the magnitudes of post-stimulus effects increased, generally preserving the relative amplitude in each muscle. Above 15 μa stimuli often affected additional muscles and evoked more complex effects. (In comparison, trains of repetitive microstimuli (400 pps; 50ms) under the same conditions evoked stronger and more widespread effects. With the monkey at rest, the threshold response to repetitive microstimuli was usually activation of the muscle which had shown the greatest PStF in StTA's.) The PStF usually appeared in several synergist muscles, even for minimal stimulus intensities. Post-stimulus suppression (PStS) was sometimes obtained in antagonists of the facilitated muscles and occasionally also in synergists. From certain cortical sites suppression was obtained without evidence of facilitation in any muscles, in both stimulus- and spike-triggered averages. The mean latency of strong PStF was 7.6±0.8 ms (mean±SD), and of strong PStS was 8.2±1.3 ms. In mapping studies 10 μa stimuli were delivered at successive points along histologically reconstructed electrode penetrations into the precentral bank. Corticospinal cells were identified by retrograde transport of HRP from cervical cord. As a function of cortical depth, the amplitudes of post-stimulus effects in different muscles typically increased and decreased together, being strongest from layer 5. In tracks tangential to layer 5 the amplitude of PStF in individual muscles exceeded half-maximal values over distances of 850±180 μm; PStS was evoked from wider zones, with a half-width of 1600±480 μm. A given muscle was often facilitated from multiple sites, usually in combination with different sets of synergists. These results suggest that output effects elicited from specific precentral sites typically affect multiple muscles and may include inhibition.[1,2]

1299 CNS SIGNAL TO MUSCLE: PARAMETERS OF MOVEMENT REPRESENTED IN EMG DURING RAMPS AND HOLDS. Marc H. Schieber* (SPON:M.H.Clare).Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

Two Rhesus monkeys were trained to perform wrist movements guided by a continuous pursuit tracking display. The target, and therefore the wrist, moved in a hold/ramp/hold track. Parameters of the target's motion were selected from preset values, directing the monkey to make a specific wrist movement for a fruit juice reward. Maintained torque load, initial holding position, ramp velocity, and final holding position were individually varied between blocks of trials while all other parameters remained constant. (Ranges: load, 0.00 to 0.24 Nt-m in either direction; position, 60° flexion to 30° extension; velocity, 8 to 29°/sec in either direction.) Bipolar electromyograms (EMGs) were full-wave rectified, digitized and integrated for analysis.

Extensor digitorum communis (EDC) was studied in greatest detail since it consistently gave the largest EMGs. Its pattern of activity was similar to that of all forearm muscles studied. During extension ramps with no imposed load, EDC showed a progressive increase in discharge as the wrist was progressively extended. This changing activity was correlated with instantaneous wrist position. Similarly, discharge during the holding periods before and after the ramp correlated with the maintained position of the wrist. EMG amplitude did not change with ramp velocity over the range tested, except when the muscle shortened against a large load. During the hold prior to flexion ramps EDC's activity was again correlated with wrist position. But during flexion ramps with no imposed load, EDC was silenced as the ramp began and remained silent until the self-paced return extension. When the monkey performed extension or flexion ramps under maintained torque loads, EDC's activity was the sum of two components: that activity present under no load; plus a maintained change in the level of activity, proportional to the load.

The representation of wrist position in EDC's activity during holds and extension ramps may be due both to the muscle working against elastic restoring forces exerted by the soft tissues of the forearm and wrist, and to the decreasing ability of the muscle to generate tension as it approaches its minimum length (length-tension relationship). The absence of a velocity representation in the EMG (except when shortening against load) implies that both the effective viscous load, and the motoneuron signal controlling velocity per se, are relatively small. No co-contraction of opposing muscles was detected in the present experiment. Nor was there any difference in muscle activity during the holding periods, dependent on the direction of the impending or completed ramp.

1300 EXCITATION AND INHIBITION OF FOREARM MUSCLES EXPLORED WITH MICROSTIMULATION OF PRIMATE MOTOR CORTEX DURING A TRAINED TASK. E.M. Schmidt and J.S. McIntosh. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Monkeys were trained to make alternate wrist flexion and extension movements against different loads at up to 6 different wrist positions. Conventional microelectrodes were used to explore the forearm area of the precentral cortex for cells that were temporally correlated to the task. The cell's sensory field, response to torque pulses, and whether or not the cell projected into the pyramidal tract was determined prior to intracortical microstimulation (ICMS) through the recording electrode. Trains of 17 stimuli (.2 ms biphasic pulses at 400 Hz and current levels to 20 μa) were delivered at specific times during the task when the motoneuron pools to the forearm muscles were involved in different phases of the movement. By applying the ICMS under the same load and movement conditions repeatable EMG responses in forearm flexors and extensors were obtained. ICMS produced a larger excitation when a movement was being initiated against a constant load than when the muscle had been opposing the same load for approximately 1 sec. The time delay between the start of the ICMS train and excitation or inhibition of forearm muscles was as short as 11 ms. Quite often when excitation was produced, a ramp increase in EMG activity was recorded as shown in Fig. 1A. This was not due to cortical reverberating circuits because the EMG activity would end abruptly 11 ms after the last stimulus pulse of the train. Areas of inhibition of a given muscle have been observed as close as 100 μm to areas of excitation of the same muscle. EMG patterns produced by ICMS have ranged from inhibition of a single muscle (Fig. 1B), inhibition and excitation of synergists, inhibition and excitation of antagonist, to excitation of single muscles. There is some indication that excitatory regions to a specific muscle are bordered by inhibitory regions to the same muscle. Experiments on additional animals are required to further explore this finding.

Fig. 1. Rectified and averaged (32 trials) EMG responses in flexor carpi radialis (FCR) to ICMS in precentral cortex. The calibration bars below the records (40 ms) indicate the time and duration of stimulation. (A) Ramp increase in EMG activity of FCR during movement. (B) Inhibition of FCR at a site 4 mm from A.

1301 PROCESSING OF CENTRALLY PROGRAMMED MOTOR COMMANDS. B.T. Shahani and R.R. Young. Clinical Neurophysiology Laboratories, Neurology Department, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts 02114

Central programs subserving the execution of stereotyped fast elbow flexion movements during a visual matching task produce a triphasic EMG pattern: an initial burst in the agonist biceps (Ag1) followed by activity in the antagonist triceps (An1) during which there is electrical silence in the agonist (Ag1-Ag2 interval) and finally a second burst in agonist (Ag2) which brings the arm to the target. The present experiment was designed to identify mechanisms at the segmental and/or suprasegmental level which could modify this "centrally programmed" EMG activity. Unloading of muscle spindles in the agonist at random intervals resulted in prolongation of the duration of Ag1 and An1 and decrease in the Ag1-Ag2 interval when a 2 kg weight was electromagnetically released 20-60 msec prior to initiation of Ag1 in seven normal subjects. With training, four subjects could overcome changes in these parameters and produce normal triphasic pattern during unloading. The timing (20-60 msec) of these changes and subjects ability to overcome them as well as their similarity to changes noted in patients with cerebellar deficits, suggests a suprasegmental site (perhaps cerebellum) for modulation of centrally programmed EMG activity.

1302 A MAPPING OF BRAINSTEM NEURONS PROJECTING TO THE SPINAL CORD IN THE GOLDEN HAMSTER. Randall C. Shults and James D. Rose. Dept. Psychol., Univ. of Wyoming, Laramie, WY 82071.

As part of an investigation into the brainstem control of estrous reflexes in the female hamster, brainstem neurons projecting to the spinal cord were identified with the horseradish peroxidase (HRP) technique. A 50% solution of HRP was pressure injected into one side of the cord at the upper cervical, lower cervical, or lumbar levels. After a three day survival period, the brains were processed by the technique of Mesulam (J. Histochem. Cytochem., 1978). Injections at all cord levels yielded labeled cells predominantly in the following regions: (1) medulla; caudal lateral tegmental field, nucleus reticularis gigantocellularis, and Deiter's nucleus, all principally ipsilaterally, as well as nucleus raphe' pallidus; (2) pons; nucleus reticularis pontis caudalis, ipsilaterally, nucleus reticularis pontis oralis, bilaterally, and a ventrolateral reticular cell group in the contralateral anterior tegmentum; (3) midbrain; contralateral red nucleus, and a few cells in the reticular formation, bilaterally. The number of cells labeled in these regions diminished progressively as a function of more caudal HRP injection placement. Relatively more neurons, especially ipsilaterally, were labeled in the medial reticular formation of the anterior medulla and caudal pons with more anterior injections. The density of contralaterally labeled cells, however, was more constant with all levels of HRP injection. In addition to labeling many more cells, upper cervical injections also resulted in labeling of some contralateral deep tectal neurons. Some neurons in the midbrain central gray and Edinger-Westphal nucleus had projections to the cervical cord.

Supported by NIH Grant NS- 13748.

1303 BEHAVIORAL RELATIONS OF MEDULLARY RETICULAR FORMATION CELLS. Jerome M. Siegel and Rebecca L. Wheeler*. Sepulveda VA Med. Ctr. and Dept Psychiatry, Sch. Med., UCLA, Los Angeles, CA 90024.

Behavioral and photographic techniques were used to determine the movement correlates of discharge in medullary RF units recorded in unrestrained cats. These cells could be divided into two major classes on the basis of the behavioral correlates of their discharge; cells with laterally asymmetrical movement relations, and cells with laterally symmetrical movement relations. Fifty-four percent of encountered cells (n=21) had laterally asymmetrical movement relations while 38% (n=15) had laterally symmetrical movement relations. The remaining cells (n=3, 8% of total) did not relate to any specific motor behavior.

The largest subgroup (n=16) of cells with laterally asymmetrical movement relations was comprised of cells related to movements of the head or vertebral column in the horizontal plane. Of these, 12 responded when the head was moved passively. In all of these cells, increased discharge was related to passive head movement to the contralateral side. None responded to passive movement to the ipsilateral side. This asymmetry is highly significant ($p<.0005$). Cells responding to passive head movement to the contralateral side did not discharge when the same movement was made spontaneously by the cat. Instead these cells discharged only when the cat turned to the ipsilateral side.

Cells without lateralized behavioral relations (n=15) could be divided into those related to head or spinal movements (n=12) and those related to other movements. Of those related to spinal movements, six discharged in relation to active forward movements of the head when it was in a lowered position, a seventh cell discharged only during active ventral movements of the lumbar spine, and an eighth discharged during fixation of the lumbar region. Four responded during spontaneous upward movements of the neck. Three of the four cells that responded to passive head movement responded only when the head was moved in a direction opposite to the optimal spontaneous movement.

The behavioral relations shown by these cells indicate that many may have a pattern of synaptic relationships that coordinates excitation and inhibition of several motoneuron pools involved in producing ipsilateral movement. The present results may reveal the cellular mechanism underlying the classic "tegmental response" of ipsilateral curvature of the spinal column after electrical stimulation of the RF.

1304 MOTOR CAPABILITIES OF THE CHRONIC SPINAL CAT: RECRUITMENT OF SLOW AND FAST EXTENSORS OF THE ANKLE. J.L. Smith, L.A. Smith*, and K.L. Dahms*. Dept. Kinesiology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

Myopotentials from two ankle extensors, the soleus (SOL) and the lateral gastrocnemius (LG) were recorded from chronic spinal cats transected at T_{13} either at 2 or 12 weeks (W) of age. Four cats in each group were exercised daily on a motorized treadmill for 10-20 min, and testing was completed 4-6 mo post-surgery. With the forelimbs and trunk suspended above the treadmill, all cats fully supported the weight of their hindquarters during stepping. Most cats periodically used their hindlimbs unassisted during quadrupedal standing and overground locomotion. Muscles were implanted with electrode wires under sterile operating conditions as described by Betts, et al (Brain Res. 117:529, 1976). The electromyography (EMG) was synchronized with the cat's movement by a video system and recorded on FM tape for subsequent integration and period analyses by minicomputer (Smith, et al, J. Neurophysiol. 40:503, 1977).

During treadmill locomotion, the SOL was recruited at all speeds (0.13 to 0.89 m/s), which elicited the entire range of gaits from a slow walk to a slow gallop. The peak amplitude of the rectified-averaged (RA) EMG, which in normal adult cats is correlated with peak tendon forces measured in vivo (Walmsley, et al, J. Neurophysiol. 41:1203, 1978), increased about 20% for SOL and about 300% for LG over the range of speeds tested. During unassisted standing and stepping overground, the SOL was recruited alone, and the RA-EMG was similar to that recorded during slow treadmill stepping.

When the cats were held vertically with hind legs pendant, air stepping was recorded at 3-5 c/s, and the SOL was active generally without the LG. Clonus, elicited by tendon taps or during slow treadmill stepping and standing, ranged from 10-15 c/s and was predominant in the SOL.

During rapid and alternate ankle movements of 10-14 c/s, produced by sticking tape to the plantar pads, the LG alone was active, as is the pattern for normal adult cats (Smith, et al, Neurosc. Abst., 1976), only in those cats in which the contraction time (CT) of the SOL, measured at sacrifice, was >50 ms. However, in those cats in which the SOL had a CT of < 50 ms, both LG and SOL were recruited simultaneously. All weight-bearing 2W cats had "fast" (21-40 ms) SOL, while all but one of the weight-bearing 12W cats had a "slow" (50-58 ms) SOL (Edgerton, et al, Neurosc. Abst., 1979). Recruitment of a "fast" SOL would not slow the rhythm of rapid paw shaking, and the variation in segmental input to motoneurons may reflect this fact.

1305 USE OF THE (^{14}C)2-DEOXYGLUCOSE TECHNIQUE TO STUDY OCULOMOTOR FUNCTION: METHODS AND PRELIMINARY RESULTS. David Sparks, Lawrence Mays and T. L. Hickey. Univ. of Alabama in Birmingham, Birmingham, AL 35294.

Macaque monkeys, trained to make repetitive saccades, were used to examine alterations in the metabolic activity of neurons in brain regions known to be involved in the generation of eye movements. Monkeys were taught to follow a saccade target presented on a large screen oscilloscope. After acquisition of the target and a variable fixation interval, the target was moved instantaneously to a new position, requiring another acquisition saccade and fixation interval. Since trials were presented without an intertrial interval and water reinforcement was delivered during the fixation period, the number of spontaneous saccades was minimized. For example, one monkey made over 2000 5^{0} rightward saccades and over 700 15^{0} leftward saccades during a 45 minute period. The number of saccades with other vectors occurring during this period was negligible.

After extensive training, the unanesthetized monkey (with indwelling intravenous catheter) was placed in the experimental chamber, the head restrained, and the tracking task begun. Horizontal and vertical eye position signals (Fuchs and Robinson, 1966) were sampled at a rate of 500/sec throughout the 45 minute session and stored on a 9-track digital magnetic tape. Thus, it was possible to reconstruct the vector of each eye movement that occurred during the experimental session. If satisfactory performance continued after an initial injection of physiological saline, a rapid injection of (^{14}C)2-deoxyglucose, 75 μCi/kg in 1.5 ml of saline was given. At the end of the 45 minute tracking period, the animal was anesthetized with Nembutal and perfused intracardially with 3.3% phosphate buffered formalin at pH 7.4. The brain was removed, blocked, and slowly submerged in Freon 22, chilled by an acetone/dry ice mixture.

Autoradiographs revealed increased levels of metabolic activity in expected oculomotor areas of the brain stem: the oculomotor, trochlear and abducens nuclei; pontine oculomotor regions; and the cerebellum. Sections from other oculomotor areas are currently being processed. Selective labelling was particularly noticeable in the cerebellum, with specific regions of discrete folia showing increases in activity. The midline vermis region showed generalized increases in label, somewhat denser in the nodulus and the deeper folia of lobes, V, VI, and VIIIB. Laterally, discrete patches of label were observed in lobules IVC and VIIIA of the vermis, in the simple and paramedian lobules and in Crus IIa. All folia of the flocculus examined showed dramatic, but uniform, increases in metabolic activity.

In combination with appropriate behavioral procedures, the (^{14}C)2-deoxyglucose technique (Sokoloff et al., 1977) appears to be suitable for investigations of the oculomotor system.

(Supported by NIH Grants EY 01189 and EY 02293).

1306 TOPOGRAPHICAL ORGANIZATION OF ASCENDING CEREBELLAR PROJECTIONS FROM THE DENTATE AND INTERPOSED NUCLEI IN MACACA MULATTA. Gregory Stanton. Dept. of Anat., Coll. of Med., Howard Univ., Washington, D.C. 20059.

Discrete elcrolytic lesions were placed in the dentate and interpositus cerebellar nuclei and the resulting anterograde degeneration was stained with the Wiitanen technique. The dentate and interpositus anterior (IA) nuclei project topographically onto the somatotopically organized divisions of the red nucleus and the ventral lateral-ventral intermediate nuclei of the thalamus (VL-Vim). Caudal parts of the dentate project to face areas in medial parts of the parvocellular red nucleus (RNpc) and VL-Vim, rostrolateral parts to central arm areas in these nuclei. There is a small projection from the rostroventral dentate to lateral hindlimb areas in RNpc and VL. Dorsal parts of the dentate project to ventral parts of RNpc and medial VLc-Vim whereas ventral parts of the dentate project to dorsal parts of RNpc (with some overlap ventrally) and dorsomedial parts of VLc. The dorsoventral topography of dentate terminals in VL-Vim may be related to proximal-distal musculature representation in these thalamic nuclei. Dentate projections to the nucleus of Darkschewitsch and the thalamic nuclei VA, area "X", and VLps also appear to be topographically organized. These nuclei are related by afferent and/or efferent connections with the premotor cortex.

Caudal and rostral parts of IA project to medial (forelimb) and lateral (hindlimb) areas in the magnocellular red nucleus (RNmc) and VLc-Vim. Projections from IA are greatest to distal musculature areas in VL-Vim. No projections from the interpositus posterior nucleus (IP) to the red nucleus could be identified but projections to the nucleus of Darkschewitsch and dorsal parts of VLc were found suggesting a functional relationship of IP to the proximal limb musculature and premotor areas of the cerebral cortex.

1307 CENTRAL AND PERIPHERAL CONTROLS OF SWIMMING IN ANURAN LARVAE. Donald J. Stehouwer* and Paul B. Farel. Dept. Physiol., Sch. Med., Univ. N. Carolina, Chapel Hill, NC 27514.

The isolated nervous system of the bullfrog tadpole spontaneously exhibits episodes of patterned motoneuronal bursting at intervals ranging from about 30 to 180 sec. Each episode is a few seconds to 60 sec in duration and consists of alternating bursts between each segmental pair of ventral roots in the thoracic, lumbar, and tail regions of the spinal cord. This patterned activity is found only in the medial division of the ventral roots, whose axons terminate in the axial musculature used for swimming. The lateral division of the eighth, ninth, and tenth ventral roots innervates the limb musculature and shows only a continuous burst beginning with the onset of each episode. It is believed that the alternate bursting of the medial rootlets reflects motoneuronal activity associated with swimming and that the discharge from the lateral rootlets is associated with the hindlimb extension that is normally observed during swimming.

The period of the medial rootlet bursts within each episode varied, but was usually about 100 to 500 msec. On each side of the cord, bursts were synchronous the entire length of the cord. Midline sections of the cord at various levels and of varying length suggested that the mechanisms generating the alternate bursting were present throughout the spinal cord. However, it was also found that patterned bursting was maintained across a divided section of the cord if, and only if, a more rostral section of the cord was intact. This suggests that patterned activity arising in rostral segments can be conducted caudally down each side of the sectioned cord, but that patterned activity generated caudally is not conducted rostrally.

Electromyograms obtained from intact, freely-swimming tadpoles were virtually identical to the root recordings obtained in vitro with respect to the rate of alternation. Unlike the in vitro preparation, these EMG's revealed a rostro-caudal phase lag. Neither peripheral destruction of the lateral line organs nor section of lateral line nerves eliminated the phase lag. Complete spinal deafferentation, leaving the lateral line system intact, was effective in eliminating the phase lag. It appears that the basic program for swimming is generated entirely within the spinal cord at the segmental level, that coordination between segments is accomplished rostrocaudally, and is modified by dorsal root input.

1308 TIMING BETWEEN HAND TREMOR OSCILLATION AND EXTENSOR EMG MODULATION AT THE TREMOR FREQUENCY. Robert N. Stiles. Dept. Physiol. and Biophysics, Univ. Tenn. Center. Health Sciences, Memphis, TN 38163.

Merton, in his classic work of 1953 on servo-control of movement (The Spinal Cord, pp. 247-255. Churchill.), proposed that the position of a limb may be controlled by a negative feedback, servo-loop mechanism (a length servo) involving primarily the stretch reflex. He also noted that, for certain limbs, the long time lag around the servo loop would have to be compensated for by derivative, or rate, feedback if oscillations of these limbs were not to occur. Merton further noted that the muscle spindles are well adapted to provide that compensation because of their very marked response to the time rate of change of muscle stretch. The question of whether the rate feedback normally does compensate for the time delay in the servo loop has been considered since by many different workers. However, it appears that the question is still unanswered.

A measure of the time lag in the servo loop(s) can be obtained for postural hand tremor by performing cross-covariance analysis of the demodulated extensor EMG and the hand motion. Using this procedure, the delay (in msec) between when the peak upward position of the oscillating hand occurred and the time later that the maximum (peak) of the amplitude modulation of the extensor EMG occurred was calculated. This time difference (designated Δt) was determined for nine normal human subjects. For seven of the nine subjects, the Δt increased from control values of between 30 and 40 msec for control tremors with root-mean-square (rms) displacements of about 50 micra, to values as large as 70 to 80 msec for hand tremors with rms displacements of between 10,000 to 30,000 micra. One subject's tremor increased very little in displacement amplitude over two different 60-min periods that the subject maintained the unsupported hand in a horizontal position. For the 56 16-sec records analyzed for this subject, the Δt values increased very little above control levels of about 30 msec. For the remaining subject, the Δt values changed very little as the subject's tremor amplitude increased from control levels of about 40 micra to its largest value of 6,000 micra. For eight of the nine subjects, the displacement amplitude of postural hand tremor appears to depend in part upon the time lag in the neural feedback pathway(s). (Supported in part by USPHS Grant NS 14730.)

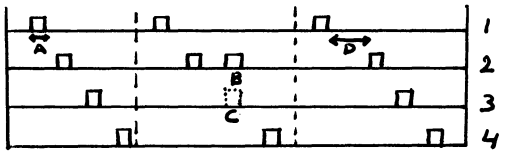
1309 **AUTOMATED AND QUANTITATIVE ASSESSMENT OF SOFT NEUROLOGICAL SIGNS.** **Cornelis L.J. Stokman. Dept. Child Psychiatry, N.Y.S. Psychiatric Institute, New York, N.Y. 10032.**

Soft neurological signs, i.e. signs without clear neuropathological focus, are associated with various forms of neuropsychiatric dysfunction. Certain soft signs show an excess prevalence in children with learning disabilities and conduct disorders as well as in schizophrenic adults. However, the high number of false positives and false negatives severely limits the value of soft signs for diagnostic or screening purposes. Operational definitions, explicit scoring criteria, normative data, etc., which are largely lacking, are essential to improve the diagnostic and predictive value of such signs.

This report illustrates the use of automated response devices, developed by the author, and response recording to operationally define and measure selected clinically important motor signs (thumb-finger apposition, hand pronation-supination, heel-toe tapping, hopping) and relevant response characteristics such as speed and frequency, errors of omission and commission, intensity or duration, rhythmicity, and asymmetry.

Data are presented on inter- and intrarater reliability in normal adults and adolescent psychiatric in-patients. For a pilot group of nine adolescent psychiatric in-patients rank order correlation coefficients for total score were significant between raters both within test ($r = 0.77$; $p < 0.01$) and retest ($r = 0.93$; $p < 0.01$) sessions, and within rater for test-retest (rater 1: $r = 0.92$; $p < 0.01$, and rater 2: $r = 0.77$; $p < 0.01$).

Figure 1 presents a drawing of the response measures for the thumb-finger apposition test, with various response characteristics such as duration (A), errors of commission (B) and omission (C), and arhythmicity (D, variable interresponse time).



1310 VISUAL ASPECTS OF POST-DEAFFERENTATION ATAXIA AND DYSMETRIA. D.E. Teodoru,* T.A. Tran,* J. Herskovic,* and A.J. Berman. Department of Neurosurgery, V.A. Hospital, Bronx, N.Y. 10468

Five preoperatively trained dorsal rhizotomized (DR) monkeys performed a visually cued reaching task within two months of surgery (D. Berman, et.al., 1978). Testing was performed in the dark and the visual cue was brief so as not to permit visual guidance of the limb. We now report that these same monkeys, in a lighted room, did not reach and grasp a food pellet from a 1.0 cm diameter platform until the fourth post-operative month. At that time, the movements used for food retrieval were severely ataxic and dysmetric. The response pattern soon changed, however, to a rapid, ballistic movement. The arm was "thrown at the target," as described by Gilman et.al. (1976) The trajectory of the movement became smooth and accurate as dysmetria and ataxia diminished. In a further test of motor function, the DR animals were required to reach horizontally into a 7.0 cm diameter cylinder as it was moved to a stop position. Ataxia and dysmetria persisted on this test longer than on the platform test. Severe oscillation of the DR limb made entry of the hand into the cylinder difficult. If, however, the cylinder was kept in a fixed position and exposed to the animal by lifting a screen, ataxia was noticeably reduced, reach trajectory improved, and reach time dramatically shortened.

When a target is immobile, reefference associated with the oculomotor command producing "foveal capture" of the target may be used to pre-program the reaching movement (Paillard, 1978). Proprioception is, therefore, not necessary. If the target is in motion, on the other hand, oculomotor reefference must constantly be updated. The movement, therefore, becomes dependent on visual feedback. In the visually cued task, without the possibility of visual guidance, animals used a visually triggered response. In the platform test, they may have initially attempted to use a visually guided response but later switched to a visually triggered one. In the cylinder test, animals may have used a visually guided response when the cylinder was in motion but a visually triggered response when it was stationary. We propose that the observed oscillations in reach of the DR limb result from the absence of velocity-related muscle afferents which normally counteract the instability of the visuomotor servo-loop (Murphy, et.al., 1975). This instability is a function of the inherent processing time of visual feedback, which has been shown to be far slower than that of somatosensory feedback to the motor cortex (Evarts, 1974) or cerebellum (Buchtel, et.al., 1972).

1311 2-DEOXY-(^{14}C) GLUCOSE AS A MARKER FOR IDENTIFYING ACUTELY ACTIVE SKELETAL MUSCLE FIBERS IN INDIVIDUAL MOTOR UNITS. J. Toop*, R.E. Burke, R.P. Dum, M.J. O'Donovan* and C.B. Smith*. (Spon. F.T. Hambrecht) Lab. of Neural Control, NINCDS, NIH and Lab. of Cerebral Metabolism, NIMH, Bethesda, MD 20205.

The injection of trace amounts of (^{14}C)-deoxyglucose (DG) permits autoradiographic evaluation of rates of glucose metabolism in structures in the central nervous system (Sokoloff et al., J. Neurochem. 28:897, 1977). The uptake of DG has also been studied in rat muscle using this technique, where it was found that electrical stimulation greatly increases the uptake of tracer (Rapoport et al., Exp. Neurol. 60:168, 1978). Our present aim has been to evaluate DG autoradiography as a label for muscle fibers belonging to an individual motor unit (i.e., those innervated by a single alpha motoneuron), which has previously been done by depleting intrafiber glycogen stores during prolonged stimulation (Edstrom & Kugelberg, J. Neurol., Neurosurg. & Psychiat. 31:424,1968). Glycogen depletion provides an independent "marker" for acutely active muscle fibers. In each of 5 adult cat flexor digitorum longus (FDL) or soleus (SOL) muscles (normal or self-reinnervated), a physiologically identified motor unit was stimulated repetitively while monitoring muscle unit force output (13 - 18 pulses in 40 Hz trains delivered once per sec. through a micropipette in the innervating motoneurons; see Burke et al., J. Physiol. 234:723, 1973). Immediately after the onset of stimulation, DG was injected intravenously (approx. 40 µC/kg in saline) and stimulation was continued for 16 to 75 minutes. Between 20 and 72 minutes was allowed to elapse between DG injection and removal of the test muscle, which was then quickly frozen whole in isopentane at -180° C and stored in a liquid nitrogen freezer. Frozen sections were cut at 10 µm in a cryostat at -20° C and quickly air-dried. Autoradiograms were made in two ways: 1.) rapidly dried frozen sections on glass slides were placed in contact with X-ray or Kodak Plus-X film in dry cassettes; or 2.) sections were picked up in the cryostat under safelight directly onto slides covered with AR.10 stripping film. In the latter case, the film-section sandwich was developed and fixed after suitable exposure and then stained by the PAS reaction for glycogen. In 2 self-reinnervated FDL muscles, there was good correspondence between groups of depleted fibers and areas of increased silver grains and in one of these, grain densities in some cases corresponded to individual glycogen-depleted fibers. In the other 3 muscles, there was much less correspondence between depleted fibers and grain densities. The results suggest that active muscle fibers take up DG, but that the use of the method to map single muscle fibers belonging to individual motor units requires refinement of present methods.

1312 EYE MOVEMENT CONTROL: THE EFFECTS OF JOINT SUPERIOR COLLICULUS AND FRONTAL EYE FIELD STIMULATION. Sean True*, Peter H. Schiller* and Janet Conway* (SPON: R. Held) Dept. Psyc., MIT, Cambridge, MA 02139.

Electrical stimulation of both the frontal eye fields (FEF) and the superior colliculus (SC) produces saccadic eye movements whose directions and amplitudes depend on the site of stimulation. Simultaneous stimulation at two loci within each of these structures produces a single saccade whose size and direction is a weighted function of the saccades produced singly from each site (Robinson, D.A. Vision Res. 12: 1795, 1972. Robinson, D.A. and Fuchs, A.F. J. Neurophysiol. 32: 637, 1969). This averaging could be produced either within these structures or at a locus to which both project.

The aim of this study was to determine what the interactions are between the FEF and the SC when they are jointly stimulated, either simultaneously or in succession. Stimulation of these structures was carried out in the alert monkey using implanted search coils to monitor eye movements. The animal's head was restrained during the experiment. Stimulation was between 10-600 μA, typically at 300Hz, 70-300 msec train durations with 0.5 msec pulse widths. For the most part microelectrodes were used for this purpose which permitted localization of each structure by recording prior to stimulation.

Our results showed that paired stimulations produce results similar to those obtained when two sites are activated within each structure: for simultaneous stimulation the resultant saccade was the weighted function of individually elicited saccades, where the relative intensity of stimulation is the weighting factor. With contralateral stimulation this can result in nulling of the saccadic response, provided the two sites stimulated produce saccades in opposite directions. Sequential stimulation showed a refractory period in which the second stimulation has no apparent effect on eye movement. This refractory period corresponds to that seen with paired stimulation in a single structure. We did not see any case of interruption of a saccade by a following saccade under sequential stimulation.

These findings suggest that the FEF and the SC converge on a site in the brainstem where the averaging function observed is performed. Since we have previously shown that ablation of the SC does not alter stimulation elicited saccades from the FEF (Schiller, P.H. Brain Res. 122: 154, 1977.), it is unlikely that the effects reported here could be attributed to the FEF → SC pathway. 1313 UNIDIRECTIONALLY PROPAGATED ACTION POTENTIAL GENERATION IN PERIPHERAL NERVE BY SHORT STIMULI. Christopher van den Honert*, and J. Thomas Mortimer. Dept. Biomed. Eng., Case Western Reserve University, Cleveland, Ohio 44106.

Electrical stimulation of peripheral nerve ordinarily elicits two action potentials propagated in opposite directions. A stimulation technique has been developed which generates a single, unidirectionally propagated impulse. Propagation in the opposite direction is inhibited by imposition of a longitudinal potential gradient in the extracellular medium which opposes the flow of excitatory action currents. The time course of that potential is roughly equivalent to the driving force behind the action currents, i.e. the action potential itself. Both stimulation and block are effected through an asymmetrical tripolar cuff electrode using a single central cathode. The total stimulating current is divided unequally between the anodes.

The method has been successfully demonstrated at rates up to 50 Hz in motor axons of cats using EMG measurements from medial gastrocnemius during sciatic nerve stimulation. The compound sciatic neurogram was recorded proximal to the electrodes. Stimuli consisted of regulated current pulses (1 - 10 mA, 0 - 8 ms) with a linear or exponential falling phase (0 - 10 ms).

This technique may be used as an investigative tool, or to effect a clinical motor nerve block by introduction of antidromic impulses on the peripheral nerve. The block arises from the head on collision (and subsequent mutual anihilation) of the natural efferent activity and the artificially generated antidromic impulses. Such a collision block could provide control of spasticity, particularly in the urinary sphincter muscle of spinal cord injury patients. Short term sphincter block would facilitate bladder voiding by electrical stimulation of the detrusor musculature.

1314 THE UNUSUAL STRUCTURE OF TRAPEZIUS MOTONEURONS IN THE ADULT CAT. S. J. Vanner* and P. K. Rose. Dept. of Physiology, Queen's University, Kingston, Ontario, Canada K7L 3N6.

Anatomical studies of the spinal cord using Golgi stains have established that dendrites of spinal motoneurons have an organization dominated by rostrally and caudally directed dendrites usually 1000 μm in length. However, the consistency of this structural framework has not been systematically studied. We now report that the trapezius motoneurons have structural characteristics which are strikingly different from other spinal motoneurons. These motoneurons are located in the cervical cord and are involved in head and forelimb movements.

Using chloralose anesthetized cats, 21 trapezius motoneurons were antidromically identified and injected intracellularly with horseradish peroxidase. Subsequent histological processing revealed that the trapezius motoneuron pool formed a column of neurons extending from the caudal C2 segment to the rostral C6 segment. The unusual feature of these motoneurons was their remarkably long rostrally and caudally directed dendrites. Occasionally these dendrites measured over 2000 μm from the soma and most exceeded 1000 μm in length. The total extent of the dendritic tree measured 3000 μm to 4000 μm. These rostral and caudal dendrites formed a distinct bundle which was usually confined to the trapezius motoneuron nucleus. Ventromedial and dorsally projecting dendrites also measured over 1000 μm in length but lacked the distinct grouping of the rostrally and caudally directed dendrites. Although few in number, lateral dendrites projected into the lateral funiculus occasionally reaching the edge of the spinal cord.

The functional significance of these long dendrites will depend on their membrane characteristics. If the membrane resistivity of the trapezius motoneurons matches that reported for hindlimb motoneurons it is possible that synapses located on the distal dendrites will have little effect on the membrane potential of the soma. Alternatively, if the membrane resistivity is substantially larger, trapezius motoneurons may have electrotonic lengths similar to hindlimb motoneurons.

1315 UNIT ACTIVITY IN THE MESENCEPHALIC RETICULAR FORMATION (MRF) ASSOCIATED WITH SACCADES AND POSITIONS OF FIXATION DURING A VISUAL ATTENTION TASK.
David M. Waitzman and Bernard Cohen, Department of Neurology, Mount Sinai School of Medicine, New York 10029

The MRF projects to the superior colliculus as well as to the ipsi and contralateral pontine reticular formation where rapid eye movements are generated. Electric stimulation of the MRF causes contralateral saccades, and MRF lesions cause ipsilateral gaze preference. We are studying whether MRF neurons participate in the production of visually guided saccadic eye movements and positions of fixation. Unit activity is monitored while monkeys fix a small spot of light on a TV screen in the Wurtz paradigm. When the spot dims, they release a bar for a water reward. Eye movements are recorded with EOG. The spot is under computer control and can jump to new locations during the task. Animals sometimes break fixation to execute off-target saccades. Their eyes usually return to the spot with an on-target saccade after several hundred milliseconds.

To date several types of task-related neurons have been found in the MRF. They were located in the region of nucleus cuneiformis, lateral to the oculomotor nucleus. The first group fires 50 to 200 msec before the onset of on-target contralateral saccades. Frequencies can exceed 600 Hz, and in some units are dependent upon the difficulty of the visual task: the smaller the contrast between spot brightness and ambient light, the higher the firing rate. A second group of neurons fires with a burst of spikes just before the animal makes small contralateral on-target saccades of less than 1^{o} to 2^{o}. These cells are silent during larger on-target saccades or spontaneous eye movements. A third set of MRF neurons fires only when the animal maintains fixation. They stop firing 100-200 msec before saccades that take the eyes off-target and begin to fire with the occurrence of the next on-target saccade. Their firing rates are also higher when the visual attention task is made more difficult. Other MRF neurons are not task-related. They fire about 50 msec after the onset of all rapid eye movements and blinks. The lesion, stimulation and unit data support the postulate that important visual-oculomotor processing occurs in the MRF. Activity of the task-related neurons could be used to generate contralateral horizontal saccades and periods of fixation during visual attention. Activity of MRF cells that follows eye movement could be used to signal the occurrence of rapid eye movements to cerebral structures.

1316 REPRESENTATION OF THE JAW MUSCLES IN THE FACIAL AND TRIGEMINAL NUCLEI OF THE PIGEON (COLUMBA LIVIA). J.M.Wild and H.P.Zeigler. Department of Animal Behavior, American Museum of Natural History, New York, N.Y. 10024.

As part of a series of anatomical and physiological studies of effector mechanisms controlling components of the feeding behavior of the pigeon, we have mapped the somatotopy of the jaw muscles in the Vth and VIIth cranial nerve nuclei using horseradish peroxidase histochemistry.

In the case of the protractor of the lower jaw, M. depressor mandibulae, the only jaw muscle innervated by the facial nerve, the labeled neurons were located totally and discretely within the medial facial nucleus lying in the center of the caudal pontine reticular formation. Labeled axons could be observed to leave the nucleus in dorsal and dorsomedial directions before turning laterally, caudally and then laterally again to pass through the brainstem immediately ventral to the rostral portions of the lateral vestibular nucleus. The axons then pierce the descending trigeminal tract and exit the lateral brainstem caudal to their nucleus of origin.

In the case of the six jaw muscles within the orbit, all but the protractor of the upper jaw, M. protractor quadrati et pterygoidei, were represented within the largest or chief motor trigeminal nucleus located lateral and rostral to the medial facial nucleus. The adductor complex was represented ventrolaterally, M. pseudotemporalis superficialis ventrally, M. pseudo temporalis profundus dorsolaterally, and the two pterygoid muscles medially, centrally and rostrally. M. protractor quadrati et pterygoidei was represented in a more scattered group of neurons predominantly located between the medial facial nucleus and the caudal pole of the chief motor trigeminal nucleus, forming, as it were, a V-VII motor column.

Many labeled axons could be seen to exit the brainstem directly from the lateral and ventrolateral aspects of the chief motor trigeminal nucleus. However, many others ascend dorsally before turning laterally to join the discrete arching bundle of axons leaving the dorsomedial facial nucleus of Karten and Hodos, (1967). The fibers from both these nuclei then descend together ventrolaterally to exit the brainstem on the ventral aspect of the entering sensory root of the trigeminal nerve.

The data suggest a somatotopic organization of the trigeminal motor complex but, just as there is considerable overlap in the position of the muscles with respect to each other within the orbit, so there is considerable overlap in their representation within the nucleus. In addition some facial and trigeminal neurons innervating the two jaw opening muscles lie in close proximity. (Supported by NIMH Grant MH 08366 and a CUNY FRAP award to H.P.Z.)

1317 POSTROTATORY NYSTAGMUS, OPTOKINETIC AFTERNYSTAGMUS AND THE VESTIBULO-OCULAR RESPONSE IN DUTCH-BELTED RABBITS. Barbara J. Winterson, Han Collewijn* and Hans van der Steen*. Dept. Physiol. Med. Fac., Erasmus U., Rotterdam, The Netherlands.

Measurements of the decay of the velocity of the slow components of postrotatory nystagmus (PRN) in rabbits gave estimates of time constants (9-15 sec) for the vestibulo-ocular response (VOR) which were inconsistent with time constants estimated from phase relations obtained during sinusoidal rotations (2-4 sec). This difference led us to examine in the same animals the following: PRN after constant velocity rotations (30, 60, & 150°/sec); VOR over a range of frequencies (0.03-2.0 Hz) and amplitudes (5-20°); optokinetic afternystagmus (OKAN) after constant velocity drum rotations (30 & 60°/sec); and the response to constant velocity rotations (15, 30, & 60°/sec) in the light.

We found: 1) The velocity of slow components of both PRN and OKAN decayed at a constant rate (0.5-4°/sec per sec) rather than the exponentially declining rate which has been reported and modelled in monkey. 2) This constant rate of decay was largely independent of initial eye velocities or whether prior stimulation was rotational or optokinetic. 3) The total compensatory response was maintained at constant gain when rotations were 30°/sec or less. 4) In response to sinusoidal rotations a small effect of amplitude on phase was found. Lower amplitudes were associated with phase advances. 5) Time constants estimated from phase relations ranged from 2-3 sec.

These results indicate the source of the inconsistency in estimates of time constants from different methods. PRN with a constant rate of decay has durations that are determined by the initial velocity of the eye and therefore can never be described by a single time constant. The higher the initial eye velocity, the longer the duration of PRN; the lower the initial velocity, the shorter the duration and thus the apparent time constant. During sinusoidal rotation of modest amplitude, velocities and durations of eye movement are not of such magnitude to appreciably affect the mechanism underlying PRN.

The similarity between the time courses of decay of PRN and OKAN suggest shared neural circuity. Fortunately, this similarity insures maintenance of constant gain during moderate rotational velocities in the light, because reductions in VOR gain are compensated by comparable growth in gain of the optokinetic response.

1318 MOTOR AND SOMATIC SENSORY CORTEX SINGLE UNIT BEHAVIOR WITH PASSIVE AND ACTIVE LIMB MOVEMENTS AND POSITION MAINTENANCE IN PRIMATES. Jonathan R. Wolpaw. Neurobiology Dept., Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

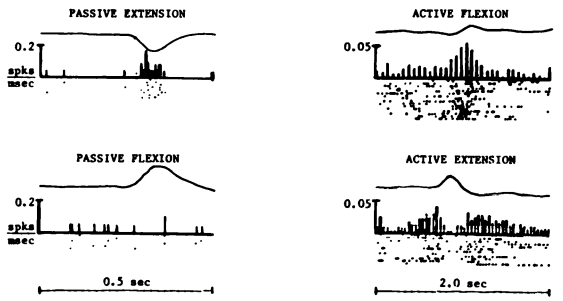
Four monkeys maintained hand position against a range of steady background forces. 50-ms force pulses, causing abrupt passive wrist flexion or extension, were superimposed. Pulse responses, background activity, and activity during active movements were recorded from 630 units in areas 4, 3, 1, 2, 5, and 7, which responded in 60 ms.

Three-quarters of task-related units in areas 4 and 2 behaved similarly with a pulse in one direction, background force in the same direction, or active movement in the opposite direction. In contrast, closely task-related units in areas 5 and 7 behaved similarly with passive or active movement in the same direction. In areas 3 and 1, few force pulse responsive units were related to background force or active movement.

Postcentral areas were similar in average response latency(27-30 ms). Area 4 was significantly later(32.5 ms). In areas 4 and 2, flexion pulses caused most excitation and extension pulses caused most inhibition.

The results resolve the discrepancy between Porter and Rack (Br. Res. 103: 201, 1976), and Conrad et al. (Br. Res. 71: 507, 1974) and Evarts and Fromm (Prog. Clin. Neurophysiol. Vol. 4, Karger, 1978, p 56) in regard to area 4 unit behavior during active vs passive movements.

The particular correlation in areas 4 and 2 between unit behavior during passive movement, active movement, and position maintenance, combined with the shorter latency of area 2, is consistent with the position that short latency sensory input, largely from muscle stretch receptors, had significant control over area 4 throughout performance, and that much of this input reached area 4 through area 2.



Area 2 unit, typical of 4 and 2, excited with passive (force pulse-induced) movement in one direction (extension) or active movement in the other (flexion). Each histogram sums the trials in the raster. Traces are hand position; up is wrist flexion, down is extension.

1319 INTERACTIONS BETWEEN THE ACHILLES TENDON REFLEX AND THE FUNCTIONAL STRETCH RESPONSE IN NORMAL SUBJECTS AND PATIENTS WITH MULTIPLE SCLEROSIS. Marjorie H. Woollacott. Neurological Sciences Institute, Good Samaritan Hospital & Medical Center, Portland, OR 97209.

The EMG activity of four leg muscles [gastrocnemius (G), tibialis anterior (TA), hamstrings (H) and quadriceps (Q)] was monitored while freely standing normal and spastic humans were subjected to unexpected movements of a platform capable of six independent degrees of rotation (horizontal, vertical and rotational displacements of each foot). At different latencies during the platform perturbations an electromechanical hammer was used to elicit the Achilles tendon reflex, in order to determine if any changes in the state of the myotatic stretch reflex occurred during unexpected postural perturbations. In 50% of the subjects tested the tap to the Achilles tendon also elicited a smaller muscle response in TA and in occasional subjects in H and Q muscles. This reflex response organization to the tendon tap also occurred in quietly standing subjects and was not correlated with functional stretch response (FSR--latency 110-120 mm) organization to platform movements.

In the majority of normal subjects results indicate that the moytatic stretch reflex in the gastrocnemius muscle is inhibited during the FSR of its antagonist muscle, the tibialis anterior. The inhibition occurred during all platform perturbations used (synchronous translateral, rotational and vertical motion in addition to reciprocal vertical motions). The duration of the inhibition was correlated with the duration of the antagonist's FSR and was usually within the range of 100-300 msec.

Previous reports by Nashner and Woollacott show that certain platform movements (vertical lifts and drops and direct ankle rotations) cause FSR's which are inappropriate for postural stability and are subsequently adapted to very low levels within 3 to 5 trials. In the present experiments the Achilles tendon reflex was still inhibited even in those instances in which the TA responses had adapted to nearly zero.

In patients with multiple sclerosis a delayed inhibition of the Achilles tendon reflex in the G was observed concomitant with a delay in the tibialis anterior FSR.

1320 ℓ-BACLOFEN PREFERENTIALLY DEPRESSES EXTENSOR VS FLEXOR VENTRAL ROOT REFLEXES IN THE UNANAESTHETIZED SPINAL CAT. Kiran Yashpal*, Steven Backman*and James L. Henry (SPON: R.B. Malmo). Dept. of Research in Anaesthesia, McGill Univ., Montréal, Québec,H3G 1Y6.

Recently we found that the ℓ-isomer of baclofen was 10-100 x more potent than the d-isomer in depressing the mono- and polysynaptic L_7 ventral root reflexes (Fed. Proc. 38:900, 1979). Because baclofen's clinical use is as an antispastic agent it was determined whether it has a preferential effect on extensor or on flexor ventral root reflexes. L_7 ventral root reflexes were elicited by electrical stimulation of the medial or lateral gastrocnemius (extensor) nerve and of the anterior tibial (flexor) nerve in the unanaesthetized, decerebrated cat spinalized at L_1, paralysed and ventilated mechanically. ℓ-baclofen was administered into the jugular vein and the effects noted on the amplitudes of the evoked reflexes. ℓ-baclofen (0.1-1.0 mg/kg) had a dose-dependent depressant effect on all evoked responses: the time course of the onset of depression was faster for the extensor nerve evoked reflexes, and at any one dose the degree of the depression was greater on the extensor nerve evoked reflexes. For both extensor and flexor nerve evoked responses, depression of the monosynaptic reflex was more rapid and greater in magnitude than the polysynaptic reflex. Low doses of strychnine sulphate (0.05-0.2 mg/kg) reversed depression induced by low doses of ℓ-baclofen (0.1-0.3 mg/kg), but higher doses of ℓ-baclofen (0.5-1.0 mg/kg) overcame this reversal. Bicuculline methiodide (1-10 mg/kg i.v.) failed to reverse the depression induced by ℓ-baclofen. The preferential effect of ℓ-baclofen on extensor nerve reflexes is consistent with its clinical use as an antispastic agent, especially in cases of increased extensor tone. Its antagonism by strychnine suggests a glycinergic mechanism is involved in the expression of its effects in the ventral horn.

1321 MOTOR PROGRAMMING PRECEDING SPEECH. Donald H. York, Tom W. Jensen, W. Casey Lenox* and John G. Rosenfeld*, Dept. of Physiology and Communications Disorder Unit. School of Medicine, University of Missouri, Columbia, MO 65212.

The question of whether there are identifiable event-related potentials preceding speech is quite controversial. The present study was designed to answer this question. In all previous studies examining averaged EEG preceding voicing, the high frequency response of the EEG amplifier was seldom set beyond 50Hz. In the present study an electrode was placed on Cz and linked ear lobes served as reference. A ground was attached to the right forearm. The electrodes were connected to a differential amplifier with bandwidth 1Hz - 1000Hz and recorded on magnetic tape. A second channel of the tape was used to record a square wave trigger pulse obtained from the voice onset phonogram. Ten right handed female subjects were studied. Each subject produced 100 utterances of the words ATE and YES. A control consisted of random sampling of the EEG while the subject was still seated in a reclined chair, in a semi-darkened room with eyes fixed on a spot 30 inches distant and no voice production. Electromyograms from obicularis oris, obicularis oculi and masseter muscles were recorded on a third channel on tape. Analysis of the data involved backward averaging of at least 100 repetitions of the utterance using the voice onset to trigger the averager. Sample periods of 128 msec were analyzed up to 668 msec preceding voicing. Averaged data were entered into a microprocessor for peak identification and latency assignment to all positive and negative going waves. A subsequent program then compared across individuals examining for identical peaks ±1 msec over the range 0 - 668 msec. The results showed that in the time period, from 216-344 msec preceding speech, in at least 6 out of 9 subjects, there were 6 - YES peaks, 8 - ATE peaks and 2 - CONTROL peaks which were positive going and did not overlap. In this period 2 - YES peaks, 5 - ATE peaks and 3 - CONTROL peaks were negative going, with only one overlap of a control peak. No averaged electromyogram activity could be found in the time period 216-344 msec. These results suggest that distinct temporal patterns of activity exist preceding the production of an utterance and furthermore that these patterns are utterance specific across subjects. The precise role and origin of this averaged EEG activity is presently being investigated.

1322 MORPHOLOGICAL AND PHYSIOLOGICAL CHARACTERISTICS OF BURST INHIBITORY NEURONS IN THE ALERT CAT. K. Yoshida*, R.A. McCrea, A. Berthoz* & P. Vidal*. Lab. de Physiol. du Travail, 41 rue Gay Lussac, 75005, Paris, France; Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, N.Y. 10016

The location and inhibitory synaptic effects of medullary burst inhibitory neurons (BIN) on abducens (Abd) motoneurons has been described by Hikosaka and Kawakami (1978) in the decerebrate cat. The purpose of the present study was to quantitatively describe the activity of BINs in the alert cat and to determine their location, somadendritic morphology, axonal trajectory and termination sites. Neurons that exhibited a burst of activity prior to ipsilateral saccades were found in the medulla 0.7-1.0 mm from the midline at the level of the caudal Abd nucleus to 3.0 mm posterior to the Abd and 0.8-3.5 mm below the surface of the IVth ventricle. BINs discharged prior to and during ipsilateral voluntary saccades as well as the quick phase of vestibular and optokinetic nystagmus. The duration of the activity was related to saccade duration and the number of spikes was related to the saccade amplitude. BINs exhibited no activity during fixation, but occasionally responded weakly during contralateral saccades. The axons of four BINs which demonstrated all the above characteristics were intracellularly injected with HRP in the alert cat. The somata of the injected neurons were located in the region described above and gave rise to 4-7 proximal dendrites. In one injected neuron, the dendritic tree extended over 0.6 mm rostrocaudally, 1 mm mediolaterally and 1.3 mm dorsoventrally. Each of the injected BIN axons terminated extensively throughout most of the contralateral Abd, although some areas were free of termination in each case. The terminal arborization usually arose as a series of branches from the main axon as it coursed rostrolaterally beneath the nucleus. The synaptic boutons of BIN axons ranged in size from 0.5 μ to 3 μ and often occurred in close clusters. BIN axons also terminated profusely in the contralateral medullary reticular formation, particularly in the area where BINs are located. The main axon of a BIN accompanied by one or more branches with terminal arborization in the Abd nucleus entered and terminated in the medial vestibular nucleus. Terminal collaterals were also given off to the contralateral rostral prepositus nucleus. No BIN collaterals were seen to ascend rostral to the Abd. In conclusion, we have demonstrated in the alert cat that BINs which discharge prior to and during ipsilateral saccades, terminate in the contralateral Abd nucleus, reticular formation, medial vestibular nucleus and prepositus nucleus. These morphological data suggest that BINs may also in part be responsible for the pause observed in some secondary vestibular and prepositus neurons during contralateral saccades. Supported by CNRS, CNAM and NS-13742.

1323 A PHYSIOLOGICAL CLASSIFICATION OF MOTOR UNITS IN HUMAN FIRST DORSAL INTEROSSEOUS. Joseph L. Young and Richard F. Mayer. Dept. Neurol., Sch. Med., U. of Md., Baltimore, Md. 21201.

Isometric twitch characteristics of 122 human First Dorsal Interosseous (FDI) motor units (MUs) have been studied using the electronic averaging, microstimulation technique. Of these, 40 units were further classified according to their twitch contraction times (Tc) and fatigabilities following repetitive trains of stimuli. MUs were considered fast (F) or slow (S) by their Tc$\leq$ 75 msec or Tc$\leq$75 msec respectively. 75 msec was chosen on the basis that:-

1. all units that fatigued have Tc$\leq$ 75 msec, and
2. all units that "sag" also have Tc$\leq$ 75 msec.

"Sag" was used in the usual sense to mean any fall in the steady-state peak tension in response to an unfused tetani. "Sag" was tested systematically in this study but was not used in classifying MUs because of the base-line often fluctuates. This inherent technical difficulty made a decision about "sag" in many cases difficult. Fast units were further divided into fatigable (FF) or fatigue resistant (FR) by comparing the initial twitch to the second twitch following 2 minutes of repetitive trains. Each train has a stimulus frequency of 30 Hz lasting 1/3 of a second. This train of stimuli was repeated once every second. In general, large MUs are fast contracting in agreement with other studies of MUs in cat and man. But there are many fast units in the FDI that produce small twitch tensions. MUs in human FDI is composed of physiologically broader groups of MUs as compared to the cat medical gastrocnemius muscle. It is concluded that the criteria set forth here is suitable for separating MUs physiologically into three groups.

1324 TETANIC TENSION APPEARS TO BE A PERFECT PREDICTOR FOR RECRUITMENT OF PLANTARIS (PL) MOTOR UNITS IN THE CAT. Felix E. Zajac and Joel S. Faden. Univ. of Maryland, College Park, MD 20742.

Various studies on the whole population of motor units in a given muscle show that recruitment is statistically ordered either according to properties which reflect the "size" of the motoneuron or to properties which indicate the contractile strength of the motor unit. These findings are consistent with the fact that for the full range of motor units there are correlations between motoneuron size, conduction velocity (CV) of the motor axon and tetanic tension(TT) of the motor unit. However, such correlations between CV and TT are not high in mixed hindlimb muscles of the cat and are non-existent in the 61% subpopulation of fast-twitch(type F) motor units. This study (for methods see Neurosci. Abstr. 3:271,1977) emphasized the recruitment order of type F units to distinguish whether the order is more related to axonal CV or to TT of the unit. Small intact filaments, each containing one PL axon, were dissected free from the L7 ventral root in decerebrate cats and axonal CV, TT and type(S,FR,F-int, FF) of each motor unit isolated was determined. Each filament was cut distally and discharges from its PL axon were recorded from its proximal end during monosynaptic reflexes. Discharge from one PL axon was compared with the presence or absence of discharge from another PL axon in another filament. Recruitment order of each pair of PL axons was compared with their motor unit properties. For each pair of units(both type S, or both type F, or of mixed type) the one with the smallest TT was recruited first(Table 1, col B). In contrast the unit with the slowest CV was recruited first in only 47% of type F pairs and in 73% of all pairs studied(Table 1, col C). These results are consistent with the probability that there is a monotonic trend between CV and TT(compare col C with D, Table 1). The probabilities were calculated on data from 134 PL motor units. TT is thus a better predictor for recruitment order in this motor pool than CV.

NEUROCHEMISTRY

1325 INHIBITION OF PYRIDOXAL KINASE BY GAMMA-AMINOBUTYRIC ACID. D. M. Abercrombie* and D. L. Martin* (SPON: A.T. Campagnoni). Dept. of Chemistry, University of Maryland, College Park, MD. 20742.

Pyridoxal kinase is inhibited by gamma-aminobutyric acid (GABA), a neurotransmitter in the vertebrate central nervous system. Because GABA is synthesized by a pyridoxal-P requiring enzyme, this inhibition raised the possibility of a metabolic feedback loop for control of GABA synthesis. The results show that there was little inhibition of pyridoxal kinase by GABA at low concentrations of pyridoxal, but that the inhibition became stronger as the concentration of pyridoxal was raised. Similar results were obtained when β-alanine and δ-aminovaleric acid were substituted for GABA. Conventional models of enzyme inhibition did not fit the inhibition data and GABA did not inhibit when pyridoxamine was the substrate suggesting that GABA did not inhibit by interacting directly with the enzyme. Substrate depletion and direct inhibition of pyridoxal kinase by the pyridoxal-GABA imine were considered as alternative mechanisms. To distinguish between the two mechanisms, the equilibrium constants for pyridoxal-GABA imine formation were determined at pH 6.2,7.3, and 8.0 (μ=0.2 M, 37°C). The values were 0.23 M^{-1}, 3.4 M^{-1}, and 14.0 M^{-1}, respectively. The association constant for the pyridoxal-glycine imine was 1.0 M^{-1} (pH 6.2). These values were used to calculate the concentrations of free pyridoxal and pyridoxal-GABA imine under assay conditions. The results showed that the pyridoxal concentration was not appreciably reduced by GABA indicating that inhibition was not the result of substrate depletion. This conclusion was supported by the failure of glycine to inhibit the enzyme. The calculated pyridoxal-GABA concentrations were used to analyze the inhibition data. The results showed that the pyridoxal-GABA imine behaved as a simple noncompetitive inhibitor with respect to pyridoxal thereby supporting the hypothesis that pyridoxal kinase was inhibited by the pyridoxal-GABA imine. In view of this indirect mechanism and the high concentration of GABA needed for inhibition, it seems unlikely that GABA inhibition of pyridoxal kinase represents a specific control point for GABA synthesis.

1326 BRAIN REGIONS AND ACTIVATIONAL STATE ALTER THE INFLUENCE OF pH ON TYROSINE HYDROXYLASE ACTIVITY. Ann Acheson*, Linda Kennedy*, Gregory Kapatos*, and Michael Zigmond. Departments of Biological Sciences and Psychology, and Department of Pharmacology, School of Pharmacy, University of Pittsburgh, Pittsburgh, PA. 15260.

Tissues from various rat brain regions were homogenized in Tris-HCl buffer, pH 6.0, and the high-speed supernatent was assayed for tyrosine hydroxylase (TH) activity in the presence of 75 μM L-(1-^{14}C) tyrosine, 6MPH$_4$, catalase, and a dihydropteridine reductase regenerating system. We found that the influence of pH on the TH activity of these crude enzyme preparations varied with brain region. Striatum, a brain region rich in dopamine (DA)-containing nerve terminals, had a pH optima of 5.65. However hippocampus and cerebellum,regions rich in norepinephrine (NE)-containing terminals, had a pH optima in the range of 6.1 - 6.2. Brain areas with mixed DA and NE innervation had intermediate pH optima(frontal cortex, 5.8), or displayed biphasic pH curves with one peak between 5.7 and 5.9 and a second peak at 6.1 (olfactory tubercle and hypothalamus). TH from areas containing cell bodies displayed less sensitivity to pH than TH from terminal regions. Activity from cell body areas was maximal over a broad range of pH values, which encompassed the individual pH optima of the terminal regions to which these cell bodies project (substantia nigra, 5.65 - 5.9; locus coeruleus, 5.95 - 6.3).

We also found that activation of TH by phosphorylating conditions (0.2mM cAMP, 1.0 mM $MgCl_2$, 0.5 mM ATP, and 2.0 mM theophylline) produced a decrease in the sensitivity of the enzyme to pH. Activated enzyme from striatum or hippocampus showed little decrease in maximal activity when assayed at a sub-optimal pH, thus increasing the effect of phosphorylation relative to basal activity. For example, the activity of TH incubated under phosphorylating conditions was 4 times that of control activity at pH 6.5, whereas at pH 6.2, the activity was not significantly different from control.

These data support previous suggestions that TH exists in different forms in DA- and NE-rich brain regions. They also suggest the importance of assay conditions in regional comparisons of TH activity and in studies of TH activation.

1327 USE OF AN ANTICHOLINESTERASE AS PROBE IN THE STUDY OF MICROWAVE-INDUCED BLOOD BRAIN BARRIER CHANGES. Y. Ashani*, F. H. Henry* and G. N. Catravas. Biochemistry Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Groups of rats were administered an anticholinesterase agent (phospholine iodide) and exposed to pulsed microwave radiation at a frequency of 2.45 GHz and average power density of 10 mW/cm^2. The pulse width was 2 μsec with a pulse repetition frequency of 500 Hz. Irradiations were conducted for a period of 10 min in an anechoic chamber under near field conditions as described by Thomas, et al. (Science 203:1357-1358, 1979). A statistically significant decrease in body temperature, compared to controls, was observed in rats that were given the drug and 10 min later were exposed to microwaves. When irradiation preceded drug administration these changes could not be observed. The enhancement of the anticholinesterase effects on body temperature in the presence of low levels microwave irradiation may be used as a potential simple rapid tool in the study of effects of low power density microwaves on biological systems such as blood brain barrier.

1328 IMMUNOCHEMICAL STUDIES OF MAMMALIAN NEUROFILAMENTS. L. Autilio-Gambetti*, M.E. Velasco*, P. Gambetti, J.M. Sipple*. Division of Neuropathology, Institute of Pathology, Case Western Reserve University, Cleveland, Ohio 44106.

Mammalian neurofilaments (NF) have recently been shown to be made of three polypeptides: 200K, 145K and 68K daltons. These three polypeptides from NF-rich fractions of rat spinal cord (Shecket and Lasek, Trans Am Soc Neurochem 10, 1979) were separated in SDS slab gels; antisera to each of the NF polypeptides were raised in rabbits by injecting the corresponding bands from these gels. By indirect immunofluorescence and peroxidase antiperoxidase (PAP) methods, antisera were seen to stain central and peripheral axons from human and rat. Electron microscopy of PAP preparations of peripheral nerve showed that the immunostain reaction takes place at the NF.

The PAP method was adapted for immunostaining of antigenic peptides in SDS slab gels. Each of the antisera stained strongly their corresponding polypeptide and less itensely the other two NF polypeptides; in addition, a band migrating with tubulin was also stained. The 50K dalton polypeptide obtained from preparations of bovine brain filaments by the axonal floatation method (Liem et al, J Cell Biol 79:637, 1978) was not stained by either antisera. These results indicate cross reactivity between the three NF polypeptides and antigenic identity between central and peripheral NF from different species.

1329 Ca^{++}-ACTIVATED NEUTRAL PROTEINASE IN NORMAL AND TRAUMATIZED SPINAL CORD. Naren L. Banik*, James M. Powers*, Karen Smith* and Edward L. Hogan (SPON: W. Boggan). Departments of Neurology, Biochemistry and Neuropathology, Medical University of South Carolina, Charleston, S. C. 29403.

Experimental spinal cord trauma affects myelinated axons and causes paralysis in animals. Myelin proteins are progressively degraded, and ultrastructurally myelin is disrupted with vesiculation of myelin lamellae and phagocytosis. The degradation of myelin proteins suggests a role for proteolytic enzymes and has prompted study of the nature and levels of proteinases in intact and traumatized spinal cord. Levels of these enzymes in extracts from animals following cord injury have previously been reported (Trans. ASN 10:153). Since calcium accumulates in myelinated axons in experimental trauma, some of these proteinases may be activated by Ca^{++}. Experimental spinal cord trauma was produced in rats by dropping 10 g from 30 cm upon exposed, dura-invested spinal cord. Extracts in distilled water, pH 5.8, were prepared from homogenates of normal and lesion regions of traumatized rats. The homogenate was centrifuged at 100,000 g (90 min.) and the supernatant freeze-dried and assayed for enzyme activity. The activity of neutral proteinase was assayed in 0.025M phosphate buffer, pH 7.6, at 37°C (60 min.). One microgram of protein extract was incubated with 30 µg of purified myelin basic protein in a final volume of 0.08 ml. The incubation was carried out with and without $CaCl_2$ (5 mM), EDTA (5 mM) and leupeptin (25 µg). The degradation of basic protein at pH 7.6 was greatly stimulated by Ca^{++} (5 mM) and a 69% loss of protein was observed. The addition of EDTA (5 mM) prevented the breakdown of basic protein. This Ca^{++}-activated neutral proteinase is inhibited by leupeptin (25 µg/0.025 ml). These results suggest that like muscle there is a Ca^{++}-activated neutral proteinase in spinal cord which is sensitive to leupeptin - and may play an important role in the breakdown of myelin in spinal cord trauma. Thus the use of leupeptin may be useful in preventing the myelinolysis in spinal cord injury.

1330 OVEREXPRESSION OF MONOAMINE OXIDASE IN NEUROBLASTOMA X FIBROBLAST HYBRIDS. James Barbosa*, John Pintar*, Uta Francke*, Morris Hawkins Jr. and Xandra Breakefield. Dept. Human Genetics, Yale Univ. Sch. Med., New Haven, CT 06510.

The effect of different chromosomal constitutions on expression of enzyme activity can be assessed using somatic cell hybrids. Cell fusions were performed using a mouse neuroblastoma clone, originally derived from the C1300 tumor, and a normal human fibroblast line, grown from a skin biopsy. The neuroblastoma parent, N1E-115TG2, is heteroploid and has no monoamine oxidase (MAO) or hypoxanthine phosphoribosyltransferase (HPRT) activity. This clone was derived from line N1E-115 which expresses MAO activity at a level of 100 pmol/min/mg protein. The fibroblast parent, GM316, has a normal diploid male complement of 46 chromosomes, and has both HPRT and MAO activity. Monoamine oxidase activity in this line is expressed at a level of 16 pmol/min/mg protein. Following hybridization, parental cells were selected against by growth in the presence of hypoxanthine, aminopterin, thymidine (HAT) and ouabain. Hybrid cells were cloned in HAT medium to select for retention of the human X chromosome which contains the gene coding for HPRT. Ten hybrid clones retained the human X and all mouse chromosomes, but only a few human autosomes. These clones expressed varying levels of MAO activity from 0 to 100 pmol/min/mg protein. This finding suggests that if there is only one gene determining expression of this enzyme, it is probably not on the human X chromosome. Hybrid clones with high MAO activity were subcloned under non-selective conditions allowing random loss of the human X chromosome. Several subclones had MAO activities of >1000 pmol/min/mg protein, over 100-fold higher than either parent. The MAO activity in these hybrids could result from a turn on of the mouse gene(s) and/or retention of the human gene(s) coding for this enzyme. The overexpression of activity reflects the interaction a few specific human chromosomes with a predominantly mouse neuroblastoma genotype. Studies are underway to identify which human chromosomes are retained and whether any alterations in the mouse chromosomal complement occur in subclones with high MAO activity. Electrophoretic techniques are being used to distinguish the species of origin of the MAO.

1331 THE EFFECTS OF SEVERAL NEUTRAL AMINO ACIDS ON d-AMPHETAMINE AND APOMORPHINE INDUCED CIRCLING IN RATS WITH LESIONS IN THE SUBSTANTIA NIGRA. John M. Beaton and Issam H. Humaideh*, Neurosciences Program, University of Alabama in Birmingham, B'ham, AL 35294.

Following unilateral destruction of the nigrostriatal dopamine system little behavioral change may be noticed. However, compounds which either directly stimulate post-synaptic dopamine receptors (e.g. apomorphine) or increase synaptic dopamine content (e.g. amphetamine) produce unilateral turning. The directionality of the turning is dependent upon whether the test compound acts pre- or post-synaptically. Amphetamine acts pre-synaptically and produces turning in the direction ipsilateral to the lesion. Apomorphine which acts post-synaptically induces contralateral turning. There is a large body of evidence which indicates that the brain levels and synthesis of the putative neurotransmitters, serotonin, dopamine and norepinephrine, can be modified by acute or chronic alterations of the peripheral levels of the large neutral amino acids (e.g. leucine, valine). The present study was carried out to study the effects of pretreatment with L-valine, D-valine or L-leucine (250 mg/kg) on rats with substantia nigra lesions, treated with various doses of d-amphetamine (2,4,6 or 8 mg/kg) or apomorphine (0.25, 0.5 or 1.0 mg/kg). The rats were lesioned electrolytically in the right substantia nigra. At least ten days were allowed between the surgery and drug testing. The various amino acids tested were all injected subcutaneously in the back 30 minutes prior to the intraperitoneal injection of either amphetamine or apomorphine. After injection of the drug the animals were placed individually in the middle of a circular open field and turns to the left or right were counted for 1 minute at 0,15,30,45 or 60 minutes after the administration of the drug. L-valine pretreatment at 250 mg/kg resulted in a marked decrease in amphetamine-induced circling in rats with unilateral substantia nigra lesions but had no effect upon apomorphine-induced circling. It is suggested that this suppression of the amphetamine effect is due to the lowering of brain tyrosine levels by the administration of the L-valine. L-leucine induced similar effects. D-valine at a similar dosage was inactive in suppressing either the amphetamine or the apomorphine-induced circling. This latter finding is not surprising since the carrier system for the entry of these amino acids into brain is thought to be stereospecific.

This work was supported in part by Intramural Faculty Research grant #82-6602.

1332 UPTAKE OF ^{3}H-CHOLINE AND SYNTHESIS OF ^{3}H-ACh BY THE RABBIT CORNEA. C. Belmonte*, C. Gonzalez* and S. Fidone (SPON: B.R. Kripke). Dept. Physiol., Facultad Med., Valladolid, Spain, and Dept. Physiol., Univ. Utah Col. Med., Salt Lake City, UT 84108.

The presence of large amounts of acetylcholine (ACh) and choline acetyltransferase (CAT) in the corneal epithelium of different species and their persistence after sensory denervation of the cornea is well established.

The uptake of choline in the cornea has been studied in several laboratories but there has been considerable controversy regarding the presence in the cornea of a high affinity system for choline uptake. In this study, we examine the uptake of choline in normal and denervated corneas, and further, we extend the investigation to a consideration of ACh synthesis in this structure.

Corneas of anesthetized white albino rabbits were visualized with the aid of a dissecting microscope and denervated by making a circular incision through the epithelial and stromal layers with a fine scalpel. Twelve days later the success of the denervation procedure was assessed by the absence of a blink reflex in response to stimulation of the central part of the cornea. The corneas from normal and denervated rabbits were removed and cut into pieces weighing 5-10 mgs. (wet weight). After establishing the period of linear active uptake (total-passive), the kinetics of the uptake process were determined by incubating corneas with ^{3}H-choline in concentrations ranging between 0.5 - 70 µM.

The incorporation of ^{3}H-choline could be resolved into two components, one with a Km = 6.1 µM and Vmax = 7.9 pmols/mg and the other with a Km = 42.0 µM and Vmax = 36.1 pmols/mg. Both components persisted after denervation with minor modifications of the kinetic parameters. In other experiments, the incorporation of ^{3}H-choline (10 µM) into corneal phospholipids and ACh together with the levels of free ^{3}H-choline in the tissue were determined. We found that the synthesis of ACh reached a plateau after a 1 hr. incubation but the incorporation of ^{3}H-choline into phospholipids continued to increase for up to 4 hrs. These values were unchanged following denervation of the cornea.

Supported by USPHS grants NS07938 and NS12636.

1333 ^{125}I-RADIOLABELED α-BUNGAROTOXIN DERIVATIVES: KINETIC PROPERTIES OF THEIR INTERACTION WITH NICOTINIC ACETYLCHOLINE RECEPTORS.
Edward L. Bennett, Hiromi Morimoto*, Michael R. Hanley and Ronald J. Lukas, Chemical Biodynamics Division, Lawrence Berkeley Lab., University of California, Berkeley, CA 94720.

Radiolabeled derivatives of post-synaptic neurotoxins have been extensively used in characterization of nicotinic acetylcholine receptors from central, autonomic and peripheral nervous tissues. Nevertheless, there is considerable variation in reported kinetic properties of receptor-toxin interactions, which may be attributable, at least in part, to use of different chemical modification procedures in preparation of radiolabeled toxins. One popular radiolabeled toxin derivative is ^{125}I-labeled α-bungarotoxin, prepared by chloramine T., lactoperoxidase or iodine monochloride procedures. We have earlier reported (Biochem. 17, 2308, 1978) that iodination of α-bungarotoxin (α-Bgt) leads to perturbations in its physical structure, as detected by circular dichroism spectra, and causes diminution of its affinity for toxin receptors in rat brain, relative to native or tritium-labeled α-Bgt. Using detailed kinetic studies, we have found evidence that alteration of toxin biological activity on iodination is more pronounced than indicated from earlier results. For example, the dissociation (following removal of free toxin and 50-fold dilution) of radiolabeled toxin from complexes of toxin and rat brain receptor is characterized by a half-time of ∿100 hr for tritiated α-Bgt, ∿60 hr for mono-^{125}I-labeled α-Bgt and ∿10 hr for di-^{125}I-labeled α-Bgt. If experiments are performed by addition of a large excess of native toxin to radiolabeled toxin-receptor complexes, dissociation of iodinated toxins appears to be further accelerated. In general, the same phenomena is characteristic of dissociation of radiolabeled toxins from sites on Torpedo californica electroplax nicotinic receptors, and peculiarities of toxin-receptor association kinetics are observed for iodinated toxin species. Thus, the possibility exists that reports of anomolous kinetics of toxin-receptor interaction may reflect the nature of the chemical modification used to introduce radiolabel, rather than intrinsic complexity of native toxin-membrane bound receptor interactions.

Supported by the Division of Biomedical and Environmental Research of the U.S. Department of Energy under contract No. W-705-ENG-48.

1334 RECENT EVIDENCE FOR MULTIPLE BENZODIAZEPINE RECEPTOR COMPLEXES WITH INTIMATE ASSOCIATION BETWEEN ɣ-AMINOBUTYRIC ACID (GABA) RECOGNITION SITES AND IONOPHORES.
Donald I. Benson*, Richard F. Squires and Claire A. Klepner*, Medical Research Division, American Cyanamid Co., Pearl River, NY 10965.

The existence of multiple benzodiazepine (BDZ) receptor complexes is strongly supported by several independent lines of evidence including selective protection of one class of ^{3}H-flunitrazepam binding sites against heat inactivation by phosphate ion, flat dose response curves for several triazolopyridazines exhibiting high affinity for the BDZ receptor with Hill coefficients near 0.6, and multiphasic dissociation of receptor bound ^{3}H-diazepam.

ɣ-Aminobutric acid (GABA) and several other GABA-mimetic substances have been found to significantly increase brain specific ^{3}H-BDZ binding. In addition, we have found that GABA, muscimol and β-guanidino proprionic acid (β-GPA) can protect the BDZ receptors against thermal inactivation at 60° C in 25 mM Tris·HCl buffer, pH 7.5. Heat inactivation time courses revealed three populations of BDZ receptors, two of which appear to be protected by GABA or muscimol. Dose response curves for GABA, muscimol and β-GPA revealed that both high and low affinity GABA binding sites are involved in the protective effects.

In contrast to GABA and muscimol, two GABA-mimetics, tetrahydroisoxazolopyridinol (THIP) and isoguvacine, inhibited BDZ binding in a highly selective manner. Dose response curves revealed a "plateau" effect at concentrations of 200 μM and above, whereby a maximum of 60% or 40% of the receptors were inhibited by THIP or isoguvacine, respectively. Interestingly, addition of 1 mM GABA fully reversed inhibition of binding produced by these substances. Also, neither THIP nor isoguvacine was found to protect against thermal inactivation at any concentration tested.

In addition to the phosphate ion, several other anions (chloride, citrate, malonate, sulfate, etc.) can protect certain BDZ receptor complexes. Furthermore, it has been found that both ^{3}H-flunitrazepam binding and the relative inhibition of binding produced in the presence of THIP is highly dependent upon anion concentration.

These results further support the contention of multiple BDZ receptor complexes consisting of a single BDZ recognition site, one or two GABA receptors and one or several ionophores.

1335 MUSCARINIC CHOLINERGIC STIMULATION INCREASES CYCLIC GMP LEVELS IN RAT HIPPOCAMPUS.
Asa C. Black, Jr., Dean Sandquist*, James R. West, James K. Wamsley*, and Terence H. Williams. Dept. Anatomy, Univ. Iowa Coll. Med., Iowa City, IA 52242, and Dept. Pharmacol. and Exptl. Therap., Johns Hopkins Sch. Med., Baltimore, MD 21205.

The rat hippocampus receives a cholinergic innervation which is derived from cell bodies located in the medial septal nucleus, the nucleus of the diagonal band, and possibly the intermediolateral regions of the septum (Brain, 90:521; Brain Res., 119:1). Considerable evidence has been produced to support the view that cyclic GMP is involved in muscarinic cholinergic neurotransmission.

Whole hippocampi from decapitated adult Sprague-Dawley rats were pre-incubated for 30 min at 37 C in Eagle's Medium containing 5 mM theophylline, and then incubated in the same solution containing 2.2 mM $CaCl_2$ and bethanechol. Samples were analyzed for cyclic GMP and protein (J. Neurochem., 32:1033).

INCUBATION CONDITIONS	CYCLIC GMP pm/mg. protein ± S.E.M. (No. samples)
0.25 Min., 500 μM Bethanechol	0.33 ± 0.01 (4)*
0.50 Min., 500 μM Bethanechol	0.30 ± 0.02 (5)*
0.75 Min., 500 μM Bethanechol	0.38 ± 0.05 (8)*
1.0 Min., 500 μM Bethanechol	0.39 ± 0.04 (5)*

*P<0.001 (Student's "t" test).

The cyclic GMP increases were calcium-dependent and were blocked by atropine sulfate. Other studies suggest that the septum gives rise to a muscarinic cholinergic projection to the basal and apical dendrites of hippocampal pyramidal cells. Acetylcholine and cyclic GMP each have excitatory effects on rabbit hippocampal pyramidal cell responses to electrophysiological stimulation of the pathway from the medial septal region to hippocampal field CA1 (Fed. Proc., 37:524). It thus seems reasonable to infer that cyclic GMP is generated by activity in the muscarinic cholinergic projection from the septum to the hippocampus in the rat (Supported by NS 11650 to THW).

1336 IN VIVO INCREASE IN HYPOTHALAMIC CYCLIC AMP FOLLOWING ACTIVATION OF SEROTONERGIC RECEPTORS IN THE RAT.
Marsha C. Bundman and Ronald A. Browning. Southern Illinois University, School of Medicine, Carbondale, IL 62901.

Recently we reported that 5-hydroxytryptophan (5-HTP) resulted in a significant increase in hypothalamic cyclic-AMP levels when administered (100mg/kg i.p.) to serotonin (5-HT) depleted rats (pre-treated with 5,7-dihydroxytryptamine, 150μg i. vent.). We postulated that this rise in c-AMP was coupled to 5-HT receptor activation (Bundman and Browning, Soc. Neurosci. Absts. 4:578, 1978). It is known, however, particularly in the absence of significant numbers of 5-HT nerve endings, that 5-HTP can be taken up by and converted to 5-HT in catacholamine neurons. In order to evaluate the specificity of the 5-HTP induced increase in c-AMP, we have now studied the effects of tryptophan on c-AMP levels and have examined the ability of serotonin receptor blockers to prevent this change.

Trytophan (100mg/kg i.p.), which is converted to 5-HT exclusively in serotonergic neurons, plus the MAO inhibitor, tranylcypromine (TCP) (20mg/kg i.p.) were administered to rats 10 days following 5,7-dihydroxytryptamine (50μg i. vent.). This resulted in a 46% increase in c-AMP levels ($p < 0.05$) as compared with animals receiving TCP alone.

The 5-HT receptor blocker, metergoline, in a dose of 5.0mg/kg i.p. given 90 min prior to challange with 5-HTP (100mg/kg i.p.) resulted in a 53% inhibition of the c-AMP increase ($p < 0.05$). However, methysergide (40mg/kg i.p., 30 min prior to 5-HTP or 10mg/kg i.p., 10 min prior) had no significant effect on the c-AMP rise, although at these doses it was successful in blocking the behavioral syndrome characteristic of 5-HT receptor activation. This suggests the possibility of two different 5-HT receptors, only one of which is coupled to changes in c-AMP.

The present findings support the hypothesis that the 5-HTP induced increase in hypothalamic c-AMP is specifically a serotonin receptor mediated phenomenon.

1337 ROLE OF GLUTAMIC ACID IN THE EARLY NEUROTOXIC EFFECTS OF 3-ACETYL PYRIDINE IN RATS. Roger F. Butterworth, François Jolicoeur*, Daniel Rondeau*, Edith Hamel* and André Barbeau. Dept. Neurobiol., Clin. Res. Inst. of Mtl., Montreal, Quebec, Canada.

Treatment of rats with a single dose of 3-acetyl pyridine ((3AP), 75 mg per kg, i.p., LD_{50}) results in severe neurological impairment in surviving animals. Histological studies have shown that 3AP produces partial degeneration of facial, hypoglossal and ambiguous nuclei and complete destruction of the inferior olive nucleus with resulting degeneration of cerebellar climbing fibres. These lesions were detectable as early as 7 hr after a single injection of 3AP and 48 hr after injection, few, if any intact climbing fibres remained (Desclin and Escubi, Brain Res., 77, 349 (1974)).

Rats showed decreased locomotor activity, catalepsy as well as a distinctive muscle rigidity 6 hr after the administration of 3AP. Abnormalities of gait (ataxia) were apparent 12 hr post treatment and by 24 hr all rats showed loss of righting reflex.

Measurement of amino acids in several discrete regions of brains of affected animals 72 hr after 3AP treatment revealed the following:-

(a) A decreased taurine concentration in cerebellum and medulla oblongata.

(b) Decreased glutamic acid concentration in cerebellum, medulla oblongata, cerebral cortex, striatum, hippocampus and olfactory bulbs.

(c) No changes in concentrations of GABA, glycine or aspartic acid in any region of brain studied.

These findings are consistent with the hypothesis that glutamic acid may be the excitatory neurotransmitter of cerebellar climbing fibres. The importance of the amino acid changes in the development of catalepsy and rigidity produced by 3AP will be discussed.

1338 SIMILARITIES AND DIFFERENCES IN THE STRUCTURE OF A AND B FORMS OF MONOAMINE OXIDASE. Richard M. Cawthon*, Maria R. C. Costa* and Xandra O. Breakefield. Dept. Human Genetics, Yale Univ. Sch. Med., New Haven, CT 06510

Three methods of polyacrylamide gel electrophoresis were used to analyze the structure of ^{3}H-pargyline-labelled monoamine oxidase (MAO) from cells with A and B activity. These two forms of the enzyme are known to differ in their substrate selectivity, drug sensitivity, and tissue distribution. It has not been clear whether these differences result from intrinsic variation in the structure of MAO or from extrinsic modulation by its membrane microenvironment. Here the irreversible inhibitor ^{3}H-pargyline was bound to crude mitochondrial fractions from rat hepatoma line MH_1C_1, with A and B activity, and rat glioma line C6, with A activity. Specific labelling of only the A or B forms of hepatoma cells was controlled by pre-incubation with selective A and B inhibitors. Electrophoresis in sodium dodecyl sulfate (SDS)-polyacrylamide gels revealed a single protein band of MW 57,000 for both forms. Electrophoresis in non-equilibrium pH gradient gels again showed a single labelled band for both forms, indicating they also have a similar charge; however, binding of ^{3}H-pargyline to the A form was more labile than to the B form under these conditions. To further examine the structure of the A and B forms of MAO, the labelled protein bands obtained by SDS-polyacrylamide gel electrophoresis were subjected to limited proteolysis and electrophoresis in SDS-polyacrylamide gels to identify peptide fragments. Site-specific proteases can be used against fully solubilized and denatured MAO to identify discrete differences in amino acid composition or modification, independent of associated lipids. Analysis of fragments of MW >10,000 generated by Staphylococcus aureus V8 protease revealed a unique fragment present only when the B form of the enzyme was labelled. The other three fragments observed were common to both A and B forms.

In conclusion, the catalytic polypeptides responsible for A and B types of activity are similar in MW and charge, but differ in their characteristics of ^{3}H-pargyline binding and in their covalent molecular structure.

1339 MODULATED RNA RELEASE FROM ISOLATED BRAIN NUCLEI IN A CELL-FREE SYSTEM. Ming J.W. Chang, Thomas E. Webb* and Adalbert Koestner. Dept. Vet. Pathobiol. and Dept. Physiol. Chem., OSU, Columbus, OH 43210.

A reconstituted cell-free system is described which supports the release (processing/transport) of rapidly labeled, putative messenger RNA from rat brain nuclei. The nuclei, prelabeled for 30 min. in vivo with [3H] uridine, are incubated in surrogate cytoplasm consisting of dialyzed cytosol, spermidine, dithiothreitol, buffer, salts, low molecular weight RNA as RNase inhibitor, ATP and an energy-regenerating system. The nuclei were completely stable in this medium. The RNA release was dependent on (a) energy (ATP), (b) non-dialyzable factors in the cytosol and (c) to some extent the age and sex of the cytosol donor. As predicted for messenger RNA, a maximum of approximately 6-8% of the nuclear counts were released in RNA over a 30 min. incubation period at 30°C and a significant fraction of the RNA was polyadenylated. Contrary to non-neural tissues this energy-dependence of RNA release is not lost during carcinogenesis (neuro-oncogenesis) nor in the transformed cell line, T22. It is suggested that this system will be useful in analyzing nuclear RNA processing and transport in normal and neoplastic brain cells.

(Supported in part by USPHS Grant CA 11224.)

1340 ISOLATION AND CHARACTERIZATION OF A PROTEOLIPID ASSOCIATED WITH (^{3}H) SPIROPERIDOL BINDING ACTIVITY. Yvonne C. Clement-Cormier and Barbara Boyan-Salyers. Depts. of Pharmacology and Neurobiology, Univ. Tex. Sch. Med. and Dept. of Microbiology, Univ. Tex. Dent. Branch, Houston, TX 77025.

A binding protein has been extracted with potassium chloride from the microsomal fraction of the calf striatum. The extract binds (^{3}H) spiroperidol with high affinity and exhibits stereoselectivity for the (+) and(-) isomers of butaclamol. The results of stability studies indicate that the solubilized component is stable to storage at -20°C for several weeks and at 4°C for one week. The IC 50 values for displacement of (^{3}H) spiroperidol binding by dopamine and other neuroleptic agents was determined to be similar to that of the native membrane binding component. Gel filtration chromatography of the soluble membrane preparation on Sephadex 100 revealed several major peaks of stereoselective binding activity for (^{3}H) spiroperidol. When the soluble microsomal fraction was extracted with chloroform methanol, stereoselective binding was recovered in both the aqueous and organic solvent phases. Fractionation of the chloroform methanol extract into the neutral and crude phospholipid (CPL) phases revealed that the highest specific binding activity for (^{3}H) spiroperidol was associated with the CPL which is enriched in hydrophobic protein. CPL binding of (^{3}H) spiroperidol represented a 1000 fold purification over that observed in the microsomal extract. Chromatography of the soluble chloroform methanol extract on Sephadex LH-20 resulted in the elution of a single peak of specific binding activity which contained both protein and lipid. Analysis of the phospholipids associated with the binding site revealed a high content of phosphotidyl inositol and triphosphotidyl inositol. Electron micrographs of the KCl striatal extract revealed the presence of electron dense particles, some of which aggregated while drying on a formvar film to form microlamellar patterns similar to that observed with highly purified proteolipids and the soluble acetylcholine receptor. Overall, these data suggest that at least one of the binding sites for the dopamine receptor in the CNS may be a proteolipid.

1341 DIHYDROERGOPEPTINE COMPOUNDS DISPLAY HIGH AFFINITY TO VARIOUS NEUROTRANSMITTER RECEPTORS IN THE BRAIN. A. Closse*, D. Hauser* and M. Seiler* (SPON: S. H. Snyder).Preclinical Research, SANDOZ Ltd., Basel, Switzerland.

A variety of labelled ligands have been used to identify α-adrenergic, serotoninergic and dopaminergic receptors in the brain. The specific binding of these ligands is inhibited by low concentrations of dihydroergopeptines, such as dihydroergotamine, dihydroergotoxine and its components.

We have now performed comparative binding studies with ^{3}H-dihydroergotamine, ^{3}H-dihydro-α-ergocryptine, ^{3}H-dihydroergocristine and ^{3}H-dihydroergocornine. All these ligands bind in vitro with high affinity to rat brain membranes, displaying dissociation constants between 10^{-9} and 10^{-10} M. α-Adrenergic, serotoninergic and dopaminergic agonists and antagonists compete variably for these ergot binding sites.

The present studies confirm the notion that dihydroergopeptin derivatives show a high affinity to various neurotransmitter receptor sites, although in different proportions. Whereas dihydroergotamine seems to prefer serotonin receptors, dihydro-α-ergocryptine binds predominantly to α-adrenergic sites. Dihydroergocristine and dihydroergocornine show about equal affinity to all three of the neurotransmitter receptors mentioned above.

1342 AN IMPROVED METHOD FOR CALCULATION OF HIGH AFFINITY CHOLINE UPTAKE: THE USE OF CHOLINE ACETYLTRANSFERASE AS A CHOLINERGIC MARKER David O. Cooper* and Dennis E. Schmidt, Vanderbilt University, Nashville, Tennessee, 37232

In current methods, the rate of Na^{+}-dependent high affinity choline uptake (HACU) is expressed in terms of total synaptosomal protein (TSP). Tissue protein is not, however, a specific index of cholinergic synaptosomal presence, and reflects primarily non-cholinergic synaptosomes, glial elements, and other subcellular fractions. In recent studies utilizing choline acetyltransferase (CAT) as a specific marker for the presence of cholinergic synaptosomes, it was found that within individual experiments there was a variable degree of correlation between TSP and CAT activity (r value range .46 - .93). When these experiments are pooled, all correlation disappears (r = .18) suggesting that TSP is a poor indicator for calculation of HACU. Furthermore, when HACU in different brain regions is calculated on the basis of TSP, the values reflect primarily the degree of cholinergic innervation. HACU rates based on CAT activity, however, are similar in different brain regions (Table 1) indicating that a relative measure of HACU per cholinergic synaptosome is being determined.

TABLE 1

	pmol choline/ug protein/min	fmol choline/pmol CAT/min
Striatum	0.161 ± 0.017 (24)	0.639 ± 0.059 (24)
Hippocampus	0.056 ± 0.008 (80)	0.695 ± 0.045 (80)
Cortex	0.057 ± 0.006 (24)	0.970 ± 0.070 (24)

Finally, HACU values based on CAT activity were consistently less variable and statistically more significant than comparable values based on TSP. It is, therefore, suggested that under conditions where CAT activity is not altered by experimental manipulations, HACU based on CAT activity represents a better and more conceptually sound method for determination of cholinergic function.

1343 CHEMICAL COMPOSITION OF NORMAL AND MULTIPLE SCLEROSIS BRAINS. W. Craelius, D. Rosenheck† D.Schaefer† and A. Shaer* Dept. Biol.,Lafayette Coll., Easton, Pa. 18042.

The lipid and elemental composition of ten control and eleven multiple sclerosis (M.S.) brain samples were determined using sensitive analytical techniques. Semi-quantitative lipid analyses were done using thin-layer chromatography. No gross abnormalities in the lipid composition of normally appearing M.S. white matter were observed. However, in white matter containing plaques,a dramatic rise in free fatty acids was noted in eight M.S. brains. Sulfatides appeared to be decreased in plaque-enriched white matter, and cholesterol esters were usually elevated.

Ten elements, Ca, Cu,Fe, K, Mg, Mn, Na, Ni, P, and Zn, were within the analytical range of detection, and accurate values for these were obtained. Twenty other elements were below detectable limits. White matter from controls was compared with normally appearing white matter from M.S. brains, and marked differences were noted in some elements, as listed below:

Element	Control White Matter (10 samples) (In ug/g(wet wt.))	M.S. White Matter (11 samples)	Significance
Ca	52.0	65.8	$p < .05$
Fe	44.1	57.6	$p < .01$
P	4212.0	3725.1	$p < .02$
Zn	5.0	10.6	$p < .001$

The significance of these elemental alterations is not known. The possibility that demyelination could be related to the differences is supported by data obtained on a M.S. plaque, whose Ca, Fe, P, and Zn levels were: 91.9, 205, 3071, and 15.3 ug/g respectively. There appeared to be no substantial elemental differences between white and grey matter.

1344 PRODUCTION OF NEUROFILAMENT ANTISERA USING AXONAL PREPARATIONS ISOLATED FROM BOVINE WHITE MATTER AS THE ANTIGEN. Doris Dahl and Amico Bignami. Spinal Cord Injury Research, West Roxbury Veterans Administration Medical Center and Department of Neuropathology, Harvard Medical School, Boston, Ma. 02132.

In a recent communication from this laboratory (Trans. Am. Soc. Neurochem. 10, 141, 1979) it was shown that the polypeptides of the neurofilament "triplet" in axonal preparations isolated from bovine white matter according to Norton's procedure have different cyanogen bromide peptide maps. It was also shown that the neurofilament antisera raised against urea-soluble chicken antigen (J. Comp. Neurol. 176, 645, 1977) allow the isolation of the ∿ 70K component of the triplet by immunoaffinity chromatography. We now report experiments aimed at producing neurofilament antisera against urea extracts of the axonal preparation. All antigens were denatured in 1% SDS and injected with an equal volume of Freund's complete adjuvant. Most rabbit produced GFA antisera due to the high antigenicity of the SDS-denatured gliofilament protein constituting one third of the axonal preparation and the major fraction in the 50K mol. wt. range (BBA, in press). However, one rabbit responded with the production of an antiserum which stained both glio- and neurofilaments by immunofluorescence, only the gliofilament activity being absorbed with GFA protein. The neurofilament activity was absorbed by the axonal preparation but not by the chicken brain antigen used to produce the antiserum against the ∿ 70K component of the neurofilament triplet. The possibility of raising antisera directed against different components of the neurofilament triplet was further investigated. The ∿ 150K band in axonal preparations was cut from non-stained SDS-polyacrylamide gels and the eluted protein injected into 2 rabbits. The immunohistological localization of the 2 antisera (anti-70K and anti-150K) was identical in sections of the rat cerebellum. Experiments aimed at determining whether both polypeptides are contained in experimentally produced neurofibrillary tangles will be presented. Supported by USPHS grant NS 13034 and by the Veterans Administration.

1345 GLUCOSE AND PROTEIN METABOLISM IN THE MONOCULARLY DEPRIVED SPLIT-BRAIN PIGEON. Dale G. Deutsch and Anton Reiner, Depts. of Biochem. and Psych. SUNY at Stony Brook, Stony Brook, New York 11794

Transection of the dorsal supraoptic decussation disrupts interhemispheric transfer of monocularly learned visual discrimination tasks in birds. In the present study, brain glucose and protein metabolism were studied in such "split-brain" pigeons after monocular visual deprivation. Split-brain pigeons were prepared (R.E. Meier, Psychol. Forsch., 34, 220, 1971), fitted with aluminum goggles, and one eye was occluded for seven days by insertion of an opaque disc into the goggle.

To monitor glucose metabolism the autoradiographic 2-[^{14}C] deoxyglucose (2-DG) technique (L. Sokoloff et. al., J. Neurochem. 28, 897, 1977) was employed. Following monocular visual deprivation there were notable differences in glucose utilization between the forebrain and midbrain visual structures of the deprived and nondeprived (control) sides of the brain. Within the telencephalon, the deprived ectostriatum and visual Wulst showed marked decreases in glucose utilization relative to the control side and in the optic lobe, the tectum of the deprived side showed a marked decrease compared to the control tectum. Non-visual structures, such as those of the auditory pathway, were unaffected by the visual deprivation.

To analyze protein levels and synthesis the telencephalic hemispheres and optic lobes were dissected from the deprived and control sides of the brain. Tissue slices were prepared and incubated in Elliot's media with [^{3}H]L-leucine for one hour at 37°C. Membrane and soluble fractions were prepared and fractionated on one- and, in some cases, two-dimensional electrophoresis. Commassie blue staining and fluorography were employed for detection of protein levels and radioactive label, respectively, and the resulting patterns were analyzed on a scanning microdensitometer. No significant differences were detected between the protein patterns from the deprived and control telencephalic hemispheres or between the two optic lobes.

These results suggest that functional alterations in brain activity, as evidenced by the 2-DG technique, may not necessarily be accompanied by changes in protein levels or synthesis. However, it is possible that protein changes occur within the ectostriatum or visual Wulst, for example, and that these changes were masked by analyzing the entire telencephalic hemisphere. We thank Harvey J. Karten and Melvin V. Simpson for their help and support during these studies. Supported by USPHS 1 F 32 NS 05682001 (A.R.) and New York State Health Research Council #855 (D.G.D.)

1346 MEASUREMENT BY HPLC WITH ELECTROCHEMICAL DETECTION OF 3,4-DIHYDROXYPHENYLACETIC ACID (DOPAC), HOMOVANILLIC ACID (HVA), AND 5-HYDROXYINDOLE-3-ACETIC ACID (5-HIAA) IN RAT STRIATUM: ALTERATIONS INDUCED BY STIMULATION OF THE SUBSTANTIA NIGRA OR DRUG TREATMENTS. D.D. Dietz*, C.D. Kilts*, R.B. Mailman, R.A. Mueller and G.R. Breese. Departments of Psychiatry, Pharmacology and Anesthesiology, University of North Carolina School of Medicine, Chapel Hill, North Carolina 27514.

A high performance liquid chromatographic (HPLC) method has been developed for the simultaneous measurement of DOPAC, HVA and 5-HIAA in rat brain homogenates. Tissues were homogenized in 0.1 N HCl and extracted with anhydrous ether. After back extraction into 0.25 M phosphate buffer (pH 6.5), aliquots were injected into an HPLC equipped with an anion exchange column (Whatman Partisil-10 SAX). A mobile phase of 0.05 M sodium acetate (pH 4.0) was pumped at 0.9 ml/min, and quantitation was by electrochemical detection (E = 0.80 v). To evoke release of dopamine, unilateral electrical stimulation of the ventral tegmentum was used (5-40 Hz; 1.5 msec duration; 20-250 μA intensity; and 15 or 30 min stimulation time). Frequency, intensity and time dependent increases in DOPAC were observed, while HVA concentrations were less markedly changed. For example, stimulation at 250 μA, 25 Hz for 15 min increased DOPAC and HVA levels 193 and 136%, whereas 30 min of stimulation increased DOPAC and HVA levels 253 and 176%, respectively. Striatal 5-HIAA content was unaffected by electrical stimulation of this site. Probenecid (250 mg/kg) and haloperidol (0.3 mg/kg) given 1 hr prior to sacrifice increased concentrations of all metabolites. (Supported by USPHS Grants HD-10570, HD-03110, ES-01104 and MH-00013.)

1347 THE USE OF HYDROPHOBIC CHROMATOGRAPHY IN THE PURIFICATION OF RAT BRAIN CHOLINE ACETYLTRANSFERASE. George W. Dietz, Jr* (SPON: G. Stone). Division of Neurosciences, City of Hope National Medical Center, Duarte, CA 91010.

Choline acetyltransferase (ChAT) has proven difficult to purify by conventional techniques, and we have sought new methods for its purification. We noted several suggestions in the literature that affinity chromatography of ChAT, for example on styrlpyridinium sepharose, reflects nonspecific interactions rather than specific interactions of a substrate-enzyme type (H.G. Mautner (1977) C.R.C.Crit. Rev. in Biochem. Nov. 341-370). However, the conditions used were not appropriate for the demonstration of hydrophobic bonding, and more critical experiments were called for. We have studied a variety of hydrophobic matrices for their ability to bind rat brain ChAT. In particular n-octyl sepharose and phenyl sepharose have been found to bind ChAT tightly. While it has not been possible to recover ChAT from the n-octyl sepharose, we were able to recover ChAT activity from the phenyl sepharose, and a chromatographic step has been developed using a gradient of ethylene glycol to elute the enzyme. The binding to phenyl sepharose seems to be unrelated to the catalytic site, since all attempts to elute ChAT with the substrate, acetyl CoA have been unsuccessful. For our final purification step we have employed an affinity chromatography on blue dextran sepharose, and have obtained highly purified preparations with specific activities in the range of 50-100 umoles of acetylcholine formed/mg/min. Our most highly purified fraction gave, upon SDS electrophoresis, three closely spaced bands with apparent molecular weights in the range of 68,000 daltons, corresponding to the reported molecular weight for the rat brain ChAT. We have not yet been able to identify the enzyme band(s) since we cannot recover activity from the gel. However, we are intrigued by the possibility that these bands represent the three charge isozymes of rat brain ChAT previously noted. (Supported by NIH grant NS 12116).

1348 FORMATION OF THE FREE RADICAL, SEMIDEHYDROASCORBATE, DURING DOPAMINE-β-HYDROXYLATION: COUPLING OF DOPAMINE-β-HYDROXYLASE TO SEMIDEHYDROASCORBATE REDUCTASE. Emanuel Diliberto, Jr.* and Pamela Allen* (Spon: James L. Howard) Dept. of Medicinal Biochemistry, Wellcome Res. Lab., Research Tri. Park, NC 27709.

Dopamine-β-hydroxylase (DBH), a mixed function oxidase, catalyzes the ascorbate-dependent oxidation of dopamine to norepinephrine. Currently, β-hydroxylation is thought to occur by the transfer of two electrons from one molecule of ascorbate to DBH with the release of dehydroascorbate; the reduced enzyme is then reoxidized by molecular oxygen and substrate with the formation of the β-hydroxylated product and water [Friedman and Kaufman, JBC, 240: 4763 (1965)]. No neural enzyme system catalyzing the reduction of dehydroascorbate has been found. Recently, Staudinger, et al. [Ann. N.Y. Acad. Sci., 92: 195 (1961)] discovered a rat liver enzyme, semidehydroascorbate reductase (SDR) which catalyzes the NADH-dependent reduction of semidehydroascorbate to ascorbate. Studies on the mechanism of catechol oxidation by DBH suggested the involvement of partially reduced DBH in the catalytic oxidation of catechol [Diliberto and Kaufman, Fed. Proc. 37: 835 (1978)]. For these reasons, the possibility of generation of the free radical, semidehydroascorbate, during β-hydroxylation and the recycling of ascorbate by SDR in the adrenal medulla was investigated. SDR was found in all membrane fractions of the bovine adrenal medulla, including the chromaffin vesicle membrane, but not in the soluble fractions. Since DBH is a chromaffin vesicle enzyme, this localization suggests a role for SDR in dopamine-β-hydroxylation. Using SDR from rat liver microsomes, the formation of semidehydroascorbate during β-hydroxylation was examined. Indeed, a tyramine-dependent oxidation of NADH was observed when SDR was present during β-hydroxylation. Further experiments confirming the generation of the free radical, semidehydroascorbate, during β-hydroxylation will be presented. In the presence of catalytic amounts of ascorbate, a coupling of SDR to DBH has been demonstrated: regeneration of active cofactor is observed by the catalytic oxidation of NADH and formation of β-hydroxylated product; delayed addition of SDR results in a decrease in the rate of NADH oxidation; and, with further delay, no oxidation of NADH was observed, indicating the lability of the free radical intermediate. At low rates of hydroxylation, a stoichiometric oxidation of NADH was obtained in the presence of SDR during the formation of octopamine from tyramine. Tyramine dependent oxidation of NADH, inhibited by fusaric acid and stimulated by fumaric acid, can be obtained with purified chromaffin vesicle membranes, suggesting a coupling of membrane bound DBH and SDR. These results are consistent with a role for SDR in β-hydroxylation through regeneration of the active cofactor, ascorbate.

1349 LOCALIZATION OF DOPAMINERGIC RECEPTORS IN RABBIT CAROTID BODY. B. Dinger*, C. Gonzalez*, K. Yoshizaki* and S. Fidone (SPON: J.W. Woodbury). Dept. Physiol., Univ. Utah Col. Med., Salt Lake City, UT 84108.

The precise role of the Type I cells and the afferent nerve terminals in the sensory transduction process of the carotid body has not been experimentally clarified. Ultrastructural studies have repeatedly demonstrated abundant dense-cored vesicles in the Type I cells, characteristic of catecholamine storage. These studies have also identified synaptic-like contacts between the Type I cells and the afferent nerve terminals. Recent biochemical studies have characterized the synthesis and release of dopamine from the carotid body, the most abundant catecholamine in this organ. Pharmacologically, it appears that exogenous dopamine is excitatory in the rabbit and inhibitory in the cat with respect to its effect on afferent fiber discharge. In order to gain further insight concerning the site of action of dopamine, we have attempted in this study to detect and characterize dopaminergic receptors in the rabbit carotid body.

Pairs of rabbit carotid bodies were rapidly removed from pentobarbital-anesthetized animals, cleaned of surrounding connective tissue, and incubated in a waterbath-shaker at 37°C for 20 min. in a modified Tyrode's solution containing different concentrations of ^{3}H-spiroperidol, with and without 0.02 µM (+)-butaclamol. Following incubation the tissue was washed for 6 min. in ice cold Ringer's solution. The weight of each carotid body was determined to the nearest tenth of a microgram. Levels of tissue and incubation media radioactivity were obtained using liquid scintillation spectrometry. Specific binding was defined as the amount of spiroperidol bound in the absence of (+)-butaclamol less the amount bound in the presence of (+)-butaclamol. The data were analyzed on a Scatchard plot. The K_A of binding was calculated to be 0.38 nM, and 4.17 pmoles of receptors are found per gram of tissue. These values compare favorably with those for high affinity dopaminergic receptors in central and peripheral nervous tissue.

In addition, we have begun a study of receptor binding in carotid bodies denervated by removal of the carotid sinus nerve 14 days previously. Preliminary results indicate that denervation does not change either the K_A or the total number of receptors. The available data is suggestive of an autoreceptor system on Type I cells similar to that of dopaminergic neurons in the corpus striatum.

Supported by USPHS grants NS07938 and NS12636.

1350 ABSORPTION AND RETENTION OF HALOTHANE IN FETAL BRAIN. P. Divakaran*, B.M. Rigor*, R.C. Wiggins (Spon H. Kaufman, M.D.). Depts. Neurobiology & Anatomy and Anesthesiology, Univ. Texas Medical School at Houston, Houston, TX 77025.

Because of current interest in the effects of chronic prenatal exposure to inhalation anesthetics, we compared the tissue concentrations of halothane in fetal and adult (maternal) tissues following exposure of pregnant rats to 0.5% halothane. Following various exposure regimes, rats were killed, tissues were collected, frozen in liquid nitrogen, and eventually extracted with 1,2-dichloroethane for analysis by gas chromatography using a flame ionization detector. Our minimum instrument sensitivity was 2 ng; our lower limit of detection in tissue was estimated at 1 µg of halothane per tissue sample. Adult rats were exposed to 0.5% halothane and the concentration in brain and liver was determined at various times between 1 and 30 minutes after start of exposure. Accumulation was initially rapid and within three minutes, adult brain values were 30-40 µg of halothane per gram. After thirty minutes brain values slightly increased to 40-50 µg/g. Adult liver increased from 14 µg/g at three minutes to 30 µg/g at thirty minutes. After exposing 18 day pregnant rats, fetal brain and whole body (minus the head) were analyzed for halothane. After an initial delay of about two minutes, during which time little halothane appeared in the fetus, the halothane concentration in fetal brain increased rapidly from about 8 µg/g at three minutes to about 25 µg/g at six minutes, and then slowly to 25-30 µg/g at thirty minutes. Thus the placental separation of adult and fetal incubation caused only an initial delay in the appearance of halothane in fetal brain. Tissue levels of fetus and mother were comparable after several minutes of exposure. Retention of halothane was determined by exposing groups of pregnant rats to 0.5% halothane for three hours and determining the percentage of halothane remaining at various times after termination of the exposure. After three hours of exposure, tissue concentrations of halothane in these rats were 29 ± 7 µg/g in maternal liver and brain, 26 ± 7 µg/g in fetal brain, and 24 ± 6 µg/g in fetal body. Within three hours after termination of exposure, all tissue values had decreased by about half. Within 24 hours, values were below our detection capability. From these experiments we conclude that interposition of a placenta causes only a brief delay in the entry of halothane into fetal tissue and after thirty minutes, or more, of exposure fetal and maternal tissues contain essentially identical concentrations of halothane. The half life of tissue halothane is about three hours, although we can not rule out long term residual trace binding below our detection limits. This work was supported by Public Health Service Grant NS-14355.

1351 CHRONIC MATERNAL ETHANOL CONSUMPTION: EFFECT ON CNS SYNAPTIC PLASMA MEMBRANE PROTEINS AND GLYCOPROTEINS IN OFFSPRING. M.J. Druse-Manteuffel and A.B. Noronha*, Dept. of Biochemistry, Loyola Univ. Med. Ctr., Maywood, IL 60153.

Female Sprague-Dawley rats were pair-fed using either the control or ethanol liquid diets of Lieber & DeCarli (BioServ) for 2 months prior to conception through parturition. At 9, 16 and 23 days of age, control and ethanol offspring were injected intraventricularly with either ^{3}H- or ^{14}C-fucose. Eighteen hours later rats were sacrificed and synaptic plasma membranes (SPM) were isolated (BBA 249, 380; 1971). ^{3}H-labeled SPM from a control animal were combined with ^{14}C-labeled SPM from an ethanol pup prior to the extraction and separation of proteins by SDS-polyacrylamide gel electrophoresis (Brain Res. 76, 423; 1974). The assignment of isotopes was also reversed. Gels were stained with Fast Green, scanned photometrically and sliced for radioactivity.

The mixture of SPM from control and ethanol pups had numerous proteins. The three major proteins had molecular weights of approximately: 1) 95-100,000; 2)55-60,000 and 3) 45-50,000. The intensity of staining of bands 2 and 3 were nearly equal in 22-day-old control rats. However band 2 stained much more intensely than band 3 in the mixture of SPM proteins from 10-, 17- and 24-day-old control and ethanol pups. This difference was greatest at 10 days. Analysis of the distribution of ^{3}H and ^{14}C radioactivity on gels demonstrated that the ethanol pups incorporated more radioactive fucose into protein 2 than controls. In addition the ethanol pups consistently incorporated more radioactivity into high molecular weight glycoproteins than control rats. These results suggest that the protein and glycoprotein composition of SPM from ethanol pups are abnormal. The observed SPM abnormalities may result in altered synaptic connectivity and function.

This work was supported by a grant from the National Council on Alcoholism. Dr. Mary Druse Manteuffel is the recipient of a Schweppe Foundation Career Development Award.

1352 THE INFLUENCE OF SODIUM CHLORIDE AND GUANYL-5'-YL IMIDODIPHOSPHATE ON MUSCARINIC RECEPTOR BINDING. Frederick Ehlert*, Lois Rosenberger*, William Roeske*, and Henry Yamamura. Dept. of Pharmacology, University of Arizona Health Sciences Center, Tucson AZ 85724

The effect of sodium chloride and guanyl-5'-yl imidodiphosphate (Gpp(NH)p) on muscarinic receptor binding in the rat brain and longitudinal muscle of the rat ileum was investigated with the specific muscarinic receptor affinity label [^{3}H](-)quinuclidinyl benzilate ([^{3}H](-)QNB). The concentrations of sodium chloride and Gpp(NH)p employed during binding experiments were 200mM and 30µM respectively. All binding assays were run using 50mM TRIS-HCL buffer (pH 7.4) as the incubation medium. When measured by competitive displacement of ileal [^{3}H](-)QNB binding, the IC_{50} of oxotremorine increased 3 to 10 fold in the presence of sodium chloride. A similar increase in the IC_{50} of oxotremorine was observed when ileal binding measurements were made in the presence of Gpp(NH)p. In contrast, sodium chloride and Gpp(NH)p only caused small increases in the IC_{50} of oxotremorine as determined in whole brain binding experiments. These results illustrate some qualitative differences between central and peripheral muscarinic receptors. The influence of sodium chloride and Gpp(NH)p on the binding of muscarinic antagonists was investigated by competitive displacement of [^{3}H](-)QNB binding by atropine and by direct saturation studies with [^{3}H](-)QNB. In both the ileum and the brain, sodium chloride and Gpp(NH)p only produced small effects on antagonist binding. Thus, sodium chloride and Gpp(NH)p appear to have a preferential effect on agonist binding to the muscarinic receptor. Supported in part by USPHS grants, Huntington's Diseased and Hereditary Disease Foundations.

1353 THE EFFECTS OF ORALLY ADMINISTERED U-0521 (COMT), AN INHIBITOR OF CATECHOL-O-METHYLTRANSFERASE. Stanley Fahn and A.L.N. Prasad*
Department of Neurology, College of Physicians and Surgeons, Columbia University, New York, New York 10032

U-0521 given intraperitoneally to rats was an effective inhibitor of COMT, but was toxic in high dosages when administered with levodopa. In this present study, U-0521 was administered p.o. to rats. To effectively inhibit methylation of orally-administered levodopa, U-0521 had to be administered 30-60 min prior to levodopa. U-0521 blocked methylation periphally and in brain for up to 4 hrs following levodopa administration. A dose-response curve revealed that 400 mg/kg of U-0521 produced maximum inhibition of methylation of levodopa. Lowering the dose of levodopa did not increase the percent of inhibition of methylation, indicating that the active sites of COMT were not saturated at a dose of 250 mg/kg or 400 mg/kg of U-0521. Of potential therapeutic importance was the observation that doses of up to 500 mg/kg of U-0521 were not toxic to rats.

1354 CYCLIC NUCLEOTIDES IN THE CONE-DOMINANT RETINA OF HIBERNATING GROUND SQUIRREL. Debora B. Farber, David Chase*, Dennis Souza* and Richard N. Lolley. Jules Stein Eye Institute, UCLA School of Medicine, Los Angeles, CA 90024, and V.A. Medical Center, Sepulveda, CA 91343.

The retina of the 13-line ground squirrel contains almost exclusively cone photoreceptors. Upon entering or emerging from hibernation, cone photoreceptors of the ground squirrel undergo major changes in morphology, some of which have been reported by Reme and Young (Invest. Ophthalmol. 16, 815, 1977) and by Kuwabara (Invest. Ophthalmol. 14, 457, 1975). In addition to a reduction in the length of cone outer segments, synaptic ribbons are decreased in size and number during the early stages of hibernation and are re-formed upon emergence from hibernation. Changes in synaptic ribbon morphology are specific to visual cells because synaptic ribbons of the bipolar terminals are unchanged during hibernation. Cyclic AMP levels of non-hibernating, dark-adapted ground squirrels exceed those of cyclic GMP by about 8-fold; white light causes a significant reduction in cAMP levels exclusively. During hibernation at 6°C, cAMP levels are modified but cGMP content is not affected. During the first days of hibernation, retinal cAMP levels rise above the values measured in non-hibernating squirrels in a dark-room environment. Following one and up to three months of hibernation, cAMP levels are stabilized at a value which is similar to that of non-hibernating animals in the light. Within three days after arousal from hibernation, cAMP levels return to pre-hibernation levels, and cone morphology re-forms simultaneously. These observations suggest that hibernation alters cone cell morphology and cAMP metabolism both. These data also support the proposition that cone photoreceptors contain higher levels of cAMP than cGMP. (Supported by NIH Grant EY02651, RCDA 1 K04 EY00144 (to DBF) and the Medical Research Service of the Veterans Administration.)

1355 SYNTHESIS AND RELEASE OF CATECHOLAMINES BY THE CAT CAROTID BODY: EFFECTS OF HYPOXIC STIMULATION. S. Fidone, C. Gonzalez* and K. Yoshizaki*. Dept. Physiol., Univ. Utah Col. Med., SLC, UT 84108.

The presence of large amounts of catecholamines (CA), mainly dopamine (DA), in cat carotid body is well established. The inhibitory effect of DA on the chemosensory activity in this animal is apparently different from its action in the rabbit, rat and perhaps dog, where its effects are reportedly mainly excitatory. In previous studies, we have characterized in detail the process of biosynthesis and release of DA from the rabbit carotid body. Because of the difference in DA actions in rabbit vs. cat, it was of interest to compare certain aspects of DA metabolism in these two species.

In experiments dealing with the synthesis of CA by cat carotid body, hypoxic stimulation was effected by exposure of the animals for a 3 hr. period in an atmosphere of 10% O_2 in N_2 immediately prior to removal of the carotid bodies for incubation in modified Tyrode's solution containing ^{3}H-tyrosine or ^{3}H-dopa. In the release experiments, the carotid bodies were first pre-loaded with labelled DA synthesized from ^{3}H-tyrosine, and then mounted in a superfusion system that permitted simultaneous collection of the superfusates and monitoring of the chemosensory discharge from the carotid sinus nerve. Hypoxic stimulation involved superfusion with media equilibrated with different O_2 tensions.

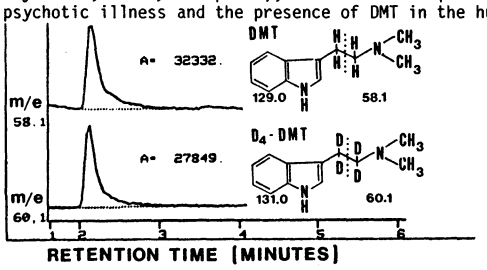
Our findings can be summarized as follows: 1) The kinetic characteristics of the process of synthesis of CA in the cat carotid body is similar to that observed in the rabbit, and both are comparable to that described for other catecholaminergic structures. 2) As in the rabbit carotid body, hypoxic stimulation in the cat does not modify the rate of synthesis when ^{3}H-dopa is used as precursor but with ^{3}H-tyrosine the synthesis is increased by more than 80% above control value. 3) There is spontaneous release of ^{3}H-DA from cat carotid body as well as a stimulus-related increase in ^{3}H-DA release which is proportional to the intensity of the hypoxic stimulation. The increase in chemoreceptor discharge from the carotid sinus nerve parallels the increase in ^{3}H-DA release. These findings are similar to our previous observations with rabbit carotid body. Thus, although other studies in our laboratory have shown clear differences between rabbit and cat with regard to the long-term effects of hypoxia on tyrosine hydroxylase activity in the carotid body, the present study fails to uncover any striking differences in the short-term synthesis of DA or its pattern of release in these two animals. Supported by USPHS grants NS07938 and NS12636.

1356 BIOCHEMICAL DEMONSTRATION OF THE MYELIN-ASSOCIATED GLYCOPROTEIN IN PERIPHERAL NERVE. D. A. Figlewicz*, R. H. Quarles*, N. H. Sternberger*, and G .R. Barbarash* (SPON, W. D. Lust). NINCDS, NIH, Bethesda, MD 20205

Recent immunocytochemical studies with antisera prepared to the CNS myelin-associated glycoprotein (MAG) revealed staining in both Schwann cells and the periaxonal portions of myelin sheaths in the rat trigeminal ganglion (Sternberger et al, PNAS 76: 1510, 1979). However, previous biochemical studies had not demonstrated MAG in the PNS. A combination of biochemical and immunological procedures has now been used to show that rat sciatic nerve myelin contains a high mol. wt. glycoprotein with properties very similar to MAG of the CNS. Sciatic nerves of adult rats were injected with 25 to 50 μcuries of (^{3}H)fucose, and myelin was isolated from the nerves 18 h later. In addition, the myelin-related "W" fraction released by osmotic shock was isolated (McIntyre et al J. Neurochem. 30: 991, 1978). Approximately, 4.4 mg myelin protein and 1.7 mg "W" fraction protein were isolated per g sciatic nerve tissue. Electrophoresis of myelin and "W" fraction proteins on SDS 10% polyacrylamide gels revealed that a large percentage of (^{3}H)-fucose was incorporated into the P_O protein, with smaller proportions into two lower mol. wt. proteins. Also, a small amount of radioactivity could be detected in several high mol. wt. proteins. The "W" fraction had consistently higher levels of incorporation into these high mol. wt. glycoproteins than the PNS myelin fraction. Some of these glycoproteins could be separated from P_O and the smaller glycoproteins by application of the lithium diiodosalicylate(LIS)-phenol procedure previously shown to selectively extract MAG from CNS myelin (Quarles and Pasnak, Biochem. J. 163: 635, 1977). Electrophoresis of the LIS extracts from the PNS myelin and "W" fractions, together with an internal standard of (^{14}C)fucose-labeled CNS myelin, demonstrated a prominent ^{3}H peak that had a small second peak or shoulder on its trailing edge which appeared to co-electrophorese with the CNS MAG. The LIS extracts of PNS myelin and "W" fractions were incubated with a specific rabbit antiserum to rat brain MAG. Addition of goat anti-rabbit IgG resulted in the precipitation of a small percentage of the (^{3}H)fucose-labeled glycoproteins. Electrophoresis of this immune precipitate revealed a single ^{3}H peak that migrated almost identically with (^{14}C)MAG from CNS myelin. Thus sciatic nerve has a minor glycoprotein with immunological and biochemical properties similar to MAG of the CNS. It seems likely that this periaxonal glycoprotein could function similarly in glial-axonal interactions in the PNS and CNS.

1357 DETERMINATION OF N,N-DIMETHYLTRYPTAMINE IN HUMAN CEREBROSPINAL FLUID (CSF), INTRAVENTRICULAR FLUID (IVF) AND RAT BRAIN USING GAS CHROMATOGRAPHY-MASS SPECTROMETRY. Joachim P. Gardemann, John M. Beaton, George B.Brown and John R. Smythies, Neurosciences Program, University of Alabama in Birmingham, B'ham, AL 35294.

The hallucinogen N,N-dimethyltryptamine (DMT), which may be produced by aberrant N-methylation of tryptamine, has been postulated as a psychotoxin responsible for the symptoms of schizophrenia. The studies to be presented here were carried out to determine (1) if exogenously administered DMT is taken up into the synaptic regions of rat brain and (2) if DMT is an endogenous substance in human CSF or IVF. Adult male Long-Evans rats were injected IP with 5, 10 or 20 mg/kg α, α, β, β-tetradeuterated DMT (D_4-DMT) 30 min. prior to sacrifice. Purified synaptic vesicles were then prepared from the brains of groups of three rats. The vesicles were extracted with methylene chloride and the extract derivatized with heptafluorobutyryl imidazole (HFBI). Samples of the derivatized extract were then analyzed on a GC/MS. The electron impact mass spectrum of the DMT as HFBI - derivative exhibits m/e 58.1 as the base peak due to alpha - cleavage of the tertiary amino group. Aliquots of 1 to 3 µl were chromatographed over a four-foot glass column, 2mm i.d., of 2% SP-2250 at 150°C for 2 min., followed by a programmed temperature increase of 10°/min. to 250°C. Under these conditions, DMT-HFB and D_4-DMT-HFB eluted at 2.2 min. Identification of the two compounds was based upon retention time and selected ion monitoring of the mass fragments 58.1 and 129.0 for DMT-HFB and 60.1 and 131.0 for D_4-DMT-HFB. The exogenously administered D_4-DMT was found to be present in the rat brain synaptosomes after intraperitoneal injection of 5, 10 or 20 mg/kg. Quantitative analyses of human CSF and IVF were achieved by using D_4-DMT as an internal standard. The occurrence of endogenous DMT could be shown in some human samples. The data below indicate approximately 100 ng DMT per 1 ml, occurring in a sample of human IVF. In extending similar studies from our laboratory (Biol. Psychiat., 1979, in press), no relationship was found between psychotic illness and the presence of DMT in the human CSF or IVF.



1358 BRAIN ALKALINE PHOSPHATASE IN MAMMALIAN SPECIES. David J. Goldstein and Harry Harris*. Dept. Human Genetics, School Medicine, University of Pennsylvania, Phila., Pa. 19104

At least three gene loci are involved in the expression of the various forms of human alkaline phosphatase (ALP); one coding for the placental form of the enzyme; at least one coding for the intestinal form; and at least one coding for the liver, bone and kidney forms. These three classes of human alkaline phosphatase can be discriminated one from another by their behavior with certain inhibitors, by thermostability, by electrophoresis and by immunologic characteristics.

We studied the alkaline phosphatase in brains and livers from several species including rodents (mouse, rat, guinea pig, hamster), a carnivore (cat), ruminants (cow, sheep) and man. By thermostabilities and degree of inhibition with L-phenylalanine, L-homoarginine and L-phenylalanylglycylglycine, the brain ALP in all these species, including man, closely resemble the liver/bone/kidney ALP.

When comparing the activities of brain ALP of certain adult and of fetal animals, a large developmental difference was discovered. Fetal guinea pig brain contained nearly twenty-fold greater activity than an adult. Newborn lamb brain contained about five-fold greater activity than adult in the cortex and cerebellum and about a ten-fold greater difference in the mid and hind brain. In addition, fetal rat brain contains six-fold greater activity than adult rat brain.

These findings raise interesting questions about the role of alkaline phosphatase in the brain.

1359 EFFECTS OF LOW Ca^{++}, HIGH Mg^{++} ON CHEMOSENSORY DISCHARGE AND RELEASE OF DOPAMINE FROM RABBIT CAROTID BODY. C. Gonzalez*, K. Yoshizaki* and S. Fidone (SPON: P.R. Burgess). Dept. Physiol., Univ. Utah Col. Med., Salt Lake City, UT 84108.

The presence of a synapse between the Type I cells of the carotid body and their sensory nerve terminals is a striking ultrastructural feature of this chemoreceptor organ. A high concentration of dopamine (DA) and numerous dense-cored vesicles in the Type I cell cytoplasm are also characteristic of carotid body ultrastructure, and it has been suggested that DA may play a key role in the mechanisms of chemoreception.

In previous studies we established that with varying levels of hypoxia the release of DA from rabbit carotid body increased with increases in chemosensory discharge. In the experiments described here, we investigated the effects of removal of Ca^{++} from the superfusion medium and its substitution by Mg^{++}. Carotid bodies were pre-loaded with ^{3}H-DA synthesized from ^{3}H-tyrosine and were then mounted in a superfusion system that allowed collection of the superfusates together with the simultaneous recording of the sensory discharges from the carotid sinus nerve. A single experiment consisted of 4 superfusion cycles, each of 45 min. duration subdivided into pre-stimulus (control), stimulus and post-stimulus collection periods. The stimulus period consisted of 5 min. of superfusion with 20% O_2 in N_2-equilibrated media. During the remaining periods, the carotid body was superfused with 100% O_2-equilibrated media. In the first and last cycles, superfusions were performed with media of normal ionic constitution, while in the middle two cycles the media contained either 0 Ca^{++} or 0 Ca^{++} plus 2.1 mM Mg^{++}. We found that during superfusion with normal-ionic media, the stimulus-related release of ^{3}H-DA was 10-13 times greater than basal release levels and the chemoreceptor discharges were 6-9 times basal levels. Neither the basal discharge or the basal release of ^{3}H-DA were affected by the 0 Ca^{++}, high Mg^{++} media, but the stimulus-related release of ^{3}H-DA was increased only 1.3-1.5 times control values and the sensory discharges were increased only 2.6-4.9 times control levels. These data suggest that the hypoxia-induced release of DA from rabbit carotid body is Ca^{++}-dependent, and that DA release may be important for the full expression of chemosensitivity in this organ.

1360 CHARACTERIZATION OF ENKEPHALINASE. Charles Gorenstein and Solomon H. Snyder. Dept. Pharmacol., Sch. Med., Johns Hopkins Univ., Baltimore, MD 21205

Enkephalinase, a membrane bound dipeptidyl-carboxypeptidase, can degrade enkephalin in a highly specific fashion. Its high affinity for enkephalin, regional variation paralleling the opiate receptor and changes during addiction suggest that the enzyme is responsible for the inactivation of the neurotransmitter (Malfroy et al., Nature 276:523, 1978; Swerts et al., Eur. J. Pharmacol. 53: 209, 1979). We have developed a binding assay using a ^{3}H-peptide ligand displaying uniquely high affinity for the enzyme. Peptide specificity for the binding site is identical to that of enkephalinase activity assayed by measuring enkephalin degradation. Binding and catalytic activity of the enzyme in mouse and rat brain have been explored in the soluble and purified state. Alterations in binding and catalytic activity have been evaluated as a function of changed sensitivity to opiates, angiotensin and Bradykinin also substrates for enkephalinase. (Supported by USPHS grant DA-00266)

1361 DISTRIBUTION OF THE OLFACTORY MARKER PROTEIN IN THE OLFACTORY MUCOSA OF PRE- AND POST-NATAL MICE. P. P. C. Graziadei, G. A. Monti Graziadei* and R. S. Stanley* (SPON: J. S. Elam). Dept. Biol. Sc., F.S.U., Tallahassee, FLA 32306.

With immunohistochemical techniques it has been shown that the olfactory marker protein (OMP) is localized in the mature olfactory neurons of adult mice. The immature stem elements of the neurons and the supporting cells do not stain with the peroxidase-antiperoxidase method, and are presumed not to contain the protein (G. A. Monti Graziadei et al., J. Histochem. Cytochem. 25, 1977). The peroxidase-antiperoxidase method can consequently be used to determine the proportion of mature versus immature elements in embryos as well as in animals of different age. Differentiated olfactory neurons, with an apycal dentrite and an axon, are present at ten days gestation in the deepest part of the olfactory pit. At 14 days the olfactory epithelium contains a continuous layer of differentiated elements. The OMP begins to appear at this time, when it is present in few scattered neurons. The number of neurons containing the OMP rapidly increases. At 17 days of gestation positive neurons are found all through the sensory area, however some regions of the neuroepithelium are devoided of marker. In neonatal mice the common histological stains evidentiate an epithelium which is not substantially different from the one of the adult animals. However, the mature neurons stained by antiserum to OMP are restricted to a small band which occupies the distal portion of the neuronal layer. The number of stained neurons increases till 30 days postnatally, when an equilibrium is reachedbetween mature and immature elements. However, the proportion mature/immature neural elements is not constant all through the sensory sheath. Even in the adult animals there are zones where the immature elements prevail over the mature ones. These data are in agreement with previous morphological and autoradiographic observations (Graziadei and Monti Graziadei, J. Neurocytol. 8, 1979) which have shown in the neuroepithelium zones where the neurogenetic process is more/less vigorous. These zones have been termed accordingly: active and quiescent zones.

1362 MOUSE PNS MYELIN: AN ANALYSIS OF PROTEIN COMPOSITION FOR YOUNG AND ADULT QUAKING AND NORMAL MICE. S. Greenfield*, M. J. Weise*, H. Sarvas*, S. W. Brostoff* and E. L. Hogan. Departments of Neurology, Biochemistry and Immunology, Medical University of South Carolina, Charleston, S. C. 29403.

In order to determine whether the abnormalities in ultrastructure and lipid content of Quaking (Qk) mouse PNS are accompanied by alterations in the protein composition of PNS myelin, mouse sciatic nerve myelin was isolated from 21-25 day old and from adult normal (N) and Qk mice. The yield of myelin isolated from adult Qk mouse sciatic nerve was two-thirds of control. In contrast to the initial characterization of the protein compositions of Qk and N adult mouse PNS myelin (Greenfield et al., Trans. Am. Soc. Neurochem. 55, 1978), a recent report (Matthieu, Biochem. J. 173, 989, 1978) has shown a drastic decrease in basic protein content of Qk compared to N sciatic nerve myelin. In our current studies, as before, we find that most differences are limited to 30% or less. Exceptions to this are 1) a 42% decrease in P_m (the small basic protein analogous to B_S of CNS myelin - Milek et al., Trans. Int. Soc. Neurochem., 1979) of Qk vs. N at 21-25 days, and 2) a two-fold increase in "10.5K" (Singh et al., Brain Res. 144, 303-311, 1978) in Qk vs. N adults. Analysis of myelin protein preparations in a basic protein RIA shows only 20-30% less basic protein for Qk vs. N mouse.

Our analysis of myelin from young and adult mice also suggests the occurrence of an age-related shift towards an increase in the ratio of the small to large PNS basic proteins (P_m and P1, respectively) similar to that observed for B_S and B_L of CNS myelin. This shift during maturation may not be as pronounced in Qk mice. Thus, although the P_m and P1 proteins have been shown by SDS gel and RIA analysis to be analogous to B_S and B_L (Milek et al.), the pathology in the Qk mouse appears to have a lesser effect on the protein composition of PNS compared to CNS myelin.

1363 BENZODIAZEPINES AND PURINERGIC DEPRESSION OF CENTRAL NEURONS. Leif Hertz, Peter H. Wu* and John W. Phillis. Depts. Anat. and Physiol., Sch. Med., Univ. Sask., Saskatoon, Canada S7N OWO.

Adenosine and adenine nucleotides depress the spontaneous firing of rat cerebral cortical neurons (Can. J. Physiol. Pharmacol. 52, 1226, 1974). Inosine, adenine and 2'-deoxyadenosine have a similar but weaker action. Hypoxanthine and guanosine are virtually devoid of depressant activity. The benzodiazepines, diazepam and flurazepam, also depress the firing of cerebral cortical neurons and in sub-threshold amounts potentiate the depressant actions of adenosine and its nucleotides. Theophylline antagonizes the depressant effects of both the purines and flurazepam. Inosine, inosine 5'-monophosphate, adenine, 2'deoxyadenosine and guanosine did not antagonize adenosine-evoked depressions.

We have previously shown that adenosine is taken up into astrocytes in primary cultures with a Km of 3.4 µM and a Vmax of 0.36 n mol/min per mg protein (J. Neurochem. 31, 55, 1978). In the present work the effects of diazepam, 2'deoxyadenosine, inosine, hypoxanthine and guanosine on adenosine uptake by cultured astrocytes were studied at an adenosine concentration of 5 µM. Uptake of adenosine was greatly inhibited by diazepam (IC_{50}=20 µM) and 2'deoxyadenosine (IC_{50} < 0.25 mM), less efficiently inhibited by inosine and guanosine (IC_{50}=0.5 and 1.0 mM respectively) and only little, if at all, by hypoxanthine (IC_{50} >2.5 mM). These findings are consistent with the hypothesis that diazepam may elicit its depressant actions by enhancing the levels of extracellular endogenously released adenosine and further suggest that compounds such as inosine and 2'deoxyadenosine exert their depressant actions, at least in part, by a similar mechanism, namely by inhibiting the uptake of adenosine into brain cells. The failure of iontophoretically applied weak agonists or inactive substances such as inosine, guanosine, adenine and 2'deoxyadenosine, which like adenosine displace diazepam from its binding site in brain tissue (Life Sci. 24, 851, 1979), to antagonize adenosine-elicited depression is a further indication that the diazepam binding site in brain tissue cannot be identical with the adenosine receptor. The diazepam binding site may therefore be the adenosine uptake site.

Supported by the Medical Research Council.

1364 EXPERIMENTAL ALLERGIC NEURITIS IN THE RAT - STRAIN DIFFERENCES IN THE RESPONSE TO BOVINE P2 PROTEIN. P. M. Hoffman*, J. M. Powers* and S. W. Brostoff* (SPON: G. F. Young). V.A. Medical Center, Charleston, S.C. and Departments of Neurology and Pathology (Neuropathology), Medical University of South Carolina, Charleston, S.C. 29403.

Bovine peripheral nerve myelin antigens were tested for their ability to produce experimental allergic neuritis (EAN) in three inbred and one outbred strains of rat. Each antigen was emulsified with complete Freund's adjuvant (CFA) (Difco H37ra) and injected intradermally into both hind footpads in a total volume of 0.2ml/animal. Clinical disease and histologic lesions characteristic of EAN were prominent in Lewis rats but not in Sprague-Dawley, Bufflo or Wistar rats, when bovine P2 or whole PNS myelin was used. Lewis rats responded with the most severe lesions and clinical signs when challenged with bovine PNS myelin (2 mg/animal) which contains P2 protein in its native configuration. Isolated P2 protein (200 ug/animal) produced definite but less severe disease. Reduction of disulfide bonds by treatment with mercaptoethanol enhanced the neuritogenicity of P2 protein. When rats were challenged with bovine galactocerebroside in CFA in the absence of bovine P2, no clinical or histologic evidence of EAN was present in any of the strains tested. These studies confirm the marked susceptibility of Lewis rats to EAN induction with isolated, intact bovine P2 protein (Nature 277, 140, 1979) in contrast to rabbit, guinea pig and monkey, which show no such susceptibility. As we earlier noted in the rabbit (Nature 268, 752, 1977), the conformation of the P2 protein may be important in determining its ability to induce EAN.

Supported in part by the Veterans Administration and by NIH Grant No. NS11867.

1365 PHOSPHORYLATION OF RIBOSOME-ASSOCIATED PROTEINS IN CEREBRAL CORTEX. Larry A. Holbrook and Sidney Roberts. Dept. Biol. Chem. Sch. Med., and Brain Res. Inst., UCLA, Los Angeles, CA 90024.

Several investigators have shown that intraperitoneal administration of a loading dose of phenylalanine to infant rats results in polyribosome disaggregation and alterations in ribosomal function in the brain. Current investigations in our laboratory indicate that protein phosphorylation mechanisms at the ribosome level are involved in these phenomena. The present studies were designed to investigate the possibility that phenylalanine treatment may alter brain protein synthesis by changing the phosphorylation state of initiation factors and other ribosome-associated proteins whose activity is known to be affected by this process. Infant (7-day old rats) were given [^{32}P]orthophosphate intracisternally and shortly thereafter, phenylalanine (1 mg/g body wt) or an equivalent volume of 0.9% NaCl was injected intraperitoneally. The animals were killed 1 h later. Purified polysomes were prepared from the cerebri and incubated in buffer containing 500 mM KCl to release ribosome-associated proteins. After repelleting the ribosomes, the supernatant was made to 70% $(NH_4)_2SO_4$. The resultant protein pellet was analyzed on sodium dodecyl sulfate slab gels. Five major phosphoproteins were consistently found in both saline and phenylalanine-treated rats with estimated molecular weights around 110,000, 72,000, 60,000, 36,000, and 31,000. A second method of isolating initiation factors after ^{32}P-labelling in vivo was also used which involved binding of proteins present in the cerebral cytosol to a heparin-Sepharose affinity column. A wide spectrum of bound proteins distinguishable by staining and ^{32}P-labelling eluted with a 70-500 mM KCl gradient. A fraction eluting around 350 mM KCl stimulated reinitiation in a cell-free protein-synthesizing system. This fraction had major phosphoproteins of approximate MW 125,000, 112,000, 49,000, 37,000, and 17,000. The high-salt wash preparation contained only ribosome-associated proteins while the heparin-bound presumably had both free and bound translational factors. The heparin-bound initiation-stimulating fraction also had protein kinase activity which selectively phosphorylated a 38,000 MW protein in the presence of cyclic AMP. Overall phosphorylation of the proteins in these preparations appeared to be increased in phenylalanine-treated animals, but the specific factors responsible for this increase have not yet been identified. These results suggest that variations in the phosphorylation of translational factors may be involved in alterations in brain protein synthesis in experimental hyperphenylalaninemia. 1366 REGIONAL DISTRIBUTION OF ACETYL-COENZYME A HYDROLASE IN RAT BRAIN. L.L. Hsu*, S.-C. Liang*, P. Hicks* and J. Claghorn (SPON: L.-P. Chao). Texas Research Institute of Mental Sciences, 1300 Moursund Avenue, Houston, TX 77030.

Acetyl-coenzyme A hydrolase (EC 3.1.2.1, AcCoA H) has been described in brain, pineal gland and blood. The distribution of this enzyme in brain, however, has not been reported. Since AcCoA H may play an important role in regulating the endogenous acetyl-coenzyme A levels in brain, and thus trigger acetylcholine synthesis, we investigated its distribution in several brain regions of the rat, for comparison with CAT activities. Five adult male Sprague-Dawley rats were sacrificed by decapitation and selected brain regions were dissected and frozen at -20°C until analysis. AcCoA H and CAT activities were determined in corpus striatum, hypothalamus, hippocampus, diencephalon, midbrain and septum. Our results showed that septum had highest AcCoA H activity (10.29 ± 0.85) followed in descending order by corpus striatum, midbrain, diencephalon and hippocampus. Hypothalamus had the lowest activity (0.66 ± 0.022 nmol AcCoA hydrolyzed/mg protein/20 min.). Similarly, septum also had the highest CAT activity (17.49 ± 1.44 nmol acetylcholine formed/mg protein/15 min.), followed in descending order by corpus striatum, (14.17 ± 0.59), hippocampus, diencephalon and midbrain. Hypothalamus again showed the lowest CAT activity (4.71 ± 0.22). In conclusion, the regional distribution of AcCoA H in brain correlates ($r = 0.82$, $p<0.05$) well with that of CAT and these observations further support the notion that AcCoA H may influence the biosynthesis of ACh in brain by regulating the acetyl-donor levels.

1367 EFFECTS OF SODIUM FLOURIDE, A PHOSPHATASE INHIBITOR, ON TYROSINE HYDROXYLASE ACTIVITY IN VITRO. T.H. Joh, M.E. Ross*, M.J. Brodsky*, D.H. Park and D.J. Reis. Lab. of Neurobiol., Dept. of Neurol., Cornell Univ. Med. College, New York, NY 10021.

We have proposed that native tyrosine hydroxylase (TH) from the caudate nucleus (CN) of rat brain is composed of a mixture of active and inactive forms, and that phosphorylation of the enzyme by cAMP-dependent protein kinase and ATP converts an inactive (-P) to an active (+P) form (PNAS, 75:4744, 1978). This implies that an active form (+P) can be converted to an inactive form (-P) by protein dephosphorylation which may be mediated by an endogenous protein phosphatase in crude enzyme extracts. If so, addition of NaF, a commonly used phosphatase inhibitor, to the TH assay mixture may block dephosphorylation, thereby increasing the TH activity. We have studied the effects of NaF on TH activity in crude tissue preparations (39,000g supernatant) in which protein phosphatase may be present. In order to examine whether the effect of NaF is tissue-specific, various tissues containing TH were used, including substantia nigra (SN) and CN (dopaminergic neurons), locus ceruleus (noradrenergic neurons) (LC) and adrenal medulla. Addition of NaF to the assay mixture of dopaminergic neurons significantly ($P<.001$) increased TH activity when using $(MePH_4)=1x10^{-4}$M: in SN it increased from 836±132 (pmol/mg/20min±SEM) to 1531±328 and in CN from 1886±292 to 3446±540. In noradrenergic neurons, TH activity in the LC was increased by only 10% (378±56 to 432 ±58) while no increase was observed in adrenal. The increase in TH activity was more apparent in measurements of initial (5 min) velocity: SN to 195%, CN to 220%, LC to 130% without change in adrenal. When $(MePH_4)=1x10^{-3}$M was used, the initial velocity of only dopaminergic neurons was increased by 30%: in SN (1108±194 to 1435±256) and CN (2716±302 to 3543±350). This NaF effect was found to be concentration-dependent with the maximum increase in TH activity occurring at (NaF)=50mM. These results indicate that dephosphorylation of TH may occur in vivo and that dephosphorylation by phosphatase decreases TH activity, especially in dopaminergic neurons. The smaller effect of NaF observed at higher concentrations of $MePH_4$ can be explained by the finding that high $MePH_4$ concentrations produce a cooperative activation of TH in crude tissue extracts, regardless of whether TH is in the (+P) or (-P) form (Trans. Am. Soc. Neurochem., 10:164, 1979). These findings confirm our hypothesis that TH, especially in dopaminergic systems, consists of (+P) and (-P) forms which coexist in a state of equilibrium. The regulation of TH activity may depend on interconversion of (-P)⇌(+P) by protein kinase (⟶) and phosphatase (⟵).

1368 ADENOSINE REGULATES CYCLIC AMP FORMATION IN SPINAL CORD THROUGH ALPHA-ADRENERGIC RECEPTORS. David J. Jones and Laurie F. McKenna*. Depts. Anesth. and Pharmacol., Univ. Tex. Hlth. Sci. Ctr., San Antonio, Tex. 78284

Previous studies from our laboratory have demonstrated norepinephrine-stimulated formation of cyclic AMP in rat spinal cord tissue slices to be mediated by both alpha and beta-adrenergic receptors. The regulation of the alpha component of this response by adenosine was investigated in the present studies using incubated rat spinal cord tissue slices. 150-175 Gm ARS/Sprague Dawley rats were decapitated and cervical to sacral spinal cord removed. The cord was then sliced bi-directionally using a McIlwain tissue chopper set at 300 μm and slices preincubated for 40 min in oxygenated Krebs-Ringer bicarbonate buffer. Aliquots of tissue were subsequently distributed into incubation flasks with fresh buffer for an additional 15 min, at which point NE, phenylephrine (PE) or isoproterenol (ISO) were added. Antagonists phenoxybenzamine (PBA) or propranolol (PPL) and/or adenosine were added 10 min prior to NE, PE or ISO addition. Following addition of agonists the incubations were carried out for 10 additional min at the end of which tissue slice protein was acid-denatured and cyclic AMP measured by radioimmunoassay. All units are pmoles cyclic AMP/mg protein.

The addition of 10^{-4} M NE stimulated cyclic AMP accumulation from 7.3 ± 0.7 to 41.0 ± 3.2. The prior addition of 10^{-4} M adenosine potentiated the response with NE to 60.5 ± 5.3 ($p<.01$ vs NE). Adenosine alone produced an insignificant increase in cyclic AMP accumulation (10.5 ± 1.8). The alpha-adrenergic receptor stimulant PE at 10^{-4} M produced only a slight increase in cyclic AMP (10.9 ± 0.9, NS). However, when added in presence of adenosine, a 4-fold increase occurred (45.4 ± 6.3). ISO at 10^{-4} M stimulated cyclic AMP formation (16.7 ± 0.9, $p < .025$) which was not altered in the presence of 10^{-4} M adenosine. 10^{-5} M PBA blocked completely the increase in cyclic AMP due to adenosine with either NE or PE, whereas PPL did not. In addition the adenosine receptor blocking agent theophylline at $5x10^{-4}$ M also blocked the enhanced response due to adenosine with either NE or PE. It is evident from this data that adenosine modulates the alpha receptor response for cyclic AMP accumulation in spinal cord tissue slices.

1369 SYNAPTOSOMAL DOPA DECARBOXYLASE (DDC) AND TYROSINE HYDROXYLASE (TH) ACTIVITIES ARE SENSITIVE TO CHANGES IN AMINO ACID TRANSPORT. Ira R. Katz* (SPON: Nansie S. Sharpless). Dept. of Psychiatry, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Previous studies of the extent to which amino acid transport limits catecholamine formation have compared the rates of transport into heterogeneous synaptosome preparations with synthetic rates. For greater specificity, I studied the effects on DDC and TH activity of amino acids expected to interact with the substrate carrier, using rat striatal P_2 fractions. DDC and dopamine formation from tyrosine (requiring both TH and DDC) were assayed by release of $^{14}CO_2$ from carboxy labelled DOPA and tyrosine; TH, by release of ^3H from 3,5-$^3H_2$-tyrosine. In intact synaptosomes, DDC is inhibited by amino acids of the "L" transport system. Lysis, osmotically or by detergent, gives variable effects on DDC activity; the remaining activity is consistently insensitive to amino acid inhibition. The requirement for synaptosome integrity implies interaction at the level of transport. At 2uM DOPA, various amino acids at 100uM gave inhibition as follows: leucine, 58%; methionine, 32%; valine, 11%; phenylalanine, 60%; p-chlorophenylalanine 58%; and aminobicycloheptanecarboxylic acid, 50%. Leucine was chosen for further study. With 2uM DOPA, 12,38, & 50% inhibitions were seen at 10,25, & 50uM Leucine. Though inhibition was not strictly competitive, it decreased with increasing DOPA. In studies of the interaction between leucine and 3-hydroxybenzylhydrazine, (NSD-1015), a potent DDC inhibitor, it was found that partial inhibition by NSD-1015 led to potentiation of leucine inhibition. This is consistent with a mechanism in which leucine gave inhibition by stimulating DOPA efflux. It would not be predicted for inhibition via inhibition of influx. The above is corroborated by studies of DOPA transport in bulk striatal synaptosomes: at 2 uM DOPA in the medium (and saturating NSD-1015), steady state synaptosomal levels of DOPA are decreased by 37,50,68, & 74% at 10, 25,50, & 100uM leucine. Efflux of DOPA from preloaded synaptosomes is stimulated by leucine. Stimulation of efflux is thus both inferred from kinetic experiments, and measured directly in a heterogeneous preparation. In general, in carrier systems with strong exchange properties, trans stimulation of efflux by amino acids in the medium is expected. Inhibition of TH is also observed. At 2uM tyrosine, $^{14}CO_2$ release is inhibited by 15,21,33, & 47% at 25, 50,100, & 250uM leucine. At 0.5uM tyrosine, $^{14}CO_2$ is inhibited by 48% at 100uM leucine and 64% at 250uM while ^3H release is inhibited by 33% at 100uM and 47% at 250uM. The differential inhibition is consistent with stimulated efflux of DOPA from the synaptosomes. Thus, efflux of substrate and intermediate amino acids must be considered as potential regulatory steps in dopamine biosynthesis.

1370 PERSISTENT ALTERATION IN BRAIN AMINO ACIDS FOLLOWING HYPOXIA AND LESIONS. A. S. Kimes and M. K. Shellenberger. Ralph L. Smith Research Center, Kansas Univ. Med. Center, Kansas City, KS 66103

We have previously reported persistent changes in the levels of catecholamines when adult rats were exposed to carbon monoxide (CO) and allowed to survive 4-6 weeks (Neurosci. Abst. 4:282, 1978). As part of an on-going study we have also examined the effects of CO-induced hypoxia and cortical lesions on the levels of amino acids (Asp, Glu, Gln, and GABA) suspected of being involved with neurotransmission.

Four groups of animals were used. The first group contained male and female adult rats (4 months old) which were exposed to CO (0.42% in air flow 4.5 l/min) until comatose and to a point near respiratory failure. In a second group of adult rats, a discrete area of frontal cortex was removed bilaterally by aspiration under light pentobarbital-ether anesthesia taking care to leave the olfactory tracts and saggital sinus intact. The last two groups were controls; one was of rats exposed to air in the chamber and a second control group consisted of sham operated animals. The brains of animals from these groups (N/group $\geq$ 6) were removed 4-6 weeks after the treatment and rapidly frozen. These brains were sectioned and the PCA soluble fraction analyzed for amino acid levels. The following sections were used: frontal cortex, striatum, midbrain-hypothalamus and pons-medulla. The amino acids were separated by ion exchange chromatography and quantitated fluorometrically.

CO exposure resulted in a significant elevation of Asp (>80%) and Gln (>100%) in the striatum ($p < .05$) in both sexes. Similar significant increases in striatal Asp and Gln were found in the sham operated animals suggesting that these animals experienced some hypoxia. Lesioning resulted in a significant reduction of Gln in the striatum while the Asp response was not consistent across sexes. Male animals showed an increase ($p < .05$) in Asp in hypothalamus and in the area surrounding the lesion in frontal cortex. On the other hand, females showed a significant decrease ($p < .05$) in striatal Asp with no alterations elsewhere.

No significant alterations were found in levels of the suspected neurotransmitters, Glu and GABA. However, the changes seen in Gln and Asp suggest that flux through the compartments of Glu and/or GABA has been altered but not to an extent large enough to be reflected in changes of levels.

In summary, exposure to CO-hypoxia and frontal cortical lesioning cause persistent alterations in amino acid levels as well as the levels of catecholamines. It remains to be determined whether these findings reflect altered metabolic or neurotransmitter functions.

1371 NEUROTOXINS FROM BUNGARUS FASCIATUS VENOM. T.P.A. Kruck* and D.M. Logan* (SPON: J.D. Vickers), Dept. Biology, York University, Toronto, Canada, M3J 1P3.

The increasing cost and limited availability of Bungarus multicinctus venom has encouraged us to examine the venom of the related snake Bungarus fasciatus as a source of specific neurotoxins and in particular a substitute for α-Bungarotoxin. Crude venom was fractionated on several different column materials with optimal separation being obtained with CM30 (Bio Rad) which resolved the venom into 21 protein peaks, 19 of which could be identified separately by 2-dimensional gel electrophoresis. Several of the peaks demonstrated toxicity in mice and subsequent characterization identified both α (postsynaptic) and β (presynaptic) neurotoxin activities. Amino acid analyses of the major peaks showed that several of the peaks had amino acid compositions that were similar to but not identical with those reported by Hanley et al. (Biochem. 16:5840, 1977). In general, however, the molecular weights of the toxin components determined by SDS acrylamide gel electrophoresis and/or amino acid composition exceed the values reported for Bungarus multicinctus α neurotoxins. All identified Bungarus fasciatus toxin components have molecular weights in the range 12,700 to about 22,000, in contrast to α neurotoxins from Bungarus multicinctus (7,000 to 8,500 M.W.). N-terminal amino acid determinations of α neurotoxin fractions identified isoleucine and methionine at the N termini as reported for other elapid α neurotoxins. The cysteine content in these proteins is also very high as has also been found in other snake venom neurotoxins. Binding studies on the individual α neurotoxin fractions will be presented.

1372 DEPLETION OF BRAIN TAURINE CONTENT BY GUANIDINOETHYL SULFONATE. Hugh E. Laird, Shirley Lippincott* and Ryan J. Huxtable*. Dept. of Pharmacology, University of Arizona, Tucson, Az 85721.

Further advances in our understanding of taurine in the brain await the development of pharmacological antagonists to taurine, and the finding of methods to modify taurine concentrations in the brain. We have found that the administration of guanidinoethyl sulfonate to rats, orally as a 1% solution, leads to a drop in taurine concentrations in all regions of the brain. For example, after 9 days of guanidinoethyl sulfonate therapy the concentration of taurine in the cerebellum, inferior colliculi, hypothalamus, midbrain,pons-medulla and cerebral hemispheres were reduced by 30, 30, 37, 51, 43 and 44%, respectively. After 20 days of guanidinoethyl sulfonate treatment taurine had been depleted by 55, 53, 49, 57, 66 and 59%, respectively in the same brain regions. Other free amino acids were not affected by the guanidinoethyl sulfonate. Furthermore, there is a correlation between the depletion of taurine and the accumulation of guanidinoethyl sulfonate. Guanidinoethyl sulfonate is the amidino derivative of taurine and is transported in place of taurine in the isolated perfused heart by a saturable process (Azari et al., Proc. West. Pharm. Soc. 22:, 1979). This transport is a one-component system with a Km of 153 μM and a Vmax of 65 nmole/g dry weight/min. By comparison, taurine is transported in the heart by a saturable process with a Km of 45 μM and a Vmax of 32 nmole/g dry weight/min. (Huxtable and Chubb, Science 198:409-411, 1977). Although the cardiac transport system for taurine has a lower affinity than the taurine transport system found in brain synaptosomes, the structural requirements for transport appear to be similar (Azari et al., vide supra; Hruska et al., Mol. Pharmacol. 14: 77-85, 1978). The experimental modification of taurine concentrations has proved to be difficult (see Huxtable, In: Taurine and Neurological Disorders, pp. 5-17, 1978, for discussion). We propose oral administration of guanidinoethyl sulfonate as a simple and effective method for the experimental manipulation of taurine concentrations in the brain and other organs.

Supported by USPHS NS 14405 and HL 19394

1373 CYCLIC GMP AND CYCLIC AMP INCREASES IN SPECIFIC BRAIN REGIONS FOLLOWING CENTRAL CHOLINERGIC STIMULATION. Robert H. Lenox, G. Jean Kant, and James L. Meyerhoff. Dept. of Medical Neurosciences, Walter Reed Army Inst. of Research, Washington, DC and Dept. Psychiatry, University of Vermont, Burlington, VT.

Evidence for cholinergic mediated increases of cyclic GMP has been demonstrated in a number of organ systems including the brain. Cholinergic agonists have been shown to increase the levels of cyclic GMP in the cerebellum of both rats and mice. Changes in reported levels of cyclic AMP have either been variable or nonexistent. We have proceeded to examine more closely the regional cyclic nucleotide response following central cholinergic stimulation in the brain of the rat.

Male albino rats WRC strain, weighing between 250-300 grams were maintained in a light cycled chamber and all experiments took place at the same time of day. Animals received an intraperitoneal injection of either oxotremorine (2 mg/kg), physostigmine (0.5 mg/kg), or saline 10 minutes prior to sacrifice by exposure to high power microwave irradiation. We used a 2.5 kilowatt, 2450 MHz, microwave inactivation system as modified in our laboratory. Animals receiving the cholinergic agonists were pretreated (30 min.) with methylatropine (0.5 mg/kg) to avoid excess peripheral cholinergic stimulation. Following sacrifice and decapitation, trunk blood was collected for radioimmunoassay for corticosterone (CS) prolactin (Prl) and growth hormone (GH), and 18 brain regions were dissected for radioimmunoassay for cyclic AMP and cyclic GMP.

Levels of cyclic GMP in the cerebellum of animals receiving oxotremorine increased significantly (0.98 ± .11 to 2.03 ± .18 pmoles/mg tissue) as did levels in several other regions, i.e., brainstem, midbrain, hippocampus and thalamus. Physostigmine only increased levels significantly in the midbrain and hippocampus. Oxotremorine increased the levels of cyclic AMP in several regions, e.g., the hypothalamus, substantia nigra and interpeduncular region, with the most dramatic increase in the pituitary (1.15 ± .13 to 14.63 ± 2.74 pmoles/mg tissue). There were no significant differences in CS or Prl levels among the groups. GH however, was significantly reduced following oxotremorine.

The regional pattern of increase in cyclic GMP levels in the animals receiving oxotremorine is similar to the response following locomotor activity (Meyerhoff et al., Life Sci., 1979) consistent with the behavioral observation of tremor. The increased levels of cyclic AMP, particularly in the pituitary and the GH response to cholinergic stimulation are presently undergoing further study.

1374 PARALLEL EFFECTS OF PHYSOSTIGMINE ON CHOLINERGIC ENZYMES IN BRAIN AND IN BLOOD. S.-C. Liang* and L. L. Hsu* (SPON: V. Davis) Texas Research Institute of Mental Sciences, 1300 Moursund Ave., Houston, Texas 77030.

Physostigmine, an anti-ChE drug known to reverse the central effects of atropine poisoning in man, has been clinically used to treat Parkinsonian conditions and extrapyramidal side effects resulting from long term therapy with phenothiazine and butyrophenone. Furthermore, it has been experimentally used in tardive dyskinesia and in the related condition of Huntington's Chorea. Recently, it has been described that I.V. and oral administration of physostigmine led to transient improvement in manics and in chronic schizophrenics. There has been evidence that CAT activity was significantly decreased in hippocampus and limbic lobe of schizophrenics. It has also been reported that during the treatment of paranoid schizophrenics with neuroleptics, there was significant reduction in RBC AChE activity and in plasma pseudocholinesterase (ChE) activity immediately preceeding the administration of anti-parkinsonism agents. There are no reports however, on the correlation between changes in cholinergic enzyme activity in brain and in blood. We have investigated such possible correlations in mice after I.P. administration of physostigmine. For this study, ten adult male DBA/2J mice were divided into two groups: five received 30 ul of physostigmine (0.3 mg/kg, i.p.) and 5 received 30 ul of distilled water (i.p.) injections. Fifty min. following the injections, mice were sacrificed by decapitation. Selected brain regions (corpus striatum, hippocampus and remainder of brain) were immediately dissected and homogenized in 0.05M Na-phosphate buffer (pH, 7.5) for determination of cholinergic Na-phosphate buffer (pH, 7.5) for determination of cholinergic enzyme activities (AChE, CAT and AcCoA hydrolase). Whole blood from each mouse was collected into 100 ul of ice cold 15% EDTA solution and fractionated into RBC and plasma and the RBC AChE plasma ChE, and AcCoA hydrolase activities were measured. Our results indicate that in the physostigmine treated mice: (a.) plasma ChE was significantly decreased (22%), RBC AChE was slightly but not significantly decreased (13%) and AcCoA hydrolase was not changed in whole blood. (b.) AChE was significantly decreased in corpus striatum (25%) and hippocampus (31%) but not changed in the remainder of brain, CAT was significantly decreased in corpus striatum but not changed in hippocampus or remainder of brain, and AcCoA hydrolase was not changed in any of the brain regions examined. In conclusion, we have observed a parallel reduction in plasma ChE and in specific brain regions, corpus striatum and hippocampus and CAT activity in corpus striatum. These observations may provide a basis for study of the possible cholinergic mechanism in schizophrenia.

1375 CHOLESTERYL ESTER CHANGES IN TISSUES OF CHICKENS WITH HEREDITARY MUSCULAR DYSTROPHY. D.M. Logan*, R. Battistella‡ M.P. Rathbone, and E.S. Werstiuk*, Dept. Biol. York Univ., Downsview, Ont., Canada, Dept. Neurosci., McMaster Univ., Hamilton, Ont., Canada.

Increased total cholesterol (TC) content at 9 days in ovo is the earliest biochemical change reported in muscles of chickens with hereditary muscular dystrophy (HMD) (Exp. Neurol. (1977) 57: 475). Subsequently, lipid infiltration of the degenerating muscles is a cardinal feature of the dystrophic process. The increased TC content of dystrophic muscle is due to an increased content of cholesteryl esters (CE). Dystrophic chickens are also hyperlipidemic (Neurosci. Letts. (1978) 8:151) and have a high liver TC content. We previously demonstrated that the TC content of the HMD muscle is neurally regulated irrespective of the cholesterol content of serum and liver (Ann. NY Acad. Sci. (1979) 317:594). As a first step in determining the molecular mechanisms underlying the abnormal neural influence on HMD muscles and the possible role of systemic alterations of lipid metabolism on the pathogenesis of HMD in chickens, we examined the nature of the CEs in muscles, livers, serum and brains of HMD and normal chicken embryos at 16 days in ovo. The cholesteryl esters were separated by thin layer chromatography, their fatty acids (FA) converted to methyl esters and separated by gas chromatography. The profiles of FAs derived from CEs differ in each of the tissues examined. There is also a difference in FAs between the corresponding normal and HMD tissues. In HMD serum the content of short, unsaturated fatty acids is reduced; 12:0 by 80%, 14:0 by 70%; the levels of 18:2, 18:3, 18:4 and 20:1 are also lower. In contrast, 18:1 is 150% higher in HMD serum. Differences between HMD and normal livers are less marked; 14:0 and 16:0 are approximately 40% lower in dystrophic livers and 18:1 is approximately 25% lower. In HMD brains 18:1 is reduced by 80%. The FA profile from thigh muscles, which are minimally affected by the dystrophic process, were identical in normal and HMD embryos. In contrast, in superficial pectoral muscles, which are severely affected, 18:1 was 350% higher in HMD. The increased 18:1 in the pectoral muscles is indicative of increased intracellular esterification of cholesterol, rather than increased uptake of CE from the plasma. Thus, the neural influence probably regulates CE synthesis in the muscles.

Supported by Grant A-4914, from NRC of Canada to D.M.L. and Grant MA-6326 from the MRC of Canada and Grant 15-14 from the Ontario Heart Foundation to M.P.R.

1376 PHYLOGENETIC DISTRIBUTION OF [^{3}H]KAINIC ACID RECEPTOR BINDING SITES IN NEURONAL TISSUE. Edythe D. London, Nikolei Klemm* and Joseph T. Coyle, Lab. of Neurosciences, GRC, NIA, NIH, Balto., MD 21224; Depts. of Pharmacol. Exp. Therap. and Psychiatry and Behav. Sci., Johns Hopkins Sch. Med., Balto., MD 21205.

The phylogenetic distribution of specific binding sites for [^{3}H]kainic acid was determined in 14 species of invertebrates and vertebrates. The highest level of binding was observed in brains of the frog (Xenopus laevis), followed by the spiny dogfish (Heterodontus francisci), the goldfish (Carasius auratus) and the chick (Gallus domesticus). Significant specific binding was noted in some (e.g. Hydra littoralis), but not all of the phylogenetically lowest forms tested. In most cases, specific binding to both high and low affinity sites was detected; notable exceptions were the cockroach brain (Periplaneta americana), which had negligible high affinity binding, and the crayfish brain (Procamburus) which had negligible low affinity binding. In the spiny dogfish, the smooth dogfish and the chick, the highest level of binding occurred in the cerebellum; less occurred in the forebrain and the least in the medulla; in the mammalian species, the highest level of binding occurred in forebrain structures; less in the cerebellum and least in the medulla.

Eadie plots of the saturation isotherms for [^{3}H]kainic acid revealed similar kinetics of binding for frog whole brain, rat forebrain and human parietal cortex with two apparent populations of binding sites: K_{D1}=25-50 nM and K_{D2}=3-14 nM. While binding in the spiny dogfish forebrain and human caudate nucleus occurred exclusively at high affinity sites, binding was only to low affinity sites in the cerebella of chick, rat and man. In the three species studied most extensively, frog, rat and man, unlabeled kainic acid was the most potent inhibitor of [^{3}H]kainic acid specific binding. L-Glutamic acid was 20- to 200-fold less potent than kainic acid; D-glutamic acid was 4- to 2,500-fold less potent than its L-isomer. Reduction of the isopropylene side chain of kainic acid to form dihydrokainic acid decreased the affinity of the derivative 115- to 3,000-fold. While the Hill coefficient derived from these inhibition studies was 1.0 for unlabelled kainic acid, it was approximately 0.5 for L- and D-glutamic acids and dihydrokainic acid, compatible with negative cooperativity. These studies demonstrated a widespread distribution throughout the animal kingdom of specific binding sites for kainic acid in neural tissue. The characteristics of these receptor sites were remarkably similar from primitive vertebrates to man, suggestive of an endogenous neuronal system that has not changed appreciably through evolution. Supported by USPHS Grants NS 13584, MH 26684, RCDA Type II KO 2 MH 00125 and a grant from the Nat'l. Found'n. to JTC and USPHS Fellowship MH 0714202 to EDL.

1377 TAURINE INTERACTION WITH CENTRAL NERVOUS SYSTEM MEMBRANES. A.M. López-Colomé* and H. Pasantes-Morales* (SPON: G.H. Vázquez). Centro de Investigaciones en Fisiología Celular, U.N.A.M., México 20, D. F., México.

Taurine has been considered as a putative neurotransmitter in the Central Nervous System; evidence supporting this function is not yet conclusive and an alternative role as a modulator of nerve excitability has also been suggested (Mandel and Pasantes-Morales, Rev. Neurosci. Vol 3 pp. 157; 1978).

Binding to synaptic membranes has been a useful tool in the identification of postsynaptic receptors for neurotransmitter candidates. It has been considered that the interactions of neurotransmitters with postsynaptic receptors is a sodium independent process which becomes more apparent in frozen and thawed membranes, while the opposite is true for other kinds of receptors - uptake sites for instance.

In the present work, we studied the characteristics of [^{3}H]-taurine binding to membranes from the chick retina,from the rat cerebral cortex and dorsal root ganglia. Parallel studies were carried out for GABA, a recognized central inhibitory neurotransmitter. Membrane preparation and binding assay were carried out following the general procedure of Enna and Snyder (Brain Res., 100: 81; 1975).

Taurine binding to chick retinal membranes in the absence of sodium was extremely low (0.014 ± 0.004 p moles/mg protein); under the same conditions, GABA binding was of 0.494 ± 0.16 p moles/mg protein. In the presence of sodium, maximum taurine binding was 22.9 p moles/mg protein. In rat cerebral cortex membranes, taurine binding was extremely low in the presence of sodium and practically undetectable in the absence of sodium. GABA binding, although considerable in the presence or absence of sodium, was higher in the later condition. In membranes obtained from dorsal root ganglia, in which no synaptic terminals are present, no specific binding of [^{3}H]-taurine or [^{3}H]-GABA was observed to frozen and thawed membranes in the absence of sodium. In freshly prepared membranes in the presence of sodium, taurine binding could not be detected whereas GABA binding was consistently observed.

According to the present results, an interaction with the characteristics adscribed to postsynaptic receptor binding was not observed for taurine in any of the preparations studied.

1378 EVIDENCE FOR FUNDAMENTAL INVOLVEMENT OF RAT BRAIN NICOTINIC RECEPTOR DISULFIDE/SULFHYDRYLS IN THE RESPONSE TO ACETYLCHOLINE. Ronald J. Lukas and Edward L. Bennett, Chemical Biodynamics Division, Lawrence Berkeley Laboratory, University of California, Berkeley, CA 94720.

The affinity of nicotinic acetylcholine receptors (nAChR) from muscle and electric organ for acetylcholine (ACh) is sensitive to modification of receptor SH/S-S residues. We earlier reported (Biochem. 18, in press, 1979) that the affinity of rat brain α-bungarotoxin (α-Bgt)/acetylcholine receptors for ACh is also sensitive to SH/S-S modification. It is of interest to determine whether alteration of the SH/S-S groups in question plays a fundamental role in agonist-stimulated function(s) of nAChR, or whether their experimental modification bears no relation to receptor activity, but merely affects ACh binding sterically.

Alkylation of dithiothreitol (DTT)-reduced rat brain membranes, whether with neutral N-ethylmaleimide (NEM) or iodoacetamide, or with anionic p-chloromercuribenzoate or iodoacetate, leaves nAChR in a low-affinity state with respect to agonist. That is, the ability of ACh to retard the rate of [^{3}H]-α-Bgt binding is diminished. As reported earlier for treatment of reduced nAChR with dithio-bis-nitrobenzoate (DTNB), treatment of native receptor with sodium bisulfite ($Na_2S_2O_5$), which cleaves S-S bonds and forms a mixed disulfide (nAChR-S-SO_3) with one of the freed sulfhydryls, leaves nAChR in a high-affinity state. Thus, the net charge or physical size of the modifying group bears no particular relation to its effect on affinity for ACh. Rather, modification effects are determined by the lability (and enhanced reactivity?) of the mixed S-S bond produced on DTT-DTNB or $Na_2S_2O_5$ reaction, relative to stable S-C or S-Hg bonds produced on alkylation. Further, reactivity of nAChR SH/S-S groups is modified by pretreatment of nAChR with agonist, but not antagonist. For instance, membranes treated with 10μM ACh for 30 prior to exposure to DTT-NEM, and then washed free of ACh, DTT and NEM, are susceptible to transformation to a high-affinity state on exposure to agonist. However, membranes treated with 1mM d-turbocurarine or with buffer only prior to DTT-NEM are "frozen" in a low-affinity state. Insofar as ACh does not block NEM-alkylation of DTT-reduced receptor, it is unlikely that ACh effects are steric in nature. Moreover, the ACh concentration dependencies of blockade of [^{3}H]-α-Bgt binding and alteration in SH reactivity are similar. Taken together, the results are consistent with a fundamental role of SH/S-S groups in ACh-stimulated nAChR function.

1379 QUANTITATION OF GOLDFISH TECTAL PROTEINS IN TWO-DIMENSIONAL POLYACRYLAMIDE GELS. W. A. Lutin*, C. F. Kyle*, and J. A. Freeman (SPON: J. S. Lappin). Vanderbilt Univ., Nashville Tenn 37232.

Proteins from goldfish optic tectum were separated by high resolution two-dimensional polyacrylamide gel electrophoresis. The separation pattern obtained from gels stained with coomassie blue yielded two hundred polypeptide spots. Individual spots were quantitated by computer-automated integration of the optical density of films of the gels. This was accomplished by approximating the optical density surface representing the scanned film with a set of best-fit two-dimensional Gaussians. This method resulted in volume integrals accurate to ±5% in six minutes of processing time on a DEC 1099 computer.

Multiple gels of tectal homogenates were compared by a local pattern matching algorithm which uses the Gaussian parameters for the protein spots in each gel as input. This method of comparison singled out 5 micrograms of creatine kinase added to a tectal homogenate as the only difference between two otherwise identical samples. The application of this method to autoradiograms of two-dimensional gels of 35S- or 14C- labeled proteins from goldfish tectum, toad optic nerve, or human fibroblasts allowed the itemization of quantitative and qualitative differences between gels containing over five hundred spots. This technique is currently being employed to identify goldfish tectal membrane proteins which are altered in concentration during regeneration of the optic nerve.

1380 COMPARATIVE EFFECTS OF PENTOBARBITAL, KETAMINE, ENFLURANE AND HALOTHANE ON CEREBROSPINAL FLUID DYNAMICS IN THE RAT. J. D. Mann, S.L. Cookson*, E.S. Mann*, Departments of Neurology and Anesthesiology, University of North Carolina 27514.

Four different anesthetic agents were studied to determine their effects on mechanisms regulating intracranial fluid dynamics in adult albino Sprague Dawley rats. Comparable anesthetic depth was achieved with pentobarbital 40 mg/kg i.p.; ketamine hydrochloride 40 mg/kg/hr i.v.; enflurane, 2.5% in oxygen; and halothane 1.0% in oxygen. Following induction of anesthesia with one of these agents, animals were paralyzed with pancuronium and artificially ventilated. Body temperature was maintained at 37°C., and heart rate, arterial blood pressure and blood gases were monitored throughout the experiment. Artificial CSF buffered to pH 7.32, was then infused into the subarachnoid space at the cisterna magna through a 20 ga. spinal needle with continuous monitoring of pressure responses. Infusions were performed at multiple rates (between 5 and 30 ul/min) until steady state pressure was achieved for each infusion rate. A previously described mathematical model of CSF dynamics was used to assess intracranial compliance, CSF outflow resistance at the arachnoid villi, and CSF formation rate (J.D. Mann, Ann. Neurol. 3:156-165, 1978).

Blood pressures were comparable in all groups (102 ± 14 SD mm Hg) with the exception of the enflurane animals (78 ± 13 mm Hg). Resting CSF pressure was lowest for the pentobarbital anesthetized rats (35 ± 19 mm H_2O) and highest for the enflurane group (130 ± 48 mm H_2O). Compared to pentobarbital, there was a significant two-fold increase in maximum outflow resistance when either ketamine or enflurane was used. Analysis of outflow resistance characteristics for the ketamine animals revealed an impairment of low pressure, transcellular CSF transport, while for the enflurane rats, outflow resistance was increased over a broader range of pressures and to a greater extent at high pressures, representing delayed activation of large volume CSF transport mechanisms. Calculated CSF formation rates were in the normal range (2-4 ul/min) for animals anesthetized with either pentobarbital or ketamine (3.97 ± 1.24 SD and 3.29 ± 1.87 ul/min). However, CSF formation was enhanced 55% ($p < .05$) with halothane, and 85% ($p < .01$) in animals anesthetized with enflurane. Our results suggest a complex interaction between anesthetic agents and the various mechanisms which regulate intracranial fluid dynamics, including CSF formation rate and resistance to reabsorption at the arachnoid villi. The biochemical bases for these changes remain to be determined. This work was supported by NIH Grant NINCDS 1 K07 NS00244.

1381 RAT PHEOCHROMOCYTOMA TYROSINE HYDROXYLASE: CHARACTERIZATION OF THE BASAL AND PHOSPHORYLATED ENZYME. K. Markey*, S. Kondo*, L. Shenkman* and M. Goldstein. (SPON. R. Margolis). New York University Medical Center, Departments of Psychiatry and Medicine, New York, N.Y. 10016.

Tyrosine hydroxylase (TH) was purified from pheochromocytoma PC-12 clonal cells to homogeneity. The purified enzyme was used as an antigen for production of antibodies in rabbits. The specificity of the anti-TH was demonstrated by immunoelectrophoretic analysis as well as by specific inhibition of the enzyme activity. The rat pheochromocytoma anti-TH reduces the activity of the homologous enzyme more effectively than the activity of the heterologous enzyme.

The activity of purified TH is stimulated by a c-AMP dependent protein kinase phosphorylating system (PKP system), and the highest % of stimulation is obtained when the enzyme activity is measured at physiological pH's. The stimulation of the purified enzyme by the PKP system results in a reduction of the apparent K_M for the co-factor 6-MePH$_4$ and in an increase of the K_i for dopamine.

Incubation of purified TH with the PKP system and ^{32}P ATP, resulted in incorporation of radioactivity into the 62,000 subunit of the enzyme. Purified enzyme which has lost some enzyme activity upon storage has incorporated less ^{32}P than the enzyme with a higher specific activity. The incorporation was approx. 1 mole of ^{32}P/mole of TH (M.W. of TH 240,000). These results suggest that either one of the four subunits of TH is phosphorylated or that under our experimental conditions only 25% of the enzyme was phosphorylated. Further studies on the incorporation of ^{32}P into TH are in progress.

1382 FRAGMENTATION OF SUBSTANCE P BY BRAIN AND PITUITARY CATHEPSIN B. Neville Marks and Alojz Suhar*. Center for Neurochemistry. Rockland Research Institute. Wards Island. N.Y. 10035

Neurosecretory regions of rat brain were found to contain high levels of cathepsin B relative to other areas suggesting a possible involvement in the processing of neuropeptides. In other tissues cathepsin B has been implicated in the activation of inactive precursors to yield active hormonal peptides. In addition, cathepsin B is considered to play a key role in the intracellular turnover of proteins but has not been studied extensively in the CNS. Enzyme, therefore, was purified from human pituitary and bovine brain over 400 fold using classical procedures yielding in some preparations an enzyme with a single protein band. Both tissues contained a family of related BANA hydrolases hydrolysing benzoyl-arginyl β-naphthylamide of which only one resembled the classical cathepsin B purified from other tissues (pH optima 6.5 in presence of -SH groups, inhibition by low concentrations of Ac-Leu-Leu-arginyl or leupeptin).

Purified enzyme from both sources cleaved a number of CNS components including histones, neurophysins, myelin basic protein, β-lipotropin and β-endorphin. The enzyme was selective since it did not cleave albumin, γ-globulin or caesin, and showed low or no activity with hemoglobin and polylysine. Surprisingly, among the best substrates tested was the unidecapeptide substance P (Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-Met.NH_2 Since cleavage products of substance P show a spectrum of activities dependent on the test system utilised then proteolytic enzymes may play a role in regulation. Among the products isolated after incubation of substance P with purified brain and pituitary cathepsin B was the tetrapeptide Phe-Phe-Gly-Leu indicating probable cleavage at the Gln-Phe and Leu-Met.NH_2 bonds. Cleavage at the first bond would generate a C-terminal pentapeptide that would retain ability to contract guinea pig gut in vitro but would lose the property of depolarisation of frog spinal motoneurons. Loss of Met.NH_2 from the pentapeptide or substance P would lead to inactivation. Cathepsin B of brain and pituitary can be added to the list of enzymes known to degrade substance P and which include aminopeptidases, neutral endopeptidases, and a specific prolyl endopeptidase.

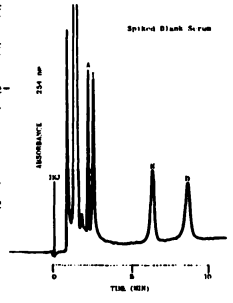
1383 A RAPID, SENSITIVE METHOD FOR THE SEPARATION AND MEASUREMENT OF TRICYCLIC ANTIDEPRESSANTS AND THEIR PSYCHOACTIVE METABOLITES IN HUMAN SERUM BY HIGH PERFORMANCE LIQUID CHROMATOGRAPHY. D. M. Martin*, A.L.C. Pottash*, and M. S. Gold. Yale University School of Medicine, New Haven, CT 06520, Psychiatric Institutes of America and Psychiatric Diagnostic Laboratories of America, Summit, NJ 07901

Recent studies indicate that the measurement of serum levels of tricyclic antidepressants (TCA) and their psychoactive metabolites may facilitate the effective pharmacological management of endogenous depression. Existing High Performance Liquid Chromatographic (HPLC) techniques employing both normal and reverse phase technologies are limited by column deterioration or complex mobile phase formulation re-respectively, making their routine application in the clinical laboratory difficult.

Tricyclics were extracted from one (1.0) ml of patient serum into a basic organic phase, freeze dumped and taken to dryness under a stream of nitrogen. The residue was injected into an isocratic system of 0.025% butylamine in methanol flowing at 1.4 ml/min. through a column of fully porous silica. Detection was in the ultraviolet at 254 nm, Amitriptyline (A), Imipramine (I), Nortriptyline (N) and Desipramine (D) respectively, were separated in a single injection(Fig). Unknowns were quantitated by comparison of peak height ratios to standard curves generated against spiked blanks run in parallel. Over five hundred (500) patient samples have been run using this technique yielding a mean day-to-day coefficient of variation of less than 7%. As little as 5 ng of each drug can be reliably detected in one (1.0) ml serum. Recovery of spiked blanks ranged from 65-75% increasing with concentration as reported in the literature. The precision, reproducibility, ease of sample preparation and simplicity of instrumentation make this technique exceptionally well suited for therapeutic monitoring of tricyclic antidepressants.



1384 2'3'-CYCLIC NUCLEOTIDE-3'PHOSPHOHYDROLASE (CNP) ACTIVITY IN NERVOUS TISSUE OF TEMPERATURE ACCLIMATED GOLDFISH (CARASSIUS AURATUS L.). D.F. Matheson*, R. Oei* and Betty I. Roots, Dept. Zool. and Erindale College, University of Toronto, Toronto, Ont., Canada.

Nervous tissue rich in myelin possesses high activity of CNP (EC 3.1.4.37). Consequently CNP activity has been accepted as a myelin index.

Previous findings from our laboratory have established that the distribution spectrum of axon diameter in the optic nerve of goldfish varies with temperature of acclimation; at 5°C there is a greater proportion of large axons greater than 0.9μm in diameter than at 25°C (cf. 71% and 22%). In order to relate these morphological observations to a biochemical assessment of myelin, CNP activity was determined in the optic nerve of 5° and 25° acclimated fish, and compared with the activity in other myelin-rich preparations (spinal cord myelin, brain myelin). As expected, the optic nerve possesses significantly higher CNP activities in the 5° fish compared with the 25°. It was found also that brain myelin has higher activities at the lower acclimation temperature. In the optic tectum, a tissue containing little myelin, there is no difference in the CNP activity with acclimation temperature. Other biochemical indices of myelination were determined in optic nerve and tectum; e.g. molar ratios of phosphatidyl ethanolamine/phosphatidyl choline (PC), and galactolipid/PC. With elevation in acclimation temperature these ratios decrease in nerve and rise in tectum. An interesting observation is that the CNP activity/μmoles galactolipid ratio is lower at higher acclimation temperatures in all myelin-rich preparations but remains the same in the optic tectum.

These findings not only confirm the findings from morphological studies that the amount of myelin changes during temperature acclimation but indicate that there may also be a change in the composition.

The significance of these findings will be discussed.

1385 CHANGES IN γ-AMINOBUTYRIC ACID RECEPTOR BINDING IN THE POST-MORTEM CAT CENTRAL NERVOUS SYSTEM. G. Keith Matheson and Godfrey Tunnicliff*. Evansville Center, Indiana University School of Medicine, Evansville, IN 47732.

Postmortem GABA receptor binding is becoming a useful measurement in the investigation of the role of GABA in diseases of the nervous system. One of the problems of studying human postmortem brains is the lack of standardized procedures for their storage. This investigation was undertaken to determine if postmortem changes in GABA binding occur when brains are stored for different periods of time before the membranes are prepared. GABA receptor binding in fifteen regions of cat central nervous system was investigated immediately postmortem, and at twenty-four and seventy-two hours postmortem. A two-fold increase in binding was observed after twenty-four hours in the cerebellum, the sensorimotor cortex, the visual cortex, and the amygdala. Substantial increases were also noted in the thalamus, caudate nucleus, hippocampus, and hypothalamus. At seventy-two hours postmortem further increases in GABA binding were seen. Membranes from the pons and spinal cord did not exhibit appreciable changes in GABA binding. These findings suggest that interpretation of GABA binding data obtained from human brains that have not been treated in a similar postmortem manner should be made with reservation.

REGION	HOURS POSTMORTEM	
	0	24
Cerebellum	263±34	594±83
Visual Cortex	136±19	322±41
Sensorimotor Cortex	130±21	314±56
Amygdala	141±33	323±39
Caudate Nucleus	110±15	166±22
Hippocampus	80±18	131±16
Thalamus	72± 9	118±13
Hypothalamus	71±10	94±14
Pons	26± 8	34± 9
Spinal Cord	24± 5	32± 7

These values are the means ±S.E.M. of GABA binding (f moles/mg protein). Each determination was done in triplicate. Three animals were used in each experiment.

1386 PUTATIVE NEUROTRANSMITTER RECEPTOR SITES IN RAT HIPPOCAMPUS. Dee Ann Matthews, Paul Salvaterra and Renee Foders*. Div. of Neurosciences, City of Hope Nat. Med. Center, Duarte, CA 91010.

The hippocampus is well suited for studies of synaptic transmission mechanisms in CNS by reason of its simple laminated organization, defined connections and variety of transmitter systems. In order to study the quantitative relationship among various neurotransmitter systems in rat brain hippocampus, the levels of several putative neurotransmitter receptors were studied by radiolabeled ligand binding techniques. The levels and affinities of the various ligands used were determined by Scatchard analysis of binding isotherm data using crude membrane preparations. All ligands showed only a single high affinity site. Data is presented in the table below. Data were also analyzed by Hill plots and all ligands had slopes near 1, indicating the absence of any cooperative interactions. Pharmacological characterization of the ligand binding sites indicated properties consistent with their identification as functional neurotransmitter receptors. The rank order of the total number of putative receptor binding sites (gabaergic>cholinergic>adrenergic) is in agreement with current estimates of the relative number of terminals contributed by each system. Supported by NIH NS 12116.

Ligand	Putative Receptor	B_{max}[a] (fmoles/mg)	K_D (M)
[^{3}H]Muscimol	GABA	1920[a]	5.47 x 10^{-8}
[^{3}H]Quinuclidinyl-benzilate	muscarinic-Cholinergic	863	2.21 x 10^{-9}
[^{3}H]Dihydroergo-cryptine	α-Adrenergic	474	6.9 x 10^{-9}
[^{3}H]Dihydroal-prenolol	β-Adrenergic	67.8	2.72 x 10^{-9}
[^{125}I]αBungaro-toxin	nicotinic-Cholinergic	43.2	1.19 x 10^{-9}

[a] Values are derived from Scatchard plots of two sets of binding isotherm data using 6 different concentrations of ligand in triplicate.

1387 BRAIN CYCLIC NUCLEOTIDE LEVELS IN RATS SENSITIVE TO AUDIOGENIC SEIZURES. James L. Meyerhoff, G. Jean Kant, T. Daryl Hawkins* and Robert H. Lenox. Dept. of Medical Neurosciences, Walter Reed Army Inst. of Research, Washington, DC.

The subjects were seventh generation Wistar-derived male rats selectively bred for sensitivity to audiogenic seizure (AS). Groups of adult AS-strain rats and adult control (C) male Wistar rats of equal size and from identical maintenance conditions were subjected to audiogenic challenge. None had ever previously been exposed.

Rats were placed singly in a metal grid chamber (size 33x24x13 cm) with a sound horn affixed to the top of the chamber. Auditory challenge was produced by an amplifier emitting white noise within 11.0 - 14.0 KHz range at an intensity of 105 ± 1 db at floor level. Each sound exposure was 1 min in duration.

Of the 15 AS rats challenged, five (33%) responded with wild running followed by clonic-tonic seizures. None of the control strain responded. Under similar testing procedures at three weeks of age, rats from the AS strain show a 95% incidence of clonic-tonic seizure. In different groups from the control strain, subjected to audiogenic challenge at 3 to 52 weeks of age, no clonic-tonic seizures have ever been observed.

Separate groups of AS (N=6) and control rats (N=6) were sacrificed for neurochemical studies. Average body weight in each group was 321 grams. Neither group was ever subjected to audiogenic challenge. Sacrifice was accomplished by a 5 second exposure to 2.5 KW microwave irradiation at 2450 MHz. Brains were dissected into 25 regions and assayed for cAMP and cGMP by radioimmunoassay and for gamma-aminobutyric acid by enzymatic-fluorimetric assay. Brain regions assayed included lateral cerebellum and vermis, midbrain, brainstem, corpus striatum, substantia nigra, hypothalamus, thalamus, olfactory bulb, olfactory tubercle, nucleus accumbens, septal region, hippocampus, amygdala, inferior colliculus, superior colliculus, medial geniculate, lateral geniculate, frontal cortex, and areas 2,17,24,29,41, and 51. The pineal and pituitary were also assayed.

In rats of the audiogenic seizure sensitive strain, cyclic GMP was elevated in the hippocampus, hypothalamus and vermis of the cerebellum.

1388 BIOCHEMICAL CORRELATES OF SELECTED ANTIDEPRESSANT DRUGS: β-RECEPTOR SENSITIVITY, MONOAMINE UPTAKE AND MAO INHIBITORY PROFILES. Laurence R. Meyerson, Wendy R. Simko*, Wayne W. Petko* and Daniel B. Ellis*. Dept. of Biochemistry, Hoechst-Roussel Pharmaceuticals, Inc., Somerville, NJ 08876.

Mechanistically the mode of action of antidepressant drugs may be related to (1) increased neuronal stores of biogenic amines with resultant augmented synaptic concentrations of specific neurotransmitters via inhibition of oxidative deamination pathways (MAO), (2) inhibition of presynaptic monoamine reuptake leading to increased neurotransmitter concentrations at receptors and enhanced activity of neuronal circuits, (3) β-adrenoceptor subsensitivity as indicated by a decrease in norepinephrine-induced accumulation of cAMP (Vetulani *et al*, Arch. Pharmacol. 293: 109, 1976) or cortical [^{3}H]-dihydroalprenolol binding (Banerjee *et al*, Nature, 268: 455, 1977; Sarai *et al*, Biochem. Pharmacol. 27: 2179, 1978). These biochemical parameters were utilized to evaluate the mode of action of a series of selected antidepressant and psychoactive agents. Extremely weak *in vitro* inhibitory effects on rat brain mitrochondrial MAO-type A or B were observed with HRP-197 and HP-505, both 3-aryl-spiroisobenzofuranpiperidines, P77-2984 a 3-aryl-spirobenzothiophenepiperidine derivative, LM-5008 an indolylethylpiperidine, desipramine, nisoxetine and P76-2543, a novel heterocycle possessing antidepressant characteristics. As anticipated, deprenyl showed potent substrate selective inhibition of MAO type B. The kinetics (B_{max} and K_D) of [^{3}H]-dihydroalprenolol binding were also studied following chronic administration of these same drugs (10 mg/kg, b.i.d.). After a 10-day treatment regimen, heterogeneous results were obtained in that some compounds elicited changes in receptor density and dissociation constant while others such as nisoxetine produced no kinetic alterations. Additionally, these same agents were tested as inhibitors of temperature dependent-high affinity synaptosomal monoamine uptake. Again, heterogeneous results were observed in terms of the selectivity of uptake blockade of either norepinephrine, dopamine or serotonin into intact synaptosomal preparations. While present biochemical antidepressant tests as utilized in this study are designed to evaluate modulations of aminergic systems in terms of neurotransmitter availability, fluxes in concentration and attendant receptor recognition site sensitivities, underlying mode(s) of action at the cellular level still remains to be elucidated.

1389 THE RELATIONSHIP BETWEEN THE INTENSITY OF THE STIMULUS AND THE METABOLIC RESPONSE IN THE VISUAL SYSTEM OF THE RAT. M. Miyaoka*, M. Shinohara*, M. Batipps*, K. D. Pettigrew*, C. Kennedy, and L. Sokoloff. Laboratory of Cerebral Metabolism, National Institute of Mental Health, Bethesda, MD 20205.

A wide variety of neurophysiological and psychological studies in sensory systems have demonstrated a direct relationship between the magnitude of the response and the logarithm of the intensity of stimulation. This is known as the Weber-Fechner Law. The recently developed [^{14}C]deoxyglucose method for measuring local cerebral glucose utilization (LCGU) has revealed a close relationship between local functional activity and local energy metabolism in the central nervous system. The present studies were undertaken to determine the quantitative nature of this relationship. The [^{14}C]deoxyglucose method was employed in pigmented Norway rats exposed to six levels of light intensity: darkness, 0.3, 1.4, 7.0, 700, and 7000 lux. LCGU was measured in the stratum griseum superficialis of the superior colliculus, the dorsal and lateral nuclei of the lateral geniculate body, the postero-lateral thalamic nucleus and the visual cortex of four rats at each level of light intensity. Mean values for LCGU (μmoles/100g/min) plotted against light intensity (lux) on a semilog scale revealed a direct linear relationship between the metabolic rate and the logarithm of the stimulation intensity in all of the above structures, except for the visual cortex. In the visual cortex a similar relationship appeared to be present up to a light intensity of 7 lux, but the slope was less than that found in the other structures and not statistically significantly different from zero. Values for LCGU in 14 non-visual structures also measured at each level of light intensity were not significantly different from the mean value obtained when the animal was in total darkness. Similar experiments were also carried out in Sprague-Dawley albino rats. In these a similar relationship was found in the structures of the visual pathway, but this was confined to a narrower range of light intensity (0-7.0 lux), above which the metabolic response decreased with increasing intensity of stimulation. These results demonstrate that the response in energy metabolism in the visual system to variations in intensity of stimulation conforms, like behavioral and perceptual responses, to the Weber-Fechner Law.

1390 THE OLFACTORY MARKER PROTEIN (OMP) DURING DEGENERATION AND RECONSTITUTION OF THE OLFACTORY SENSORY NEURONS. G.A. Monti Graziadei* and David W. Samanen* (SPON: P.P.C. Graziadei). Dept. Bio. Sci., Florida State University, Tallahassee, FL 32306.

Section of the fila olfactoria induces degeneration of the olfactory sensory neurons which is followed by differentiation of new neuronal elements from the basal cells of the neurepithelium. The disappearance of the olfactory marker protein (OMP) after axotomy, and its return to normal values after thirty days, has been shown to correlate with the process of degeneration and reconstitution of the olfactory neurons (Harding, et al., Brain Res., 1977). We used immunohistochemical techniques (Monti Graziadei, et al., J. Histochem. Cytochem., 1977) to observe the morphological changes of OMP content in the neurepithelium following axotomy. Adult mice (60 - 100 days) were unilaterally axotomized at the cribiform plate. The animals were then sacrificed at regular intervals (5 to 64 days) and serial section of the entire head was performed. Alternate sections were stained respectively with iron hematoxylin and peroxidase-antiperoxidase methods.

At five days survival time, the mucosa was almost completely devoid of OMP. In hematoxylin stained sections all the mature neurons had disappeared; only a few immature elements were present. By the 12th day the neuronal population had reconstituted and contained only young maturing neurons. A few mitoses remained, the peak having already occurred between the 8th and 11th days (Monti Graziadei and Graziadei, J. Neurocytol., 1979, in press). The OMP was present only in a few scattered neurons and in very fine bundles of axons leaving the epithelium. At twenty days survival time, the content of OMP had increased and larger bundles of positive axons were present beneath the epithelium. At 30 days the mucosa, which in hematoxylin stained sections appeared normal, had regained a full population of neurons. However, the OMP was not evenly distributed. Many regions of negativity were still distinguishable as well as zones where all cells possessed full positivity. All basal cells remained unlabelled. At 64 days the operated side was indistinguishable from controls, both in hematoxylin and peroxidase-antiperoxidase sections. (Supported by BNS grant 77/16/37 and NIH grants NS 08943 & 5/T/32 07010).

1391 MITOCHONDRIA AND SARCOPLASMIC RETICULUM AS MODEL TARGETS FOR NEUROTOXIC AND MYOTOXIC PHOSPHOLIPASES A. Ronald H. Ng, Tod Brown*, Herman H. Higa*, Gail A. Wong* and Bruce D. Howard, Biol. Chem. Dept., Sch. Med. UCLA, Los Angeles, CA 90024.

Certain snake venoms contain neurotoxic phospholipases A that inhibit acetylcholine release from nerve terminals. Some of these toxins are also myotoxic in that they damage skeletal muscle independently of their action on neurons. Although the phospholipase A (PLA) activity of the toxins appears to be required for their toxicity, there is no simple correlation between enzyme activity and toxicity. Most well known phospholipases A are not neurotoxic or myotoxic in spite of having greater specific enzyme activity than the toxic enzymes. We previously reported that one of these toxins, β-bungarotoxin, initially acts to depolarize synaptosomes. This activity correlates well with the neurotoxicity of β-bungarotoxin and is not simply due to the non-specific hydrolysis of membrane lipids by the toxin's PLA activity. The ion fluxes involved in the toxin-induced depolarization are unidentified but β-bungarotoxin may depolarize by altering the flux of Ca^{2+} across synaptosomal membranes. In order to facilitate study of the effect of PLA toxins on Ca^{2+} transport we have turned to two Ca^{2+}-transporting structures that are simpler and better characterized than synaptosomes. These are mitochondria (mito) and sarcoplasmic reticulum (SR). We found that several neurotoxic and myotoxic phospholipases A have the ability to inhibit Ca^{2+} uptake by brain mito and SR and this ability appears to be a biologically relevant correlate of their toxicity. β-Bungarotoxin and notexin had 5% and 50% respectively of the PLA activity of IVa PLA (a non-neurotoxic enzyme); however, β-bungarotoxin and notexin each had greater ability to inhibit Ca^{2+} uptake by brain mito. β-Bungarotoxin lost its neurotoxicity but not its PLA activity after modification with ethoxyformic anhydride in the presence of lecithin. The modified toxin also lost most of its ability to inhibit Ca^{2+} uptake by brain mito. The ability of a PLA to inhibit Ca^{2+} uptake into SR correlated well with its myotoxic potency. Each of the myotoxic enzymes substantially inhibited Ca^{2+} uptake into SR, notexin being the most potent. A 10 min incubation with 1 nM notexin caused an 80% inhibition of Ca^{2+} uptake. Two non-myotoxic phospholipases A at 10 nM had only a small effect on Ca^{2+} uptake although one of them had twice the PLA activity of notexin. The effect of notexin on SR was Ca^{2+}-dependent, temperature-dependent and time-dependent. Notexin treatment caused a slight activation of the SR Ca^{2+}-ATPase activity and an efflux of previously accumulated Ca^{2+}. SR vesicles reconstituted from solubilized SR accumulate Ca^{2+} and retain their sensitivity to notexin.

1392 KAINIC ACID AND CEREBELLAR GLUTAMATE METABOLISM IN VITRO. William J. Nicklas, Barbara Krespan* and Soll Berl. Dept. of Neurology, Mt. Sinai School of Medicine of C.U.N.Y., New York, New York, 10029.

The mechanism of neurotoxicity of kainic acid (KA) may involve presynaptic inhibition of glutamate (GLU) uptake (hence, increased extracellular levels of GLU) and/or receptor-mediated post-synaptic depolarization. The cerebellum (CB) was chosen to examine this problem in vitro because the slice has an intact glutamergic neuron, the granule cell. In 0.3mm thick parasagittal CB slices, KA caused a dose-dependent decrease in ATP levels; the effect was maximal at 1 mM KA, a 30-40% reduction. 2-Amino-4-phosphonobutyrate did not block this change. No such alterations in ATP levels were noted with striatal slices even at 10 mM KA. Treatment of CB slices for 30 min with 1 mM KA caused decreases in tissue levels of GLU, aspartate (ASP) and glutamine (GN) (15-20%, 15-35% and 60-70%, respectively). Concomitantly, levels of GLU and ASP increased in the incubation medium by 2 to 4-fold. Medium GN levels did not change; hence, total GN was markedly reduced. Metabolic studies with ^{14}C-glucose/^{3}H-acetate, ^{14}C-GLU, ^{14}C-GN and ^{14}C-GABA were consistant with an inhibition of GLU uptake and a decreased GN turnover. Striatal slices treated with KA showed only minimal metabolic alterations. Synaptosomal preparations of cerebral cortex, striatum and CB showed moderate inhibition by KA of high affinity GLU uptake with no concomitant net release of intra-synaptosomal GLU. Thus, the altered flux of GLU and GN between neurons and glia may play a role in the neurotoxic action of KA. The data are consistent with the findings of McGeer et al. (Brain Res., 139: 381, 1978) that an intact glutamergic neuron may be required to produce the biochemical changes associated with the neurotoxicity of KA.

1393 THE ACTIVATION OF ADENYLATE CYCLASE AND PHOSPHODIESTERASE IN C-6 GLIOMA CELLS BY THE CALCIUM-DEPENDENT REGULATOR PROTEIN. Jon A. Norman. Friedrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.

C-6 astrocytoma cells provide a homogeneous cell type for studying the role of Ca^{++} in regulating the enzymes involved in cyclic nucleotide metabolism. Adenylate cyclase and cyclic nucleotide phosphodiesterase, the enzymes responsible for cAMP synthesis and degradation, respectively, are present in different isozyme forms in C-6 glioma cells. The calcium-dependent regulator (CDR), a calcium-binding protein, is also present in C-6 cells and this protein, when complexed with Ca^{++} can bind to and activate one form of both adenylate cyclase and phosphodiesterase. A procedure has been developed for the partial purification of CDR-sensitive phosphodiesterase using affinity chromatography with CDR attached to sepharose. The CDR-sensitive form of phosphodiesterase will bind to the CDR-sepharose column in the presence of Ca^{++} and will elute from the column in the presence of EGTA. This procedure utilizes a preliminary chromatographic step on DEAE cellulose which removes CDR and modulator-binding protein from phosphodiesterase. The modulator-binding protein is an inhibitor of CDR-stimulated phosphodiesterase and will copurify with CDR-sensitive phosphodiesterase in other CDR affinity chromatography procedures. This two step procedure allows the partial purification of CDR-sensitive phosphodiesterase in high yields from C-6 cells to allow the final purification of the enzyme by sephacryl S-200 chromatography. The activation of CDR-sensitive phosphodiesterase under physiological ionic conditions is presently being investigated in addition to an analysis of the subunit structure of this enzyme by SDS gel electrophoresis. A similar purification procedure for adenylate cyclase is being developed.

1394 IN VITRO INHIBITION OF ACETYLCHOLINESTERASE BY SEROTONIN AND BY AN UNIDENTIFIED SEROTONIN-DERIVED COMPOUND(S) AS STUDIED AT PHYSIOLOGICAL SUBSTRATE LEVELS. B. Oderfeld-Nowak*, J.R. Simon, L. Chang*, and M.H. Aprison. The Institute of Psychiatric Research Depts. of Biochemistry, Pharmacology and Psychiatry, Indiana U. School of Medicine, Indianapolis, IN 46223.

Inhibition of acetylcholinesterase activity (AChE) by serotonin (5-HT) and by an unknown compound(s) derived from 5-HT was investigated under conditions employing biological concentrations of acetylcholine (ACh) as substrate (10^{-5}M). Freshly prepared solutions of 5-HT (10^{-5}M) were found to inhibit AChE from rat striatum as well as purified AChE from bovine red blood cells. The degree of inhibition was dependent on the ratio of inhibitor to enzyme as well as on preincubation of the enzyme with inhibitor. Inhibition was not dependent on ACh concentration nor on the duration of the enzymic reaction. Inhibition of AChE by freshly prepared solutions of 5-HT was found to be concentration-dependent in the range of 10-100 μM 5-HT with resulting inhibition of approximately 10-30%. Kinetic analysis of the observed inhibition indicated it to be of a noncompetitive nature with a K_i of approximately 0.2 mM. When 5-HT solutions were exposed to air and light at room temperature ("exposed 5-HT"), greater inhibition of AChE was observed than when freshly prepared solutions were employed. Inhibition obtained with "exposed 5-HT" solutions also revealed noncompetitive inhibition; however, the K_i was reduced by 50% (0.1mM). The enhanced inhibitory potency of the "exposed 5-HT" solutions suggested the formation of some additional compound(s) derived from 5-HT under conditions of exposure to light and air. Analysis of these solutions employing the techniques of high performance liquid chromatography and thin layer chromatography indicated this to be the case. Following the time course of production of the unknown compound(s), a progressive increase in peak height was observed. A concomitant increase in inhibition of AChE was noted up to 12 days of exposure. The maximum peak height of the unknown corresponded to approximately 5% of the 5-HT peak height. At this time, the inhibition of AChE was 60% suggesting that the unknown was a better inhibitor than 5-HT. Preliminary checks of factors which influence the production of this unknown inhibitor indicated that (a) both oxygen and light enhance this production, and (b) these two factors can act synergistically. The inhibitory effects of 5-HT and/or"exposed 5-HT"on AChE appeared to be highly specific since no effects were observed on other cholinergic parameters such as high affinity uptake of choline, choline acetyltransferase or muscarinic receptor binding. The process by which the unknown in this in vitro model might be produced in brain becomes important to elucidate from both the biological and clinical point of view.(Grant MH03225-20 and Fogarty Fellowship (BON))

1395 LOCALIZATION OF GLUTAMATE AND CYSTEINE SULPHINATE DECARBOXYLASE SUBUNITS ON TWO-DIMENSIONAL ELECTROPHORESIS BY USE OF A RADIOACTIVE SUICIDE SUBSTRATE ANALOGUE. Wolfgang H. Oertel*, Donald E.Schmechel*, John W. Daly* and Irwin J. Kopin. Lab. Clin. Science, NIMH, and Lab. Bioorganic Chem., NIAMDD, Bethesda, Md. 20205

Glutamic acid decarboxylase (GAD) has been reported to be purified from mouse, bovine, rat and human brain and, when tested, to contain cysteine sulphinate decarboxylase (CSD) activity throughout all stages of purification. In the present study a partially purified rat brain GAD/CSD preparation was analyzed by high resolution two-dimensional electrophoresis (2DE). Since the enzyme activity is lost completely during this procedure, a radioactively labelled irreversible inhibitor of GAD was used to localize the enzyme. (^{3}H)-γ-Acetylenic GABA (4-amino-hex-5-ynoic acid, GAG) was synthesized to a specific activity of 3 mCi/mM. GAG is an irreversible inhibitor of GAD (Jung et al., Biochem. 17:2628,1978) acting as a "suicide substrate" by covalent bond formation at the active site. GAG inhibits in parallel both CSD and GAD activity in brain. After reacting the enzyme with ^{3}H-GAG two radioactive bands of identical pI (5.3-5.6, 9M urea) and of molecular weight of 54000 and 58000 (±1500) are found in the 2DE pattern of the GAD/CSD preparation. These two radioactive areas are enhanced by reacting the radioactive inhibitor with GAD/CSD-antiGAD/CSD immune complex and using the immune precipitate for 2DE. These two areas found on 2DE represent the presumptive catalytic site bearing subunits of GAD/CSD. It is, however, still not possible to answer the question of whether GAD and CSD represent the same active site and/or are located on the same molecule as suggested by Davison (Biochim.Biophys. Acta 19:66, 1956). The use of labelled suicide substrate analogues permits unequivocal localization of enzymatically active subunits even after the denaturation which attends 2DE. In the case of GAD/CSD separate immunization using the proteins present in the two areas may provide definitive evidence for the non-identity of GAD/CSD-enzymes or support the view that the enzyme activities are the result of catalytic sites on the same enzyme molecule. This procedure should prove particularly useful for enzymes which are difficult to purify.

1396 RESPIRATION IN DISSOCIATED NEONATAL RAT BRAIN PRIMARY CELL CULTURES. James E. Olson and David Holtzman*. Depts. of Neurology and Pediatrics*, Stanford Univ. School of Medicine, Stanford, CA.

Astrocytes are believed to possess certain unique properties of metabolism and respiration important in brain physiology. We have utilized the methods of Booher and Sensenbrenner (Neurobiol. 2:97, 1972) to obtain a relatively pure preparation of astrocytes in culture. This affords the possiblilty of measuring the respiratory parameters in a controlled environment, uncontaminated with neurons or endothelial components.

Neonatal rat cortical brain tissue was dissociated by treatment with trypsin followed by filtration through an 80 μm mesh. The cells were grown to confluence (two to eight weeks). 90% of the cells stained positively for the astrocyte-specific glial fibrillar acidic protein (GFAP). At various times after culturing, the nutrient medium was replaced in some culture dishes with a medium lacking fetal calf serum, but containing 0.25 mM dibutyryl cyclic-AMP (dbc-AMP). The cells in dbc-AMP treated cultures took on the morphological appearance of mature, multipolar astrocytes typically seen in vivo. This morphological transformation persisted as long as the dbc-AMP medium was present.

Cells grown to a monolayer were removed from the culture dish with a mild trypsin exposure, suspended in a phosphate-buffered saline and placed in a sealed oxygen chamber at 37° C for polarographic measurement of O_2 utilization. The rate of respiration was constant over a wide range of pO_2. The average basal rate was measured at 11.6±0.1 natom·min^{-1}·mg protein^{-1}. Addition of oligomycin (approximately 2 nmol/mg protein) reduced this to 42.4±0.5% of the basal rate. Additions of dinitrophenol (40 μM DNP) could overcome this inhibition. The maximal DNP-stimulated rate was 104±3% of the basal rate in dbc-AMP treated cells compared to 148±3% in untreated cells ($p<0.01$). With DNP added directly to the respiring cells (without prior oligomycin addition) there was no difference in the relative rates of treated (155%) and untreated cells (149%). Increased osmolality (produced with KCl, NaCl or sucrose) causes a decrease in basal rate and an increase in the rate in the presence of DNP for both treated and untreated cells.

These results will be compared with observations on brain slices and isolated brain mitochondria.

1397 EFFECT OF INORGANIC LEAD ON RAT BRAIN MITOCHONDRIAL RESPIRATION IN VITRO. J.J. O'Neill, B.R. Melamed*, D. Epstein*, K. O'Neill*, Depart. of Pharm., Temple Univ. Medical School, Phila.,Pa. 19140.

Inorganic lead, added to the diet of suckling rats in high doses has been shown to produce a cerebellar encephalopathy, and to inhibit the respiration of subsequently isolated cerebellar and, to a lesser extent, cerebral mitochondria (Holtzman and Shen Hsu, Pediat. Res. 10:70-75, 1976). Little data exists on the in vitro effects of lead on mitochondria isolated from the brains of naive rats, largely due to the problems of Pb^{2+} chelation and precipitation by EDTA and inorganic phosphate.

Mitochondria were isolated from rat brain (cerebellum removed) by a modification of the method of Nicklas and Clark (JBC 245:4724, 1970). The mitochondrial pellet was washed twice with an EDTA free medium containing mannitol 0.3 M, BSA 0.1%, HEPES 10 mM, pH 7.4, and suspended in the same medium. Omission of EDTA from the incubation medium produced a large decrease in the respiratory control ratio with pyruvate (10 mM) plus malate (2.5 mM) as substrates. Pb-acetate (5uM) when added following the addition of substrate but 2 min prior to the addition of inorganic phosphate (5mM) completely blocked the transition to State 3 respiration on the addition of ADP, 0.5uM Pb-acetate produced a 25% inhibition of State 3 respiration. The amount of lead bound to the mitochondria was determined by anodic stripping voltometry following digestion of the filter in nitric:sulphuric: perchloric acid (24:1:24). The present experiments demonstrate a dose-response relationship between lead and inhibition of mitochondrial respiration.

1398 POTASSIUM INDUCED SWELLING OF A GLIAL ENRICHED PREPARATION: THE FROG FILUM TERMINALE. D. J. Packey, T. Richie, M. C. Trachtenberg, and B. Haber. Div. of Neurosurgery, Marine Biomedical Institute, and Depts. of Neurology, Physiology & Biophysics and Human Biol. Chem. & Genetics, University of Texas Medical Branch, Galveston, TX., 77550.

The phenomenon of potassium (K+) induced swelling of neural tissue has to date been largely studied in a variety of preparations containing both neurons and glia. The frog filum terminale (FT), which contains largely glia and myelinated fibers, offers a unique opportunity to study the same aspects of K+ induced swelling in a normal glial preparation devoid of neurons. In these experiments the extracellular space was measured by incubating excised portions of FT in the presence of ^{3}H-inulin in an oxygenated bicarbonate buffered frog ringer at 15^{o}C containing various concentrations of K+ (Na+ was covarred to maintain isotonicity). Parallel experiments were performed using excised spinal cord (SC), which contains both neurons and glia. Results (extracellular space, ECS) are expressed in microliters per mg. wet weight tissue.

The FT, which has been shown to have a lower cellular density than the SC on the basis of DNA measurement, has a correspondingly larger ECS (58%). Increases in the extracellular K+ greater than 30 mM result in changes in the ECS of both FT and SC. The magnitude and rate of swelling are similar in both preparations. The enzyme, carbonic anhydrase, has been implicated in K+ induced swelling in mammalian neural tissues. However, addition of acetazolamide, an inhibitor of carbonic anhydrase, does not change the extent of K+ induced swelling in the frog FT or SC. Furthermore, the range of K+ concentrations necessary to induce swelling is far higher in the frog than those previously reported for mammalian preparations. In other experiments, frog FT and SC are shown to have relatively low levels of carbonic anhydrase activity. Taken together, these data indicate that K+ induced swelling in amphibian neural tissue, and particularly in glia, is mediated by carbonic anhydrase independent mechanisms, in contrast to those seen in mammalian brain. The specific ionic dependencies of K+ induced swelling of amphibian neural tissue is under further investigation.

1399 IMMUNOCHEMICAL EVIDENCE FOR INDUCTION OF CHOLINE ACETYLTRANSFERASE IN THE MEDIAL PREOPTIC AREA OF RAT BRAIN ELICITED BY ESTRADIOL. Dong H. Park, Victoria N. Luine, Tong H. Joh, Bruce S. McEwen and Donald J. Reis. Laboratory of Neurobiology, Cornell Univ. Medical College, and Rockefeller University, New York, New York 10021.

The circulating ovarian hormone estradiol (E_2) is accumulated and retained with regional selectivity in brain, notably in the medial preoptic area and hypothalamus. These brain regions contain binding sites for the hormone in nuclear and cytosol fractions. In the preoptic area of ovariectomized (OVX) rats, E_2 increases the activity of choline acetyltransferase (CAT)(Endocrin. 100:903, 1977), the enzyme catalyzing acetylcholine synthesis. We sought to establish by immunochemical titration using a specific antibody to CAT (Nature 275:324, 1978), whether the increase of CAT activity elicited by E_2 is due to an increase in enzyme molecules or to change in its catalytic activity. In the first experiment, thirty days after removal of ovaries and adrenals, female rats (Long-Evans) received estradiol benzoate (EB)(100ug/220g body weight, s.c.) dissolved in sesame oil or sesame oil alone. The rats were sacrificed 24h later, the preoptic area removed and CAT activity measured. E_2 increased CAT activity to 125% of control (15.5 to 19.3nmol/ug protein/10min). In the second experiment, three groups of female rats (Sprague-Dawley CD strain) were ovariectomized and 14d later received the following agents, were sacrified 3h after the last injection, the preoptic area removed, and assayed for CAT. The injection schedule and CAT activity were:

	d1	d2	d3	d4	CAT activity (nmol/ug/10min)	
Group A	v*	v	v	v	7.71	100%
Group B	v	v	v	100ugE$_2$	7.33	102%
Group C	30ugEB	30ugEB	30ugEB	v	10.20	132%

*sesame oil as vehicle

This experiment shows that E_2 increases CAT activity in preoptic area after chronic but not acute treatment. Immunochemical titration of CAT showed that the equivalence point was shifted to the right by approximately 30%, demonstrating that the increases in CAT activity are entirely attributable to increases in CAT protein. The study demonstrates for the first time that: (a) the activity of CAT, like catecholamine synthesizing enzymes can be increased by the accumulation of the enzyme protein (induction), and (b) estradiol induces CAT regionally in rat brain.

1400 A COMPARISON OF CHRONIC PRENATAL AND POSTNATAL HALOTHANE EXPOSURE ON BRAIN MYELIN SYNTHESIS. Patsalos, P.N.*, Rigor, B.M.* and Wiggins, R.C.; Dept. Neurobiology and Anatomy, Univ. Texas Medical School, Box 20708, Houston, TX 77025.

Long-Evans rats were exposed prenatally or postnatally to 0.5% halothane for 8 hours/day during the specified age interval. Synthesis of brain subcellular membrane proteins (myelin, nuclear, synaptosomal, mitochondrial, and microsomal) was examined by a double isotope procedure as we have described previously. Typically, experimental rats were injected intraperitoneally with ^{3}H-leucine; controls, with 1-^{14}C-leucine. Brains of experimental and control pups were combined, subfractions prepared, and delipidated. ^{3}H/^{14}C ratios (test/control) were determined for each subfraction and the myelin, synaptosomal, nuclear, and mitochondrial values for each pair of rats were normalized to the corresponding microsomal value for that preparation. The resultant percentage is a measure of relative synthesis for each subfraction (Wiggins et al., 1976), normalized to test and control microsomal synthesis.

Table [1]Relative myelin synthesis in halothane exposed rats (percentage)

	Exposure regime[2]	(17)	Postnatal Age (20-22)	(25)	(30)
I	5d, G - Birth	97±3	96	103±2	
II	Birth - 5d, P		93±7		
III	Birth - 10d, P		87±14		92±3
IV	Birth - 15d, P		92±5		

[1]Mean ± S.E.M. (N=3); [2]G=gestational age; P=postnatal age.

Results show that the myelin ratio was consistently low at 20-22 days, the period of most rapid myelin synthesis, reflecting a relative decrease in synthesis (about 8%, $P<0.05$, paired t-statistic). Isotope reversal showed that the relatively low myelin values are not artifacts of isotope utilization. Prenatal exposure had comparatively little effect on subsequent brain myelin synthesis. All intervals of postnatal exposure produced about the same degree of myelin reduction, and the effect persisted at 30 days, well past peak myelination. Thus, the decrease is not the result of a delay in maturation. Synthesis of nuclear membrane protein was also decreased (6%, $P<0.01$, paired t-statistic) at 20-22 days. Relative synthesis of the synaptosomal, mitochondrial, and microsomal protein fractions were identical to one another. (This research was supported by Public Health Service Grant NS-14355.)

1401 GABA LEVELS IN CEREBROSPINAL FLUID OF NEUROLOGICAL PATIENTS. A.L.N. Prasad* and S. Fahn (SPON: S.P. Mahadick). Department of Neurology, College of Physicians and Surgeons, Columbia University, New York, NY 10032

Recently we have developed a simple and sensitive assay for the measurement of GABA in fluids and tissues by high performance liquid chromatography (Proc. International Soc. Neurochem. 6, 644, 1977). The only sample preparation required is deproteinization and usually 100 µl of CSF is all that is required for a reliable determination of GABA. We have measured GABA CSF levels in patients with various neurological disorders as well as in a few control specimens. The control values, around 300 µM, agree with published results. Patients with Parkinson's disease or Huntington's chorea had CSF GABA levels ranging from 26-150 µM with occasional high values and are in general agreement with those reported by Enna et al. (Arch. Neurol. 34, 683, 1977).

GABA CSF levels in patients with myoclonus, stroke, dystonia and other miscellaneous neurological disorders ranged from 50-600 µM, without any recognizable pattern. From the results obtained thus far, low levels of CSF GABA are not necessarily limited to patients with Huntington's chorea or Parkinson's disease.

1402 AVOIDANCE OF L-DOPA DECARBOXYLATION BY METAL CHELATION - IN VITRO STUDIES. K. S. Rajan, M. Robinson*, IIT Research Institute, Chicago, IL 60616, and John M. Davis, Ill. State Psych. Inst., Chicago, IL 60612

Consistent with a metal chelation approach, in vivo studies on the administration of Cu(II)- and Zn(II)-L-DOPA chelates to experimental rats have shown up to 200% increased replenishment of DOPA (and its metabolites) in the whole brain compared to the unchelated L-DOPA controls. (Rajan, K. S., et al, Brain Res. 107, 317 (1976) and Rajan, K. S., et al. Pharmacologist, 20, 216 (1978), Neuroscience abstracts #164.5 (1978)). This approach is based on a theoretical speculation that the pyridoxal phosphate-dependent decarboxylation of the aromatic amino acid, L-DOPA, might be largely avoided if its aminocarboxylate group is chelated to a suitable metal ion prior to its in vivo administration. In Vitro studies have since been carried out to investigate the activity of the DOPA-decarboxylase on the ^{14}C-L-DOPA chelates of Cu(II) containing equimolar amounts of citric acid, dipyridyl and ATP. Warburg-technique was used to determine the $^{14}CO_2$ released from the decarboxylation reaction. The chelate substrates investigated were: ^{14}C-L-DOPA-Cu(II)-citric, ^{14}C-L-DOPA-Cu(II)-dipyridyl, ^{14}C-L-DOPA(II)-ATP (1:1:1) and ^{14}C-L-DOPA-Cu(II) (2:1). In the range of concentration of 0.1 to 0.4 m moles of the substrates, a substantial inhibition of the decarboxylase activity was observed, i.e. two to five fold decrease in the catechol amines produced as compared to ^{14}C-L-DOPA controls. Kinetic analyses of the saturation of binding curves for the chelates and the control were undertaken. The inhibitory activities of the chelate substrates are examined in the light of the metal L-DOPA binding strengths. The potential clinical significance of this approach to Parkinsonism is discussed.

1403 HEXOSAMINIDASES IN HUMAN BRAIN AND TUMORS OF THE NERVOUS SYSTEM. Robert B. Ramsey. Department of Neurology, Saint Louis University, St. Louis, MO. 63104.

Total hexosaminidase activity of nervous system tumors has been found to be consistently greater than that of normal brain. Studies utilizing tissue homogenates for determination of apparent Km values have suggested that hexosaminidase derived from tumor tissue differs from that in brain in other respects as well. Since this enzyme may serve as a key enzyme in maintaining the neoplastic condition, we have sought to further characterize the hexosaminidase of nervous system tumors. Using a resuspended ammonium sulfate derived from the 37,000 x g supernatant of a homogenate of lyophilized brain and tumor preparations, it could be shown that initial gel filtration on G-150 Sephadex yielded two peaks of enzyme activity; the lesser peak of activity was associated with the void volume (peak I), the greater activity with an approximate MW of 135,000 (peak II). In normal brain tissue, peak I represented 35% of the total activity in grey matter, and 15% of the total activity of white matter. In comparison to normal white matter, the void peak was significantly reduced ($P<.01$) in preparations of glioblastomas. Other tumors which have been analyzed (meningiomas, astrocytomas and tumors metastatic to the nervous system) also demonstrate a reduction in peak I. DEAE-cellulose chromatography of the two peaks derived from gel filtration demonstrated that peak II was dominated by hexosaminidase A in normal white and grey matter. Isozyme A constituted 85% of the total eluted activity of human grey matter and 92% of white matter activity. Only 13% of the total eluted activity of grey matter was isozyme B. It represented 6% of the white matter activity. The remainder of the activity was derived from isozyme I. In normal brain tissue, peak I contained only isozymes B and I. Analyzing glioblastoma samples in the same manner, it was found that DEAE-cellulose chromatography of peak II yielded a significant ($P<.01$) increase in the relative content of the B isozyme, compared to normal white matter, and a significant ($P<.01$) reduction in the relative A isozyme content. Isozyme I was not always present in these tumors. Peak I activity from these tumors could not generally be eluted from DEAE-cellulose using a 0-.3M NaCl gradient. Comparable isozyme patterns were observed in tumor preparations when p-nitrophenyl N-acetyl-β-D-galactosaminide was used instead of *p-nitrophenyl N-acetyl-β-D-glucosaminide as substrate.* Although specific properties of the isozymes derived from these tumors have yet to be defined, it is already obvious the alterations in total enzyme activities also reflect changes in isozyme content as a result of neoplasia.

1404 DECREASED AMINO ACID CONCENTRATIONS IN BRAIN OF PATIENTS WITH LESCH-NYHAN SYNDROME. D. K. Rassin, K. G. Lloyd and I. Fox.* Dept. Human Dev. & Nutr., Inst. Basic Res. Ment. Ret., S.I., NY, Dept. Neuropharmacol., Synthelabo, LERS, Paris, France, and Dept. Int. Med., Univ. Mich., Ann Arbor, MI.

Lesch-Nyhan Syndrome (LNS) is an X-linked recessive disease associated with a deficiency of the enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT). Increased uric acid production has been found in patients with this disease. Glutamine and glycine are associated with the affected metabolic pathway but have not been indicies of the state of the disease.

In an effort further to understand the pathogenesis of LNS we have analyzed amino acids in autopsy material obtained from five patients and six controls. The free amino acid pool of the occipital cortex, limbic cortical area, cerebellar cortex, hippocampus and putamen was measured with an automatic amino acid analyzer after precipitation of protein with TCA. Amino acids in brain areas from the LNS patients were usually lower in concentration; most dramatically decreased were threonine, serine, valine, isoleucine, leucine, lysine and arginine. Only glutamine and urea were higher than controls. Glutamate, gamma-aminobutyrate and cystathionine were essentially unaffected. High concentrations of glycine have been found in cultured mutant mouse cell lines of neural origin that lack HGPRT (Skaper and Seegmiller, J. Neurochem. 26:689, 1976; 29:83, 1977). Glycine was slightly decreased in the brain areas analyzed in the current study. Some of the results are given in the following table:

	Occipital Cortex		Hippocampus	
	LNS	Control	LNS	Control
	(µmoles/100 g)			
Threonine	54±12*	82±5	55±4*	97±7
Serine	115±15*	174±13	161±23*	227±18
Valine	53±11*	80±5	65±3*	94±7
Isoleucine	24±6*	40±4	28±5*	53±6
Leucine	57±13*	90±10	70±13*	112±12

*p <0.05

Our findings suggest that patients with LNS have a generally lower free amino acid pool in brain. This decreased pool may limit the capacity of the brain to make proteins essential for normal function and, thus, be related to the pathogenesis of the disease.

1405 SPECIFICITY OF ASSOCIATION OF A Ca^{2+}/Mg^{2+} ATPase WITH CHOLINERGIC SYNAPTIC VESICLES FROM TORPEDO ELECTRIC ORGAN. Joan E. Rothlein* and Stanley M. Parsons* (SPON: Harry J. Carlisle). Marine Science Institute and Department of Chemistry, University of California, Santa Barbara, CA 93106.

Purified cholinergic synaptic vesicles from the electric organ of Torpedo californica have been subjected to analytical scale separation techniques not utilized in the isolation procedure, and the ATPase activity of separated fractions determined. Most of the ATPase activity migrated with the vesicles. Sensitivity of the ATPase activity to 16 potential inhibitors also was determined. Most of the ATPase activity was inhibited by low concentrations of 4-chloro-7-nitrobenzo-oxadiazole (NBD-Cl) and dicyclohexylcarbodiimide (DCCD), but not by a water soluble carbodiimide. Chlorpromazine also inhibited significantly. The close association of the ATPase with the vesicles and the pattern of inhibition obtained provide further support for the authentic presence of a membrane bound Ca^{2+}/Mg^{2+} ATPase in the cholinergic synaptic vesicle.

1406 REGIONAL DISTRIBUTION OF MULTIPLE BENZODIAZEPINE RECEPTORS IN RAT BRAIN. M. C. Sano*, B. Beer and A. S. Lippa*. Dept. of Central Nervous System Research, Medical Research Division, American Cyanamid, Pearl River, NY 10965.

Brain specific benzodiazepine receptors appear to mediate the pharmacological properties of benzodiazepines. Multiple classes of benzodiazepine binding sites have recently been reported and triazolopyridazines have a high affinity for one class of these binding sites (Type I) (Squires et al., Proc. Natl. Acad. Sci., in press). In the present studies, we have used CL 218,872 (3-methyl-6-[3-(trifluoromethyl)phenyl]-1,2,4-triazolo[4,3b]pyridazine) to investigate the regional distribution of multiple benzodiazepine binding sites. In confirmation of prior reports, diazepam displaced specifically bound ^{3}H-diazepam (1.5 nM) with equal potencies in frontal cortex, cerebellum, striatum and hippocampus (IC_{50} ranged from 4-6.5 nM). Hill coefficients for diazepam approached unity in all regions suggesting that diazepam has equal affinity for the various classes of binding sites. In contrast, the potency of CL 218,872 to displace specifically bound ^{3}H-diazepam (1.5 nM) varied as a function of region: cerebellum (IC_{50} = 25 ± 7 nM); frontal cortex (IC_{50} = 113 ± 28 nM); striatum (IC_{50} = 167 ± 24 nM); hippocampus (IC_{50} = 238 ± 36 nM). The Hill coefficients for CL 218,872 also varied as a function of region: cerebellum (α = .82); frontal cortex (α = .69); striatum (α = .63); hippocampus (α = .71). The findings that CL 218,872 is very potent in cerebellum, and its Hill coefficient approaches unity, suggest that benzodiazepine receptors in cerebellum may be relatively homogeneous and of the Type I class. Calculations suggest that approximately 78% of ^{3}H-diazepam binding in cerebellum represents Type I receptors; while 64, 52 and 34% of binding in frontal cortex, striatum and hippocampus represents Type I receptors in these regions. Scatchard analysis of cerebellar ^{3}H-diazepam binding in the presence of different concentrations of CL 218,872 demonstrates the competitive nature of this inhibition.

1407 THE ECC SYNDROME: POSSIBLE CHOLINERGIC INVOLVEMENT IN AN ANIMAL MODEL OF HYPERKINESIS. A.C. Sconzert, B. Haber, and S. Gabay. Marine Biomedical Institute, UTMB, Galveston, TX 77550, V.A. Hospital, Brockton, Mass.

The ECC syndrome is characterized by behavioral excitation, circling, and choreiform head and neck movements. This syndrome is induced in rats by the administration of β-β'-iminodipropionitrile (IDPN) and is permanent once established. Thus the ECC rat is a potentially useful model system in which to explore some of the neurochemical parameters underlying hyperkinetic behavior. Evidence to date indicates involvement of dopamine, serotonin, and GABA systems in the behavioral expression of this syndrome. In the present studies, female ECC rats were sacrificed 15 months post injection of IDPN, and the brains analyzed for choline acetyltransferase (CAT) and acetylcholinesterase (ACE) activity on a regional basis (cortex, striatum, hippocampus, hypothalamus, cerebellum, and brain stem). Enzyme activities were determined radioenzymatically. In IDPN treated rats, CAT activity was depressed in striatum and cerebellum (81 and 60% of control, respectively). ACE activity was depressed in all regions except cerebellum. ACE activity was particularly depressed in cortex (65.2% of control, $p<0.05$) and striatum (77.4% of control, $p<0.001$). The changes in the activity of CAT, the rate limiting enzyme to acetylcholine synthesis, parallels the depression of acetylcholine levels in some, though not all, brain areas examined. These changes in the cholinergic enzymes CAT and ACE are additional to those previously shown by us in the GABAergic system in the ECC rat. These long term effects of this drug, which persists for fifteen months post injection, make it unlikely that they reflect direct inhibitory effects of IDPN on CAT and ACE per se. It is possible that IDPN results in the destruction of either GABA or acetylcholine containing neurons, particularly in the striatum, as has been shown in other movement disorders such as Parkinson's disease and Huntington's disease. The examination of these possibilities and the relationships of multiple neurotransmitter pathways in the development and maintenance of the ECC syndrome are currently underway.

1408 PLASMA AMINO ACIDS AND OTHER METABOLITES FROM NORMAL AND DEPRESSED PATIENTS UNDER DIETARY MONITORING. P.A. Shea, M. DeMyer*, and H.C. Hendrie*. The Institute of Psychiatric Research and Depts. of Biochemistry and Psychiatry, Indiana University Medical School, Indianapolis, IN 46223.

Eighteen unipolar depressed (drug free) patients and ten normal controls were voluntarily hospitalized for six days and five nights. Under controlled conditions dietary effects on particular biochemical measurements were monitored. Using standard biochemical procedures the following measurements were made on blood drawn after a 12 hour fast on days two, three, and five: (a) plasma levels of free and total tryptophan, (b) twenty other amino acids, (c) choline, (d) cortisol and (e) free fatty acids. Total protein, fat, and carbohydrates consumed with each meal were measured by a nutritionist. Each patient was rated daily for severity of depression using Hamilton and Beck questionnaires. In general, there were no significant effects of dietary protein, fat or carbohydrate on any of the plasma biochemical measurements performed. It was noted that although both groups consumed the same amounts of protein and carbohydrates, depressed patients consumed significantly higher amounts of fat. No differences were noted in the levels of plasma metabolites between the two groups except for tyrosine and phenylalanine which were significantly higher in depressed patients when expressed as the mean ± S.D. Thus tyrosine levels in the depressed group were 60.4 ± 9.4 nmol/ml and 51.3 ± 12.9 nmol/ml for controls. Phenylalanine in depressed patients was 56.0 ± 12.2 whereas controls were 47.6 ± 8.2. Significant differences ($p < .04$ and $p < .06$, respectively) were obtained using a student t-test based on the sum of the means of the three day blood measurements. There were no differences in the ratios of either free or total tryptophan to the sum of the five competing amino acids (valine, leucine, isoleucine, phenylalanine and tyrosine). These neutral amino acids have been shown to block the uptake of tryptophan into the CNS. The data on ratios follow: Free tryptophan/sum five amino acids: depressed patients 0.023 ± 0.005, control 0.024 ± 0.005; total tryptophan/ratio: depressed patients 0.089 ± 0.02, control 0.101 ± 0.03. Further, these ratios showed no significant differences in both groups irrespective of the concentrations of either free fatty acids and cortisol in plasma or dietary amounts of protein, fat and carbohydrate in the diet. The increased levels in the two competing neutral amino acids tyrosine and phenylalanine found in depressed patients suggests that tryptophan transport into the CNS of these patients may be affected. (Supported in part by Indiana Dept. Mental Health 178-679-005 and Indiana Attorney Generals Fund, 1979).

1409 PREFERENTIAL LOCALIZATION OF γ-GLUTAMYL TRANSPEPTIDASE IN GLIA. H.D. Shine, L. Hertz, J. deVellis, and B. Haber. Marine Biomedical Institute, UTMB, Galveston, TX 77550, UCLA School of Med., Los Angeles, CA.90024, Univ. of Saskatchewan, Canada.

γ-glutamyl transpeptidase (γ-GTP) is an enzyme which may have a role in transport of amino acids and peptides across biological membranes. High levels of γ-GTP activity found in the brain suggest that this enzyme may well have such transport functions within neural tissues. We observe that in the central nervous system levels of enzymatic activity are greatest in the capillaries, followed by white matter and are significantly lower in gray matter. The higher levels of γ-GTP activity in white matter suggest a preferential association of γ-GTP with glia. To determine the cellular localization of γ-GTP in neural tissues we have employed cultured cells of neuronal and glial origin as models of neurons and glia in vivo. γ-GTP activity was measured using a highly sensitive fluorometric assay which employed the synthetic substrate 7-γ-glutamylamido-4-methyl coumarin and high pressure liquid chromatography or fluorescent spectroscopy. Enzymatic activity in clonal cell lines of glial origin uniformily expressed greater activity than did a variety of neuroblastoma cell lines. Furthermore the γ-GTP activity of normal non-transformed rodent astrocytes and oligodendrocytes was also higher than neuronal levels. No significant difference in γ-GTP activity was found between the normal astroglia and oligodendroglia. Taken together this data strongly suggest that the bulk of CNS γ-GTP activity is primarily associated with astroglia, oligodendroglia and CNS capillaries.

1410 **ACTIONS OF LEAD (PB) ON GABAERGIC NEUROTRANSMISSION: DISCREPANCIES BETWEEN IN VIVO AND IN VITRO EFFECTS.** **E. Silbergeld, R. Hruska, J. Lafferman*, NINCDS, NIH Bethesda, MD 20205.**

Exposure to Pb in vivo produces convulsions and, at lower levels of exposure, appears to sensitize animals to convulsant agents (Neurosci. Abstr. (1977) 3:1039). This effect can be produced by chronic exposure of rats from birth (to 10 mg/ml Pb acetate in drinking water) or by intraperitoneal injection of Pb acetate (7.58 mg/kg) for 3 days. Doses producing convulsions are decreased and duration of clonus is increased in both chronic and acute Pb rats challenged with mercaptopropionic acid or bicuculline. Neurochemical studies were done on synaptosomes and synaptic membranes prepared from caudate (CN), cortex (CX), cerebellum (CB) and substantia nigra (SN) of acute and chronic Pb rats. Na-Dependent high affinity ^{14}C-GABA uptake, release of ^{14}C-GABA (in the presence of 5 mM or 35 mM K+), and Na-independent specific ^{3}H-GABA binding were studied. In Pb rats, GABA uptake was inhibited in CN, CB, and SN. Kinetic analyses demonstrated that in these regions Vmax was reduced without significant effects on Km. Release of GABA was also inhibited under conditions of spontaneous and K+-stimulated release. No changes were observed in any region for Na-independent GABA binding. The results suggest that in vivo Pb exposure primarily affects presynaptic elements of GABAergic function, which may reflect either a selective destruction of GABA-releasing and transporting elements or a blockade by Pb of presynaptic GABA cycling. We attempted to study mechanisms of action of Pb by exposing synaptosomes and synaptic membranes from these regions to Pb in vitro. However, at concentrations as high as 100 uM, Pb in vitro has no effects on GABA uptake, release, or receptor binding, even when long exposure times are used. The discrepancy between in vivo and in vitro data suggests that the actions of Pb in vivo on GABA uptake and release may result from indirect effects of Pb on other neurotransmitter systems or from the action of a toxic metabolite. In vivo, Pb can decrease CNS acetylcholine release and increase CNS dopamine release (Life Sci (1977) 20:309). A possible toxic metabolite affecting GABAergic function is δ-aminolevulinic acid (ALA); concentrations of ALA in tissue and plasma are greatly elevated after Pb exposure in vivo. However, ALA in vitro (as high as 1 mM) has no effects on synaptosomal GABA uptake or release; ALA inhibits GABA receptor binding but only weakly (IC50 = 1 mM). The mechanisms of action of Pb in vivo on GABAergic function are at present still unclear.

1411 ISOENZYME FORMS OF ACETYLCHOLINESTERASE IN RAT AND MOUSE TISSUE. K.A. Skau* and W.S. Brimijoin, Mayo Fdn., Rochester, MN 55901.

Acetylcholinesterase (AChE) is present in rat skeletal muscle in at least three isoenzymic forms identified by sucrose density gradient centrifugation as 4S, 10S and 16S (Hall, J. Neurobiol. 4:343,1973; Vigney et al, J. Neurochem. 27:1347, 1976). The 16S form has been called the endplate specific form as it is absent from non-innervated regions of the muscle and disappears from endplate regions after denervation. The 4S and 10S forms are present in endplate-free sections as well as in endplate-rich sections and decrease upon denervation. We have studied the pattern of isoenzyme forms in various rat and mouse tissues to determine whether there are species or tissue differences with respect to these isoenzymes.

Five to 20% linear sucrose density gradients were used to investigate the isoenzyme forms of detergent solubilized muscle extracts. Denervated extensor digitorum longus muscles (EDL) or hemidiaphragms were produced by sectioning the sciatic nerve in the mid-thigh region, or the phrenic nerve in the thoracic cavity at least 6 days prior to sacrifice.

	% of Total AChE					
	Control			Denervated (6 days)		
Rats	4S	10S	16S	4S	10S	16S
Hemidiaphragm	21	52	15	21	63	5
EDL	43	29	18	10	90	0
Mouse						
Hemidiaphragm	30	no peak	46	51	no peak	12
EDL	30	32	34	30	30	37

There were large species differences as well as differences between muscles within a species. Of particular significance was the persistence of the 16S form in mouse EDL after denervation. The 16S form was a major peak in this tissue up to 27 days after denervation whereas in the rat EDL the 16S form disappeared within 6 days. Another striking observation was the lack of a 10S peak in mouse hemidiaphragms.

These species and tissue differences lead us to question the specific localization of the 16S form of AChE. In related studies we detected small but significant 16S peaks in a nerve segment just proximal to a ligature of rat vagus nerve and in mouse cardiac tissue. These results indicate that the pattern of AChE isoenzyme forms is more complex than previously proposed and that the 16S form is not restricted to endplate regions of skeletal muscle. (Supported by NIH Grants NS 11855 and NS 14304. W.S.B. is a recipient of Research Career Development Award NS 00119 from NIH.)

1412 Ontogeny of γ-Hydroxybutyrate in Human and Rhesus Monkey Brain. O. Carter Snead, III, and Barbara J. Morley. Dept. Pediatrics and the Neuroscience Program, Univ. Alabama in Birmingham Sch. Med. B'ham. Al.

Gamma Hydroxybutyrate (GHB) is a GABA metabolite that produces age specific EEG and behavioral effects in experimental animals that resemble human petit mal epilepsy (Snead, Neurology 28:643, 1978). We have used an electron capture gas liquid chromatographic assay method (Doherty, Snead & Roth, Anal. Biochem. 69:268, 1975) to determine the regional distribution of GHB in infant and adult rhesus monkey brain as well as discrete regional concentrations in post mortem brain from humans, ranging in age from 4 weeks gestation to 57 years old (Table 1). GHB is present in human brain at 4 weeks gestation in a concentration of 9 nmol/g. It gradually increases in concentration until 14-22 weeks gestation when it peaks in cerebellum at 50-100 nmol/g. Concentrations fall postnatally in cerebellum but rise in the striatum. The highest concentration of GHB in children under ten was found in globus pallidus I, caudate and putamen. Similarly in the rhesus monkey, the neonatal brain concentrations of GHB were twice those of adults with the highest concentration occurring in neonatal cerebellum.The marked elevation of GHB in immature human brain, the propensity of this substance to produce age specific absence seizures in primates experimentally, and the younger age predominance of petit mal seizures in human all point toward the possibility that GHB may play a role in the pathogenesis of human petit mal epilepsy.

TABLE 1
CONCENTRATION OF GHB IN HUMAN BRAIN* (NMOL/G±S.E.)

	AGE			
	12-14 Wk. Gest.	4 Years	14 Years	50 Years

1413 PHARMACOLOGICAL CHARACTERIZATION OF DIFFERENT TYPES OF DOPAMINE RECEPTORS: STUDIES WITH ERGOT DERIVATIVES AND SUBSTITUTED BENZAMIDES. P. F. Spano* & M. Trabucchi* (SPON: J.P. Schwartz) Depts. of Pharmacol., Universities of Cagliari & Brescia, Italy

Many lines of evidence have recently indicated the presence of multiple receptors sites for dopamine (DA) in mammalian central nervous system. In this report we will show that two classes of drugs, dopaminergic ergot derivatives and substituted benzamides interact with DA receptors in a way which is basically different from the classical DA-mimetic and DA-antagonist agents such as apomorphine and neuroleptics, respectively. In fact, DA-stimulated adenylate cyclase activity in cell free preparations from rat striatum is not blocked by DA ergot drugs such as bromocriptine and lisuride. Moreover, sulpiride and other substituted benzamides endowed with antipsychotic activity are not able to inhibit DA stimulated adenylate cyclase either in vitro or in vivo. However both classes of drugs can displace ^{3}H-haloperidol from putative DA binding receptor sites in membranes prepared from rat striatum. Experiments performed using ^{3}H-sulpiride have shown a specific binding for this ligand in dopaminergic regions of the brain. Our data provide strong indication that two distinct populations of DA receptors, one coupled and the other uncoupled to adneylate cyclase, are present in rat striatum. Thus, we have defined as D_1 and D_2 respectively these DA receptor sites.

1414 ALTERATIONS IN MYELIN BASIC PROTEIN AND MYELIN-ASSOCIATED GLYCOPROTEIN IN JIMPY MICE. Nancy H. Sternberger*, Richard H. Quarles*, Steven R. Cohen*, Kathryn Winchell* and H. deF. Webster. NIH, Bethesda, MD 20205.

To study the distribution of myelin basic protein (MBP) and myelin-associated glycoprotein (MAG) during development, 10 to 25-day jimpy mice and littermate controls were perfused with a $HgCl_2$-formaldehyde fixative. Vibratome sections of the brainstem and anterior commissure were immunostained with antiserum to MBP or MAG according to the peroxidase-antiperoxidase technique. In littermate controls, a normal distribution of MBP staining was found in oligodendroglial cytoplasm, oligodendroglial processes, and in compact myelin. In contrast, jimpy MBP staining had the following characteristics: 1) oligodendroglial cytoplasm and processes were stained and there were collars of staining surrounding axons, 2) the staining around axons was more frequent than could be accounted for by the small amount of myelin seen in phase and electron microscopic sections of jimpy brainstem, 3) the axonal collars were easily and intensely stained throughout development, suggesting that they were not compact myelin sheaths but were oligodendroglial processes containing mesaxons and/or loosely wrapped myelin spirals, 4) the number of stained axonal collars decreased with development, 5) staining was less than in littermate controls and irregularly distributed, 6) during the earlier stages of myelination, as in the 10-day anterior commissure, little difference was found between jimpy and littermate MBP staining but with further development, the rapid increase in MBP staining seen in littermate controls was not present in the jimpys. Littermate controls stained with MAG antiserum also showed a normal distribution of staining in oligodendroglia, processes and myelin. However, in sections of jimpy brainstem and anterior commissure stained with MAG antiserum, we observed that 1) only a few stained oligodendroglia were present; they were stained much less intensely than oligodendroglia in littermate control sections, 2) many fewer collars of axonal staining were seen than had been observed in jimpy sections stained with MBP. These observations suggest that in jimpys, axonal ensheathment by oligodendroglia is less severely affected than the subsequent formation and growth of compact sheaths. The results also indicate that the deficit in oligodendroglial synthesis of MAG is much greater than that of MBP.

1415 EVIDENCE FOR NEURONAL SYNAPSES ON THE BASEMENT MEMBRANE OF CEREBRAL CAPILLARIES. R.L. Suddith, K.E. Savage*, P.S. Baur*, J.S. Crawford*, and H.M. Eisenberg. Division of Neurosurgery, Shriner's Burns Institute and Department of Surgery, University of Texas Medical Branch, Galveston, Texas 77550.

While innervation of large cerebral vessels by adrenergic and cholinergic nerve fibers have been shown, similar innervation of the cerebral microvasculature has not been demonstrated. In this study isolated cerebral microvessels were examined for presence of neuronal synapses. The microvessels were isolated from the cerebral cortex of mature Sprague-Drawley rats by a process of serial filtration and differential centrifugation. The isolate contained numerous capillary segments and fewer segments of small arterioles and venuoles.

Transmission electron microscopy showed that the capillary segments were circumferentially complete, the endothelial cells being surrounded by an intact basement membrane. Electron dense areas containing numerous uniform vessicles were found external and adjacent to this membrane. Morphologically these areas were similar to neuronal terminals found on larger vessels. Using histochemical techniques the presence of monoamine oxidase was found in association with capillaries and using radioenzymatic assay techniques the microvessel isolate was shown to contain this enzyme.

These studies show that electron dense bodies present on the basement membranes of cerebral capillaries have the appearance of neuronal synapses and that the enzyme monamine oxidase is present in the cerebral microvessel preparation. If these structures are functional synapses they may then have a role in the control of cerebral blood flow and vascular permeability.

This work was supported in part by NIH Grants CA18877, NS073 77, and GM07204.

1416 CHARACTERIZATION OF ^{3}H-SPIPERONE BINDING TO BRAIN MEMBRANES OF THE RAT. R. H. Sundermann*, C.-H. Cheng*, and G. F. Wooten. Depts. of Neurology and Pharmacology; Washington University School of Medicine; St. Louis, MO 63110

The biochemical properties of ^{3}H-Spiperone binding were defined in vitro using a crude homogenate of rat corpus striatum and separation by filtration. In this system saturable binding constituted greater than 90% of the total binding. Scatchard analysis revealed a high affinity site with a K_d of 1.3 nM and a low affinity site with a K_d of 62 nM. B_{max} for the high affinity site was 175 f moles/mg of tissue. The binding was stereospecific in that (+)-butaclamol was 1000 times as potent as (-)-butaclamol in displacing bound spiperone. The binding demonstrated other properties of a specific protein receptor. ^{3}H-Spiperone binding was pH dependent, being maximal at pH 7.6 to 7.8. Thermal inactivation of specific binding was demonstrated at temperatures greater than 50°C. Incubation at 60°C for 5 minutes resulted in 50% loss of specific binding, while 5 minutes of incubation at 70°C caused total loss of specific binding. Extremes of pH and temperature did not affect non-specific binding. The rate of association of the ligand with the high affinity binding sites was rapid at 37°C, specific binding being half maximal in less than 30 seconds. The concentration of the cations Na^{+}, Ca^{++}, Mg^{++} and Mn^{++} had no significant effect on the amount of saturable ^{3}H-Spiperone binding to the high affinity site.

The potencies of several neurotransmitters and pharmacological agents in blocking specific high affinity ^{3}H-Spiperone binding were determined. Of the neurotransmitters, dopamine was the most potent with an IC_{50} concentration of 2×10^{-5}M. The IC_{50} for serotonin was 1.8×10^{-4}. Epinephrine and norepinephrine were much less potent, both with IC_{50} concentrations greater than 10^{-2}M. The inhibitory potencies of apomorphine and three other novel, putative dopamine receptor agonists were studied. Bromocryptine was the most potent inhibitor, followed by, in decreasing order, apomorphine, lergotrile and piribedil.

Nine regions of the rat brain were assayed for ^{3}H-Spiperone binding and the affinities and concentration of binding sites were quantified by Scatchard analysis. The concentration of binding sites in each region varied directly with the dopamine concentration.

1417 **SEROTONIN BINDING PROTEINS IN RAT PLATELETS.** H. Tamir, R. J. Bebirian*, D. Casper*, and F. Muller*. Division of Neuroscience, N.Y. State Psychiatric Institute and Department of Psychiatry, Columbia University, New York, NY 10032.

A protein with high binding affinity for serotonin is present in homogenates of both CNS and PNS (myenteric plexus). This protein is enriched in brain synaptic vesicles. When enteric neurons are stimulated both serotonin and serotonin binding protein are released by a Ca^{++}-dependent mechanism. The protein binds newly synthesized serotonin; serotonin binding is inhibited by reserpine. We now wish to report the properties of serotonin binding protein in the high speed supernatant of rat platelets. Platelet rich plasma, obtained by centrifuging rat blood drawn by cardiac puncture, was frozen and thawed, and the resulting suspension was centrifuged (100,000g; 60 min) to obtain the high speed supernatant. The binding of serotonin to the protein in this supernatant was highly specific (92%), dependent on Fe^{++}, trypsin sensitive and partially heat stable (42% decrease of activity at 100°). Two proteins with serotonin binding capacity were present: a glycoprotein and albumin. Both were also present in platelets sedimented and washed to remove the plasma. They were purified using $(NH_4)_2SO_4$ fractionation, Sephadex sieve chromatography and affinity column chromatography. The two proteins differed in most characteristics. However they showed two similar properties: sensitivity to trypsin (85% loss of binding activity with 0.2 mg trypsin/ml at 28° for 20 min) and enhanced binding (5 to 10 fold) in the presence of total brain lipid (25 µg lipid/25 mg protein). The proteins exhibited several differences: 1) migration on 5% acrylamide gel of the complex [protein-Fe^{++}-^{3}H-serotonin]: glycoprotein, Rf 0.41, albumin Rf 0.76. 2) heat stability (100°, 15 min); glycoprotein unstable, albumin stable. 3) molecular weight (SDS gels): glycoprotein 100,000; albumin 64,000. 4) carbohydrate reaction: glycoprotein stains strongly with Schiff's reagent after periodate oxidation; albumin, no reaction. 5) binding capacity and binding constants: glycoprotein 0.02 nmoles/mg protein; Scatchard plot, complex; albumin 0.125 nmoles/mg protein, two dissociation constants $K_{D1}=2.0\times10^{-8}$M and $K_{D2}=50\times10^{-8}$M. The properties of both the glycoprotein and albumin differ considerably from those of the serotonin binding protein of brain. It appears from these results that the storage form of serotonin in platelets is different from that of the brain.

Supported by NIH grant NS 12506.

1418 DEACYLATION-REACYLATION ACTIVITY OF MOUSE BRAIN PHOSPHOLIPIDS DURING CARBAMYLCHOLINE INDUCED CONVULSION. Wilson Tang* and Grace Y. Sun. Sinclair Research Farm and Biochemistry Dept., Univ. Missouri, Columbia, MO 65211.

Brain microsomes and synaptosomes were prepared from placebo controls and from mice after becoming convulsive by injecting intracerebrally with carbamylcholine (CC) (4 µg/brain). When the membrane samples (app 800 µg protein) were incubated with labeled oleoylCoA (0.1 µCi in 5 nmol), a large portion of the label was hydrolyzed by the acylCoA hydrolase to form free fatty acids, but a small portion of the oleoyl group was transferred and subsequently incorporated into the phospholipids. The acylCoA hydrolase activity was lower (12%) in synaptosomes isolated from CC-stimulated mice as compared to controls. CC-induced convulsion gave rise to a 3-fold increase in oleoyl transfer to diacylglycerophosphocholines (GPC) in the synaptosomes. The most rapid increase was observed during the initial 5 min after onset of convulsion. Among other phospholipids in synaptosomes, the diacyl-glycerophosphoinositols (GPI) also indicated an increase in acylation (app 1-fold) with respect to CC-induced convulsion, but the effect was not readily discernable due to low incorporation activity. The increase in acylation activity was pertaining only to synaptosomal phospholipids, suggesting that specific types of lyso-phosphoglycerides were released in synaptosomes during CC-induced convulsion. Calcium (4 mM) inhibited acylCoA hydrolase activity by app 25% but enhanced the acyl transfer into phospholipids, especially diacyl-GPC and diacyl-GPE (ethanolamine). The calcium-enhanced acyl transfer to diacyl-GPC and diacyl-GPE in synaptosomes was further stimulated during CC-induced convulsion. Some increase in acylation of phospholipids due to calcium was also observed in microsomes but among them, the increase in oleoyl transfer to diacyl-GPS (serine) was most dramatic, giving a 3-fold difference with respect to CC-induced convulsion. The calcium-associated increase in oleoyl transfer to membrane is attributed to the release in lyso-phosphoglycerides due to a stimulation of the phospholipase A_2. Apparently, the sensitivity of calcium-stimulated phospholipase A_2 towards diacyl-GPC and diacyl-GPE in synaptosomes and diacyl-GPS in microsomes is altered with respect to convulsion. Results of this experiment have demonstrated for the first time an involvement of deacylation-reacylation mechanism in membrane phosphoglycerides during CC-induced convulsion. The increased deacylation activity with respect to brain stimulation may be mediated through an unknown mechanism of interaction between calcium and phospholipase A_2. (Supported in part by NS-12960 from NIH and BNS 76 24338 from NSF.)

1419 COMPARATIVE ASPECTS OF CARBONIC ANHYDRASE ACTIVITY: POSSIBLE FUNCTIONAL SIGNIFICANCE. M. C. Trachtenberg and D. J. Packey. Div. Neurosurg. and Dept. Physiol. and Biophys., Univ. Texas Med. Bra., Galveston, TX 77550.

It has been suggested that in the neuroepithelia of warm blooded animals the demand for protons and bicarbonate requires the presence of the enzyme carbonic anhydrase (CA). Thus the choroid plexus of mammals exhibits high CA activity. In contrast, the choroid plexus of a cold-blooded species such as frog is devoid of the enzyme. To test the idea of a relationship between body temperature and CA activity we have measured the CA activity in a number of poikilotherms and homeotherms with emphasis on nervous system strucutres. In nervous tissue CA is specific to neuroglia and absent from neurons.

We observe that in general poikilotherms exhibit much lower CA activity than do comparable tissues in homeotherms. There are exceptions to this observation, however. The blood of poikilotherms has quite appreciable CA activity - almost 14,000 U/mg ww for the saltwater catfish. The lower brainstem (LBS) of the saltwater catfish exhibits as much CA activity as does LBS of the rat and more than is present in LBS of the cat, for example (1532, 1602 and 906 U, respectively). An interspecies comparison of nervous system CA activity shows that for each species retina and choroid consistantly display maximal CA activity. The retina/choroid of homeotherms however, have 12-40 times more activity than do those of poikilotherms. In the saltwater catfish and sting ray LBS CA activity is as high as that in their respective retinae. These animals have a well developed lateral line system with synaptic centers in LBS. This observation may suggest a functional relationship between neuronal metabolism and glial CA activity. This supposition would be supported by a decrease in CA activity in neuropil poor tissues. The neural filum terminale (FT) of the frog is a structure devoid of neuronal somata but enriched in glia, surrounded by axons. CA activity in the frog FT is less than half that of the sacral or lumbar segments of the spinal cord of this animal. In contrast, the FT of all of the other species studied is about equal to that of the remaining spinal cord.

Our data suggest that the relationship between a requirement for protons and bicarbonate and body temperature is not straight forward. A functional relationship based on ion movement and acid-base balance requirements might better explain our observations. As for the nervous system distributions, it might be tempting to speculate that structures central to the functioning of the animal may have higher metabolic needs or require finer regulation of extracellular ionic concentrations and therefore such regions require greater CA activity.

1420 **CYCLIC NUCLEOTIDES AND β-ADRENERGIC BINDING IN THE CEREBELLUM OF pcd (PURKINJE CELL DEGENERATION) MUTANT MICE DURING PURKINJE AND GRANULE CELL DEGENERATION.** **Lewis L. Truex*, Bernardino Ghetti and Michael J. Schmidt (SPON: J. Clemens). Eli Lilly and Company and Indiana University School of Medicine, Indianapolis, IN 46206.**

Norepinephrine-stimulated accumulation of cyclic AMP (cAMP) was studied in vitro in the cerebellum of pcd mice before, during and after total degeneration of Purkinje cells. The cerebellar concentration of cAMP in the presence of norepinephrine in pcd mice was 300 pmoles/mg protein compared to 80 pmoles/mg protein in controls. First evidence of hyperresponsiveness was detected at 24 days of age, the time when ataxia developed and Purkinje cells started to degenerate. The difference in hormonal response persisted even when all Purkinje cells had disappeared, as documented by histologic examination of pcd cerebellum. The accumulation of cAMP was greater in sections of the cerebellar cortex than in regions containing the deep nuclei. The difference observed between mutant and normal mice in the magnitude of cAMP accumulation was maximal between 30 and 130 days of age and then lessened until there was no detectable difference by the age of 270 days. At 1 yr norepinephrine elicited a smaller cAMP accumulation in pcd mice than in unaffected controls. After 6 months of age a progressive and substantial loss of granule cells was noted.

The differences in cAMP accumulation were not accompanied by changes in ^{3}H-dihydroalprenolol binding, indicating that the increased response to norepinephrine was not due to an increase in the number of beta adrenergic receptors in pcd cerebellum. Adenylate cyclase activity was similar in control and pcd mice. Theophylline, an adenosine receptor blocking agent, did not attenuate the cAMP accumulation in pcd cerebellum. This suggests that the exaggerated accumulation of cAMP seen in slices from pcd mice following NE-stimulation could not be explained through the phenomena of adenosine synergism. The exaggerated accumulation of cAMP was also found in the cerebellum of "nervous" mice in which 80% of the Purkinje cells are lost. Therefore, the phenomenon is not restricted to the pcd mutation.

The data confirm that cAMP synthesis and beta adrenergic receptors occur in the cerebellum in cells other than Purkinje cells. We speculate that the exaggerated norepinephrine-elicited accumulation of cAMP in pcd mutants might be due to astrocytosis or changes in granule cells in the cerebellar cortex.

1421 EFFECTS OF 3,4-DIHYDROXYPHENYLETHANOL AND ITS QUINONE ON THE UPTAKE AND RELEASE OF ^{3}H-CATECHOLAMINES IN A RAT BRAIN CRUDE SYNAPTOSOMAL FRACTION. Anthony D. Vanker, Stephanie J. Prevost*, and Frank L. O'Brien*. Depts. of Biology and Chemistry, Georgia State University, Atlanta, Georgia 30303.

The inhibitory effects of 6-hydroxydopamine (6-OHDA) on catecholamine uptake into presynaptic elements are well known. There is evidence that at least some of the effects of 6-OHDA are due to its oxidation to the corresponding quinone which then undergoes nucleophilic reactions. Similar quinones can be formed from normal catecholamine metabolites such as 3,4-dihydroxyphenylethanol (DHPE). Previously we reported on the use of controlled potential coulometry as the means of oxidizing DHPE and the effects on the uptake of ^{3}H-norepinephrine (^{3}H-NE) (Soc. Neurosci. Abts. 4, 1041). Crude synaptosomal fractions of rat forebrain were isolated and mixed with a TES salts buffer (NEP).

Different portions were then used in each of the following experiments: 1) NEP + stirring 2) NEP + stirring + DHPE 3) NEP + stirring + DHPE + electrolysis. The time interval for each experiment was 10 min. Immediately following each experiment, standard procedures were used to measure the uptake of ^{3}H-dopamine (^{3}H-DA) into synaptosomes found in the NEP. The DHPE quinone inhibited uptake in a 'step-function' manner with essentially no inhibition at 10^{-6}M and complete inhibition at 10^{-5}M. DHPE itself exhibited a weaker but potent inhibition in an apparent competitive manner. This inhibition of ^{3}H-DA uptake obtained with DHPE and its quinone is similar to but more pronounced than that reported previously for ^{3}H-NE. In some experiments a brain mince was incubated in the TES salts buffer with either ^{3}H-DA or ^{3}H-NE to 'preload' presynaptic elements prior to homogenization and differential centrifugation. The preloaded crude synaptosomal fraction was resuspended and treated as before to determine whether DHPE or its quinone act as releasing agents. DHPE did not cause the release of ^{3}H-DA or ^{3}H-NE at any of the concentrations used in the uptake study. The quinone was a weak releasing agent (25% for both ^{3}H-DA and ^{3}H-NE) only at the highest concentration used. Electrochemical data indicated substantial secondary oxidation reaction occur in the presence of synaptosomes. (Supported in part by NS-14338).

1422 CALCIUM-DEPENDENT ACTIVATION, STABILIZATION, AND DESTABILIZATION OF TRYPTOPHAN HYDROXYLASE FROM RAT MIDBRAIN. Anthony Vitto and Arnold J. Mandell. Dept. Psychiatry, Sch. Med., UCSD, La Jolla, Ca 92093

Inactivation of tryptophan hydroxylase from rat midbrain was followed at 37°C in the presence and absence of various pathway-related ligands and other compounds. Control studies indicate a multiphasic inactivation characterized by a rapid initial loss within 15 minutes of 30-40% of the initial enzyme activity. After 15 minutes, the rate of inactivation declined until stability of 40-50% of the initial activity was achieved at about one hour. This pattern of inactivation was unaltered by tryptophan (0.1, 0.25, 1.0 mM), tetrahydrobiopterin (0.1 mM), reduced nicotinamide adenine dinucleotide (0.1 mM), dithiothreitol (0.1 mM), ethanol (1.0%), and phenylmethyl sulfonyl fluoride (0.1 mM); however, the effects of combinations of the above were not studied.

In the presence of greater than 200 uM calcium, loss of activity was rapid and followed classical first-order kinetics. At low and intermediate levels of calcium (200-800 uM), first-order loss of activity commenced after an initial period of stability lasting as long as 40 minutes. With higher levels of calcium, rapid loss of activity proceeded with no or minimal periods of stability. The range of calcium concentrations at which stabilization and destabilization are observed parallels that for the previously reported calcium activation of tryptophan hydroxylase (Life Sci. 16: 1583, 1975), suggesting that the molecular events underlying these three phenomena are intimately related, if not identical. The possibility of a calcium-activated protease, which mediates these events through an activating limited proteolysis followed by an inactivating proteolysis, is being examined. Enzyme preparations stored in the frozen state for several days, when thawed, showed slightly higher initial activity but exhibited rapid first-order loss of activity when incubated at 37°C. The slow release of endogenous calcium and/or activation of a proteolytic system may explain the time-dependent appearance of a destabilized enzyme population.

Preliminary observations indicate that tryptophan hydroxylase from rats housed at 30°C shows marked instability at 37°C when compared to the enzyme from rats housed at 22°C. We speculate that modulation of enzyme stability by a system, proteolytic or otherwise, sensitive to ambient temperature may represent a mechanism for the apparent role of the serotonergic system in thermoregulation.

1423 INHIBITION OF RAT BRAIN AND SCIATIC NERVE ENOLASE ACTIVITY BY ACRYLAMIDE. Ivy L. Vyas*, Richard D. Howland*, and Herbert E. Lowndes (SPON: J.J. McArdle). Dept. Pharmacol., CMDNJ, N.J. Med. Sch., Newark, N.J. 07103.

Acrylamide may produce peripheral nerve degeneration by interference with axonal energy metabolism (Spencer and Schaumburg, in Waxman, S.G.(ed.): Physiology and Pathobiology of Axons, N.Y., Raven Press, 1978). The effect of acrylamide on the glycolytic enzyme, enolase, was investigated in rats in vitro and in vivo since inhibition of the neuron-specific form (Marangos et al., J. Neurochem. 31: 727, 1976) could offer an explanation of the relative specificity of acrylamide for initially producing degeneration of distal portions of peripheral long axons. Enolase was isolated in the soluble fraction of rat whole brain homogenates (WBH). Activities were determined from initial velocity measurements. Homogenates were taken to 80% $(NH_4)_2SO_4$ saturation according to the method of Marangos et al., (Biochem. Biophys. Res. Commun. 68(4): 1309, 1976) and the P80 fraction was obtained. Enolase in WBH and in the P80 fraction was inhibited in vitro by acrylamide (I_{50} 4.0 mM and 3.7 mM, resp.). When the P80 fraction was incubated at 50°C for one hour, approximately 20% of the total enolase activity remained. This fraction was termed HP80 and was assumed to reflect neuron-specific enolase activity (Marangos et al., J. Neurochem. 31: 727, 1978). Enolase activity in the HP80 fraction was inhibited by acrylamide in vitro (I_{50} 3.3 mM). Double reciprocal plots of data obtained on WBH showed a complex inhibition pattern. Hexanedione, another neuropathic agent, caused no inhibition at a 10 mM concentration. For in vivo experiments, rats were treated with acrylamide (50 mg/kg/day i.p.) to a cumulative dose of 350 mg/kg or 550 mg/kg. Enolase activity was determined in brains and sciatic nerves of control and treated animals. In rats receiving 350 mg/kg or 550 mg/kg brain weights were decreased and soluble fraction protein content was decreased when compared to controls. Enolase specific activity was increased. Enolase activity was decreased but protein content unchanged in the soluble fraction of sciatic nerve homogenates. No enolase activity was detectable in the HP80 fraction from sciatic nerve preparations from 550 mg/kg acrylamide treated rats, suggesting that in vivo inhibition of the neuron-specific form of enolase by neurotoxic doses of acrylamide may be involved in the etiology of this distal axonopathy.

1424 BLOOD-BRAIN BARRIER PERMEABILITY TO CYSTINE AND CYSTEINE. Lester A. Wade, Helen M. Brady* and Delynne J. Myers*. Dept. Physiology, Tulane Univ. Sch. Med., New Orleans, La. 70112.

Cysteine, a sulfur-containing amino acid in the reduced form, exists in equilibrium with cystine, the oxidized form. We measured the degree of blood-brain barrier penetration by cysteine and cystine using the carotid injection technique of Oldendorf in the rat. A mixture of a radioactively-labeled amino acid and ^{3}H-H_2O was injected into the carotid artery, the rat was decapitated at 5 or 15 seconds, and the brain dissected into 5 regions before counting. When ^{35}S-cystine was injected, we found BUI values that were very close to the background values of this technique. The addition of non-radioactive cystine (200-600 µM) had no effect on the uptake of two neutral amino acids, ^{14}C-cycloleucine (25 µM) and ^{14}C-methionine (50 µM) or of the basic amino acid, ^{14}C-arginine (10 µM). In carotid injections using ^{35}S-cysteine (10 µM), we found that this amino acid was readily taken up (BUI of 20). When non-radioactive cycloleucine (4 mM) and alanine (4mM) were added to the injectant, the uptake of ^{35}S-cysteine was inhibited by 35% and 30%, respectively. Although cystine and cysteine are chemically related, their transport characteristics do differ. For the disulfide cystine, we were unable to demonstrate any significant degree of blood-brain barrier transport at the concentrations tested. Cysteine, the sulfhydryl form, did penetrate the blood-brain barrier. Cycloleucine's inhibition of cysteine uptake suggests that the leucine (L) neutral amino acid transport system accounts for a componed of cysteine's total uptake. Another possible componed of cysteine's uptake is the alanine-serine-cysteine (ASC) neutral amino acid transport system, which remains to be further evaluated.

1425 DE NOVO SYNTHESIS OF NEURON SPECIFIC ENOLASE IN A RABBIT RETICULOCYTE TRANSLATION SYSTEM PROGRAMMED BY POLY(A)-RNA FROM RAT BRAIN. William A. Walker* and Claire Zomzely-Neurath. Dept. Biochem., Roche Institute of Molecular Biology, Nutley, N.J. 07110.

Poly(A)-RNA prepared from the brains of 30 day old, male rats has been shown to direct the synthesis of neuron specific enolase (NSE) in a cell-free system derived from rabbit reticulocytes. Rat brain RNA was obtained by treating total polysomes with EDTA and SDS followed by LiCl precipitation. Poly(A)-RNA was then isolated by oligo(dT)-cellulose chromatography.

The reticulocyte lysate was treated with Staphylococcal nuclease to render the system completely dependent on exogenous m-RNA. The ability of the lysate to translate Poly(A)-RNA from 30 day old rat brains was optimal at 1.5 mM magnesium and 100 mM potassium while spermidine had no stimulatory effect. The cell-free reactions were immunoprecipitated by either anti-NSE antisera or preimmune sera coupled to cyanogen bromide activiated Sepharose. Analysis of the immunoprecipitates on sodium dodecyl sulfate-polyacrylamide slab gels and autoradiography indicated the synthesis of a product that co-migrated with purified NSE and was recognized only by the anti-NSE antisera. Similar immunoprecipitation of reticulocyte lysates programmed with total RNA derived from embryonic chick heart failed to indicate the synthesis of NSE. These results show that the m-RNA coding for NSE contains a poly(A) sequence and that brain specific factors are not required for its translation. This is the first demonstration of the de novo synthesis of a neuron-specific protein which is 1% of the total soluble protein and whose biological function is known.

1426 VOLTAGE-SENSITIVE CALCIUM INFLUX ACTIVATES cAMP-DEPENDENT PROTEIN KINASE (cDPK) IN ADRENAL MEDULLARY CELLS. J.C. Waymire and R.E. Boehme. Dept. of Psychobiology, Univ. of Ca., Irvine, Irvine, Ca. 92717 and Dept. of Neurobiology, Univ. of Texas Med. Sch., Houston, Tx. 77025.

We have characterized adrenal medullary cell cDPK and instituted procedures to analyze, in the crude extract, the activation of cDPK following stimulation of intact cells. These procedures indicate that 1) adrenal medullary cell cDPK is predominantly type II and 2) the activation of cDPK occurs through a voltage-sensitive influx of calcium.

Treatment of isolated medullary cells with ACh in the presence of Ca^{++} produces a time- and dose-dependent increase in the cDPK activity index which appears to be nicotinic in nature; being both mimicked by nicotine and blocked by hexamethonium. At high ACh (100 uM), the increase in cDPK index is rapid, but less prolonged; reaching a maximal level in 5 min and decaying by 20 min. At lower ACh (10 uM) the activation proceeds more slowly, but is maintained longer; reaching a similar maximum in 10 min and decaying by 30 min. Other agents, known to depolarize medullary cells, veratridine, KCl and angiotensin II, produce a similar calcium-dependent activation. In all cases, theophylline potentiates the activation by the above agents by about 33%, but has no influence alone. The involvement of extracellular Ca^{++} in this depolarization induced response is indicated by the observation that no alteration in cDPK index occurs in its absence. Further, 5 uM A23187, although not inducing an activation in the absence, produces a marked increase in cDPK in the presence of 1.5 mM extracellular Ca^{++}.

A possible explanation of these results, that Ca^{++} is directly activating cDPK, is unlikely since Ca^{++} does not activate isolated cDPK when added directly to the in vitro enzyme incubation. Another possibility, that Ca^{++} indirectly stimulates cDPK by elevating cAMP through the secretion of catecholamines (CA), which in turn stimulate an auto receptor-linked adenylate cyclase, is also unlikely since α or β receptor blocking agents were found not to prevent the Ca^{++} dependent cDPK activation. Also CA themselves would not produce an activation of cDPK. Unless some presently unknown agent, secreted in response to Ca^{++}, is stimulating adenylate cyclase, a likely explanation of these results is a Ca^{++} interaction with calmodulin to modulate chromaffin cell cAMP through sequential activation of adenylate cyclase and phosphodiesterase. The shapes of the time response curves at different agonist concentrations supports this conclusion. Supported by USPH NS-11061 and AG 00538.

1427 P2 PROTEIN FROM BOVINE PNS MYELIN - NH_2-TERMINAL SEQUENCE AND NEURITOGENIC ACTIVITY. M. J. Weise*, D. L. Hsieh*, S. Levit*, P. M. Hoffman*, J. M. Powers* and S. W. Brostoff* (SPON: B. B. Wannamaker). Departments of Neurology and Pathology (Neuropathology), Medical University of South Carolina, Charleston, S.C. 29403 and V.A. Medical Center, Charleston, S.C.

Three peptides denoted CN1, CN2 and CN3 are generated by CNBr digestion of bovine P2 protein. Overlapping peptides provided by trypsin digestion and BNPS-skatole cleavage of the tryptophan at residue 8 enable us to order these peptides in the P2 protein. CN3 is at the NH_2 terminus, followed by CN1 with CN2 at the COOH terminus. The sequence of the first 65 residues of the protein which overlap CN3 and CN1 is:

NH_2-Ac-Ser-Asn-Lys-Phe-Leu-Gly-Thr-Trp-Lys-Leu-Val-Ser-Ser-Glu-Asn-Phe-Asp-Glu-Tyr-Met-Lys-Ala-Leu-Gly-Val-Gly-Leu-Ala-Pro-Arg-Lys-Leu-Gly-Asn-Leu-Ala-Lys-Pro-Arg-Val-Ile-Ile-Ser-Lys-Lys-Gly-Asp-Ile-Ile-Thr-Ile-Arg-Thr-Glu-Ser-Pro-Phe-Lys-Asn-Thr-Glu-Ile-X-Phe-Lys-COOH.

When tested for their ability to produce disease in guinea pigs, rabbits and Lewis rats, CN3 proved inactive while CN2 produced disease in all three species. Experimental allergic neuritis (EAN) was produced in Lewis rats by peptide CN1 as well, with this peptide being more active than CN2 in this species.

CN2, which is neuritogenic in all species tested, is a disulfide-linked dipeptide accounting for approximately 18 residues at the COOH terminal end of the P2 protein. In the intact isolated protein, adjacent regions of the single amino acid chain near the COOH terminus appear to be covalently linked through a disulfide bond, which remains intact after cleavage of the two methionines resulting in CN2. The presence of this intra-chain disulfide bond in the native, membrane bound P2 protein and its effect on the disease-inducing properties of the P2 protein remain to be determined.

Supported in part by the Veterans Administration and by NIH Grant No. NS11867.

1428 SYNTHESIS AND TRANSPORT OF A SPECIFIC PROTEIN BY ASTROCYTES. Fredric P. White, Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland A1B 3V6.

When rat telencephalon slices are used to label protein with radioactive amino acids and these slices are subsequently fractionated by rate and density gradient centrifugation, two fractions, nuclei and blood capillaries, are found which have very high specific activities of radioactively labeled protein (White, 1979). Only the blood capillary fraction, however, appears to be transporting some of this newly synthesized protein to other sites on a translocation system which is inhibited by colchicine, vinblastine, and low Ca^{++} concentrations (White, 1976; 1979). SDS-PAGE of those fractions and others shows that more than 10% of the radioactivity in the capillary fraction is in a protein of molecular weight 71,000 daltons, and that this protein is exported from particles in this fraction, and imported into particles in a myelinated axon fraction, microsomal fraction and soluble/cytosol fraction. Present studies were undertaken to identify the particle responsible for this specific synthesis and subsequent transport.

Rat telencephalon slices were incubated in a Krebs Ringer phosphate solution containing [^{3}H] leucine for one hour. Some of the slices were fixed immediately after incubation while others were homogenized in 2.0 M sucrose containing 1 mM $MgCl_2$. A nuclei and capillary fraction was prepared by centrifugation in sucrose density gradients. Autoradiographs were prepared from these fractions and from 25 μ transverse sections of the tissue slices. After developing the radiograph all sections were stained with either thionin blue or Basic Fuchsin. Results show that the vast majority of the radioactivity found in the capillary fraction is located over the capillaries themselves. The radioactivity in the nuclear fraction is associated with both the light staining (neuronal and astrocyte) nuclei and dark staining nuclei. However, the grain count is much higher over the light staining nuclei, and the grain densities appear to be associated with material adhering to the nuclei (possibly Nissl substance). The autoradiographs of the tissue slices confirm that the high grain densities are associated with blood capillaries. The pattern of labelling over the capillaries shows that the astrocyte end feet are probably responsible for the synthesis of large amounts of protein in the brain slice. This data suggest that astrocytes synthesize a 71,000 dalton protein in their end feet and transport this protein to other sites away from the capillaries on a vinblastine sensitive translocation system. This research was supported by grant MA-5404 from the MRC of Canada.

1429 REGULATION OF PINEAL HYDROXYINDOLE O-METHYLTRANSFERASE (HIOMT) BY ADRENAL CORTICAL HORMONES. Dona L. Wong*, Alfred W. Sandrock, Jr.* and Roland D. Ciaranello. Dept. of Psychiatry & Behavioral Sciences, Stanford University Sch. Med., Stanford, CA 94305.

Recent work from this laboratory has shown that adrenal glucocorticoids control the steady-state levels of adrenal medullary phenylethanolamine N-methyltransferase (PNMT) by inhibiting the in vivo proteolysis of this enzyme. Further investigation disclosed that glucocorticoids were not acting directly, but through S-adenosylmethionine (SAM), an important constituent in the PNMT reaction. Hypophysectomy reduced the levels of glucocorticoids and of S-adenosylmethionine. This, in turn, resulted in a loss of stability of PNMT to in vivo proteolysis. SAM is a critical methyl donor in a variety of methylation reactions involving biogenic amines. Our current research shows that pineal hydroxyindole O-methyltranferase, like adrenal PNMT, is under glucocorticoid regulation. Hypophysectomy reduces the levels of HIOMT, while dexamethasone administration restores them. SAM, both in vitro and in vivo stabilizes HIOMT against proteolytic degradation, resulting in a restoration of enzyme levels. Thus the levels of two important biogenic amine methyltransferases, HIOMT and PNMT, are under glucocorticoid regulation through mechanisms involving SAM stabilization of the enzyme against proteolytic breakdown. 1430 RELATIONSHIP BETWEEN FUNCTIONAL ACTIVITY AND GLUCOSE UTILIZATION IN THE RAT SUPERIOR CERVICAL GANGLION IN VIVO. P. Yarowsky, J. Jehle*, D. H. Ingvar*, and L. Sokoloff. Laboratory of Cerebral Metabolism, NIMH, Bethesda, MD 20205.

The rat superior cervical ganglion (SCG) was studied as a model system for correlating in vivo glucose utilization, as measured by the deoxyglucose method (SOKOLOFF et al. J.Neurochem. 28:897, 1977), with electrical activity. The SCG is particularly suitable for such a study. One can modulate and monitor both the preganglionic input as well as the output of the postsynaptic neurons. Three different experimental conditions have been studied: normal controls, unilateral decentralization, and electrical stimulation. In normal conscious rats, mean (± S.E.M.) glucose utilization of the SCG in vivo was 35 (± 1) µmoles/100 g/min (n=20) with no significant side-to-side difference. This value is higher than the in vitro glucose utilization at 37° of the SCG, 23 µmoles/100 g/min, reported by Horowitz & Larrabee (J. Neurochem. 9:407, 1962). Glucose consumption was not uniform throughout the SCG. In the rostral portion of the SCG the rate of glucose utilization was 3 times higher than the rate in the rest of the ganglion. This region of high metabolic activity corresponds to the anatomical distribution (demonstrated by the horseradish peroxidase technique) of postganglionic neurons which give rise to the axons of the internal carotid nerve (Bowers & Zigmond, J.Comp.Neurol. 288:227, 1979). In unilaterally decentralized animals, the left cervical sympathetic trunk (CST) was severed at least 1 cm from the SCG, and a piece of the nerve was removed 7-9 days prior to the measurement of glucose utilization. Following the decentralization, the animals developed both miosis and ptosis unilaterally. The mean (± S.E.M.) glucose utilization of the decentralized SCG was reduced to 22 (± 2) µmoles/100 g/min (n=8), and the region of high activity was obliterated. Glucose utilization in the contralateral control SCG was the same as that found in the normal animals. Experiments in which the CST was electrically stimulated were carried out under urethane (1 g/kg) anesthesia. The CST was placed on platinum electrodes and stimulated via a stimulus isolation unit. Stimulation was initiated 5 min prior to the onset of measurement of glucose utilization. In all cases stimulation caused ipsilateral mydriasis and widening of the palpebral fissure. With stimulation frequencies of 5, 10, and 15 hz, there was an apparent frequency-dependent increase in the mean rate of glucose utilization of the SCG above control levels under urethane anesthesia. The region of high utilization was still present and enhanced. These studies suggest that the glucose consumption of the SCG is modulated by functional and/or electrical activity.

NEUROCYTOLOGY

1431 NUCLEUS PARAGIGANTOCELLULARIS LATERALIS IN THE RAT: ANALYSIS WITH GOLGI IMPREGNATIONS. Joseph A. Andrezik. Department of Anatomical Sciences, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

The nucleus paragigantocellularis lateralis (PGCL) lies lateral to the medullary pyramid and extends caudally from the trapezoid body through the rostral one-third of the inferior olivary nucleus. At least eight neuronal types of the PGCL can be distinguished in Nissl preparations, and some of these are distributed preferentially within the nucleus. On the basis of cytoarchitecture and the distribution of afferent fibers, the PGCL may be divided into rostral and caudal subdivisions (Andrezik and Chan-Palay, Anat. Rec. 187:524, 1977).

Brains of adult Sprague-Dawley rats were impregnated with the rapid Golgi, Golgi-Cox, or several variants of the Golgi-Kopsch technique. The brains were sectioned in coronal, horizontal, or sagittal planes for examination.

At caudal levels, the dendrites of most PGCL neurons are oriented in the coronal plane with the longest dendrites extending in the medial to lateral direction. Examinations of sections cut in horizontal or sagittal planes reveal a few categories of neurons whose arborizations are nearly equal in transverse and longitudinal extent. One type of arborization is essentially planar - dendrites emanate from a spherical or fusiform perikaryon either directly opposite or at right angles to one another, often resulting in a cruciate appearance. Another type exhibits a dendritic tree forming three cones, each commencing from an apex of the pyramidal-shaped perikaryon. Dendrites of some other neurons form a sphere with the perikaryon at the center. At more rostral levels, PGCL neurons are situated medial to the facial motor nucleus. A striking feature in this area is that dendrites of PGCL neurons follow the contours but do not penetrate the borders of the facial nucleus. The converse is not true.

Most PGCL neurons have relatively unbranched dendrites and a smooth surface. Some, however, exhibit spines on the perikaryon and dendrites, but these are rare. Spines usually are simple in form, being either sessile or pedunculated. Dendritic bundles are found in the PGCL and are formed by 5-7 dendrites each from a different neuron. The bundles course between fascicles of passing fibers and are most easily visualized in sections cut in coronal or horizontal planes. The various forms of PGCL neurons probably reflect the number and types of afferents which contact them and ultimately influence their activity.

1432 A NEW DESIGN FOR ULTRA-RAPID FREEZING OF NERVE-EFFECTOR CELL JUNCTIONS. Robert T. Bailly*, Jack McC. Baggett*, Åsa Thureson-Klein and Richard L. Klein. Department of Pharmacology and Toxicology, Univ. Miss. Med. Ctr., Jackson MS 39216.

An ultra-rapid freeze apparatus has been designed to study vesicle dynamics at peripheral noradrenergic terminals in thin strips of blood vessels and vas deferens. The apparatus consists in linear sequence of (1) a warmed superfusion chamber for stimulation and recording, (2) two closely opposed copper blocks pre-cooled to liquid nitrogen temperature, (3) a similarly pre-cooled tissue vice specially constructed to mount in a Denton freeze fracture apparatus, and (4) a taught spring.

A 0.1-0.2 mm thick tissue strip is placed within an opening in a fabric belt. The tissue and belt are enclosed in a teflon carrier. The belt fits snugly in a channel with dimensions of 1.0 cm x 0.2 cm x 15.0 cm which is continuous through the surface of one of the opposed copper blocks. The belt is attached at the end to the taught spring. About 2.0 cm of teflon and 3.0 cm of open space insulate the carrier from the pre-cooled copper freezing blocks. The entire unit is flushed with dry nitrogen gas. During superfusion the taught spring is released. The fabric belt, tissue and carrier combination is drawn toward the copper freezing blocks where the teflon carrier stops. The belt and tissue continue through the channel and between the copper freezing blocks leading to the vice, where the tissue comes to rest some 2 msec later.

Premature cool-down of tissue has been essentially eliminated by the use of a warm teflon carrier enclosing the tissue and separated from the freezing blocks until the moment of rapid freeze. Freezing block warm-up has been rendered insignificant by providing for the continuous movement of the tissue across the surface of the freezing blocks with a traverse time of 2 msec. The design of operation provides uninterrupted electrical stimulation up until and during rapid freezing. This may be mandatory to study vesicle dynamics during exocytosis.

Upon completion of the freezing process, the vice is tightened on the tissue, packed in freon 22 snow, unscrewed from its copper mounting post and transferred to the Denton freeze fracture device after which routine processing can procede.

Supported by grants from the Am. Heart Assoc.-Miss. Affil. and the NIH GM15490.

1433 PSEUDOPODIAL INVASIONS OF NERVE TERMINALS IN RAT AMYGDALA. Alan F. Boyne and Sally B. Tarrant* Depart. of Pharmacology, Northwestern Medical and Dental Schools, Chicago, Ill 60611.

Stimulation-induced exocytosis has been shown to cause pseudopodia to grow from nerve terminals in Torpedine ray electric organ (Boyne & McLeod, Neuroscience 1979). They invade adjacent, abutted terminals and can then be pinched off. We are exploring the possibility that a similar process could occur in electro-convulsed mammalian brain.

The central nucleus of the amygdala was chosen for study because its encephalinergic-opiate receptor system may (1)utilise abutted, axo-axonal presynaptic inhibitory synapses and (2) it may regulate the depression-euphoria mood spectrum (Snyder, Sci. Amer. 1977).

We have been surprised to find that pseudopodial invasions of nerve terminals are present in the control, unstimulated amygdala. They are present amongst abutted terminals synapsing with dendrites in the neuropil adjacent to large neurons. They are found in terminals containing a mixed population of small clear and large dense-cored vesicles. The penetrating element generally contains clear vesicles but dense-cored vesicles have also been seen. We have not found synaptic specializations associated with the penetrating element.

Questions we are now trying to approach include: (1) What is the origin of the pseudopodia ? (2) Does the ultrastructural relationship imply a physiological interaction ? (3) Are either or both elements encephalinergic ? (4) Are the invasions detached during seizures ?

This work was supported by NIH grant # 13043.

1434 MYELINATED DENDRITES AND NEURONAL PERIKARYA IN THE MOUSE OLFACTORY BULB. Gail D. Burd and Aldo Rustioni. Neurobiology Program and Depts. of Anatomy and Physiology, UNC, Chapel Hill, N.C. 27514.

Myelinated dendrites have been reported in the olfactory bulb of the human (Braak, et.al., 1977), monkey (Pinching, 1971), and the cat (Willey, 1973). In addition, myelinated neuronal perikarya were observed in the olfactory bulb of man (Braak, et.al., 1977) and the rat (Diaz-Flores, et.al., 1977). This is the first report of myelinated dendrites in the olfactory bulb of rodents and of myelinated neurons in the mouse olfactory bulb. Observations were focused on the glomerular and external plexiform layers of control and experimental mice with olfactory nerve lesions, but mitral cell, internal plexiform, and granule cell layers were also examined. Mice were perfused with mixed aldehydes. Olfactory bulbs were cut into 1-2mm blocks, osmicated, dehydrated, and embedded in Spurr-Epon. Thin sections were stained with UA and LC. Only a very small population of dendrites and perikarya of the olfactory bulb were myelinated, and no difference was observed in the relative frequency of these myelinated structures in control vs experimental mice. Large dendrites with 6-10 lamellae of myelin were observed in the periglomerular region of the glomerular layer and external plexiform layer. Identification of the myelinated dendrites as mitral cell dendrites or large tufted cell dendrites was based on the large diameter and cytological detail of the myelinated dendrites. Myelinated dendrites contained: rough endoplasmic reticulum, free ribosomes, mitochondria, smooth endoplasmic reticulum and microtubules. On one myelinated dendrite cut in longitudinal section, synaptic contacts were present on a portion of the dendrite devoid of the myelin sheath. A thinner layer of myelin (2-5 lamellae) was observed to surround partially the sparse myelinated neurons present in the periglomerular region and the external plexiform layer. From a comparison of the cytological detail of these neurons with the descriptions of normal neurons in the olfactory bulb by Pinching and Powell (1971), these myelinated neurons appear to be small tufted cells or superficial short-axon cells. The cell bodies contained: moderate amount of rough endoplasmic reticulum, free ribosomes, mitochondria, stacks of Golgi, slightly indented nucleus, and frequently, a well defined nucleolus in the nucleus. The origin of the myelin sheaths cannot be determined for all the myelinated profiles. Oligodendrocytes may contribute myelin lamellae to the myelinated dendrites and perikarya, but this was not observed. However, in a few instances, myelin lamellae surrounding small myelinated axons were observed to leave the axon and contribute myelin lamellae to the myelinated dendrite or perikarya.

1435 FINE STRUCTURAL ANALYSIS OF THE MOTOR TRIGEMINAL NUCLEUS OF THE RAT. John P. Card* and Robert Y. Moore (SPON: J.C. Sipe). Department of Neurosciences, UCSD, La Jolla, California 92093.

Recent histofluorescence examination of the monoamine innervation of various brainstem nuclei of the rat (Levitt and Moore, 1979) have demonstrated that the motor trigeminal nucleus (MTN) receives a heavy noradrenergic innervation from lateral tegmental cell groups. The present investigation was therefore undertaken to examine the ultrastructural organization of this nucleus as a basis for further fine structural analysis of the pattern of catecholaminergic innervation of this area. Adult female rats anesthetized with Nembutal (42mg/kg) were subjected to intracardiac perfusion fixation with glutaraldehyde-paraformaldehyde solutions. The motor trigeminal nuclei were then dissected from the brainstem and prepared for transmission electron microscopic examination using conventional procedures. Large (40-60 μm) motor trigeminal neurons were a prominent feature among the numerous large dendritic trunks and myelinated axons that characterized the neuropil in this region. The cytoplasmic constituents of these cells were typical of those generally described in neurons throughout the neuraxis. However, of primary interest in the present study was the large number of axosomatic contacts which were routinely observed on the perikarya of all cells examined. In some instances, as much as 94% of the cell soma was covered by axon terminals. Such terminals could be subdivided into categories on the basis of axoplasmic density and vesicle shape. The presence of either clear or dense axoplasm within the endings provided an easily recognized morphological criterion for subdividing axosomatic terminals into two distinct populations. In addition, analysis of vesicle morphology within endings indicated that both clear and dense terminals could be further subdivided on the basis of their vesicular content. In each case, endings were observed which contained either exclusively lucent spherical vesicles (0.04 μm) or mixed populations of spherical and flattened (0.06 μm) vesicles. Thus, four morphologically distinct terminal types have been identified in synaptic contact with the soma of MTN neurons. In addition ultrastructural analysis of the neuropil of the MTN revealed that the numerous dendritic profiles characteristically present in this area were also contacted by the same types of terminals observed on the soma. Whether or not the distinct morphological differences in axosomatic and axodendritic endings reflect differences in neurotransmitter content cannot be determined at the present time. However, studies are presently underway to determine if the dense noradrenergic innervation of this nucleus can be correlated with one or more of the demonstrated terminal morphologies. Supported by USPHS Grant NS 12080.

1436 APPLICATION OF HIGH MAGNESIUM CONCENTRATION PERFUSION-FIXATION TO RAT VISUAL CORTEX. Fen-Lei Chang, Mary Kay Floeter* and William T. Greenough, Dept. Psychol. and Neural & Behav. Biol. Prog., Univ. of Ill., Champaign, IL 61820.

Birks (J. Neurocytol., 1974,3:133) suggested that artifically low vesicle density may be seen in synaptic boutons with conventional glutaraldehyde fixation procedures due to the activation of transmitter release by glutaraldehyde. He used a high Mg^{+2} concentration (110 mM) solution during glutaraldehyde perfusion of cervical ganglion to block synaptic transmission and found dense packing of vesicles in about 2% of synapses. McKinlay & Usherwood (J. Ultrastructure Res., 1978,62:83) demonstrated that glutaraldehyde can increase the frequency of miniature EPSPs at locust neuromuscular junction, and that addition of Mg^{+2} attenuates this effect. They also used high Mg^{+2} concentration during fixation and found a very dense vesicle packing in synaptic boutons.

We applied Birks' method to rat visual cortex. Three concentrations of Mg^{+2} ($MgCl_2$) were used - 110, 160 and 210 mM. Adult rats were anesthetized with pentobarbital and perfused through the heart first with 200 ml of a high Mg^{+2} solution (besides the $MgCl_2$, KCl 5.0 mM, Hepes buffer 10 mM at pH 7.0), and then with 500 ml of the same vehicle with glutaraldehyde added to a final concentration of 3%. After fixation in the same fixative for 1 hour, 1 mm tissue blocks were dissected and post-fixed for 1 hour with 1% OsO_4 in sodium phosphate buffer. Tissue was embedded in Epon, sectioned in silver to grey range (about 50 - 75 nm) and stained with uranyl acetate, and lead citrate.

Preliminary results using this technique indicate that 1) High Mg^{+2} perfusion does appear to result in fixation in which a higher packing density of vesicles is present in presynaptic terminals. There is a tendency in some, but not all cases, for vesicles to be aggregated in the center of the terminal (away from membrane other than the synaptic apposition). Whether absolutely greater numbers of vesicles per terminal are present with Mg^{+2} perfusion remains unclear (quantitative studies are in progress). 2) 110 mM Mg^{+2} appears to be sufficient concentration for increased vesicular packing density. 3) With higher concentrations there are some indications of increased extracellular space and/or shifts of cytoplasmic structures other than vesicles, but the aggregation of vesicles seems not to be accounted for in terms of shrinkage of presynaptic terminals. Work is in progress to evaluate the effects of a wider range of Mg^{+2} concentrations as well as chelating agents and other divalent ions.

1437 THE CELLULAR AND SYNAPTIC ORGANIZATION OF THE INTERMEDIOLATERAL NUCLEUS OF THE RAT SPINAL CORD: A COMBINED FM AND EM STUDY. Frank D.H. Chen*, Jean Y. Jew and Terence H. Williams, Dept. Anat. Univ. Iowa Col. Med., Iowa City, IA 52242

The intermediolateral nucleus (IMLN) of the thoracic cord in the rat was studied by using fluorescent and electron microscopic techniques. As visualized with the fluorescence microscope, the IMLM somata primarily are surrounded by dense axonal varicosities and terminal boutons. At regular intervals these somata aggregate to form "islands". These aggregations are bridged by fluorescent preterminal fibers and presumed dendritic processes. At an early stage (2½ days) after animals were treated with 6-hydroxydopamine (6-OHDA) or 5,7-dihydroxytryptamine (5,7-DHT with desipramine pretreatment), those varicosities surrounding somata became less dense, and the preterminal fibers bridging the aggregated cell bodies were usually interrupted or less dense.

As visualized with the electron microscope, the IMLN somata have a fusiform shape, a high nucleus to cytoplasm ratio, an extremely light nuclear chromatin, and a paucity of cytoplasmic organelles. Dendritic elements are long and intertwine among unmyelinated axonal bundles in a parallel and longitudinal fashion. This longitudinal arrangement of axonal and dendritic plexuses and terminals demarcates the IMLN zone and is a characteristic feature of this nucleus.

The synaptic arrangement in the neuropil is mainly axo-dendritic which could consist of one axonal terminal contacting several dendrites or vice versa. There are also axo-somatic,axo-spinous, and axo-axonic contacts, but these are comparatively rare. Sometimes these contacts form serial synapses. In general, approximately 60% of the terminals in the IMLN form morphologically identifiable synaptic junctions.

The majority of monoaminergic terminals in the IMLN, which are very similar to those reported in other areas of the CNS,contain large granular vesicles (about 900 Å) and numerous small, round, clear visicles (about 500 Å). If 5-OHDA was injected, small, round, clear vesicles in some boutons were tagged and thus appeared electron dense.

At an early stage (2½ days) after 6-OHDA or 5,7-DHT treatment, terminals in the IMLN showed morphological changes. In the selective administration of 6-OHDA these changes included (1) a reduction in the number of synaptic vesicles, (2) the presence of degenerated electron dense elements, and (3) the increasing presence of dense granules in vesicles within some terminals similar to the appearance after 5-OHDA. Dense granules were visible also in small vesicles (about 500-650 Å) found in neuronal cell bodies and processes. It is inferred that some neurons in IMLN are monoaminergic in nature.

1438 NERVE FIBERS IN THE IMMATURE SHEEP THIRD VENTRICLE. Penelope W. Coates and Steven L. Davis*. Dept. Anat., Texas Tech Univ., Sch. Med., Lubbock, TX 79430 and Dept. Animal Sci. Univ., Idaho, Moscow, ID 83843.

The third ventricle of normal ewe and ram lambs (four - six months of age) was examined by scanning (SEM) and transmission electron microscopy (TEM). SEM of the ventrolateral floor (VF) revealed that tanycytes were covered predominantly by microvilli in the ewe lamb. The ram lamb VF had a more patchy appearance due to fewer surface features on some cells. Distinct fibers were not observed on the VF. The dorsolateral wall (DW) was thickly ciliated. Underlying ependymal surfaces could not be observed except in places where the cilia were parted, revealing a surface studded with microvilli and occasional protrusions. Even in these more exposed areas, SEM images which might be interpreted as nerve fibers on the DW were rare. Yet when the same regions on the opposite side of the third ventricle were examined with TEM many nerve profiles were revealed along the ventricular surface of the DW under the canopy of cilia. These small caliber unmyelinated nerve fibers contained small clear vesicles, occasional small dense core vesicles, neurotubules and mitochondria, and were interpreted as axons seen in section. Occasional attachment plaques between axons and the ependyma, and microvilli partially wrapped around some nerve fibers were noted. Single fibers as well as groups of fibers suggesting plexus-type organization were present. Possible myelinated fibers were rare. A noteworthy, though rare finding under the DW cilia were large dendrite-like profiles interpreted as sensory endings filled with mitochondria, neurotubules and other organelles. In comparison to the abundance of nerve fibers along the DW, TEM of the VF revealed few nerve fibers, although similar fine caliber unmyelinated nerve fibers were found close to the lumen of the third ventricle in spaces between tanycytes of the VF. Few such fibers were observed between ciliated ependymal cells of the DW. Taken together these data suggest the following: Nerve fibers, both axons and possible dendrites, are present in the third ventricle of immature sheep. There appears to be regional variation in the distribution of intraventricular fibers. Cilia tend to obscure their detection with SEM on the DW. These new observations in sheep extend previous observations on the presence of intraventricular nerve fibers in mammals. Of special note are possible dendritic sensory terminals. The apparent scarcity of nerve fibers on the VF of lambs contrasts with SEM and TEM data on the monkey and other species. The origin, destination and role of intraventricular nerve fibers (axonal or dendritic) in the immature sheep third ventricle remains to be determined. (Supported by USPHS Grant HD 12833 from the National Institutes of Health.)

1439 PERSISTENCE OF BASAL LAMINA DEFECT IN CULTURES OF DYSTROPHIC MOUSE SCHWANN CELLS IN CONTACT WITH NORMAL MOUSE NEURONS. M. Cochran,* C. Cornbrooks, F. Mithen,* AND R. P. Bunge. Dept. Anat. & Neurobiology, Wash. Univ. Sch. Med., St. Louis, Mo.

Dystrophic mice (C57 BL dy 2J/dy 2J) have patchy discontinuities of the basal lamina of Schwann cells in the dorsal and ventral roots and the sciatic nerve (Madrid et al., '75). This abnormality is expressed in organotypic cultures of sensory ganglia from newborn dystrophic mice (Okada et al., in preparation), and also in cultures containing only Schwann cells and neurons. Basal lamina production by cultured Schwann cells ceases when neurites are removed, and resumes when the axon-Schwann cell relationship is restored (Williams et al., '76). The basal lamina defect in the dystrophic mouse could therefore be the result of an abnormality of the Schwann cell and/or the neurite.

To determine which of these possibilities exist, cell recombination experiments were carried out in tissue culture. Dorsal root ganglia from newborn dystrophic and normal C57 BL mice were explanted into collagen-coated Aclar dishes. Using methods adapted from Wood ('76), we were able to produce cultures containing only neurons (N-DRG) and cultures containing only neurons and Schwann cells (SN-DRG). Small patches of the substrate with Schwann cells from the SN-DRG cultures were transferred to neuritic regions of the N-DRG cultures. Such recombinant groups included: 1) dystrophic Schwann cells onto normal neurites, 2) normal Schwann cells onto dystrophic neurites and 3) dystrophic Schwann cells onto dystrophic neurites.

By five weeks after transplantation, Schwann cells had proliferated and migrated to occupy a substantial region of the neuritic outgrowth. At this time, the cultures were fixed and examined by electron microscopy. Schwann cells derived from dystrophic mice had a characteristic patchy basal lamina when related to either normal or dystrophic neurites. Schwann cells derived from normal mice produced a thick, uniform basal lamina when cultured on dystrophic mouse neurites. The basal lamina abnormality in tissue culture is therefore an expression of an abnormality of the dystrophic Schwann cell rather than of the neurite.

1440 SUPRAEPENDYMAL AND EPIPLEXUS CELLS IN RODENTS. Perry Cohn (SPON: Ruth Bleier). Dept. Neurophysiol., Univ. Wis., Madison, WI 53706

Abundant monocyte and macrophage-like supraependymal (SE) and epiplexus cells were observed with transmission and scanning electron microscopy in neonatal rats, mice and hamsters. In white Holtzman rats, which were most extensively studied, their numbers are elevated from 3-20 days of age. Some display microprocesses, ridges and ruffled and spreading lamellipodia, others have smoother surfaces and lengthy, branching pseudopodia and still others are rounded. Their ultrastructural characteristics include an extensive and varied group of lysosome-like organelles, a prominent Golgi zone, a nucleus possessing clumped, marginated chromatin and often a number of lucent 500-2000 nm vacuoles. Cilia are often deeply invaginated into SE cells. Occasional cells resemble lymphocytes and ependymal cells.

The macrophage-like SE cells are usually found in the relatively unciliated areas of the ependymal walls. The remaining descriptions are of the well studied third ventricle. In the fetus and the newborn SE cells can be seen throughout the ventricle, which at this time is mostly unciliated. In suckling rodents more than a few days old, the relatively unciliated area is restricted to an area roughly overlying the hypothalamic ventromedial, infundibular and premamillary nuclei and harbors about 75-100 SE cells per side. Most are found rostrally of caudally in this area. In adult rats the few SE cells (10-20 per side) congregate near the border between the ciliated and unciliated ependyma.

In suckling rats macrophage-like cells are also associated with capillaries that cross the ventricular lumen and with clusters of cells on the floor of the ventricle. The ultrastructure of the clustered cells includes a euchromatic nucleus, a prominent nucleolus, an active Golgi zone, a smooth surface and occasional synaptic endings on their surface. They are often embedded in a mat of fibers. As many as three separate clusters may be present.

The ependymal cells overlying the infundibular nucleus display many rounded excrescences (commonly known as blebs) in suckling female rats over 2 days old. Some male rats 3 to 6 days of age also have blebs. In adult rats preliminary investigation of the estrus cycle revealed little predictable variation. SE cells are not observed particularly over ependyma displaying blebs, though they are usually located nearby.

1441 NEUROSECRETORY TRACT IN THE CRICKET. William R. Colquhoun* SPON: R. Oesterreich, Biology Department, SUNY at Albany Albany, New York 12222

This communication describes the morphology of a neurosecretory tract in the cricket having exceptional properties for experimental study. A small (17μ) nerve emerges from the anterior end of the last abdominal ganglion in the cricket, *Acheta domesticus*. This nerve courses anteriorly between paired connectives and inserts into the next to last ganglion between connectives. Two-thirds of the way along this tract two branches emerge and extend laterally. These branches ramify just short of the cuticle and may function in spiracle opening.

Electron microscopy shows that this nerve contains approximately 18 axons most of which are densely filled with neurosecretory vesicles. Because of the great accumulation of vesicles in this nerve, it is highly refractile and easily distinguished from other nerves by phase contrast optics. Cobalt backfills have localized 11 of the cell bodies contributing axons to this tract from the last abdominal ganglion. These occur in three groups of three soma each lying along the anterior dorsal and anterior ventral mid-line. Two other cell bodies are laterally disposed. One group of three cells occurs at the point of departure of the connectives from the ganglion and should be easily sampled by electrode and E.M. sectioning techniques. Cobalt fills have also identified four cells in the next to last ganglion which contribute posteriorly coursing axons to this tract. The extraordinary accumulation of neurosecretory vesicles in this nerve (not just its endings) and the ability to easily locate several of the neurosecretory cell bodies makes this system especially amenable to experimental study.

1442 MORPHOMETRIC DETERMINATION OF MEMBRANE DENSITIES IN NORMAL AND 'GLIAL' OPTIC NERVES OF NECTURUS. Mary K. Dolack*, C-M. Tang* and Paula M. Orkand* (SPON: R.K. Orkand). Dept. Physiol. & Pharmacol., Sch. Dent. Med., Univ. Pennsylvania, PA 19104.

To measure the density of membrane sodium channels with radiolabelled saxitoxin and specific electrical properties of glial membranes one requires a determination of membrane areas of axons and glial cells. Intersection counting morphometry was used to determine axon and glial membrane densities from electron-micrographic montages of entire cross sections of Necturus optic nerves. Normal nerves and ones in which all the axons had degenerated due to enucleation of the eye 2 months previously were studied.

In 8 normal nerves, the cross sectional area was 5600 μ^2 (range: 3000 - 7700 μ^2). Axon diameters ranged from 0.2 - 2.0 μ. The cellular volume was 61% axon and 39% glia. Axonal membrane densities in the whole normal nerve were about 5 μ/μ^2 while those of glia were about 2 μ/μ^2. Following enucleation the cross sectional area decreased to 4500 μ^2 (range: 2500 - 5900 μ^2) and the density of glial membrane increased about two-fold.

Supported by USPHS NS 12253.

1443 DOUBLE-WALLED COATED VESICLES IN MITRAL CELL BODIES OF THE MOUSE OLFACTORY BULB: INCREASED NUMBERS DURING POSTNATAL DEVELOPMENT. Maryellen F. Eckenhoff and J.J. Pysh. Department of Anatomy, Northwestern Univ. McGaw Medical Center, Chicago, Ill. 60611

Previously, we have found a massive and transient increase in the formation of double-walled coated vesicles (DWCV's) from surface membranes of the cerebellar glomerulus during late postnatal development in the mouse.[1] In an attempt to determine whether this was specific to the cerebellum, or represented a more general phenomenon during brain development, we have examined another brain region. Since similar structures were reported in adult mitral cell bodies of the olfactory bulb we examined these cells. The purpose of this study was to describe the distribution and frequency of occurrence of DWCV's in the mitral cell bodies during postnatal development.

Mice were perfused through the left ventricle with dilute Karnovsky's fixative at 1, 5, 10, 16, 20, 26, 37 and 70 days of age. The olfactory bulbs were removed and prepared for electron microscopy.

We frequently observed DWCV's in random electron micrographs of immature mitral cell bodies. DWCV's consist of a coated invagination of the plasmalemma of the mitral cell body and an inner evagination of the plasmalemma of either an adjacent granule cell axon or mitral cell body. Also, coated invaginations of the plasmalemma of the granule cell axon were observed with inner evaginations of the plasmalemma of the adjacent mitral cell body. In addition, DWCV's were observed free in the cytoplasm of the mitral cell bodies and granule cell axons. A morphometric analysis revealed that the highest numbers of DWCV's were found at 37 days, (.055 DWCV's per μ^2 of mitral cell cytoplasm), some 23 fold more than at 1 day and 8 fold more than at 70 days of age. A lesser peak was found at 20 days, (.032 DWCV's per μ^2 of mitral cell cytoplasm), some 13 fold more than at 1 day and 5 fold more than at 70 days of age. In an attempt to determine whether there was a relationship between the occurrence of DWCV's and synaptogenesis, the number of synaptic terminals per μ of mitral cell body were counted. We found the number of synaptic terminals on the mitral cell bodies reached adult levels by the 20th day. The higher frequency of occurrence of DWCV's at 20 and 37 days of age follows synaptogenesis, as we observed in the cerebellum.

Thus, DWCV's are present in highest numbers during late postnatal development in at least two brain regions. It is possible that the formation of DWCV's may provide a mechanism for removal of specific surface constituents present on immature membranes. (Supported by NIH Grants #NS 10657 and 11325.)

1444 THE MONKEY CLAUSTRUM: AN ELECTRON MICROSCOPIC ANALYSIS Lawrence R. Edelstein and Frank J. Denaro*. Dept. of Psychol., SUNY At Stony Brook, Stony Brook, NY 11794.

While the claustrum has been studied for several years on both a light- and electron-microscopic level in several mammals, there is in fact a paucity of research in terms of the monkey claustrum. Of late, the use of HRP has aided investigators in the study of the connections of the monkey claustrum (Riche & Lanoir, JCN 177: 435, 1978). However, to our knowledge, the only published EM study done previous to this report on the monkey claustrum was carried out by Norita (Acta Anat. Nippon. 49: 47, 1974), who gave a brief report on the claustrum of Macaca irus. Therefore, we offer the following preliminary report on our study of the claustrum of Macaca arctoides.

While under deep Nembutal anesthesia, the subject was initially perfused with physiological saline at body temperature, followed by a second perfusion with a cold (~3°C) mixture of 2% EM Grade glutaraldehyde and 1% paraformaldehyde in a 0.12M phosphate buffer (pH 7.4). Postfixation of tissue cores from the body of the claustrum (taken with the "punch" technique using a glass pipette) was carried out with a 2% osmium tetroxide solution in 0.12M phosphate buffer (pH 7.4) and allowed to sit overnight. Following ethanol dehydration, the cores were flat-embedded in Spurr's resin and ultrathin sections were stained with uranyl acetate and lead citrate. Sections were viewed with a JEM 100B electron microscope.

The predominant cell type in the sections studied was slightly elongated (~10μm), displaying a large invaginated nucleus (containing chromatin clumps) with a thin perikaryon containing poorly organized ribosomes and a fair number of round and elongated mitochondria. Axo-somatic synapses were noted.

With respect to synaptic morphology, axo-somatic, axo-dendritic and axo-axonic synapses were observed, with a predominance of the axo-dendritic variety. Most of these were of the asymmetric type, and contained clear, spherical vesicles of a regular diameter (~600Å).

1445 AN EM AND HVEM STUDY OF NEURONS AND SYNAPSES IN THE FELINE DORSAL COLUMN NUCLEI. Leland C. Ellis, Jr. and Aldo Rustioni, Depts. of Anatomy and physiology, UNC, Chapel Hill, N.C. 27514

Previous EM studies on the synaptic organization of the feline DCN have focused on the identification of terminals of afferent projections, e.g., primary, cortical, and non-primary afferents (Rustioni and Sotelo, 1974; Rustioni and Ellis, 1978). As part of an ongoing study of the intrinsic organization of the DCN, the present study has concentrated on the identification and characterization at the ultrastructural level of the cell types in the "clusters region" of the feline DCN.

Light microscopical studies (Ellis et al, 1979) have demonstrated that greater than 90% of cells in the clusters are labelled with HRP following injection of HRP (30%, Boehringer) in the contralateral ventrobasal complex. For EM, cats with such an injection were perfused with mixed aldehydes, and 40um vibratome sections of the caudal medulla were reacted with Hanker-Yates substrate, osmicated, dehydrated in graded ethanols, and wafer-embedded in Spurr (1969). In thin sections (60nm) examined at 80kv, and in thick sections (.25um) at 1Mev (at the HVEM facility at Madison, Wisconsin), the thalamic relay neurons (TRN) labelled with HRP are typically round, average approx. 25um in diameter, and have a round nucleus with a small nucleolus. The HRP reaction product is localized in membrane bound, lysosome-like, organelles in the cytoplasm surrounding the nucleus. Profiles labelled with HRP, and interpreted as dendrites of TRN, were also seen in .25um sections at 1Mev. Stereo pairs demonstrate that these processes are postsynaptic to large terminals. In animals after dorsal rhizotomy, examination of serial .17um sections at 1Mev using computer reconstruction techniques demonstrates that these large terminals are primary afferent terminals distributed along the surface of the dendrites of TRNs.

The neurons unlabelled after HRP injection have distinct cytological characteristics. They are located at the periphery of clusters of HRP-labelled TRNs. They are typically smaller (average approx. 10um in diameter) than the TRN, fusiform, and have a nucleus that is often highly indented or lobulated. Membrane specializations, identified as puncta adherentia in thin sections and in stereo pairs of thick sections at 1Mev, have been observed between the TRN and these small cells. These small cells are also found away from the clusters, surrounded by bundles of myelinated fibers. For their cytological characteristics, these small cells are identical to the neurons identified in a LM study using HRP and Golgi techniques as interneurons (Ellis et al, 1979). Further study of these cell types and their synapses, using EM-Golgi techniques, is currently in progress. Supported by USPHS NS 12440 to A.R. and NIH RR-570 to the HVEM facility at Madison, Wisconsin.

1446 ASTROCYTE FORM IN HUMAN CEREBRAL CORTEX. Martin L. Feldman. Dept. of Anat., Boston Univ. School of Med., Boston MA 02118.

The purpose of the present study was to examine, in rapid Golgi preparations, the form of astrocytes in human temporal neocortex and hippocampus. Six blocks from 3 epilepsy patients (ages 22-35) were surgically removed and placed, within 60 sec, in EM fixative. Although in one patient histopathological evidence of a low-grade astrocytoma was present in the amygdala, the Golgi findings were similar in all 6 blocks. The major findings were also confirmed in a separate surgical block from human frontal cortex and in normal EM-perfused macaque area 17 and hippocampus.

The two major astrocytic forms encountered are radiate (R) and shrubby (S). R astrocytes have numerous (15-100/cell) primary processes, each ~50μm in length, which radiate out in relatively linear fashion from the soma. Branching is rare. These processes are rather heavily studded with small spinelike and irregular excrescences and usually taper to pointed tips. A small number of them, however, which frequently extend somewhat beyond the typical primary process length, give rise to distal fanlike endfeet about 6-10μm in diameter and of highly irregular form. In addition, a small number of primary R processes continue as long (up to ~ 750μm), radially oriented axon-like processes (ALPs). ALPs are unbranched, lack excrescences, and terminate distally in small (2-4μm) end knobs. S astrocytes have discrete spherical territories, ~ 100μm in diameter. Primary processes branch frequently and form thick perisomatic tangles. The processes are quite densely studded with excrescences and terminate bluntly. A small number of S processes, of somewhat greater length, bear endfeet similar to those of R cell primary processes. ALPs are lacking.

Both R and S forms are found in white and grey matter and at the pial surface, where many R cell ALPs course in a surface-parallel orientation and contribute to the glia limitans. In all cases, ALP knobs and R and S endfeet are in contact with vascular walls; the remaining primary processes do not typically exhibit this relationship. R cell ALPs commonly project to distant vessel segments which are very much closer to other R and S perikarya. While both R and S primary processes occasionally display a diffuse red margin, this lacks the multilocular character and definitiveness of the velamentous astrocytic appendages seen in macaque cerebellum. For these and other reasons, such cells are not considered to be the velate-type astrocytes of Palay & Chan-Palay.

A final astrocytic form, seen only with extreme rarity, corresponds to the classical smooth protoplasmic astrocyte. These cells have thin branched processes with numerous kinks. (supported by NIH Career award AG00016 and NIH grant AG00001).

1447 CLASSIFICATION OF SYNAPSES IN ELECTRON MICROGRAPHS BY MORPHOMETRY AND COMPUTER ANALYSIS. Victor L. Friedrich, Jr. and Gary E. Korte*. Dept. Biobehavioral Sci., Univ. of Connecticut, Storrs, CT 06268

We recently identified three types of synaptic boutons in cat superior vestibular nucleus, based on our impressions of their synaptic vesicles. Unilateral destruction of the vestibular ganglion resulted in loss of one type ipsilateral (lesioned side) but not contralateral (control side) to the lesion. In addition, we measured synaptic vesicles and found that the three putative types differed.

We have since analyzed the data on synaptic vesicles with two widely available statistical 'package' programs which perform classification of cases from numerical data: DISCRIMINANT, Statistical Package for the Social Sciences; and BMDP2M, cluster analysis, Biomedical Computer Programs.

The mean size and some other statistics on the vesicles in each bouton were entered to the discriminant program. In the 'training' phase, the program compared the three groups, as defined by us; in the 'classification' phase, each ending was reclassified solely from the vesicle data and without reference to our subjective label.

Agreement between our classification and that of the discriminant program program was better than 95%. When trained on the control side data only, the program repeated to 90% agreement our tabulation of the endings on the lesioned side and confirmed the preferential loss of the putative primary afferent type.

The cluster program associated the endings into a hierarchy of progressively larger and more heterogeneous groups; the pattern agreed with our subjective classification and indicated the presence of subclasses which we had not detected visually.

The discriminant analysis described here required the prior imposition of subjective labels to each ending, an undesirable feature. Subjective labeling may be unnecessary when techniques such as axonal transport, intracellular injections or cytochemistry are employed.

Our experience shows that these two programs, which are examples of statistical pattern recognition analysis, can classify synapses as well as human observers, when given good data. Furthermore, even in our apparently simple paradigm, one program detected patterns unnoticed visually. The approach of morphometry and statistical pattern recognition analysis may be generally useful in the analysis of synaptic connections by electron microscopy.

1448 REVERSIBLE DEPLETION OF SYNAPTIC VESICLES INDUCED BY A SINGLE-GENE MUTATION OF DROSOPHILA MELANOGASTER. Kazuo Ikeda and Kogaku Saito*. Div. of Neurosciences, City of Hope National Medical Center, Duarte, CA 91010, USA.

It has been shown that a reversible, temperature-dependent blockage of neuromuscular transmission occurs in the single-gene mutant, shibire^{ts1} (shi^{ts1}). The neuromuscular junction of the dorsal longitudinal flight muscle was observed by electron-microscope. shi^{ts1} and the control, wild-type Oregon-R, were raised at a constant temperature (17° C). Four-day old adult flies were dissected in a phosphate buffer and fixed in a para-formaldehyde-glutaraldehyde mixture. The temperature was under precise control during these procedures. Electronmicroscopy revealed the following results: At 19° C, where normal transmission is confirmed by observing the postsynaptic potential, both shi^{ts1} and Oregon-R showed normal-looking synapses with clear vesicles gathered around the presynaptic dense body. The mitochondria, pre- and postsynaptic membrane, and other structures also appeared normal in both shi^{ts1} and Oregon-R. At 29° C, which is the critical temperature where complete disappearance of postsynaptic potentials occurs in shi^{ts1}, the shi^{ts1} synapse showed almost complete depletion of vesicles; and in addition, many cisternae-like structures appeared. The Oregon-R synapse remained the same as at 19° C. In order to see the reversibility of the temperature effect, shi^{ts1} was exposed to 29-30° C for 20 min. prior to dissection. The dissection and fixation were then done at 19° C. The structure of the shi^{ts1} synapse was returned to normal, i.e., the cisternae-like structure disappeared and the vesicles reappeared. Since high temperature (27-29° C) causes motor output to this muscle in shi^{ts1}, the depletion of vesicles might be caused by temperature-induced synaptic input. To determine this, the nerve innervating this muscle was cut before exposure to high temperature. The results were the same as those obtained with the nerve intact. Thus, the depletion is a direct result of the mutation on the presynaptic terminal, rather than the result of presynaptic activity. The above observations coincide with our previous physiological finding that the neuromuscular transmission of shi^{ts1} is reversibly blocked by high temperature (29° C). The physiological blockage of transmission may be attributable to the reversible depletion of synaptic vesicles.

1449 A COMPARISON OF THE SHORT AND LONG TERM EFFECTS OF AXOTOMY ON THE FACIAL, VAGAL AND HYPOGLOSSAL NEURONS OF THE ADULT HAMSTER. S.K. Jacob and T.E. Durica. Dept. Anat., Rush Coll. Health Sci., Chicago, IL 60612.

The purpose of this study was to observe the cytology of the axon reaction of different cranial neurons in the adult hamster. In one group of animals the right facial and hypoglossal nerves were severed, while another group of animals underwent a right vagotomy. The left nerves remained intact to serve as a control. Animals were allowed to survive 5, 30 and 60 days postoperative (dpo). Following cardiac perfusion brain stems were double-embedded, serially sectioned, and stained with buffered thionin. Histological examination at all dpo times revealed cytological differences between the three neuronal groups.

Facial motor neurons showed classical signs of chromatolysis at 5 dpo. By 30 dpo the cells were hyperchromic due to heavy clumping of the Nissl substance, however, their overall somal and nuclear appearance resembled those of the normal side. Some of the nucleoli were seen to have a normal appearance at this time. Facial neurons were normal at 60 dpo though slightly hyperchromic.

Hypoglossal neurons exhibited central chromatolysis at 5 dpo. By 30 dpo a variety of responses could be found in the cells. Most neurons were hyperchromic though they had a normal configuration. Some cells were irregular in shape with a dark, finely granular cytoplasm, while others continued to show a central chromatolysis. No normal nucleolar pattern could be found in any of these cells. Only the first two types of responses were seen at 60 dpo, no chromatolytic cells remained.

Vagal neurons displayed a central type of chromatolysis at 5 dpo, however, their nucleoli were normal in appearance. By 30 dpo neurons continued to show a pale cytoplasm with a highly irregular outline, also the nucleolar appearance was not normal at this time. There was a marked neuronal cell loss by 60 dpo; the few remaining large neurons were swollen with a pale cytoplasm and an eccentricly placed nucleus.

While the short term response is similar in all 3 groups of neurons, the long term cytological changes are markedly different. The differences in the axon reaction seen in this study reflect the ability of the different cells to recover from the stress of injury. Variations in the cytological aspects of this response may indicate differences in the metabolic state of these neurons at the time of their injury.

1450 AN IMMUNOHISTOCHEMICAL METHOD TO DEMONSTRATE PIA-GLIAL BASAL LAMINA ON LIGHT MICROSCOPIC SECTIONS. Tim F. Kowalski, Earl R. Feringa and H. Lee Vahlsing*. Depts. Neuro. and Path., V.A. and Univ. of Mich. Med. Ctrs., Ann Arbor, MI 48105.

The basal lamina (BL) at the pia-glial interface is an ultramicroscopic structure which may be a guide or an impediment to axonal regeneration in the central nervous system (CNS). Existing staining methods for pia-glial BL, (P.A.S. and immunofluorescent antibody stains) are inappropriate for permanent light microscopic preparations. We have developed a staining technique for epithelial BL which is highly specific, extremely sensitive, permanent, relatively inexpensive and is suitable for light or electronmicroscopy (EM).

The basement membrane (BM) from CNS tissue of isogeneic female albino Wistar rats was isolated by the technique of Meezan(1975). Using this BM preparation as an antigenic source, we developed a hyperimmune serum. This serum was exhaustively absorbed on rat splenic pulp to remove undesirable antibodies to endothelial BL and collagen. Using the PAP indirect antibody staining technique, we tested the specificity of this splenic absorbed (SA) serum to various tissues. The following table lists the results of our staining specificity checks. These results indicate that this BL staining technique is specific for epithelial BL of the rat and of some other species.

PURPOSE	SERUM	TISSUE	BL STAINED
positive control	crude	rat spinal cord	endothelial mesodermal
			epithelial ectodermal
	SA	rat spinal cord	epithelial ectodermal
negative control	SA*	rat spinal cord	none
	SA**	rat spinal cord	none
specificity for epithelial BL	SA	rat spleen	none
	SA	rat lens capsule	epithelial ectodermal
specificity for ectodermal BL	SA	rat tongue	epithelial ectodermal
	SA	rat esophagus	epithelial entodermal
	SA	rat sciatic nerve	epithelial ectodermal
interspecies crossreactivity	SA	mouse, monkey, dog spinal cord	epithelial ectodermal
EM stain localization	SA	rat spinal cord	epithelial ectodermal

* goat anti-rabbit globulin step omitted during staining
** SA adsorbed on rat CNS BM antigen

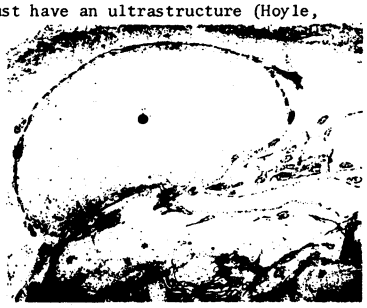
1451 ULTRASTRUCTURE OF THE SOMA OF AN IDENTIFIED DOPAMINE-CONTAINING NEURON OF THE SPINY LOBSTER CNS. Pinky Drosten Kushner and Eric Schabtach*. Dept. of Biology, U. of Oregon, Eugene OR 97403.

Each commissural ganglion of the spiny lobster contains a large (150 μm) neuron, readily identified by its characteristic somal position and primary neurite projection within the ganglion. This cell exhibits catecholamine histofluorescence (Kushner and Maynard, Br.Res.129 13, 1977), synthesizes dopamine from labeled tyrosine (Barker, Kushner and Hooper, Br.Res.161 99, 1979), and contains measurable amounts of dopamine (0.31 pmoles) (Kushner and Ono, Neurosci.Abs.4 610, 1978). We have examined its ultrastructure seeking possible unique morphological features.

The cell is characterized by dense cytoplasm with closely packed rough and smooth endoplasmic reticulum, in random array. There are numerous Golgi (~8 Golgi/10 μm^2), in close proximity to which are vesicles of varying sizes and densities, with many coated vesicles on the concave side. Multivesicular bodies are common with inclusions of small irregular vesicles of varying densities. Although the fixation we used was designed to emphasize densely staining vesicles associated with biogenic monoamines (Wood's fix as modified by Friend, Cell Tiss. Res. 175 369, 1976), we see few typical dense-cored vesicles, either Golgi associated or cytoplasmic.

Near parallel swirls of microtubules concentric to the nucleus funnel into the large primary neurite. The nucleus is small (25 μm) relative to the size of the soma and possesses a smooth unindented nuclear membrane.

This somal architecture is very different from that of the identified molluscan dopamine neuron (Anodonta: Zs.-Nagy in Neurobiology of Invertebrates, ed. Salanki, 1968; Planorbis: Berry in Biochemistry of Characterized Neurons, ed. Osborne, 1978) where granular vesicles are abundant. Likewise the octopamine neurons of locust have an ultrastructure (Hoyle, J. Neurobiol., in press) more similar to the molluscan dopamine neuron than to this lobster dopamine neuron. The paucity of densely precipitating vesicles is a feature shared with the presumed dopamine neuronal somata of the vertebrate substantia nigra. (Hokfelt and Ungerstedt, Br. Res. 60 269, 1973).



1452 POTASSIUM FERRICYANIDE: AN IMPROVEMENT IN NEURAL FIXATION Lauren A. Langford and Richard E. Coggeshall. Departments of Anatomy and of Physiology and Biophysics, The Marine Biomedical Institute, The University of Texas Medical Branch, Galveston, Texas, 77550.

After most electron microscopic fixation procedures, the myelin sheath appears frayed and the gyres of myelin often appear to be artificially separated in many places. This problem is particularly difficult for central myelin. In addition, numerous randomly distributed unmyelinated axons in peripheral nerves and spinal roots often show swellling or marked indentations. In our experience, the use of potassium ferrocyanide, as recommended by Karnovsky (1971, Abst. Am. Soc. Cell Biol., p. 146) helps alleviate these problems and in addition improves the contrast of membranes. The difficulty with the ferrocyanide procedure is that many cytoplasmic organelles such as ribosomes are not well preserved and the chromatin pattern of nuclei seems altered for the worse. Thus the ferrocyanide mixture is very useful for certain problems but probably cannot be used as a general procedure. Recently, however, we have found that the addition of potassium ferricyanide to the osmic acid postfixation solution has many of the virtues of the Karnovsky ferrocyanide procedure but seems to preserve the cytoplasm and nucleus like the regular fixation methods. If 1.5% potassium ferricyanide is placed into the buffered osmium tetroxide postfixation fluid, the number of frayed myelin sheaths and poorly fixed unmyelinated axons is reduced. There is usually a great improvement in the appearance of the tissue at the light microscopic level and a significantly decreased number of "bad" myelin sheaths, "swollen" axons, "blown" mitochondria, etc., and the contrast of the tissue is usually enhanced. It is to be emphasized that the most important varibles in the quality of the finished pictures are still such things as the success of the perfusion, but in our experience, the addition of potassium ferricyanide to the osmium tetroxide solution makes good fixation better and allows some data to be obtained from otherwise hopeless material. Pictures to show the differences between 1) regular, 2) ferrocyanide, and 3) ferricyanide fixation procedures will be presented. This work is supported by NIH grants NS 07377 and NS 10161.

1453 OBSERVATIONS ON THE FINE STRUCTURE AND CONNECTIONS OF THE AREA SUBPOSTREMA OF THE CAT. R. A. Leslie and D. G. Gwyn. Dept. Anat., Sch. Med., Dalhousie Univ., Halifax, N.S., Canada B3H 4H7.

The area subpostrema (ASP), corresponding to the parvocellular and gelatinous parts of the nucleus of the solitary tract, has been examined with the electron microscope. In some cases the nodose ganglion was removed unilaterally several days prior to microscopy. The neuronal complement of the ASP was seen to consist of a population of a single type of small cell bodies, about 10μm in diameter. Nuclear membranes were very deeply indented and were surrounded by an often attenuated perikaryon containing highly irregular arrays of rough endoplasmic reticulum with no regular parallel cisternae. Surrounding these somata were narrow flanges of astrocyte-like cells which often were linked to each other with gap junctions. The associated glial cell bodies were usually closely apposed to the neuronal somata. Many bundles of fine, unmyelinated axons coursed through the ASP usually in a rostro-caudal direction. Typical axo-dendritic and axo-somatic asymmetric synapses were seen to contain either round, clear vesicles or pleomorphic vesicles. Some round vesicle-containing terminals also contained a few large (80nm diameter) dense-cored vesicles. Dendo-dendritic and dendro-somatic synapses were occasionally seen and contained only pleomorphic vesicles. Very rarely an axo-axonal synapse was seen associated with a terminal containing round, clear vesicles. Degenerating terminals of vagal origin contained round, clear vesicles together with occasional large dense-cored vesicles. These terminals seemed to make up only a small percentage of the axo-dendritic synapses of the ASP and occurred singly throughout the substance of the area. Some of these were undoubtedly of gastric origin since the ASP has been recently shown to receive afferent fibres from the wall of the stomach (Gwyn, Leslie and Hopkins, 1979).

1454 AXOTOMY INDUCED LONG TERM NUCLEOLAR ALTERATIONS. L. Kirschen McLoon and A. LaVelle., Dept. Anat., Univ. Ill.-Med. Center, Chicago, IL 60612.

Changes in nucleolar structure, a primary neuronal response to axotomy indicating alteration in RNA and protein metabolism, have been especially well characterized in adult hamster facial neurons. An intranucleolar body (INB), composed of ribonucleoprotein, is present within the normal nucleolus of most of these neurons. The formation of the INB, the final step in nucleolar cytomaturation, occurs well after adult somal size and Nissl body configuration are present. Axotomy causes dispersion of the INB in the adult and prevents its normal formation in development. This study examined the long term effect of injury to developing neurons on their nucleolar morphology as seen with the light microscope.

INB formation was examined after either ligature/axotomy or crush performed at 15 days postnatal age before the INB had formed, at 20 days when the INB was just beginning to form, and at 25 days when the mature nucleolus was present. Animals were sacrificed at 4, 10, 15, 30, 50, 100 and 200 days after injury.

For all operative ages, crush injury resulted in complete INB return by 50 days. By 200 days INB return was still at control levels. With regeneration, the state of nucleolar maturation at the time of operation did not seem to be a decisive factor in eventual INB return after crush injury.

Although both types of injury extended the normal timetable for nucleolar maturation, lig./axotomy at 15 days postnatal age drastically delayed the formation of the INB. Even by postoperative day 200 the number of INBs were significantly depressed on the injured side. Thus, lig./axotomy, and the concomitant lack of reconnection, affected the long term capability of the youngest neurons to recover. This appeared dependent on the stage of nucleolar maturation at the time of injury. In contrast, after lig/axotomy at 20 and 24 days, the normal nucleolar configuration was attained by postoperative day 100 and maintained at 200 days. Therefore, once the final stage of nucleolar maturation, INB formation, was initiated, axotomy did not depress eventual full INB recovery.

In summary, injury was seen to result in long term alterations in nucleolar configuration. Full INB recovery was dependent on the level of nucleolar maturation at the time of injury only in the absence of functional nerve regeneration. These nucleolar changes correlate well with previous studies of the reactive metabolism of these neurons.

1455 PHYSICAL DEVELOPMENT: NEW APPLICATIONS TO SILVER STAINING OF NEURAL TISSUE. Bjorn H. Merker*. (SPON: A.M. Graybiel). Dept. Psychol., M.I.T., Cambridge MA 02139.

Gallyas has introduced a set of silver stains based on the principle of physical development (e.g. Acta Neuropath. 1970, 16: 35-43). In these stains a chemical pretreatment selectively enhances the argyrophilia of a given component of neural tissue. That component is then made visible by deposition of metallic silver through the "seeding" process of physical development, identical for all the stains. In comparison with conventional chemical reduction methods of silver staining, the generation of pigment by physical development is slow, allowing precise control over the degree of impregnation. Furthermore, pigmentation is not limited by the amount of ionic silver bound to histological elements in pretreatment steps, making high levels of contrast achievable. The application of physical development to silver impregnation of Nissl substance and to contrast enhancement of normal axons will be described.

If sections of formalin-fixed brain are exposed to physical development after oxidation in a highly acidic medium, Nissl substance stains black on a virtually colorless background. In addition to its excellent photographic reproducibility, this high contrast Nissl stain offers the advantage of outlining electrode and pipette tracks in black, greatly facilitating their identification in the setting of cytoarchitectonic boundaries.

In that physical development removes the limitation of tissue-bound silver from the staining process, it was postulated that methods from photographic chemistry for manipulating contrast on photographic plates might be adapted for use on silver stained neural tissue. The approach was successfully applied to the Fink-Schneider stain for normal axons (Science 1969, 163: 895-902, note 31), in which high levels of background pigmentation impede visibility, particularly in tissue with short post-fixation time. After completion of the Fink-Schneider procedure, background pigmentation is removed from sections by a modified Farmer's Reducer. Silver is then re-deposited by physical development in greater amounts than originally present. The "bleach-intensify" cycle can be repeated, each time resulting in a higher level of contrast between axons and background. Usually 2 cycles of progressive contrast enhancement suffice to produce stark black impregnation of even the finest fiber components on a virtually colorless background.

Supported by NIH grant EY00126to G. Schneider, and by a Whitaker-Health Sciences Fund Fellowship to B. Merker.

1456 IMMUNOCYTOCHEMICAL LOCALIZATION OF THE GLIAL FIBRILLARY ACIDIC (GFA) PROTEIN IN THE MUELLER CELL OF THE HUMAN RETINA. D.K. O'Dowd* and L.F. Eng. Dept. Path., VA Med Cen and Stanford U. Sch. Med., Stanford, CA. 94305

Mueller cells have been classified as modified retinal astrocytes (Polyak 1941, Maghales and Coimbra 1971) that span the thickness of the retina. These purported glial cells, recognized by classical morphology, have been the subject of a number of recent studies, attributing them with what have been traditionally considered neuronal functions. Some of these include storage and synthesis of neurotransmitters (Riepe and Norenburg, 1977), uptake and degradation of certain neurotransmitters (Sarthey and Lam, 1978) and electrophysiological activity, as demonstrated by the b-wave of the electroretinogram (Miller and Dowling, 1970).

The immunocytochemical technique of Sternberger, the peroxidase-anti-peroxidase method, was employed to localize the GFA protein in formalin-fixed, paraffin-embedded 6 micron sections of the human eye. Rabbit antiserum to the GFA protein and seven human eyes obtained at autopsy were utilized. At the light microscopic level, the positive staining of the Mueller cells for the GFA protein clearly delineated the glial network of the retina. The most prominent area of staining revealed a laminated structure formed by horizontal glial processes in the nerve fiber layer of the entire retina. We have observed that GFA protein was present in the Mueller cells, throughout the thick radial processes, and in the fine villous projections. Since GFA protein has been localized specifically in astroglial elements (Eng and Rubinstein, J. Histochem. Cytochem. 27:513, 1978), this study confirms the classification of the Mueller cell as an astrocyte. With this technique, we were also able to partition the ora serrata into three distinct regions, representing alterations in the Mueller cell morphology, on the basis of GFA protein staining.

1457 SEQUENTIAL CHANGE IN CYTOPLASMIC AREA AND LYTIC ENZYME DISTRIBUTION IN A REACTIVE GLIAL CELL POPULATION. Linda L. Phillips and James E. Turner, Dept. Anat., Bowman Gray Sch. Med., Wake Forest Univ., Winston-Salem, NC 27103.

The glial cell population of the newt optic nerve has been shown to respond to lesion over a time interval of the first 30 minutes after transection, involving a series of morphological changes, visible at the light and EM levels (Soc. for Neurosc. Abst. IV:399, '78). Portions of the response appear to involve cytoplasmic hypertrophy and lytic enzyme (Acid Phosphatase) distribution. The purpose of this study was to determine what pattern these two parameters follow during the 30-minute response period. Newts were anesthetized, orbital nerves cut and animals sacrificed at 5, 10, 15, 20 and 30 minutes post lesion (mpl). Nerves were removed, one group processed for electron microscopy, and a second for the EM localization of Acid Phosphatase. Random regions, both central and peripheral in the nerve cross section, were sampled and with a computer interfaced digitizer the areas of neuronal and glial compartments were calculated. A determination of Acid Phosphatase localization was made in comparable regions. Results showed decrease in the ratio of peripheral neuronal to glial area (N/G) from values of 3.13 ± .377 (5 mpl), to 2.55 ± .398 (15 mpl) and 2.76 ± .295 (20 mpl). Each of these values was significantly different ($p < .001$) from that of lesioned control nerves (N/G = 6.24 ± .495), whereas central N/G values were not significantly different. Preliminary histochemical results show no qualitative difference between experimental nerves 10 mpl and unlesioned controls, both presented random background distribution of reaction product. At 20 mpl Acid Phophatase localization was specific for the extracellular spaces between degenerating axons. Few vesicular localizations were presented, in contrast to that of 30 mpl, where vesicles associated with glial cytoplasm were labelled in addition to the extracellular enzyme pockets. These results indicate 1.) a sequential increase in glial compartment area which correlates with the change in both mitochondrial and Golgi density during the first 30 mpl (Anat. Rec. 193: 653, '79), and 2.) the possible differential distribution of a lysosomal enzyme (Acid Phosphatase) over the same time period.

(Supported by a Basil O'Connor Starter Research Grant from the National Foundation-March of Dimes; the National Society for the Prevention of Blindness made possible through the Alder Foundation and NIH Grant NS 12070 awarded to James E. Turner.)

1458 SYNAPTIC VESICLE DEPLETION IN FROG SYMPATHETIC GANGLIA STIMULATED BRIEFLY IN VITRO: DEMONSTRATION BY RAPID-FREEZING AND ELECTRON MICROSCOPY. J.J. Pysh and Gery K. Florek*. Dept. Anat., Northwestern Univ., Med. and Dent. Schs.

The purpose of this study was to investigate the distribution and concentration of synaptic vesicles in nerve terminals of sympathetic ganglia following short periods of tetanic stimulation. The method of rapid-freezing and freeze-substitution was utilized in order to estimate reliably the distribution of synaptic vesicles in nerve terminals in the living state.

The ninth sympathetic ganglia of bullfrogs were used because most, if not all, preganglionic fibers enter through the trunk. Experiments utilized a specially designed stimulation - recording specimen carrier upon which ganglia were mounted, electrically stimulated and recorded, and finally lowered into a modified Van Harreveld apparatus for rapid freezing. Five ganglia served as unstimulated controls and 5 were stimulated supramaximally, by way of the preganglionic trunks, at 20-25 Hz for 5 minutes. Rectangular pulses, 0.25-1.0 msec, were used. Postganglionic recordings were obtained from ganglial rami. After freezing, ganglia were processed by freeze-substitution in 2% OsO_4 in acetone for 3 days at -80°C and then prepared conventionally for transmission electron microscopy. Several hundred preganglionic terminals near the surface of the ganglia were obtained for analysis.

Ultrastructural evaluation indicated synaptic vesicles in preganglionic nerve terminals had a more uniform distribution in rapidly frozen ganglia than those chemically fixed. Morphometric analysis of 40 control and 40 stimulated axosomatic synapses revealed that the concentration of clear-cored vesicles within 500Å of the plasma membrane of the active zone and in the entire terminal declined 35% and 37% respectively after 5 minutes of stimulation. This suggests that the concentrations of the two populations of vesicles are related. This decrease in synaptic vesicle concentration approximated the decline in amplitude of postganglionic potentials recorded in vitro and approximates declines in acetylcholine release, EPSP amplitudes and postganglionic potentials, after 5 minutes of electrical stimulation, reported by others in sympathetic ganglia.

These data provide further evidence that transmitter is secreted in sympathetic ganglia by the exocytosis of synaptic vesicles and that the rate of transmitter secretion is dependent, in part, upon the availability of vesicles for release.

(Supported by NIH Grant NS11325).

1459 INFANT BRAINSTEM: CORRELATIVE SCANNING ELECTRON MICROSCOPY AND GOLGI STUDY. James J. Quattrochi*, Leopold Liss, Nobuhisa Baba*, P. T. McBride*, and Darrell N. Simone*. Dept. Pathology, Sch. Med., Ohio State University, Columbus, Ohio 43210.

Reticular ultrastructure was studied in the magnocellular and parvocellular complexes of postmortem infant brainstem with the application of scanning electron microscopy (SEM). A correlative technique using SEM and the rapid Golgi method identified neurons and reticular processes in thirty-four infants ranging in age from 1 day to 8 months. In all cases the postmortem time did not exceed six hours. Suitable verification of apparent dendritic projections exhibiting spine-like extensions was established by examination of adjacent sections using light microscopy. These spine-like extensions were observed to be of the three morphological types described by Peters and Kaiserman-Abramof (1970). Stellate neuronal-like bodies were observed to be contained within the surrounding neuropil. In addition, neurites in close parallel apposition appeared to resemble a topographical synaptic arrangement. SEM analysis of the infant pons and medulla may provide new data concerning ultrastructural reticular correlates.

1460 MYELIN ULTRASTRUCTURE IN COPPER DEFICIENCY. Frank A. Rawlins, Victor Canestri*, Carmen López-Jiménez*. Dept. Biophysics. I.V.I.C. Apartado 1827. Caracas 101, Venezuela.

There are several biochemical and histological studies indicating that a deficiency of copper have severe consequences on the normal development of the nervous system in humans and other vertebrates. From these studies it seems that myelination is largely affected by copper deficiency although no ultrastructural analyses are available. The purpose of the present work is to provide information on the role played by copper in the maintenance of the myelin sheeth ultrastructure in optic nerve of adult rats. A group of 25 day old female rats was fed a copper-free diet and deionized double distilled water for 8 weeks. Control rats were fed the same diet and distilled water with 15 µg/g of copper added to it, during the same period. The optic nerves were processed for electron microscope examination and myelin was isolated from the whole brain. It was found that copper concentration in plasma and brain as well as quantity of myelin isolated from copper-deficient rats were significantly less than that from controls. Concentration of copper in myelin isolated from copper deficient brains was slightly lower than controls but the difference was not significant. The electron microscope analysis showed advanced edema at the innermost region of the myelin sheeth with marked axonal compression in 15% of the fibers analysed. Edema seems to be formed by swelling of the inner loop with expansion of the myelin sheeth which surrounds it. Edema is observed mainly in large caliber fibers. Small and medium caliber fibers showed only a slight swelling of the myelin inner loop. The results indicate that the innermost region of the myelin sheeth is highly sensitive to copper deficiency and suggest that copper distribution may not be homogeneous within the myelin sheeth. Supported partialy by CONICIT Grant 31.26.S1-0754.

1461 PUTATIVE TISSUE BASOPHIL/MAST CELL: A RESIDENT OF THE PIGEON OLFACTORY BULB. Garl K. Rieke, Daniel E. Bowers*, and Marvin S. Cannon*. Department of Anatomy, College of Medicine, Texas A&M University, Olin E. Teague Res. Center, College Station, Texas, 77843.

Small cells (8-10 µm) with a single nucleus and metachromatic granules have been observed in the various laminae of the olfactory bulbs of 16 pigeons (Columba livia). These cells have not been observed in the spinal cord, cerebellum, paleostriatal complex and the hyperstriatum. The cells were present in the bulbs of birds perfused through the heart (0.05 M phosphate and sucrose buffer, 3% glutaraldehyde, 1% paraformaldehyde, 600 mOsmol, pH 7.3) and in bulbs fixed by immersion. The presence of the putative tissue basophil or mast cell in the bulbs fixed by perfusion or immersion is important since forced diapedesis cannot account for their presence. The cells are rarely seen adjacent to blood vessels. Electron micrographs show these cells in the neuropil. Their cell surface possesses small pseudopodia, which suggest motility. By light microscopy utilizing blood smears and buffy coats, and Azure B staining, coarse granules within these cells stain metachromatically and average one micrometer in diameter. By electron microscopy, the granules appear membrane-bound and demonstrate a grid-like substructure. A second type of granule having a dense pleomorphic center surrounded by a pale zone, also is seen. The coarse granules may contain acid-mucopolysaccaride. In addition, histochemical staining suggests that histadine may be present in these granules. Cells in blood smears and buffy coats of the pigeon that are identified as basophils closely resemble the cells seen in the olfactory bulb. Further histochemical studies on frozen sections of the bulbs and ultrastructural observations of blood basophils should clarify whether the cell observed in the bulb is the same as that seen in the peripheral blood.

Basophils or mast cells have not been described in the neuropil of other avian species. Mast cells have been found in the brain of dogs and hedgehogs. The putative basophil or mast cell in the pigeon bulb may have functions similar to those proposed for this cell in connective tissue or as yet undisclosed functions.

1462 ABNORMALITIES OF AXOLEMMAL MEMBRANE SPECIALIZATIONS IN MYELIN DEFICIENT "SHIVERER" MICE. J. Rosenbluth, Departments of Physiology and Rehab. Medicine, New York University School of Medicine, New York, N. Y. 10016.

The mouse mutant known as "Shiverer" is characterized by a paucity of central nervous system myelin. Examination of thin sections of spinal cord, cerebellum and optic nerve reveals thin myelin sheaths with numerous irregularities. "Loops" of glial cytoplasm are apposed to axons in various locations not necessarily related to nodes of Ranvier. Although typical paranodal structures are uncommon, junctions containing "transverse bands" occur frequently between glial processes and axon plasma membranes. Peripheral nerves exhibit subtle irregularities consisting of myelin lamellae that terminate against the axolemma in internodal regions and greater numbers of loose lamellae containing cytoplasm. Peripheral myelin sheath thickness appears to be within normal limits, however. Analysis of freeze-fracture replicas of central nervous system fiber tracts shows few examples of typical paranodal membrane specializations in the E fracture face. However, distorted and bizarre junctional membrane specializations occur frequently in the form of isolated patches or strips of membrane revealing the characteristic paracrystalline pattern but oriented longitudinally or obliquely rather than nearly transversely. Occasionally several such strips, none of which encircles the axolemma, may occur side by side. The orientation of the strips may shift within a given region and the direction of the paracrystalline pattern within such a strip may also change abruptly. A few examples of typical E face nodal particle accumulations have been encountered adjacent to more or less normal paranodal or hemiparanodal regions. However, isolated paracrystalline patches are usually not associated with particle accumulations in the immediately adjacent membrane, except in instances where "lakes" of membrane are entirely surrounded by the paracrystalline membrane. The results indicate that even though myelin formation is grossly deficient in quantity and bizarre in structure, glial cells and axons in the central nervous system of Shiverer mice are still capable of forming the unique junctions normally found in the paranodal region. The lack of consistent association of E face particle accumulations with isolated paracrystalline patches is compatible with the hypothesis that complete spiral collars of paracrystalline membrane are required for effective restriction of the movement of intramembranous particles resulting in their local concentration.

1463 TISSUE CULTURE STUDIES OF SCHWANN CELL PROLIFERATION DURING DEVELOPMENT AND DEGENERATION. J. Salzer*, L. Glaser*, and R.P. Bunge. Dept. Anat. & Neurobiology, Washington Univ. Sch. Med., St. Louis, Mo.

Periods of substantial Schwann cell proliferation occur during embryonic development and following peripheral nerve transection or crush (Wallerian degeneration). The wave of proliferation observed during development (Asbury,1967) may be stimulated by an axonal mitogen (Wood and Bunge, 1975). By contrast, the increase in the number of Schwann cells in the distal transected nerve (Abercrombie and Johnson,1946) may result from a breakdown product of the axon (Abercrombie and Santler,1957) or the myelin sheath, or be engendered by the space vacated by the degenerating nerve fibers (Joseph,1950). These suggestions would explain their observation that proliferation is greatest in degenerating myelinated nerves and least in degenerating unmyelinated nerves

When rat dorsal root ganglia (DRG's), treated with antimetabolites to suppress fibroblast outgrowth (Wood,1976), are placed in tissue culture neurites elongate and become ensheathed by Schwann cells. Initially Schwann cells proliferate rapidly, but as each neurite is fully ensheathed division slows considerably and myelination commences. Using autoradiography to follow the incorporation of tritiated thymidine, we studied the effect of DRG excision (e.g. axotomy) on Schwann cell proliferation. In the young explant (two weeks in vitro), as in the developing peripheral nervous system, Schwann cell proliferation is very high (labeling indices of 30% or more). In these cultures if the neuronal somas, which are confined in the ganglion, are mechanically excised proliferation rapidly decays to less than 1% only 48 hrs. later. In more mature cultures (six weeks in vitro), most cells were quiescent at the time of excision and remained quiescent indefinitely post-axotomy. However the myelin forming Schwann cells (which could be recognized specifically by their intracellular myelin debris) did divide in response to axotomy. The peak labeling period occurred at four days post-excision at which time approximately 35% of the cells which had been myelin related, incorporated thymidine. These results suggest that the mitogenic signals during development and degeneration are distinct. Breakdown of myelin debris or turnover of Schwann cell membranes may be the signal operative in Wallerian degeneration.

1464 APPLICATION OF SCANNING ELECTRON MICROSCOPY TO THE CENTRAL NERVOUS SYSTEM. A. B. Scheibel, L. Paul*, and I. Fried*. Departments of Anatomy, Psychiatry and Physiological Psychology, University of California, Los Angeles, CA 90024.

Scanning electron microscopy (S.E.M.) has been used for several years in the delineation of surface topography of biological systems, i.e., villous linings of the respiratory and female reproductive tracts, ependymal surfaces of ventricles, dissociated elements from tissue culture, etc. We now report on the use of S.E.M. methodology in the study of structure and interrelationships within the central nervous systems of several species, including man. Neuronal, dendritic, axonal, glial and vascular tissue surfaces are made available to scanning methods by blunt dissection and "creative" tearing techniques which follow natural cleavage planes along the surfaces of these elements.

Following perfusion (where possible) with buffered paraformaldehyde solutions, further fixation for 24-48 hr of small selected tissue block and careful "tearing" of tissues across areas which were to be examined, the resulting blocks were post-fixed in 1/3 of 1% osmium tetroxide solution, then critical point freeze-dried, sputter-coated with palladium-gold in an argon-filled medium, and examined in an ETEC scanning electron microscope at magnifications of up to 20,000 x.

As indicated by the series of accompanying drawings and photographs, sensitive 3-dimensional delineations of neuronal-glial interrelations, synaptic topography and neuropil-vascular configurations can be examined. Characteristic topographies of specific brain areas are gradually becoming clear, particularly in cerebellum, hippocampus and spinal cord. We are in process of developing labeling techniques to enable identification and tracing of individual cell-membrane molecular species.

1465 ISOLATED RAT BRAIN CAPILLARIES; FREEZE-FRACTURE CONFIRMATION OF INTER-ENDOTHELIAL JUNCTION INTEGRITY. Richard R. Shivers and Gary W. Goldstein. Department of Zoology, University of Western Ontario, London, Ontario, and Department of Neurology,University of California Medical Center, San Francisco, California.

Fractions of rat brain tissue containing high concentrations of intact brain capillaries have been proposed as useful models for in vitro studies of blood-brain barrier permeability (Goldstein et al, J. Neurochem., 25, 1975). Preliminary studies of these preparations have suggested that the zonulae occludentes of the isolated segments of capillaries retain the impermeability to the protein tracer horseradish peroxidase exhibited by them in vivo. These junctions are therefore assumed to be functionally "tight" in vitro. In order to determine the precise structural organization of these occluding junctions, including an estimate of their tightness, and to demonstrate a method of simple but precise assessment of junctional integrity, pellets of isolated rat brain capillaries were freeze-fractured and then replicated with platinum and carbon. The freeze-fracture images of inter-endothelial zonulae occludentes reveal complex intramembrane arrays of ridges and grooves characteristic of tight junctions. Longitudinal fractures of the cellular lining of capillaries expose vast expanses of inter-endothelial plasma membrane interfaces and the junctional complexes situated between the cells. From such images, the complex and elaborate architecture of the zonulae occludentes can be readily appreciated. Situated on PF fracture faces are 6-8 parallel ridges which display a high degree of anastomosing between adjacent strands. The EF fracture face contains grooves complementary to the PF face ridges. The zonulae occludentes of these capillary endothelial cells are similar in complexity to those reported for reptilian brain capillaries (Shivers, Brain Res., 1979) and can be presumed therefore "very tight". This study demonstrates that freeze-fracture of pellets of brain capillaries alleviates sampling problems inherent in whole tissue preparations and, in addition, demonstrates the usefulness of freeze-fracture as a tool to monitor junction structure during in vitro investigations of the blood-brain barrier. (Supported by the National Research Council of Canada, National Foundation-March of Dimes, and USPHS).

1466 LYSOSOMES AS SPECIFIC STORAGE DEPOTS FOR NEUROTRANSMITTER. Ludmila J. Shkolnik*, Daniel J. Goldberg, and James H. Schwartz. Div. of Neurobiol. & Behav. & Depts. of Physiol. and Pharm., Columbia U., New York, N.Y. 10032. U.S.A.

Large lysosomes containing wear-and-tear pigment are characteristic of many nerve cells, both vertebrate and invertebrate. In *Aplysia* attention has been drawn to these particles because they were shown to be an intracellular Ca^{++} sink and can release Ca^{++} in response to light. They are typically situated in a dense perinuclear layer together with the Golgi apparatus, smooth endoplasmic reticulum and vesicles in cell bodies of pigmented *Aplysia* neurons, which make chemical synapses with other neurons and with peripheral organs. We now have an indication that these lysosomes, in addition to being degradative in function, may also serve as a specific depot for transmitter substance in the cell body.

We have been studying the localization of ^{3}H-serotonin injected directly into the cell body of the giant cerebral neuron (GCN), the identified serotonergic cell in the *Aplysia* cerebral ganglion, and have found a striking association of the labeled transmitter with large lysosomes. This localization is specific: ^{3}H-serotonin was not found in similar lysosomes in the perikaryon of R2, an identified *Aplysia* cholinergic neuron. ^{3}H-dopamine, ^{3}H-histamine, and ^{3}H-N-acetylgalactosamine injected into the serotonergic neuron were not localized in lysosomal bodies. These organelles are indeed lysosomal: we showed that they contain acid phosphatase by electron microscope cytochemistry. Moreover, examination of isolated GCN cell bodies by fluorescence microscopy revealed the presence of abundant autofluorescent yellow pigment characteristic of lipofuscin.

It is our working hypothesis that ^{3}H-serotonin labels organelles containing membranes that once were components of the serotonergic vesicle. Lysosomes might accumulate the transmitter with a high degree of specificity because they contain membranes, perhaps recycled from the neuron's terminals, that retain their ability to concentrate and bind serotonin. Alternatively the lysosomes may not take up serotonin directly from the cytoplasm, but may engulf new serotonergic vesicles already charged with transmitter. Thus the lysosomes would regulate the supply of vesicles as well as the supply of the transmitter. Whatever the mechanism, lysosomal binding of exogenously introduced transmitter may be a useful technique for identifying the transmitter type of a neuron.

1467 FURTHER NOTES ON THE SEARCH FOR "DOUBLE" RETROGRADE AXONAL LABELING TECHNIQUES: "EVERYTHING BUT THE KITCHEN SINK." Dennis A. Steindler. Dept. of Anat., Michigan State University, East Lansing, MI 48824

Several macromolecules have been tested as potential "double-labels" to be used in combination with horseradish peroxidase (HRP) for determining the degree of axonal branching within particular regions of the central nervous system. Previous investigators have reported retrograde axonal transport and subsequent autoradiographic, fluorescent and histochemical demonstrations of 3H-adenosine, 3H-HRP, 3H-apo-HRP, 125I-tetanus toxin, 125I-wheat germ agglutinin(WGA), bovine serum albumin, certain fluorescent substances (i.e.Evans Blue), and iron dextran complex (Schubert and Kreutzberg,'75; Geisert,'76; Hayes and Rustioni,'78; Price et.al.,'77; Schwab et.al.,'77,'78; Kristensson and Olsson,'71; Steward and Scoville,'76; Kuypers et.al.,'77; Olsson and Kristensson,'78).

This investigator has injected various dyes, iron dextran complex, tritiated RNA precursors (i.e.orotic acid), alkaline phosphatase, and labeled WGA in different regions of mouse cerebrum, cerebellum, basal ganglia and related brainstem nuclei. Preliminary observations are encouraging using lectins such as WGA that are either tritium-labeled (New England Nuclear, S.A. 4.37 Ci/mmol) or covalently linked to enzymes (i.e.alkaline phosphatase) or biotin (E.Y.Laboratories, San Mateo, Ca.). The mechanisms of uptake and transport are not known, but the sequence most likely begins with WGA binding to specific glycoproteins and glycolipids located on the cell surface (Schwab et. al.,'78). In addition to autoradiography, there are also several alternatives for histochemically demonstrating the lectin, all of which utilize lectin or substrate conjugates. For example WGA (M.W.35,000) bound to alkaline phosphatase (M.W.140,000) will hydrolyze the phosphate group of 5-bromo-4-chloro-3-indolyl-phosphate producing an insoluble blue indigoid dye (Chu,pers. com.; Tsou et.al.,'67) that is compatible with a brown reaction product using 3,3' diaminobenzidine tetrahydrochloride in HRP histochemistry. WGA bound to biotin (M.W.244) may afford better uptake and transport because of the considerably smaller molecular weight of biotin compared to AP, and sections can be reacted with avidin (which displays an extremely high binding affinity for biotin) bound to either AP or ferritin for light and electron microscopic detection of the transported lectin.

Analysis of degrees of divergence in the collateralized projections within the motor system will ensue following technical refinements of the aforementioned procedures.

1468 COMPLEMENTARY REPLICAS OF FREEZE-FRACTURED NODES OF RANVIER IN AMPHIBIAN PERIPHERAL NERVE. J.H. Tao-Cheng* and J. Rosenbluth. (SPON: K. Rubinson). Departments of Physiology and Rehab. Med., New York University School of Medicine, New York, NY 10016.

Sciatic nerves of frog tadpoles were fixed and freeze-fractured, and complementary replicas of nodes of Ranvier examined. The results confirm a previous study of amphibian myelinated fibers in the central nervous system (J.Neurocytol.5:731) in showing equally high concentrations of intramembranous particles in the E and P fracture faces of the nodal axolemma but low concentrations of E face particles in the internodal region relative to the internodal P face particle concentration. By comparing complementary replicas it is possible to demonstrate unequivocally that a large proportion of the nodal E face particles are large in diameter and cast long shadows, while in the P fracture face the proportion of large particles is distinctively lower and many more small particles and irregularly-shaped structures are present. Tracings of E and P fracture faces of the nodal and paranodal axolemma and of the junctional Schwann cell membranes were prepared and superimposed face to face in order to determine whether the particles in the respective tracings overlap. Almost none do, indicating that the particles in the respective fracture faces are distinct from each other and do not represent fragments of the same units. In the paranodal axolemma the helical groove (E face) or ridge (P face) that faces the extracellular space between terminating Schwann cell "loops" contains particles similar in size and shape to those in the nodal axolemma, and here too the particles in the complementary faces do not overlap. In addition, in this study replicas were consistently viewed shadowed side up, and examination of the junctional region of the paranodal axolemma showed that the orientation of the diagonal pattern is invariably the same. The angle formed by the diagonal pattern and the ridges or grooves is always positive (~+30°) in the E face and negative (~−30°) in the P face. Moreover, this angle is rather consistent with respect to the ridges or grooves regardless of the angle between them and the long axis of the fiber. The Schwann cell membrane forming the paranodal junction exhibits regularly spaced (30 nM) rows of particles in both fracture faces. There are more particles (~70%) in the P face than in the E face (~30%) and the particles in the two faces do not overlap. Since the particles in the two faces of this specialized Schwann cell membrane fall into approximately the same size range and are aligned with each other without overlapping, they may be members of the same population, most of which which remain attached to the P face in the cleaving process.

1469 NORADRENERGIC NERVES AND MAST CELLS AFTER ELECTRICAL STIMULATION IN THE PRESENCE OF PHENTOLAMINE. Å. Thureson-Klein, R. L. Klein and L. Stjärne.* Dept. Pharmacol. Univ. Miss. Med. Ctr. Jackson, MS 39216 and Karolinska Inst. Stockholm, Sweden.

Biopsy specimens of omental veins were obtained during surgery under general anesthesia. These were normotensive female patients who had not been exposed to any medication known to release histamine. The excised veins were divided into segments, mounted in a bath and subjected to electrical field stimulation at 1 Hz for 60 sec. with or without the α-receptor blocking agent, phentolamine (7.5×10^{-7}M) present. Control segments were superfused for the length of time of the experiment. Small tissue blocks from several areas of all segments were prepared for electron microscopy. Noradrenergic nerve terminals with typical large and small dense-cored vesicles and mast cells with large characteristic scroll-containing granules were well preserved and easily identified in control veins. The distance between mast cells and noradrenergic axons and terminals was frequently in the same range as that between nerve terminals or mast cells and smooth muscle cells, i.e., 1 µm or less. After electrical stimulation without phentolamine present there was an increase of presumptive exocytotic profiles along the terminal membrane and an increase in the total number of small vesicles by 30% when compared with unstimulated controls. There was no obvious change in the mast cell ultrastructure. However, after stimulation in the presence of phentolamine, both nerve terminals and mast cells showed morphological changes. In the nerve terminals there was a significant increase of both small and large vesicles that were in immediate contact with the terminal membrane. The total number of large and small vesicles had declined when compared to superfused controls but there was an increase of small clear vesicles. In the mast cells, many of the intracellular granules had fused and showed decreased electron density. Granules and released scrolls were present extracellularly. Anastomosing cavities filled with amorphous material were prevalent in other mast cells. It is possible that the degranulation of mast cells following electrical stimulation in the presence of phentolamine reflects a direct releasing effect of a compound which is structurally reminiscent of histamine. It may also be due to an indirect effect involving noradrenaline and ATP overflow after blockade of the prejunctional α-adrenergic receptors.

1470 A NETWORK OF SUBEPENDYMAL POLYANIONIC ELECTROLYTES IN THE LATERAL VENTRICLE OF THE RAT. Richard M. Torack and Lois Grawe*. Dept. Pathol., Washington Univ. Sch. Med., St. Louis, MO 63110

A system of acidic mucopolysaccharides in in the brain of young adult rats has been demonstrated by means of histochemical and electron microscopical techniques. This extracellular material appears to be present in the lateral wall and angle of the lateral ventricle. In contrast to other extracellular mucopolysaccharide which can be identified in cryostat sections, this network is not extracted by chloroform/methanol (2:1) or xylene. Cationic aldehyde fuschin is bound selectively at pH 1.5. The system has an affinity for alcian blue at pH 1.0 and in a medium containing 0.3M-0.5M Mg_2Cl_2. Staining with alcian blue at pH 1.0 will block subsequent treatment with aldehyde fuschin. Metachromasia is demonstrable with toluidine blue at pH 1.5. The network binds cationized iron (Hale's colloidal iron) at pH 1.5.

Electron microscopic study of rat brain fixed by perfusion and immersion in 2% glutaraldehyde and 5% paraformaldehyde reveals an expanded extracellular space (ECS) measuring up to 1000 Å in width at the lateral angle and underlying the lateral wall of the lateral ventricle. An ependymal-like cell is present in the lateral angle which is partially bounded by this expanded E.C.S. space. At the lateral wall, the expanded E.C.S. is confined to the immediate subependymal area. Tissue chopper sections reacted with cationized iron reveal a localization of electron dense material in the dilated E.C.S. beneath the ependymal lining.

These findings are considered to be consistent with a network of polyanionic electrolytes in the periventricular extracellular space at these sites, which should be important in trans-ependymal ionic movement.

NEURO-ENDOCRINOLOGY

1471 EFFECTS OF CASTRATION ON DOPAMINE METABOLISM IN RAT STRIATUM AND LIMBIC FOREBRAIN. Lloyd M. Alderson*, Matthew S. Starr*, and Michael J. Baum. Laboratory of Neuroendocrine Regulation, M.I.T., Cambridge, MA 02139.

Psychopharmacological studies have suggested that increased activity in dopaminergic pathways facilitates the expression of sexual behavior in the male rat. Castration of the male rat leads invariably to the disappearance of masculine sexual behavior. Experiments were carried out to determine whether this castration-dependent reduction in copulation is correlated with changes in catecholamine synthesis or in dopamine (DA) metabolism in brain regions rich in DA-containing nerve terminals.

In an initial experiment catecholamine synthesis was estimated in castrated and sham-operated adult male rats (Long-Evans) by measuring the accumulation of dihydrophenylalanine (DOPA) by radioenzymatic assay 30 min after injection of NDS-1015 to inhibit aromatic L-amino acid decarboxylase activity. Males were killed at night either 15 or 30 days after castration or sham-operation. The levels of DOPA measured in striatal slices and in limbic forebrain (Nucleus Accumbens plus lateral septal region) were identical in castrated and sham-operated males at both postoperative times. Thus we were unable to confirm the report (Engel et al., 1979, Pharm. Biochem. Behav. 10:149) of increased DOPA accumulation in each of these neural tissues after castration.

Dopamine metabolism was studied in striatum and limbic forebrain by estimating the levels of 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) using high pressure liquid chromatography. Males were again killed 15 or 30 days after castration or sham-operation. In striatum the levels of DOPAC were significantly lower in castrated males 30 days post-operatively. Striatal HVA also tended to be lower in castrates than in sham-operated males at both times, although this difference did not reach statistical significance. In limbic forebrain no significant differences between castrated and sham-operated males were detected in DOPAC or HVA, although DOPA levels tended to be lower in castrates both 15 and 30 days postoperatively. The results are consistent with the notion that testicular steroids, or their neural metabolites, normally facilitate the release of dopamine in the male rat striatum and thereby contribute to the activation of sexual behavior.

1472 CHARACTERISTICS OF CATECHOLAMINERGIC NERVES IN THE NEUROINTERMEDIATE LOBE OF THE RAT PITUITARY. R.H. Alper, K.T. Demarest and K.E. Moore. Dept. Pharmacol. & Toxicol., Michigan State Univ., East Lansing, MI 48824.

Histochemical fluorescent techniques have revealed that the neurointermediate lobe (NIL) of the rat pituitary contains catecholaminergic nerves (Björklund, Z. Zellforsch. 89: 573, 1968). Dopamine (DA) nerves terminating in the NIL originate in the arcuate nucleus, forming the tuberohypophyseal system; there is some controversy concerning the origin of the norepinephrine (NE) nerves. Using a radioenzymatic assay it was determined that the rat NIL contains approximately 7 ng DA/mg protein and 2 ng NE/mg protein. Superior cervical ganglionectomy reduced the content of NE by one-third but did not alter the content of DA. This suggests that all of the DA and two-thirds of the NE in NIL is contained within nerves of central origin. The activity of the catecholamine nerves was estimated by determining the rate of turnover of DA and NE in the NIL. The concentrations of both monoamines declined exponentially following the administration of α-methyltyrosine (250 mg/kg, i.p.). Synthesis rates calculated from these data revealed that the synthesis of NE (0.3 ng/mg protein/hr) is much less than that of DA (2.6 ng/mg protein/hr).

The activity of nigrostriatal DA nerves has been estimated by quantifying the accumulation of DOPA in the striatum after the inhibition of DOPA decarboxylase. Since the synthesis of DA (estimated from decline of this amine after α-methyltyrosine) represents 90% of the total catecholamine synthesis in the NIL, the accumulation of DOPA in NIL should be appropriate for estimating the activity of tuberohypophyseal DA nerves. In the following experiments the concentration of DOPA in various brain regions containing DA nerve terminals was measured 30 minutes after administration of 3-hydroxybenzylhydrazine (NSD 1015, 100 mg/kg, i.p.). DOPA accumulation increased in the NIL, but not in the median eminence or striatum, after 48 hr of water deprivation or the addition of 2% NaCl to the drinking water. DOPA accumulation was also selectively increased in the NIL 60 and 90 min following the administration of α-melanocyte stimulating hormone (100 µg/kg, s.c.). These results suggest that DA nerves of the tuberohypophyseal system are regulated, in part, by hormones released from NIL. (Supported by USPHS grants NS09174, Fellowship NS06026 and Training Grant GM07392.)

1473 SUPPRESSION OF LORDOSIS BEHAVIOR IN THE FEMALE RAT DURING MESENCEPHALIC ELECTRICAL STIMULATION. Gary W. Arendash* and Roger A. Gorski. Dept. Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

It has been shown that serotonin (5HT) may play an inhibitory role in the control of sexual receptivity in the rat. Since all known serotoninergic neurons have their cell bodies within the brainstem raphe nuclei, the effects of biphasic electrical stimulation of the mesencephalic raphe nuclei and adjacent periaqueductal grey (PAG) on lordosis behavior were investigated, using four different sets of stimulation parameters. Ovariectomized, estrogen-primed animals that had been previously implanted with concentric bipolar electrodes were tested between 4-8 hrs after a progesterone injection (0.5 mg) which normally produces high levels of receptivity during this period. A 25 mount control period was obtained prior to each stimulation period, which also lasted for 25 mounts. Most rats were tested with 3 or often all 4 sets of stimulation parameters. During stimulation within the dorsal raphe nucleus (DRN) at frequencies of 10/sec (0.5 msec pulse duration) or 2/sec (2 msec pulse dur.), lordosis behavior induced by male rat mounting remained at high control levels. However, DRN stimulation at frequencies of 100/sec (0.5 msec pulse dur.) or 10/sec (2 msec pulse dur.) caused a marked and immediate suppression (53% and 56%, respectively) in receptivity ($p<0.001$). This suppression may not be due to activation of serotoninergic neurons originating in the DRN since DL-p-chlorophenylalanine (320 mg/kg, an inhibitor of 5HT synthesis), given 71 h prior to stimulation, did not modify the suppression. In contrast to the effects induced by DRN stimulation, activation of the median raphe nucleus had no significant effect on lordosis. However, stimulation within the PAG adjacent to the DRN at a frequency of 10/sec (0.5 or 2 msec pulse dur.) produced an immediate, dramatic decrease (81% and 80%, respectively) in receptivity ($p<0.001$), although PAG stimulation at frequencies of 100/sec (0.5 msec pulse dur.) or 2/sec (2 msec pulse dur.) was ineffective. All currents used were below threshold for eliciting noticeable behavioral effects, and never exceeded 200 uA. These results indicate that electrical stimulation of the mesencephalic DRN-PAG region in highly receptive estrogen-progesterone treated rats can markedly suppress lordosis behavior. This suppression could be due to either 1) activation of a midbrain ascending neuronal pathway(s), such as the dorsal longitudinal fasciculus in the PAG; or 2) activation of a descending inhibitory pathway(s) originating in or passing through the DRN-PAG region which may inhibit the lordosis reflex arc at the level of the medulla or the spinal cord. Since the DRN-PAG region contains significant numbers of estradiol-concentrating cells, estrogen may act to decrease the efficacy of a DRN-PAG inhibitory pathway, thus removing a tonic inhibitory influence on the reflex arc for lordosis. (Supported by HD-01182 and F32 HD-05671).

1474 HORMONE ACCUMULATION IN THE BRAIN OF THE ZEBRA FINCH AFTER INJECTION OF VARIOUS STEROIDS AND STEROID COMPETITORS. Arthur P. Arnold. Dept. Psychol. and Brain Res. Inst., UCLA, Los Angeles, CA 90024.

In castrated male zebra finches (Poephila guttata), the autoradiographic method was used to determine the distribution of hormone accumulating cells in selected brain regions after injection of tritiated testosterone (T), 5α dihydrotestosterone (DHT), or estradiol (E). The brain regions selected for analysis all show cellular accumulation of hormone after T injection. They were: the magnocellular nucleus of the anterior neostriatum (MAN), caudal nucleus of the hyperstriatum ventrale (HVc), robust nucleus of the archistriatum (RA), nucleus intercollicularis (ICo), tracheosyringeal portion of the hypoglossal motor nucleus (nXIIts), periventricular magnocellular nucleus (PVM), and infundibular region (INF). The first five of these brain areas are thought to be involved in the control of song and other vocalizations, and the last two are hypothalamic regions.

Labelled cells are found in MAN, HVc, RA, and nXIIts after injection of T and DHT but not after E; labelled cells are found in ICo after injection of any of these; in PVM and INF, labelling is greatest after E and least after DHT.

Other males were injected with one of a number of non-radioactive steroids before receiving an injection of tritiated T to determine which steroids would prevent cellular accumulation of radioactivity, presumably by competing for receptor sites. Non-radioactive steroids used as pre-injected competitors were T, DHT, E, cyproterone acetate (Cyp A), androstenedione (AE), and androstanedione (AA), and these were injected at 1000 or 100 times the dose of tritiated T. Non-radioactive T was effective in eliminating cellular accumulation in all brain regions. The other steroids, when injected at the 1000 times dose, reduced accumulation in all brain regions to some extent. However, DHT, Cyp A, and AA were relatively more effective in their competition in MAN, HVc, and nXIIts, and less effective in PVM and INF. E and AE were more effective in PVM and INF, and relatively less effective in MAN, HVc, and nXIIts. These results, when taken together, suggest that T or its non-aromatized metabolites are predominantly accumulated in cells in MAN, HVc, RA, and nXIIts, whereas T or its aromatized metabolites are predominantly accumulated in PVM and INF.

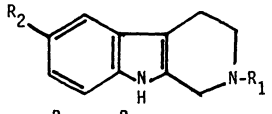
1475 THE IDENTIFICATION AND QUANTIFICATION OF 1,2,3,4-TETRAHYDRO-β-CARBOLINE AND 6-METHOXY-1,2,3,4-TETRAHYDRO-β-CARBOLINE IN RAT BRAIN AND ADRENAL GLAND. S. A. Barker* and R. E. Harrison* (SPON: J. A. Monti), Neurosciences Program, University of Alabama in Birmingham, B'ham, AL 35294.

GC/MS analyses of rat brain and adrenal gland extracts have led to the identification of 1,2,3,4-tetrahydro-β-carboline (THBC) and 6-methoxy-THBC (6-MeO-THBC) as naturally occurring constituents of these tissues. Trace amounts of 2-methyl-THBC (2-MTHBC) were also identified.



R_1	R_2		
H	H	=	THBC
H	OCH_3	=	6-MeO-THBC
CH_3	H	=	2-MTHBC

Rat brains and adrenal glands from individually housed animals were homogenized and spiked with deuterated standards for 6-MeO-THBC and THBC. The samples were extracted and derivatized to form the corresponding heptafluorobutyryl compounds (Barker et al., Biochem. Biophys. Res. Commun. 87:146-154, 1979). Analyses were conducted by selected ion monitoring, comparing ion mass ratios and retention times of the added deuterated standards with peaks for the endogenous β-carbolines.

	THBC	6-MeO-THBC	2-MTHBC
BRAIN	17.5 ± 4.86 ng/g	35.6 ± 16.6 ng/g	TRACE
ADRENAL	325 ± 45 ng/g	1113.7 ± 300 ng/g	TRACE

The implications of these findings, in view of the known pharmacological effects of these compounds on amine uptake and monoamine oxidase activity, will be discussed.

1476 DECREASED SODIUM CONSUMPTION AND IMPAIRED NATRIURESIS FOLLOWING ELECTROLYTIC ABLATION OF ANTEROVENTRAL THIRD VENTRICLE (AV3V) PERIVENTRICULAR TISSUE IN RATS. S. L. Bealer, M. J. Brody*, J. R. Haywood*, G. D. Fink*, K. A. Gruber*, V. M. Buckalew*, and A. K. Johnson. Cardiovascular Center, Univ. Iowa, Iowa City, IA 52242 and Bowman Gray School of Med., Winston-Salem, NC 27103.

Electrolytic ablation of anteroventral third ventricle (AV3V) periventricular tissue results in temporary adipsia, chronic hypernatremia and expanded blood volume, suggesting that mechanisms of sodium regulation are altered. The present experiments were designed to determine if AV3V lesions change sodium consumption under ad lib conditions and the natriuresis typically seen following isotonic blood volume expansion.

Rats were maintained on sodium deficient chow with continuous access to 2.0% NaCl solution and water. Animals were equated for sodium solution intake and received either electrolytic lesions in the AV3V region or sham lesions. NaCl solution and water intakes were recorded for 16 days postsurgery and following the hyponatremia induced by s.c. Formalin. Separate groups of animals underwent AV3V ablation or sham lesions. These animals were implanted with venous, arterial and bladder catheters, and isotonic NaCl solution was infused intravenously at .51 ml/min until 10% of body weight was given. Urine and sodium excretion was measured during the infusion period. In addition, blood samples were taken, pooled and bioassayed for natriuretic hormone according to the procedures of Gruber and Buckalew (Proc. Soc. Exp. Biol. Med., 159:463-467, 1978).

Animals with lesions surrounding the AV3V consumed significantly less sodium solution and showed lower sodium preference following surgery than sham lesioned animals. However, both groups increased sodium solution consumption following s.c. Formalin. These data indicate that AV3V lesions attenuate sodium intake but do not render animals insensitive to their sodium levels.

In addition, AV3V lesioned animals showed markedly attenuated urine and sodium excretion compared to control animals during volume expansion. Bioassay for natriuretic hormone revealed high levels in control animals, while no activity was seen in blood samples from animals with AV3V lesions.

These data demonstrate that rats with AV3V periventricular tissue lesions ingest less sodium than controls while on sodium deficient chow, but remain sensitive to body sodium concentrations. In addition, rats with AV3V lesions have a low capacity for natriuresis when volume expanded. This could be the result of impaired release of natriuretic hormone. These studies suggest that the integrity of the AV3V periventricular tissue is essential for normal sodium regulation.

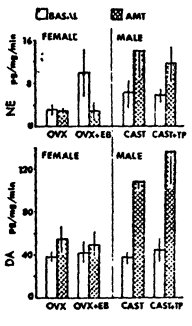
1477 A SEX DIFFERENCE IN THE ENDOGENOUS RELEASE AND IN THE EFFECT OF TEMPERATURE ON THE RELEASE OF PROLACTIN AND LH FROM THE ANTERIOR PITUITARY OF RATS IN PERIFUSION. Deborah Beaudry* and V.D. Ramirez (SPON: R. Gillette). Dept. of Physiol. and Biophys. and Neural and Behavioral Biology Program, Univ. of Illinois, Urbana, IL 61801.

Holtzman rats were decapitated at the same time each afternoon, the anterior pituitary gland removed and immediately placed in ice cold Krebs Ringer phosphate buffer glucose-BSA medium at pH 7.4. Pituitary glands were quartered and placed into individual perifusion chambers bubbled with a mixture of 95% O_2-5% CO_2, and maintained in a 37°C water bath. The medium was pumped into the chambers at a constant rate of 1 ml/4 min. After a 1 hour stabilization period perifusate was collected in 4 min intervals on ice. The samples were stored at -20°C until the RIA's were performed. The average release rate of prolactin from female glands was, diestrus: 4.00±.28; proestrus: 3.98±.27 and estrus: 4.62±.30. The average rate of prolactin release from male glands was 2.13±.10. The release rate of LH in females was, diestrus: 2.70±.12; proestrus: 4.89±.47; and estrus: 5.40±.38 while in males was 16.5±1.5. The effect of temperature on this system was analyzed as part of the validation of the technique. As expected the basal release of prolactin decreased for both males and estrous females when the temperature was lowered from 37°C to 0°C. In two estrous female glands the rate of prolactin release decreased from 3.6 and 2.8 ng/mg/min to 0.46 and 0.81 ng/mg/min, respectively. Prolactin secretion from male glands (n=6) went from 2.06±.20 at 37°C to 0.67±.05 at 0°C. Pituitary LH release showed quite a different response. In the male, decreasing the temperature resulted in a marked stimulation of this release from 18.0± 2.7 to 61.1±4.6 (n=6). In two estrus female rats the anterior pituitary glands did not respond to the challenge of temperature: the release rates were 4.10 and 5.70 ng/mg/min at 37°C and 5.10 and 5.40 ng/mg/min at 0°C, respectively. In summary, pituitary glands perifused in vitro show a clear sexual difference in the endogenous release rates of both prolactin and LH. In addition, 0°C temperatures reduced the secretion rates of prolactin in both male and female pituitaries. In marked contrast, LH secretion from the male gland increased with decreasing temperature. Curiously, the temperature change produced no observable effect on LH release from the pituitaries of estrous females.

1478 SEX DIFFERENCES IN THE AMPHETAMINE STIMULATED RELEASE OF ENDOGENOUS CATECHOLAMINES IN VITRO. Jill Becker and V.D. Ramirez. Dept. of Physiology and Biophysics and Neural and Behavioral Biology Program, Univ. of Illinois, Urbana, IL 61801.

Employing a perifusion system from which the release of endogenous norepinephrine (NE) and dopamine (DA) can be measured (Neurosci. Abst. 4, 267, 1978), we have investigated the effects of gonadal steroids on basal and 10^{-3}M d-amphetamine sulfate (AMT; initial conc. in chamber) stimulated release of catecholamines (CA) from brain tissue fragments.

Small pieces of tissue were taken from the medial basal hypothalamus (MBH) and striatum of intact males, castrated males + 500 µg testosterone propionate (CAST + TP) and castrated males + oil (CAST); as well as from ovariectomized females + 5 µg estradiol benzoate (OVX + EB) and OVX + oil. Tissue was taken 11 days after surgery; TP, EB or oil admin. last 4 days. Six animals were used for each of these perifusions. Striatal tissue was also taken from intact females on each of the 4 days of the estrous cycle, but only 1 animal was used for these experiments.



Release of NE and DA from striatal fragments of male and female rats by AMT: effect of castration and hormone replacement (n=3)

In the male groups, a pulse of AMT stimulated a dramatic release of both NE and DA from the striatum and MBH. Neither CAST nor CAST + TP had any effect on the AMT stimulated release of the CA's. In females, AMT stimulation of the striatum in OVX and OVX + EB did not result in release of either CA. In contrast, MBH taken from OVX + EB but not OVX + oil responded to AMT with release of both NE and DA. During the estrous cycle, there was a fluctuation in the responsiveness of striatal tissue to AMT. NE release was observed only on diestrus-2. However, release of DA was seen on all days of the cycle except proestrus. In addition, basal release of DA and NE was highest during proestrus, a time when tissue levels of DA are also their highest (Crowley et al., Brain Res. 147, 315, 1978).

In conclusion, a clear sex difference in the in vitro amphetamine-stimulated release of CA's from these two areas of the brain has been demonstrated. This AMT-stimulated release is dependent on the in vivo presence of gonadal steroids in females but not in males. (RIAS Grant NSF-SER 76-18255)

1479 HORMONE ACCUMULATION IN MOTONEURONS INNERVATING PENILE STRIATED MUSCLES IN THE RAT. S.Marc Breedlove and Arthur P. Arnold. Dept.Psychol. and Brain Res.Inst., UCLA, Los Angeles, CA 90024.

Male rats with a mid-thoracic spinal transection display clusters of penile flips in response to restraint of the preputial sheath (B.Hart, Science 155, 1283, 1967). In castrated males these spinal reflexes are maintained by daily injections of testosterone (T). These penile reflexes can also be maintained by the implantation of T in the spinal cord, without causing an increase in accessory sex gland weight (Hart & Haugen, Phys. & Bhr.3, 735, 1968). This latter finding, in conjunction with the report of Sar & Stumpf (Science 197, 77, 1977) that spinal motoneurons accumulate 5α-dihydrotestosterone (dhT) or its metabolites, suggests that the T may facilitate these reflexes by direct action on the spinal cord. We now report the use of horseradish peroxidase (HRP) to localize motoneurons innervating penile muscle that may be involved in these spinal reflexes. We also report autoradiographic studies showing that the motoneurons of this particular spinal region are labeled after injection of tritiated T or dhT, but not estradiol (E).

The muscle bulbocavernosus of male rats was injected with 15-30 µl of 30% HRP. After 24 hours the rats were sacrificed and the lumbar through coccygeal spinal cord removed, sectioned, and the HRP stained by a modification of the de Olmos method. Labeled motoneurons were consistently found in the medial ventral horn, adjacent to the ventral funiculus and 200-400 µ ventral to the central canal, from L4 to S1, especially L5 and L6.

For the autoradiographic study, radioactively labeled T, dhT, or E was injected i.v. into previously castrated and adrenalectomized male rats (N=3 per hormone). The rats were sacrificed 1 hour later, the spinal cord (L1 to Co3) frozen, sectioned, and processed for autoradiography. Following injection of labeled T or dhT, neurons that accumulated radioactivity (i.e. had 5 times the background level) included motoneurons in the area labeled following injection of HRP into the bulbocavernosus muscle. The hormones were also accumulated by other motoneurons of the ventral horn, lamina X of Rexed, the sacral and lumbar intermediolateral nucleus, and a few cells of the dorsal horn. These results agree with those of Sar & Stumpf (1977). Estradiol, or its metabolites, was not taken up by the motoneurons, but was taken up by neurons of lamina X and cells of the dorsal horn, especially laminae I and II, confirming the results of Pfaff & Keiner (J.Comp.Neurol. 151, 121, 1973) and Keefer et.al. (Proc.Soc.Exp.Biol.Med. 143, 414, 1973).

1480 DOPAMINE ANTAGONIST ACTIVITY OF TETRAHYDROISOQUINOLINES. D. R. Britton, C. Rivier*, T. Shier*, F. Bloom and W. Vale. Peptide Biology Lab. and Alcohol Research Center, The Salk Institute, La Jolla, CA 92037.

Tetrahydroisoquinolines (TIQ's) have been tested for their ability to act as opiate and dopamine receptor agonists or antagonists in several systems. The TIQ's were tested for their in vivo and in vitro capacity to modulate prolactin (PRL) secretion from the pituitary and for their ability to antagonize the binding of ^{3}H-Naloxone and ^{3}H-Spiroperidol to membrane preparations from rat hypothalamus and from bovine anterior pituitary. Receptor binding studies demonstrate that some TIQ's could be classified as having higher affinity for opiate receptors (tetrahydropapaverine, papaverine, 6-methyl-salsolinol, i-carboxysalsolinol and 3,4-deoxynorlandanasoline carboxylic acid), others having higher dopamine receptor affinity (salsolinol and 7-methyl-salsolinol) or approximately equal affinity for the two binding sites (6,7-dimethylsalsolinol and tetrahydropapaveroline). Freely moving male Sprague-Dawley rats were prepared with indwelling venous catheters for administration of various TIQ's and blood sampling for assessment of PRL immunoreactivity. Tetrahydropapaveroline (THP) which was equipotent in binding to dopamine and opiate receptors produced a several-fold increase in plasma PRL. This finding might result from either an agonist effect at extrapituitary opiate receptors or a dopamine antagonist effect at the level of the pituitary. This latter hypothesis is supported by the observation that concomitant administration of the opiate antagonist, naloxone, did not block the stimulatory effect of THP on PRL secretion while dopamine significantly reduced THP-induced PRL secretion.

Incubation of rat anterior pituitary cells with TIQ's produced no changes in basal secretion of PRL. However, several TIQ's shown to compete with ^{3}H-Spiroperidol for binding sites were effective in reversing the inhibition of PRL secretion by dopamine. The potency of the various TIQ's in this system correlates well with their ability to displace ^{3}H-Spiroperidol from binding sites. The data derived from these three systems support the hypothesis that THP and other TIQ's stimulate PRL secretion by their ability to act as dopamine antagonists.

1481 CATECHOLAMINE SECRETION BY ELECTRICALLY STIMULATED SLICES OF BOVINE ADRENAL MEDULLA. J.C. Brooks, D.H. Burke* and S. Treml*. Dept. Basic Sci., Sch. Dent., Marquette Univ., Milwaukee, WI 53233.

Chemical stimulation has been used in numerous studies of catecholamine secretion from slices of adrenal medulla. However, chemical stimulation cannot simultaneously excite all of the cells in the slice because of the time required for diffusion of the secretagogue to reactive sites in the interior of the slice. In contrast, electrical stimulation should simultaneously excite all of the chromaffin cells in the tissue slice. Therefore, we felt that electrical stimulation might provide the basis for kinetic experiments involving stimulus-induced secretory processes, including ion movements, protein synthesis and catecholamine synthesis and release.

The studies reported here have been designed to determine if electrically-induced catecholamine secretion is real, and not a consequence of cell damage or secretion secondary to stimulation of cholinergic terminals remaining in the tissue. Thin slices of bovine adrenal medulla were stimulated in air with teflon mesh-covered platinum electrodes applied to two surfaces. Catecholamine secretion for 24 mm^2 slices was linearly related to voltage from 20-60 volts using the following stimulus parameters: square monophasic pulses of 0.8 m sec. duration, 50/sec for 10 sec. Secretion was not enhanced by increasing voltage over the range 60-100 volts. At 60 volts electrically-induced secretion is about 2.5 times that of unstimulated control slices, a value comparable to that for carbachol-induced secretion. Lactic dehydrogenase (LDH) release after stimulation was used to determine if apparent catecholamine secretion was due to electrically-induced cell damage. For both unstimulated and electrically stimulated slices, the amount of LDH release was about 7% of the total tissue content of the enzyme, indicating that secretion is not due to cell damage.

Electrically-induced secretion was not affected by the presence of the muscarinic antagonist atropine (0.01 mM) while 0.01 mM hexamethonium, alone or in mixtures with atropine, reduced secretion by 27%. Thus, approximately 75% of the electrically-induced secretion is due to direct stimulation of the chromaffin cells, the remainder being secondary to acetylcholine release by cholinergic terminals present in the tissue slice.

Acetylcholine-induced secretion from chromaffin cells is dependent upon extracellular calcium concentration. With electrical stimulation in calcium-free medium, secretion was reduced by only 19% compared to stimulation in complete or calcium-enriched media. Thus it appears that sufficient calcium for a nearly normal secretory response is available from internal cellular compartments.

Based upon these results, electrical stimulation is a useful means of evoking secretion. (Supported N.I.H. 1508 RR 09076-01).

1482 SERUM PROLACTIN IN HUMANS PARALLELS NEUROLEPTIC INDUCED CHANGES IN DOPAMINE RECEPTOR SENSITIVITY. Walter Armin Brown, Thomas P. Laughren# and Phillip H. Robzyk#. Neuroendocrine Res. Lab. VA Medical Center and Brown University, Providence, RI 02908

Studies of nigrostriatal and mesolimbic dopamine (D) activity in rats have consistently shown an increase in D receptor sensitivity and receptors following withdrawal from neuroleptic (N). We and others have also shown enhanced D receptor sensitivity in tuberoinfundibular D system following N treatment as indicated by changes in both baseline and apomorphine induced serum prolactin (pro) concentration. We now report that patients withdrawn from chronic N treatment, maintained drug-free for several months and then treated acutely with N, show systematic predictable shifts in serum pro which parallel the changes in central D activity observed in rat studies.

Subjects were 20 male schizophrenics who had been taking N for 2 to 15 years. They were maintained on their usual dose of N for 2 weeks, had N gradually withdrawn over 2 weeks, and were then maintained drug-free indefinitely or until symptoms warranted resumption of N. Blood samples were drawn between 8 and 9 a.m. once weekly following an overnight fast at which time patients also underwent clinical assessment. Serum pro was measured by radioimmunoassay.

Serum pro showed systematic changes over time during and following N withdrawal ($F=2.74$ $p<.025$). Mean pro fell rapidly during N withdrawal reaching its lowest point (2.8 ± 0.9 ng/ml) one week after complete withdrawal. After this first drug-free week, pro rose to a stable baseline level (3.9 ± 1.5 ng/ml) which showed little variation over the ensuing drug-free weeks and months. In all patients pro was lower after the first drug-free week than in subsequent drug-free weeks. The mean pro after return to N treatment was considerably higher (mean=86%) than that during chronic treatment. In all instances, pro was highest during the first week of acute N treatment showing a slight but consistent fall over subsequent weeks. Patients with tardive dyskinesia had a more rapid rate of fall in pro following N withdrawal than those without tardive dyskinesia, and also showed the greatest change in pro between chronic and acute N treatment.

Our findings of transient enhanced inhibition of pro secretion following N withdrawal and both early and delayed tolerance to the pro elevating effects of N parallel the known N-induced changes in receptor sensitivity and D turnover. These data suggest that assessment of serum pro under suitably controlled conditions may provide a method for identifying patients who have disorders involving alterations in central D systems.

1483 EFFECTS OF ADIPSIA-PRODUCING LESIONS OF THE ANTEROVENTRAL THIRD VENTRICLE (AV3V) ON FINE STRUCTURE OF THE SUPRAOPTIC NUCLEI AND NEURAL LOBE IN THE RAT. J.R. Carithers*, H.-D. Dellmann*, S.L. Bealer, M.J. Brody and A.K. Johnson (Spon: D.G. Emery). Dept. Vet. Anat. ISU, Ames, IA 50011 and Dept. Pharm. Sch. Med., SUI, Iowa City, IA 52240.

Small lesions of the AV3V in rats cause adipsia, but there is no compensatory antidiuresis, and plasma levels of antidiuretic hormone (ADH) are lower than control values. Therefore, the ultrastructure of the supraoptic nucleus (SON), the main site of synthesis of ADH, and the neural lobe of the hypophysis (NL), where ADH is stored and released, were examined in rats which had received adipsia-producing lesions in the AV3V three days earlier. Controls were rats which had received sham lesions three days earlier and intact rats deprived of water for three days. The fine structure of the SON and NL of sham lesioned rats resembles that of intact animals. Neuronal somas in SONs of water-deprived rats show signs of stimulated secretory activity. The sizes of the cells, their nuclei and especially nucleoli are increased, endoplasmic reticulum is hypertrophied and more often dilated and a striking accumulation of neurosecretory granulated vesicles (NGV), especially dense immature forms, occurs. A considerable decrease in the number of NGV is observed in many axons of the NL, and numerous axon terminals are devoid of NGV and contain only electron lucent vesicles of varying sizes; frequently an extensive smooth axonal endoplasmic reticulum and large vacuoles occur within these axons.

In rats rendered adipsic by AV3V lesions, most neuronal somas in the SON resemble those of sham lesioned animals, although occasional cells contain accumulations of NGV. Degenerating fibers are common, and nerve terminals undergoing degeneration are present in axodendritic synapses and synapses on neurosecretory somas. In the NL of AV3V-lesioned rats many axons and axon terminals are enlarged and contain an increased number of NGV, usually densely packed; abundant dense bodies and multilamellar bodies are evidence of increased crinophagic activity. Occasional axons are degenerating and being phagocytosed by pituicytes.

Responses to osmotic stimuli and to angiotensin are abolished or severely attenuated in rats with AV3V lesions. It appears likely that degenerating axons and terminals present in SONs of lesioned rats are processes of osmoreceptors and angiotensin receptors, the somas or fibers of which are damaged by effective lesions. Consequently, in this study the ADH-producing neurons were not stimulated by the severe dehydration to release their NGV. Their accumulation in the NL indicates that synthesis and transport of NGV is not impaired within this time period.

1484 TEMPORAL EFFECTS OF MELATONIN: MORNING INJECTIONS OF MELATONIN ABOLISH THE REPRODUCTIVE INHIBITORY EFFECTS OF AFTERNOON INJECTIONS OF MELATONIN IN THE FEMALE SYRIAN HAMSTER. H. J. Chen*, G. C. Brainard*, and R. J. Reiter, Dept. of Anatomy, UTHSC at San Antonio, Texas 78284.

In male or female Syrian hamsters kept under a light:dark cycle of 14:10, melatonin (Mel) exerts inhibitory effects on gonadal function only if injected in the late afternoon or shortly before the onset of darkness. In male hamsters, such an effect can be blocked by the subcutaneous implantation of Mel pellets (Reiter et al., Endocr. Res. Commun. 4:35, 1977). The purpose of the present experiment was aimed at determining if the inhibitory effects of afternoon (p.m.) administration of Mel on gonadal function could be blocked by a large dose of Mel given in the morning (a.m.) or by 5-methoxytryptophol (5-Mtol) given 1 hour preceeding the p.m. injection of Mel. Female Syrian hamsters, 3-4 months of age, were kept under LD 14:10 (lights were on from 0600 to 2000 hours) and were given either vehicle (Veh) at both 11 a.m. and 5 p.m. (controls); 1 mg Mel at 11 a.m. and Veh at 5 p.m.; 1 mg Mel at 11 p.m. and 25 µg Mel at 5 p.m.; 100 µg 5-Mtol at 4 p.m. and 25 µg Mel at 5 p.m.; or Veh at 4 p.m. and 25 µg Mel at 5 p.m. Daily vaginal discharges were examined to determine the stage of the estrous cycle and, at the end of the experiment, reproductive organ weights were recorded. By the eighth week of treatment, 80 to 100% of animals in groups treated with 25 µg Mel at 5 p.m. and Veh in the morning, or 5-Mtol or Veh at 4 p.m. stopped cycling. Their uteri were infantile in appearance and uterine weights were significantly ($P<0.001$) depressed. Controls or animals injected with 1 mg Mel at 11 a.m. and Veh or 25 µg Mel at 5 p.m. demonstrated normal 4-day estrous cycles throughout the experiments. Uterine weights were 3 times larger than those of the animals treated with p.m. Mel without a.m. Mel. These results indicate that a single injection of 1 mg of Mel in the morning can render the neuroendocrine-reproductive axis of the female Syrian hamster completely refractory to the inhibitory effect of the late afternoon injections of Mel. It is postulated that the relatively large dose of Mel given in the morning had so saturated the Mel receptors of the target tissues that the p.m. injection of Mel could no longer exert its inhibitory effects. Presumably the Mel receptors are down regulated by the administration of the indoleamine itself. (Supported by NSF Grant No. PCM 77-05734).

1485 THE RESPONSE OF HIPPOCAMPAL CA1 PYRAMIDS TO GONADAL STEROIDS: In Vivo Effects of Estradiol in Male Rats. Nicolas L. Chiaia, Richard M. Vardaris, and Timothy J. Teyler. Kent State Univ., Kent, OH 44242 and Northeastern Ohio Universities College of Medicine, Rootstown, OH 44266.

In a prior experiment we observed gender-related changes in the excitability of CA1 pyramidal cells when gonadal steroids were administered to hippocampal slice preparations (Vardaris & Teyler, 1978, Neurosci. Abst., no. 1145). Enhanced amplitudes of CA1 field potentials were obtained from male slices 10 and 20 minutes after exposure to 100 pM 17-beta-estradiol in the superfusate. The present study was designed to determine whether similar effects occur in the intact preparation.

Male rats were curarized and respirated with room air and metafane gas during stereotaxic surgery. Wound margins and pressure points were procainized. Final placement of the recording micropipette tip in the cell body layer of CA1 and the tip of the steel stimulating electrode in the Schaffer collateral system was verified electrophysiologically through laminar analysis. A presteroid input/output function was recorded 40 minutes after withdrawal of general anesthesia. Stimulus voltages were selected to permit recordings of extracellular EPSPs as well as population spikes. The presence of paired-pulse facilitation and recurrent inhibition served as criteria for appropriate physiological status of the preparations.

One hundred and 200 microgram doses of 17-beta-estradiol benzoate were administered by intraperitoneal cannulation. Input/output functions were obtained 20, 40, and 60 minutes after infusion of the steroid. The same series of stimulus intensities was used in all input/output functions for a given preparation. Analysis of the recorded potentials revealed that both dosages increased the amplitudes of monosynaptic EPSPs and population spikes in the CA1 subfield. This effect was reflected in steepened slopes of the post-steroid input/output functions with no significant change in thresholds.

These results are consistant with our findings using in vitro slices from male hippocampus. It thus appears that the changes in excitability produced by estradiol can be obtained from intact preparations in the presence of normal metabolism.

1486 BIOCHEMICAL CHARACTERIZATION OF LHRH ACTIVITY IN HYPOTHALAMUS, PITUITARY PORTAL PLASMA AND SYSTEMIC PLASMA OF RAT. Melvin Ching, Dept. Anat., Med. Col. of Virginia, Richmond, Va. 23298.

Current studies focused on the separation, by electrophoresis followed by solvent run on TLC plates, of LHRH immunoreactive elements in methanol or acetic acid-ethanol extracts of systemic plasma, portal plasma and hypothalami. The specificity of our radioimmunoassay was re-examined by quantitating the displacement of radiolabelled LHRH from the Sorrentino E22 and F3 antibodies by LHRH analogues relative to equal weights of synthetic LHRH. RIA of eluates of silica gel scrapes from all TLC plates to which extracts were applied revealed LHRH activity confined to a radius not exceeding 2 cm from where synthetic LHRH spots. This region comprised less than 3% of the plate's surface area. Patterns of peak immunoreactive LHRH distribution of both extracts of systemic plasma were similar and fell within the zone of 3H-LHRH migration. LHRH extracted from portal plasma was more evenly dispersed over a wider area encompassing zones of radiolabelled and non-labelled synthetic LHRH migration. Hypothalamic LHRH also displayed a dispersed profile, similar to that of portal plasma, but with more components that exhibited lower and higher electrophoretic mobility. Only portal extracts exhibited a sizeable component (25%) having slightly lesser Rf values. Progressive declines in displacement of radiolabelled LHRH from the E22 antibody occurred with D ala^6 (67%), D phe^2, D ala^6 (51%), Des gly^{10} ethylamide (21%), and D ala^6, Des gly^{10} ethylamide (4%) LHRH analogues when compared to synthetic LHRH (100%). However, amino acid substitutions at the 6 or 2 and 6 positions resulted in marked enhancement of binding affinity to the F antiserum (522% and 576%, respectively) whereas removal of glycine at the C-terminal with or without alanine substitution at position 6 caused precipitous declines in relative activity (1% and 0%, respectively). Moreover, 11 TLC zones were simultaneously tested for LHRH activity with E and F antisera and in 5 of these the F antiserum measured more than 10 times the quantity of LHRH as the E. Precipitous declines in exogenous LHRH activity in heated (30min at 60 deg. C) as well as unheated plasma occurred during the first 10min followed by smaller decrements or a plateauing of hormone decline over the remaining 30min to a final concentration of 100-300pg/ml. Thus, these studies suggest that the LHRH immunoreactive elements in hypothalamus, portal plasma and systemic plasma are biochemically similar with perhaps only minor modifications in molecular structure or configuration. Moreover, they point to the possible existence of a heat resistant enzyme whose action appears directed at the C-terminal. The possibility remains that more than 70% of the radioimmunoassayable LHRH in the peripheral circulation may exist as the Des gly^{10} analogue. These studies reiterate the importance of characterizing the antiserum employed in the radioimmunoassay. (Supported by USPHS Grant HD 12276).

1487 EFFECTS OF SEPTAL LESIONS WITH KAINIC ACID IN PREPUBERAL FEMALE RATS ON THE RELEASE OF LUTEINIZING HORMONE AND THE ONSET OF PUBERTY. Richard W. Clough* and Jorge F. Rodriguez-Sierra. Dept. Anat., Univ. Nebraska Med. Ctr., Omaha, NE 68105

Estradiol benzoate (EB, 5 µg/rat, sc in oil) injected into 25 day old Sprague-Dawley female rats results in a pronounced increase of plasma luteinizing hormone (LH) released from the pituitary gland during the afternoon two days later. Kainic acid (KA, 2.5 µg/2 µl), an excitotoxic analogue of glutamic acid, or saline were injected into the septal region prior to administration of EB. Plasma samples were obtained by jugular puncture at 1000 and 1600 hours two days after EB. Determination of plasma LH was made by RIA. Intraseptal administration of saline had no effect on the EB induced LH surge in plasma, in contrast to the administration of KA which markedly inhibited the response:

		Mean Plasma LH (ng/ml)	
Groups	(n)	1000 h	1600 h
Controls	6	15.8 ± 3.3	2918.3 ± 800.3
Saline infusion	6	22.5 ± 5.7	2521.2 ± 677.2
KA infusion	5	32.4 ± 10.5	130.2 ± 27.3

In order to test whether the septal area was involved in the normal onset of puberty in the female rat, a different group of animals received septal KA or sham lesions at 25 days of age and were monitored daily for vaginal opening (VO) and vaginal smear cyclicity. KA lesioned animals showed a delayed onset of VO in contrast to that of control rats. Sham-lesioned rats had a slight delay in the onset of their VO, probably due to non-specific damage by the vehicle saline infused into the septal area. Vaginal cyclicity was normal in all animals after VO. All rats reached puberty at approximately the same body weight, pointing to a delay in somatic growth in the KA and sham lesioned groups. Since KA destroys cell bodies without disrupting fibers of passage, our results suggest that intrinsic septal neurons are involved in the ontogenesis of the positive feedback of estrogen on LH release. In addition, our results point to a role of the septal area in the normal somatic development of the female rat and the development of events that lead to the onset of adult female reproductive ability. Supported by NIH grant HD-11011 and NSF RIAS-SER77-06922.

1488 CHANGES IN PITUITARY AND PLASMA LH LEVELS IN OVARIECTOMIZED RATS: EFFECTS OF NALOXONE, ACTH, PHOTOPERIOD AND ADRENALECTOMY. Ilene R. Cohen* and David R. Mann* (SPON: Jane Bos Downer). Dept. Biol. Sci., SUNY, Binghamton, NY 13901, and Dept. Physiol., School of Medicine, Morehouse College, 223 Chestnut St., SW, Atlanta, GA 30314.

The ability of naloxone to inhibit the actions of ACTH on LH secretion was examined in ovariectomized rats maintained in either a 14h light:10h dark (14:10) cycle or an 8h light:16h dark (8:16) schedule. Adult rats were ovariectomized (OVX) or ovariectomized and adrenalectomized (OVX/ADX) and implanted sc with a silastic capsule of naloxone. Beginning the following day and continuing for seven days rats received daily injections of ACTH (4IU/100g BW) at 1000h. Animals were sacrificed by decapitation at 1200h on day 7. Regardless of treatment, OVX animals housed in 8:16 had higher pituitary LH concentrations than those housed in a 14:10 schedule (43.9±2.5 vs 34.5±1.7µg/mg, $p<.002$). This effect of photoperiod was enhanced by naloxone; in 8:16 pituitary LH values were elevated by naloxone (47.5±4.2 vs 40.2±2.3µg/mg for sham implanted rats), and in 14:10 they were reduced (32.4±2.6 vs 36.4±2.1µg/mg for sham implanted rats). ACTH treatment did not affect pituitary LH levels in OVX animals. Plasma LH levels in OVX rats were not significantly altered by photoperiod or any treatment. Very different results were obtained with OVX/ADX rats. No effect of photoperiod on pituitary or plasma LH was seen in these animals. ACTH treatment increased pituitary LH (29.3±2.1 vs 23.8±1.5µg/mg for saline injected rats, $p<.03$), but had no effect on plasma LH. Naloxone significantly lowered plasma LH in OVX/ADX animals regardless of treatment or photoperiod (187.3±15.5 vs 283.7±25.4 ng/ml for sham implanted rats, $p<.002$), while having no effect on pituitary LH levels. Our data demonstrate that: (1) the action of naloxone on pituitary LH is influenced by the length of the photoperiod and the presence of the adrenal glands is necessary for this effect, and (2) only in the absence of the adrenal glands did ACTH elevate pituitary stores of LH. (Supported by NSF Grant no. PCM 79-06684)

1489 LOCAL INCREASE IN THE UPTAKE OF [^{14}C] 2-DEOXYGLUCOSE AFTER ELECTROCHEMICAL DEPOSITION OF IRON IN THE BRAIN. J.A. Colombo and S. Saporta, Department of Anatomy, College of Medicine, University of South Florida, Tampa, Florida 33612.

Since the original description by Everett and Radford (1961), electrochemical stimulation technique has been widely used in the field of neuroendocrinology. It has been assumed that delivering anodic direct current through a stainless steel electrode increases local neuronal activity, and that this increase in activity is mediated through the release of iron ions into the surrounding brain tissue. One of us has previously shown that multiunit activity recorded within the area of iron deposition undergoes a significant increase (Colombo et al, 1974; 1975). We now report evidence that electrochemical stimulation will increase the uptake of [^{14}C] 2-deoxyglucose within the area of iron deposition in the brain. Adult male rats were anesthetized with pentobarbital and an indwelling catheter placed in one femoral vein. A pair of electrodes were lowered stereotaxically into the preoptic suprachiasmatic region. The electrode pair consisted of an insulated 00 stainless steel insect pin and a 125µm teflon insulated platinum wire. The electrodes were allowed to stabilize for 10 minutes before the onset of 30µA ADC stimulation delivered for 30 sec sequentially through each electrode. Three to four minutes after stimulation, a bolus of 40µCi/100g body weight of [^{14}C] 2-deoxyglucose was injected in 0.5 ml of saline. The injection was completed in 1 minute. Thirty minutes later, the animal was decapitated, the brain removed and frozen. Brain sections (20µm) were taken alternately for either autoradiography or for identification of the area of iron deposition with Gamori's iron stain. The sections were exposed to x-ray film for 6 days. Autoradiographs show a clear increase in the concentration of the radiolabeled 2-deoxyglucose which overlaps with the area of iron deposition. A comparatively reduced concentration of labeled 2-deoxyglucose is visible immediately surrounding the lesioned area at the tip of the platinum electrode. These results indicate that iron deposition produced by electrochemical means results in increased local metabolic activity of the exposed neuronal population. Experiments with [^{3}H] 2-deoxyglucose are currently under way in order to analyze this effect in a more quantitative manner.

1490 EFFECTS OF GONADAL STEROIDS ON THE DEVELOPMENT OF THE HAMSTER CIRCADIAN PACEMAKER. Fred C. Davis*, Janet D. Alvis* and M. Menaker. Institute of Reproductive Biology, University of Texas, Austin, TX 78712.

Sexual dimorphism of the circadian pacemaker that underlies locomotor activity of hamsters has been previously reported (Alvis et. al., 1978, The Physiologist 21:). This dimorphism, measured as a difference in the ability of males and females to entrain to a light/dark cycle with a period greater than 24 hours (24.75), persists following castration, demonstrating that the dimorphism does not depend on circulating gonadal steroids or on estrus cyclicity. This suggests that sexual differentiation of the pacemaker occurs during development. The present study was carried out to determine if neonatal (within 24 hours of birth) castration or neonatal treatment with testosterone propionate affects the differentiation of the circadian pacemaker underlying locomotor activity in hamsters.

Three treatment groups were studied:

1) Neonatally sham castrated males and oil injected females
2) Neonatally castrated males and females
3) Neonatally injected (TP, 600µg,SC) males (simultaneously castrated) and females (castrated at 21 days of age).

Entrainment behavior of these groups was observed under a light/dark cycle identical to that used by Alvis et. al. The results are summarized below.

1) As previously reported, intact males showed a greater ability to entrain to this cycle than did females.
2) There were no differences among the three groups of males.
3) Both castrated and TP injected females were masculinized relative to intact females.

These results indicate that neonatal castration does not influence the male circadian pacemaker as tested in this entrainment paradigm. The female pacemaker, however, was dramatically affected by castration. Any effect of TP on the females is obscured by the prepubertal castration of these females. Confirmation of the importance of the ovaries will depend on additional studies that include prepubertal castration, neonatal estrogen treatment, and long term adult castration. Because the mechanisms underlying ovarian cyclicity include a circadian pacemaker, the present findings suggest that differentiation of the pacemaker may be involved in the differentiation of reproductive control mechanisms.

Additional evidence that gonadal steroids influence the mechanisms of circadian rhythmicity was seen in the effects of TP on the day to day variation of activity onset in males. The single TP injection restored stability that would otherwise be lost as a result of neonatal castration. Supported by NIH grant HD-03803

1491 RAT PARS INTERMEDIA ACTION POTENTIALS AND THEIR RESPONSE TO VARIOUS AGENTS.

M. Duff Davis* and Aubrey Gorbman* (SPON: P. E. Pickens). Department of General Biology, University of Washington, Seattle, Washington 98195.

Action potentials have recently been recorded from a number of endocrine glands and their tumors. It appears that this electrical activity is related to cell secretion. Prolactin, from the pars distalis, and MSH, from the pars intermedia, have several phenomona in common. They both respond to similar releasing or inhibiting factors of hormone release, both spontaneously secrete in the absence of hypothalamic control, and action potentials can be recorded from either one. Thus, data obtained from prolactin secretion seems to fit well with MSH secretion and vice versa. There is difficulty in obtaining information on electrical activity from the pars distalis because of its heterogeneous population of cells. One has a hard time defining exactly which cell is being recorded from and consequently must usually rely on tumors. The pars intermedia lobe has the advantage of having relatively few cell types and presents a better target for electrophysiological studies.

Following the decapitation of 250 gram rats (SD), neurointermediate lobes, containing the pars intermedia and pars nervosa complex, were carefully separated from the rest of the pituitary and placed in a container with Kreb's Ringer. The preparation was then gassed in a 95% O_2-5%CO_2 mixture. Glass microelectrodes, filled with 4M NaCl, were lowered into the tissue to record extracellular potentials. When a cell with spontaneous electrical activity was found, various agents were added to the surrounding media and any changes observed. At a 10^{-6}M concentration of isoproterenol, a rapid increase in spike frequency was found, lasting several minutes. High potassium (10X) and norepinephrine (10^{-5}M), on the other hand, caused a decrease in spike frequency and, in some cases, eliminated the activity all together. The latency between the application of experimental solutions and the onset of any change was about 30 seconds. Therefore, agents which enhance or reduce the release of MSH are correlated with an increse or decrease in the frequency of action potentials in the pars intermedia.

1492 AGGRESSIVE BEHAVIOR IS DEPENDENT ON GONADAL STEROIDS IN MALE BUT NOT FEMALE RATS.

Joseph F. DeBold and Klaus A. Miczek. Dept. Psychol., Carnegie-Mellon Univ., Pittsburgh, PA 15213.

Intense and frequent male aggression is seen when a strange male rat is placed into a small colony containing resident male and female rats. Under these circumstances, males and females differ markedly in their level of aggression. However, when confronting a strange female, the pattern of male-female differences reverses. The present study compared the aggressive behavior of male and female colony residents in response to male and female intruders and the importance of hormonal condition for attack.

Ten small colonies were established each with two Long-Evans male rats and two females. After each colony began producing litters they were tested for response to a male intruder. Within a few weeks one of the two males in each colony reliably attacked male intruders. This alpha male and one of the two females were then tested together biweekly for response to male and female intruders. Male residents intensely attacked intact, castrated and testosterone propionate (TP) treated male intruders; less male aggressive behavior was seen toward castrated intruders treated with estradiol benzoate (EB) or EB plus progesterone (P). Male residents rarely attacked or mounted female intruders independent of the hormonal condition of the females. Female residents, on the other hand, intensely attacked all female intruders, except for lactating intruders. Females also attacked castrated male intruders which had been treated with EB or EB + P. Less female attack was directed at intact and castrated TP males. Female aggressive behavior was not correlated with the female residents' reproductive condition (e.g. pregnancy, lactation). In a second series of experiments the importance of resident endocrine condition was examined. Half of the resident males and females were gonadectomized and then tested for aggressive behavior for 7 weeks. The intensity and probability of male attack toward male intruders declined slowly after castration. The rate of decline in male aggressive behavior by castrates was similar to the decline of their mounting of receptive females seen in parallel tests for sexual behavior. Ovariectomy was not followed by any decrease in female aggression toward female intruders. In fact, ovariectomized females were somewhat more aggressive than gonadally intact females.

These experiments demonstrate that both male and female rats can be highly aggressive but that this behavior is sexually dimorphic, both in terms of the characteristics of the most effective stimuli and in the gonadal control of the behavior. The hormonal determinants of male and female aggressive behavior are obviously quite different.

493 EFFECTS OF INTRAVENOUS DOPAMINE ON HUMAN SERUM PROLACTIN ON AND OFF NEUROLEPTICS.

E.G. DeFraites,* A.P. Zis,* D.P. van Kammen,* R. Rebar,* F.K. Goodwin* and P.W. Gold* (SPON: C.A. Tamminga). BPB, CPB, NIMH, Bethesda, MD 20205 & UCSD, La Jolla, CA, U.S.A.

The role of central and peripheral dopamine in the regulation of prolactin (PRL) secretion has been studied extensively. Alterations in dopaminergic function (which have been implicated in the pathogenesis of schizophrenia) are reflected in changes of circulating levels of serum PRL. We report here the effects of sustained intravenous dopamine administration on PRL secretion in normal unmedicated male volunteers (N = 6), and in male schizophrenic patients (N = 6) during and following discontinuation of treatment with a dopamine receptor blocker (pimozide). Dopamine was infused at a rate of 4 ug/Kg/min. for three hours. Blood samples were collected every 15 min. one hour prior to, during and two hours postinfusion. Six patients were infused on chronic pimozide and the procedure was repeated twice, one and four weeks following treatment discontinuation. In normal subjects circulating PRL levels were significantly suppressed during the infusion; following cessation of the procedure PRL rebounded to levels significantly above baseline. Baseline serum PRL was significantly higher in patients on pimozide compared either to controls or to the same patients off pimozide. No significant differences in baseline serum PRL were detected between one and four weeks off pimozide in patients. Prolactin secretion was suppressed by dopamine under all three experimental conditions. However, percent suppression of serum PRL was greater when patients were on or one week off compared to four weeks off pimozide. In addition, rebound of serum PRL above baseline levels occurred only when patients were off pimozide four weeks. The implications of these findings regarding (a) the effects of neuroleptic withdrawal on dopaminergic function and (b) the regulation of PRL secretion by peripheral and central dopamine will be discussed.

1494 TUBEROINFUNDIBULAR DOPAMINERGIC NERVE ACTIVITY ESTIMATED FROM THE ACCUMULATION OF DOPA IN THE MEDIAN EMINENCE.

K.T. Demarest and K.E. Moore. Dept. Pharmacol. & Toxicol., Michigan State Univ., East Lansing, MI 48824.

The rate of accumulation of DOPA in the striatum (ST) following the administration of a decarboxylase inhibitor has been used to estimate the activity of nigrostriatal dopaminergic nerves (Carlsson et al., Pharmacol. Rev. 24: 371, 1972). The present study was undertaken to determine if DOPA accumulation in the median eminence (ME) could be used to estimate the activity of tuberoinfundibular dopaminergic nerves. The concentration of DOPA in ME and ST of the rat was determined 30 min after the administration of 3-hydroxybenzylhydrazine (NSD 1015; 100 mg/kg, i.p.) by a radioenzymatic assay sensitive to 50-125 pg of DOPA. In this assay tissue extracts containing DOPA are incubated with catechol-O-methyltransferase and ^{3}H-S-adenosylmethionine and the radioactive product, 3-methoxytyrosine, separated by ion-exchange chromatography and charcoal adsorption. Since the ME, unlike the ST, contains appreciable amounts of norepinephrine (NE), experiments were designed to estimate the relative contributions of the synthesis of DA and NE to the observed accumulation of DOPA. The accumulation of DOPA in ME was essentially the same in control rats and in rats treated with intraventricular injections of 6-hydroxydopamine in order to selectively deplete NE. This result is consistent with the observation that the rate of synthesis of DA greatly exceeds that of NE in the ME as calculated from the rate of decline of these amines following the administration of α-methyltyrosine (αMT). These results suggest that DOPA accumulation in the ME can be used as an index of tuberoinfundibular DA nerve activity. To confirm this proposal the accumulation of DOPA was analyzed after pharmacological manipulations which have been shown previously (using the αMT-induced decline of DA) to selectively alter DA neuronal activity in the ST and/or ME. Ninety minutes after the administration of the DA agonist, piribedil (30 mg/kg, s.c.), DOPA accumulation was reduced in the ST but not in the ME. The DA antagonist, haloperidol (2.5 mg/kg, s.c.), increased DOPA accumulation in the ST at 2 and 8 hr after injection and in the ME at 16 hr after injection. Three daily injections of estradiol benzoate (25 µg/kg, s.c.) increased the accumulation of DOPA in ME, but not ST; this estrogen-induced increase in DOPA accumulation in ME was not observed in hypophysectomized rats. These results are consistent with previous findings utilizing the decline of DA after αMT to estimate DA turnover in ME and ST, and they indicate that DOPA accumulation after NSD 1015 provides a reliable means of estimating the activity of tuberoinfundibular DA nerves. (Supported by USPHS Grant NS 9174 and Fellowship NS 6026.)

1495 EFFECTS OF ESTROGEN TREATMENT ON NORMAL AND SENSITIZED RAT STRIATAL DOPAMINE (DA) RECEPTORS AND DA-SENSITIVE ADENYLYL CYCLASE. T. Di Paolo*, F. Labrie*, A. Dupont*, N. Barden* and P. Langelier* (SPON: S. Radouco-Thomas). Laboratory of Molecular Endocrinology, CHUL, Québec, G1V 4G2, Canada.

Estrogen treatment has recently been found to exert potent antidopaminergic activity at the pituitary and striatal levels. Such treatment decreases the apomorphine-induced acetylcholine accumulation in rat striatum. Since behavioral supersensitivity to DA drugs has been associated with increased striatal DA receptor levels, we have examined the effect of estrogen treatment on this parameter. Estrogen treatment (17ß-estradiol, 10 µg twice a day for 7 days) of adult ovariectomized rats led to a small increase (20%, $p < 0.05$) of [^{3}H] spiroperidol binding in rat striatum, nucleus accumbens + olfactive tubercle and frontal cortex. The increased binding is due to a corresponding increase in the number of binding sites with no change of affinity. Specificity of binding remained unchanged after estrogen treatment. In order to dissociate possible pre- and post-synaptic effects of estrogens, the binding of [^{3}H] apomorphine and [^{3}H] -spiroperidol was studied in animals bearing an unilateral lesion of the substantia nigra or injected at the same site with 6-OH-DA. The striatal [^{3}H] apomorphine and [^{3}H] spiroperidol binding sites were 30-50% increased on the lesioned side with no change of apparent dissociation constants. The stimulatory effect of estrogen treatment was of similar magnitude on the intact and lesioned sides with no change of affinity for the two labeled ligands. Lesion of the substantia nigra reduced basal adenylate cyclase by 50% but increased the sensitivity and maximal response to DA. Chronic treatment with estradiol failed to modify striatal adenylate cyclase of normal or supersensitized (following lesion) striatal tissue. The present data suggest that the potent desensitizing effect of estrogen treatment on DA action at the striatal level is exerted at a step subsequent to binding to the DA receptor and activation of adenylate cyclase. Moreover, they indicate that the estradiol-induced hyposensitivity and lesion-induced supersensitivity are caused by different mechanisms.

1496 SEXUAL BEHAVIOR IN MALE RATS FOLLOWING INTRACEREBRAL ESTROGEN Gary P. Dohanich* and Ingeborg L. Ward* (SPON: O. B. Ward, Jr.) Dept. Psychol., Villanova Univ., Villanova, PA 19085.

Sexual behavior and reproductive morphology were examined in gonadally-intact male rats following implantation of estradiol benzoate (EB) or cholesterol into the medial preoptic area (MPOA). Three groups of males with varying potentials for lordotic and ejaculatory behavior were chosen. These were normal copulators, normal noncopulators and prenatally stressed noncopulators. Previous studies have indicated prenatally stressed males to have a high potential for lordotic behavior (Ward, Science 175:82, 1972). Every male implanted with EB (N=17 into the MPOA showed lordotic behavior within 7 days of chronic treatment. There were no significant group differences. Highest levels of responding were obtained after 13-16 days (LQ=70-82). Cholesterol (N=15) was not effective. The study provides the first unequivocal demonstration that, like females, male rats are capable of high levels of lordotic behavior following application of EB to behaviorally sensitive CNS sites.

Central EB failed to activate male copulatory behavior in both the control and prenatally stressed noncopulator group. Ejaculatory behavior was impaired in some males that had copulated prior to central EB treatment. Animals treated with EB for 19 days also showed a significant depression in the weight of the testes and epididymis suggesting that EB applied to the MPOA reduces androgen secretion in intact males by acting on the CNS-pituitary-gonadal feedback system.

1497 HYPERPROLACTINEMIA AND MATING BEHAVIOR IN THE MALE RAT: EFFECTS OF PREVIOUS SEXUAL EXPERIENCE AND BROMOCRIPTINE TREATMENT. P.C. Doherty, Jr.*, A. Bartke*, and M.S. Smith*. (SPON: N. Hagino) Depts. of Anat. and Ob/Gyn, University of Texas Health Science Center, San Antonio, TX 78284 and Dept. of Physiol., University of Massachusetts Medical School, Worcester, MA 01605

We have recently reported that hyperprolactinemia induced by grafting four pituitaries under the kidney capsules suppresses mating behavior in male rats and mice (Svare et al., Biol. Reprod., in press). We have also noted that sexual experience after induction of hyperprolactinemia can attenuate the behavioral deficits produced by grafting. To determine whether sexual experience prior to grafting can alter the effects of hyperprolactinemia, the effects of pituitary grafts on sexual behavior were compared in experienced and naive male rats. Sexual experience was provided by housing males with cycling females until spermatozoa were found in the vaginal smears (taken daily), and by testing with an ovariectomized receptive female. Three weeks after pituitary transplantation or sham surgery, evaluation of copulatory behavior was begun. Males were placed in observation chambers with ovariectomized females made receptive by injections of estrogen and progesterone and were scored for mount latency, number of mounts, intromission latency, number of intromissions, ejaculation latency and number of ejaculations. Each test lasted for a period of one hour. Pituitary grafts had a significant suppressive effect on mating behavior in both groups of animals. Experienced animals showed deficits in all parameters studied except the number of mounts, while the naive animals differed from their respective controls only in latency to mount, latency to intromission and number of intromissions.

Treatment with bromocriptine (CB-154, an inhibitor of prolactin release) at 1 mg/day for 14 days, injected 12 hrs. prior to testing, led to increases in sexual activity in both the shams and the grafted animals. Although there were no significant differences in individual measures of behavior in CB-154 treated and control rats, the frequency of measures showing improvement was significantly greater in the CB-154 treated animals.

These results indicate that 1) hyperprolactinemia induced by pituitary grafts can cause deficits in mating behavior in male rats despite previous sexual experience, and 2) that the inhibition of prolactin secretion by bromocriptine may not be the sole mechanism by which CB-154 improves sexual behavior in hyperprolactinemic animals.

1498 CORTICOSTERONE AND RNA METABOLISM IN THE RAT HIPPOCAMPUS. Linda A. Dokas* (Spon: H. J. Waller), Department of Biochemistry, Medical College of Ohio, Toledo, OH 43699

Recent reports have provided evidence that corticosteroids may have direct biochemical effects upon the hippocampus. Corticosterone, the functional glucocorticoid in the rat, enhances the synthesis of a particular hippocampal protein of 54,000 daltons (Etgen, Lee and Lynch, Brain Res. 165:37). Adrenalectomy and glucocorticoid replacement have effects on a high affinity uptake system for GABA in hippocampal synaptosomes (Miller, et al., Psychoneuroendocrinology 3:155). Since autoradiographic evidence suggests that effects of corticosterone in the hippocampus are mediated by nuclear localization of the steroid with subsequent incorporation of [^{3}H]-uridine into RNA, the present study was initiated to characterize hippocampal RNA metabolism in the rat in response to corticosterone.

The hippocampus was removed from anaesthesized adult male Sprague-Dawley rats before 11 a.m. to minimize the endogenous levels of corticosterone in the animals. Each hippocampus was halved bilaterally and divided between Hepes-salts-glucose media with and without 1.8×10^{-8}M corticosterone. Following incubation of the tissue from 4 animals for 1.5 hrs ± steroid, 100µCi of [^{3}H]uridine was added to each incubation for an additional 2.5 hrs. Incorporation of the [^{3}H]uridine into RNA was measured as total TCA-precipitable radioactivity/mg protein, 85% of which was RNase-sensitive. The uptake of [^{3}H]uridine into hippocampal tissue was determined as TCA-soluble radioactivity/mg protein. Incubation with corticosterone decreased the labeling of the hippocampal TCA-soluble fraction by -17.3 ± 1.5% (n=6), relative to controls. In spite of this reduction in the labeled RNA precursor pool, corticosterone-treated hippocampal tissue showed incorporation of [^{3}H] uridine into total RNA equal to or greater than that seen in control incubations. The TCA-precipitable radioactivity to total radioactivity ratio for corticosterone incubations showed an increase of +24.8 ± 7.3% (n=6) as compared to control incubations. When cytoplasmic and nuclear fractions were prepared, increased incorporation of [^{3}H]uridine into RNA in response to corticosterone was found in the nuclear fraction only, where a +32.0 ± 10.4% (n=3) increase was seen, while there was no measureable increase in cytoplasmic RNA labeling. This work indicates that corticosterone induces alterations in both hippocampal RNA and RNA precursor metabolism. The increased labeling of nuclear RNA in response to corticosterone may represent synthesis of hippocampal hn nuclear RNA species which serve as precursors for particular mRNA fractions whose translation mediates the final neurochemical events which are a consequence of the binding of corticosterone to hippocampal receptors. Supported by NIH Endocrinology Training Grant 94120.

1499 ANALYSIS OF THE INFLUENCE OF TESTOSTERONE AND TRIAMCINALONE ON DIFFERENT SKELETAL MUSCLE GROUPS by Debra DuBois*, Joseph E. Tropea*, Joan Warrenski*, and Richard R. Almon, from the Division of Cell and Molecular Biology, Department of Biological Sciences, State University of New York at Buffalo, Buffalo, NY 14260, supported by a grant from the Muscular Dystrophy Association of America.

Skeletal Muscle has two primary functions within the organismal context: movement and storage of metabolic substrates. Both of these functions are controlled and balanced by chemical messengers from the nervous and endocrine systems. Among these are Acetylcholine, Insulin, Epinephrine, Androgens, and Corticosteroid. In the present series of experiments we have examined the effect of Testosterone and Triaminalone on several groups of skeletal muscles in the rat. Normal and castrated male rats were treated for 12 days with either Testosterone or Triamcinalone or both steroids simultaneously. The extensor digitorum longus, soleus, levator ani, tibialis, and gastrocnemius muscles were removed for analysis following the treatment.

Comparisons were made among treatment groups as well as with untreated and sham injected control groups. The analyses includes: gross body weight; the weights of the 5 muscle groups; weights of the liver, kidney, prostate and adrenals; the interaction of ^{125}I-α-Bungarotoxin, ^{125}I-Insulin and ^{125}I-Hydroxybenzylpindolol with membrane fractions from the various skeletal muscles; the interaction of five androgens (Testosterone, 5-α dihydro testosterone, Androstanediol, Androstenediol, R1881) and 5 corticosteroids (cortisol, corticosterone, dexamethazone, triamcinalone, aldosterone) with cytesol from the several muscle groups; and glycogen content of the several muscles. It has previously been suggested that the anabolic actions of androgens may antagonize the catabolic influence of glucocorticoids. The results clearly demonstrate this hypothesis to be incorrect. The results suggest that androgens may modify the glucocorticoid effects and that glucocorticoids may modify the androgen effect but that a clear antagonism between these two steroids is not indicated. Furthermore, although each muscle group examined responds uniquely, slow fibers appear to be much less sensitive to both Testosterone and Triamcinalone.

1500 EFFECT OF ELECTRICAL STIMULATION ON PLASMA CORTICOSTERONE LEVELS IN URETHANE ANESTHETIZED FEMALE RATS. Jon D. Dunn, Dept. Anat., Sch. Med., Oral Roberts Univ. Tulsa, OK 74171.

Although it is commonly stated that the hippocampus inhibits pituitary-adrenal function, data obtained in several laboratories indicate that the hippocampus may also provide stimulation. To pursue the question of a defferential hippocampal influence on pitutiary-adrenal function, plasma levels of corticosterone (CpdB) obtained prior to and following sham or electrical stimulation were determined fluorometrically for adult female rats which had been anesthetized with urethane (1.35g/kg). All rats were tracheotomized and connected to a respirator, placed on a heating pad and subsequently positioned in a stereotaxic apparatus. Cortical EEG, ECG, Heart rate (HR), blood pressure (BP) and respiration were routinely monitored; timed blood samples (0.3ml) were obtained from a catherized femoral artery. In sham stimulated rats HR, BP and Cpd B were obtained every 30 min over a 2.5 hr. period. The HR (Bts/min), BP (mm of Hg) and Cpd B (μg/100ml) for 7 sham stimulated rats averaged over 6 sampling periods were 385± 19, 95± 6 and 79.3± 5.8 respectively. In electrically stimulated rats, timed blood samples were taken 30 min before, just prior to stimulation (biphasic square waves, 100μA, 50HZ, 1msec, 10 sec on/10 sec off for 30 min) and 5, 10, 15, and 30 min after initiation of stimulation. Whereas stimulation of the dorsal hippocampus produced an increase in plasma Cps B at 15 min (17%) and 30 min (21%), stimulation of the ventral hippocampus resulted in decreased plasma Cpd B levels at similar sampling times (18% and 27%). No change in Cpd B levels was observed following stimulation of the corticomedial amygdala, corpus callosum, fornix or cerebral cortex. Of interest, the largest increase in Cpd B levels was observed following stimulation of the caudate nucleus and globus pallidus (30 min, 36%). These data indicate that the hippocampus differentially influences pituitary-adrenal function, the dorsal hippocampus being facilitory whereas the ventral hippocampus is inhibitory, and suggests that electrical stimulation of the urethane anesthetized rat may provide information regarding sites inhibitory to pituitary-adrenal activity.

1501 CHANGES IN LOCOMOTOR ACTIVITY ASSOCIATED WITH THE PHOTOPERIODIC RESPONSE OF THE TESTES IN MALE GOLDEN HAMSTERS. Gary B. Ellis* and Fred W. Turek (SPON: C. Enroth-Cugell). Dept. of Biological Sciences, Northwestern University, Evanston, IL 60201.

The light-dark environment is known to be a major environmental signal entraining circadian rhythms of locomotor activity. Recent evidence indicates that steroid hormones also influence vertebrate activity rhythms. The precise contributions of such external (e.g., photoperiod) and internal (e.g., hormones) environmental factors in regulating activity are not well defined. In order to assess the effects of the light-dark cycle and changes in the reproductive system upon locomotor activity, male golden hamsters were exposed to either 14 h of light per 24 h (LD 14:10) or to LD 6:18 for 210 days. Wheel-running activity was recorded continuously, and testicular size and serum testosterone were measured periodically throughout the study.

The short photoperiod induced a decrease in testicular width, serum testosterone, and the number of wheel revolutions per 24 h period, when compared to the levels of these variables exhibited by LD 14:10 hamsters. Prolonged exposure to LD 6:18 resulted in a spontaneous increase in these three parameters to levels indistinguishable from those observed in LD 14:10 animals.

Coincident with LD 6:18-induced testicular regression was an increased lability of the time of daily activity onset. A return to stability in the day-to-day time of activity onset was coincident with spontaneous testicular regrowth in LD 6:18 hamsters.

LD 6:18 exposure induced an expansion of the daily activity time. This increased duration of the daily active phase persisted even after the spontaneous increase in testicular width, serum testosterone, and number of wheel revolutions per day.

The onset of activity in all hamsters exposed to LD 14:10 occurred between 0-1 h after lights-off and did not vary appreciably for individual animals during the 210 days of LD 14:10. The time required for stable reentrainment following a shift from LD 14:10 to LD 6:18 varied between 30-120 days among individual hamsters, and the phase relationship of activity onset to lights-off after 200 days of LD 6:18 ranged between -1 and -6 h. The phase relationship of activity onset to lights-off was not affected by an increase in serum testosterone during spontaneous testicular recrudescence.

These results indicate that the number of wheel revolutions per day and the lability of daily activity onset are correlated with photoperiod-induced changes in the hamster reproductive system. In contrast, the duration of the daily active phase and the phase relationship between activity onset and lights-off are relatively independent of changes in the reproductive system and are a function of the entraining light-dark cycle. (NIH HD-09885)

1502 IN VITRO INTERACTIONS OF ESTRADIOL AND TWO ANTIESTROGENS WITH CYTOPLASMIC ESTROGEN RECEPTORS FROM FEMALE RAT HYPOTHALAMUS. Anne M. Etgen and Richard E. Whalen. Department of Psychobiology, University of California, Irvine, CA 92717.

Several synthetic antiestrogens, including nafoxidine and tamoxifen, are capable of antagonizing estrogen induction of female sexual behavior (lordosis) and have therefore been used as a tool to examine potential molecular mechanisms of estrogen activation of behavior. The ability of such compounds to prevent cytoplasmic estrogen-receptor complex formation in neural and peripheral target tissues led to the proposal that antiestrogens operate by direct competition for the estrogen binding site on the receptor protein, i.e., by competitive inhibition. The present experiments investigated this possibility by comparing the ability of estradiol (E_2), which is presumably a competitive inhibitor of its own binding, and the antagonists nafoxidine and tamoxifen to compete for hypothalamic estrogen receptor binding in vitro when the concentrations of both the agonist (^{3}H-E_2) and competitor are varied over a wide range.

Unlabeled E_2 produced a linear, dose-dependent inhibition of ^{3}H-E_2-receptor binding in hypothalamic cytosols isolated from ovariectomized adult female Sprague-Dawley rats; the shape of the competition curves indicated that, as predicted for a competitive inhibitor, the estrogen appeared to reduce the affinity of ^{3}H-E_2 for its receptor. In contrast, neither nafoxidine nor tamoxifen generated simple, linear competition curves. Unlike E_2, these antagonists reduced ^{3}H-E_2 binding at extremely low competitor concentrations. A comparison of the relatively linear portion of the antiestrogen competition curves with the same portion of the E_2 curves further suggested that the former compounds produced a significantly sharper decrease in ^{3}H-E_2 binding than did E_2 itself at high competitor concentrations. These results are inconsistent with a competitive inhibition model and indicate that the synthetic antiestrogens may antagonize estrogen action via allosteric (conformational) interactions with the hypothalamic receptor. It is proposed that the synthetic antagonists bind with high affinity to a non-estrogen binding site on the receptor, thereby inducing conformational changes in the receptor which reduce its affinity for E_2 and alter its functional competence to interact with the nuclear components involved in estrogen activation of lordosis.

1503 EFFECT OF ELECTROLYTIC LESION OF THE MEDIAL RAPHE NUCLEUS ON 5-HTP + LU10-171-INDUCED INCREASES IN SERUM PROLACTIN LEVELS IN RATS. Richard G. Fessler and Herbert Y. Meltzer. University of Chicago Pritzker Schl. Medicine, Chicago, Ill. 60637.

Previous studies have demonstrated serotonin (5-HT) can stimulate prolactin secretion in the rat. In vitro studies have shown that 5-HT does not induce prolactin release by a direct effect on the pituitary. Several studies have suggested the median or dorsal raphe may be the locus of a 5-HT-induced release of a peptidergic prolactin releasing factor (PRF). To examine this question further, the effect of low dose 5-hydroxytryptophan (5-HTP) (30 mg/kg ip) plus 5-HT reuptake blockade with either Lilly 110140 (10 mg/kg ip) or Lu10-171 (5 mg/kg ip) was examined in rats which received either electrolytic lesion of the medial raphe nucleus (MR) or sham lesion. MR lesion one week prior to study significantly antagonized the serum prolactin increases in response to this drug regimen in four separate replications. In these experiments, it was further demonstrated that: 1) neither 5-HTP, at this dose, nor administration of a 5-HT reuptake blocker alone, induced significant increases in serum prolactin in either lesioned or sham animals, 2) the increased serum prolactin levels following 5-HTP + reuptake blocker were positively correlated with 5-HT concentrations in the median eminence, 3) the increased serum prolactin concentrations were not dependent upon decreased concentrations of dopamine (DA) in the median eminence, and 4) total destruction of the MR was necessary to demonstrate total blockade of the 5-HTP + reuptake blockade-induced increases in serum prolactin. These results suggest that presynaptic 5-HT terminals located in the median eminence and arising from cell bodies located in the MR, are necessary for serotonergically mediated effects on prolactin secretion induced by 5-HTP.

1504 EFFECTS OF DIFFERENTIAL FORNIX ABLATIONS ON THE CIRCADIAN RHYTHMICITY OF ADRENAL CORTICOSTEROIDS AND LOCOMOTOR ACTIVITY - A 48 HOUR STUDY. Christine T. Fischette, Henry M. Edinger, and Allan Siegel. Depts. of Physiology and Neuroscience, College of Medicine & Dentistry of New Jersey, Newark, NJ 07103.

In a previous study we showed that lateral fornix ablation in adult male rats disrupts the circadian rhythmicity of adrenal corticosteroids that is normally attuned to light-dark cycles, while medial fornix ablation and neocortical ablations do not. We hypothesized that the anteroventral subiculum, the source of the medial corticohypothalamic tract (mcht), is responsible for modulating this periodicity by nature of its input to the suprachiasmatic nucleus and the medial basal hypothalamus. In the present study we confirm and extend our previous findings by, 1) lengthening the period of observation to 48 hours, and 2) by examining the effect of differential fornix ablations on other rhythmic parameters, i.e., locomotor activity, body temperature, and food and water intake. Seven to ten days after medial or lateral fornix ablation, animals were placed on activity platforms. Blood samples were withdrawn at 4h intervals over a period of 48h by tail vein venipuncture in order that corticosteroid determinations could be obtained simultaneously with locomotor activity measurements. In addition, rectal body temperature, food and water intake were recorded.

Spectral analysis revealed that in 7 out of 10 lateral fornix ablated animals, the dominant period of the adrenal corticosteroid rhythm (r) appeared outside the circadian range ($20h \leq r \geq 28h$). One of the animals exhibited a significant period at 30h, while the others demonstrated significant periods in the ultradian range ($0 \leq r \leq 20h$). In contrast, intacts exhibited dominant periods within the circadian range with hradly any significant ultradian components. With regard to locomotor activity, all animals displayed dominant circadian rhythms regardless of corticosteroid pattern. In half of the lateral fornix ablated group we obtained a clear dissociation between dominant periods of locomotor activity and dominant periods of adrenal corticosteroids. The circadian rhythm of rectal body temperature was also disrupted in the lateral fornix ablated group. Our study supports the hypothesis of separate oscillators controlling circadian functions, and suggests that the anteroventral subiculum, via the mcht, is an important modulator of some, but not all, circadian parameters.

1505 RESPONSES OF SERUM CORTICOSTERONE, FREE FATTY ACIDS, AND GLUCOSE TO FOOTSHOCK AND CONDITIONING STIMULI IN RATS. Michael J. Frey* and Gary D. Coover, Dept. Psych., Northern Illinois Univ., DeKalb, IL 60115.

Three experiments involving a session of intense electric footshocks delivered for 2 sec every 2 min were performed with male hooded rats. In the first two experiments elevations of serum corticosterone, free fatty acids (FFA), and glucose concentration were found within 10 min of the onset of the footshock session except under two conditions. That is, FFA did not increase significantly when the blood samples were obtained from the jugular vein or decapitated trunk of ether-anesthetized rats (Exp. 1), but did increase significantly when the blood sample was obtained from the decapitated trunk of unanesthetized rats (Exp. 2). Also, the glucose elevation was not significant in nondeprived rats using unanesthetized decapitation, but was in 24-hr food-deprived rats (Exp. 2) and in both deprived and nondeprived rats using prior anesthetization (Exp. 1). Of course, 24-hr deprivation elevated baseline (presession) FFA and lowered baseline glucose concentrations. With longer shock session durations, corticosterone elevated further by 40 min but no higher by 80 min regardless of food deprivation or sampling condition, but food deprivation did cause greater elevations. Glucose elevated further by 40 min in 24-hr deprived rats, but then declined with 80 min of footshock. The response of FFA was nonmonotonic, decreasing to baseline levels with 40-min shock sessions, and then rising to the highest concentration of all by 80 min. This explains, in part, apparent contradications in the literature regarding short-latency responses of FFA to stress in rats.

In Experiment 3, nondeprived rats were tested for responses to placement in the chamber where they had been shocked, or not (simply placed in the chamber), for 1 hr, 48 hr previously. The former, fear conditioned, rats exhibited significantly greater corticosterone, but not FFA or glucose, elevations than the latter, never-shocked, controls. No glucose elevations occurred during the testing session, in previously shocked or unshocked groups by 40 or 80 min of testing. However, even the unshocked rats exhibited a corticosterone elevation, and an overall FFA increase occurred with testing, indicating that mild stress does not necessarily produce a nonmonotonic FFA response. The corticosterone elevations of the fear conditioned rats were smaller if the wall color and lighting of the chamber were altered on the test day from what they had been during fear conditioning. This stimulus generalization decrement indicates that conditioned fear, and not solely sensitization, mediates the increased corticosterone response in previously shocked rats. The results indicate the comparative value of corticosterone as an emotional response measure.

1506 DEVELOPMENT OF NORMAL FETAL SUPRAOPTIC NEURONS GRAFTED INTO ADULT HOSTS WITH A CONGENITAL LACK OF VASOPRESSIN PRODUCING NEURONS. Don Gash*, John R. Sladek, Jr. and Celia Sladek. (SPON: D.E. Scott). Depts. of Anatomy and Neurology, Univ. of Rochester, Rochester, NY 14642

The region of the hypothalamus containing the supraoptic nucleus was dissected out of normal 17-day post coitus Wistar/Lewis rat embryos and stereotaxically transplanted into the median eminence of adult female Brattleboro rats (which congenitally lack vasopressin-producing neurons). The adult hosts were sacrificed either 20- or 40-days following transplantation. Their median eminences were dissected out and either processed for light microscopic fluorescence and immunohistochemistry or homogenized for radioimmunoassay. In 4 out of 6 animals examined, the transplants were found growing in the 3rd ventricle, juxtaposed to and receiving a blood supply from the median eminence. The transplants ranged up to 2mm long in a rostral-caudal direction and 1 x 1.5mm in width and height. Hypothalamic homogenates from 3 of 8 animals receiving supraoptic transplants contained radioimmunoassayable vasopressin ranging from 580 to 870pg/animal. Sham operated animals or animal receiving a comparably sized transplant of hippocampus did not have detectable levels of vasopressin. Vasopressin-containing neurons, with axons coursing to the host's median eminence, were identified in the transplants by immunohistochemistry. By fluorescence microscopy, catecholamine-containing neurons were also found in the transplants. Some catecholamine-containing fibers from the host seemed to traverse the interface between the host and the transplant. Studies are in progress to determine the ability of the transplant to release vasopressin into the host's circulation and thus enhance the host's ability to conserve water.

1507 CHRONIC DEXAMETHASONE ALTERS CONTENT OF IMMUNOREACTIVE ACTH-LIKE MATERIAL IN RAT ARCUATE NUCLEUS. M.J. Gibson, D.T. Krieger, A.S. Liotta‡ M.J. Brownstein‡ and B.S. McEwen. Mt. Sinai Sch. Med., Dept.Med., Div. Endocrinol., New York,NY 10029; Lab. Clin. Sci., NIMH, Bethesda, MD 20014 and Rockefeller Univ. New York,NY 10021.

Immunoreactive ACTH-like material has been reported in the hypothalamus of several species. Cell bodies containing such material are localized to the arcuate nucleus area. In view of previous studies on differential effects of corticosterone and dexamethasone on pituitary suppressibility, the present study was designed to study the effect of these steroids on concentrations of immunoreactive ACTH-like material in specific rat hypothalamic nuclei, pituitary, and plasma.

Solid pellets were implanted subcutaneously in male Sprague-Dawley rats (200-250 gm). Pellets were either 100% cholesterol (CHOL), 100% corticosterone (B), 50% cholesterol and 50% dexamethasone (DEX 50), or 75% cholesterol and 25% dexamethasone (DEX 25). One week later, animals were decapitated within 20 seconds of original contact. Trunk blood was collected for subsequent ACTH immunoassay and corticosterone (CBG) assay. Anterior pituitaries were removed and frozen in 0.1 N HCl. Brains were immediately frozen on dry ice. Median eminence, arcuate nucleus, ventromedial hypothalamus, and dorsomedial hypothalamus were removed by microdissection and for each area pools of three specimens were homogenized in 0.2 M HCl for determination of immunoreactive ACTH-like material. Adrenals were removed and weighed.

[a]West "midportion" antibody; [b]p<0.05; [c]p<0.01; [d]p<0.001; [e]n = 3 pools of 3

Significant depression of adrenal weight was seen in all steroid treated groups, while pituitary ACTH content was significantly lower only in the dexamethasone treated group. Dexamethasone treatment however was associated with a significant increase in arcuate nucleus immunoreactive ACTH-like concentration; while (data not presented) ACTH-like content of the other brain regions studied was not affected. Studies are in progress to determine whether differential effects can be seen in other brain areas.

1508 INFLUENCE OF ESTROGEN ON GLUTAMIC ACID DECARBOXYLASE (GAD) ACTIVITY: TIME COURSE AND LOCALIZATION. John H. Gordon, Marilyn Y. McGinnis* and Roger A. Gorski. Dept. of Anat. Sch. Med. UCLA, Los Angeles, CA 90024.

Ovariectomized female rats treated systemically with estradiol benzoate (EB: 2 µg/day for 3 days) are known to show decreased GAD activity in the substantia nigra (SN) and ventral tegmental region (VTR) relative to oil treated controls. The aim of the present study was to characterize the effect of estrogen on GAD activity in spayed female rats by examining both the response to local intracranial estrogen implants and the time course of the response following systemic estrogen treatment. In the first experiment, estradiol-17β (E_2) or cholesterol was implanted unilaterally into one of five different brain areas. After three days of steroid exposure, animals were sacrificed, and GAD activity was measured in right and left halves of the SN and the VTR. When E_2 was implanted in the preoptic area (POA) or ventral medial nucleus of hypothalamus (VMN), two regions heavily labeled with tritiated E_2, no significant GAD response to EB occurred. However, GAD activity was decreased in the SN when E_2 was implanted in the caudate nucleus (CPU) or amygdala (AMY), and in the VTR when implanted in the nucleus accumbens septi (ACB). Thus changes in GAD activity were found in brain regions rich in dopamine terminals and containing presumed sites of origin of gabaminergic fibers having their terminals in the SN and VTR. No response to cholesterol occurred regardless of implant site. In addition, there was localization with respect to the side of brain in which the response was found in that GAD activity was decreased only in the side of the brain in which the E_2 was placed. Lastly, there was localization with regard to the SN and VTR: ie, E_2 implanted in the CPU or AMY decreased GAD activity only in the SN while E_2 implanted in the ACB decreased GAD activity only in the VTR. In the second experiment, the time course of changes in GAD activity was measured in ovariectomized rats given a single systemic injection of either 8 µg EB or oil. Rats were sacrificed at 0, 12, 29 or 53 h post injection. It was found that GAD activity in the SN was maximally suppressed at 29 h after EB, whereas decreased GAD activity in the VTR was apparent 12 h after EB but had returned to normal by 29 h. Oil injections had no significant effect on GAD activity. These results suggest that there may be two separate and distinct gabaminergic pathways which are differentially responsive to estrogen; a striato-nigral system projecting to the SN and a mesolimbic-VTR system possibly having cells of origin in the ACB.

1509 INHIBITORY ACTION OF OPIOID PEPTIDES ON THE RELEASE OF DOPAMINE INTO HYPOPHYSIAL PORTAL BLOOD. G. A. Gudelsky and J. C. Porter, Depts. Ob/Gyn. & Physiol., Cecil H. and Ida Green Ctr. for Reprod. Biol. Sci., Univ. of Texas, Southwestern Med. Sch., Dallas, TX 75235.

Opioid peptides are present in the arcuate-median eminence region of the hypothalamus (Bloom et al., 1978; Sar et al., 1978; and others), suggestive of a role for these compounds in the regulation of pituitary function. Indeed, administration of opiate-like peptides results in an elevation of serum prolactin concentrations (Cusan et al., 1977; and many others). Since prolactin secretion is believed to be under the tonic inhibitory control of tuberoinfundibular dopaminergic neurons, we have addressed the issue of whether the effect of opioid peptides on prolactin secretion is the result of an inhibition of the release into hypophysial portal blood of dopamine from these hypothalamic neurons. The concentrations of dopamine in pituitary stalk blood of rats were measured after the intraventricular administration of 10µl of a solution containing β-endorphin (10µg), the enkephalin analog, [D-Ala^2]met-enkephalinamide (100µg), or the solvent vehicle (0.15M NaCl). Pituitary stalk blood was collected for 1 hr from pentobarbital-anesthetized rats. Dopamine was analyzed in acidified plasma extracts employing a sensitive radioenzymatic procedure. The concentration of dopamine in pituitary stalk plasma of vehicle-treated, ovariectomized rats was 1.2 ± 0.3 ng/ml (mean ± SE). Compared to these vehicle-treated control animals, the dopamine concentrations were significantly lower in ovariectomized rats which had received either β-endorphin or the enkephalin analog. In these two groups of animals the mean concentration of dopamine was approximately 0.2 ng/ml. The concentration of dopamine in stalk plasma of ovariectomized rats injected with estradiol benzoate (25 µg/kg, sc) for 3 days was 4.0 ± 0.8 ng/ml. In estrogen-primed, ovariectomized rats treated with the enkephalin analog, the mean concentration of dopamine in stalk plasma was 0.3 ng/ml which was less than 10% of the dopamine concentration in the vehicle-treated control animals. When ovariectomized, estrogen-primed rats were pretreated with the opiate antagonist, naloxone (5 mg/kg, sc), the enkephalin analog was no longer effective in reducing the concentration of dopamine in pituitary stalk plasma. These findings are supportive of the view that the inhibitory effect of opioid peptides on the release of dopamine into pituitary stalk blood is one mechanism by which these peptides stimulate prolactin secretion. In addition, these results are suggestive that endogenous opioid peptides may regulate the release of dopamine from tuberoinfundibular neurons.

1510 A CELLULAR ANALYSIS OF ANDROGEN- AND ESTROGEN-INDUCED SEXUAL DIFFERENTIATION IN THE ZEBRA FINCH SONG SYSTEM. Mark. E. Gurney and Mark Konishi. Div. Biology, Caltech, Pasadena CA 91125.

Male zebra finches sing a brief song phrase to the female during courtship. Castration of an adult male reduces the bird's frequency of singing; testosterone replacement reinstates the behavior. Testosterone treatment of female zebra finches does not activate song nor induce other elements of courtship behavior.

We find that correlative changes of brain and behavior in zebra finches are organized by sex hormones during development. Newly hatched zebra finch chicks were subcutaneously implanted with silastic pellets containing either 50 µg of dihydrotestosterone or 50 µg of 17 β-estradiol. Testosterone treatment activates song in adult females which were implanted with estradiol when chicks, but fails to activate song in those females which had received dihydrotestosterone. The singing females approach a sexual partner with pivoting movements, straighten to an erect posture, fluff their throat feathers, and rapidly repeat their song phrase in a behavioral sequence which closely resembles that of the male.

In zebra finches, brain nuclei of the efferent pathway for control of song show dramatic sex differences in their volume (Nottebohm and Arnold; Science 194 [1976] 211-213). We find that 17 β-estradiol treatment of genetically female chicks organizes male-like cytoarchitectonic differentiation of the telencephalic song nuclei RA, HVc, MAN, and X. Dihydrotestosterone induces masculinization of the brain stem song nuclei nXII and DM. Dendritic field spread, soma size, and the consequent volume of the brain nucleus is larger in males than females at all levels of the song system. The exposure of female chicks to either androgen or estrogen supports growth of the hormone's respective target neurons in either the brain stem or telencephalic song nuclei. These neurons reach a size identical with that of the equivalent cell type in a normal male. Our anatomical comparison of normal adult male and female song systems reveals that all cell types and all identified connections are present in both sexes. Thus, the specification of cellular identity - i.e., position, number, dendritic morphology and efferent synaptic projection - is expressed independently of the hormonal environment. Rather than selecting pathways of anatomical differentiation, androgens and estrogens exert a similar pleiotrophic effect on their respective target neurons. Although in the female song system we identify all the cell types and connections of the male, testosterone does not activate song. Thus, 17 β-estradiol may also exert a specific inductive effect on the telencephalic song neurons which renders them physiologically competent to respond to testosterone in the adult. (Supported by NIH Grant No. HD10501)

1511 OXYTOCIN AND VASOPRESSIN RELEASE BY SUBSTANCE P INJECTED INTO THE CEREBRAL VENTRICLES OF RATS. Jaya Haldar*, Donald L. Hoffman*, Gajanan Nilaver* and Earl A. Zimmerman. Departments of Pharmacology and Neurology, College of P&S, Columbia University, New York, N.Y. 10032.

Substance P (SP) has been found by immunocytochemical methods in fibers innervating a number of hypothalamic nuclei. These may be sites where this peptide acts to regulate the secretion of anterior pituitary hormones such as gonadotrophins, growth hormone and prolactin. Since we have recently demonstrated relatively dense projections of SP fibers to magnocellular nuclei of the hypothalamus, particularly the paraventricular nucleus, central effects of substance P on the release of neurohypophysial hormones produced in these regions was studied.

Via chronic indwelling cannulae into a lateral cerebral ventricle (LCV), SP was administered to urethane anesthetized lactating rats and milk-ejection pressure was recorded as an indication of oxytocin release. Antidiuretic responses were followed after LCV injection of SP in alcohol-anesthetized water-loaded rats. Injection of 1-4 μg (1-4 μl) produced a sustained increase of milk-ejection pressure in lactating rats and 0.2-0.4 μg produced long lasting antidiuresis in water loaded rats. 1 μg LCV β-endorphin blocked the milk-ejection response to SP, while the same dose caused profound potentiation of the antidiuresis induced by SP. Both the inhibitory and the potentiating effects of β-endorphin lasted at least 90 min.

Although vasopressin is known to have an intrinsic milk-ejecting activity it is unlikely that its release accounts for this response in these experiments since β-endorphin had opposite effects on the antidiuretic and milk-ejecting responses to substance P. If vasopressin accounted for the milk-ejection response then β-endorphin should have enhanced rather than inhibited the SP effect. The results also suggest that β-endorphin may participate in the regulation of differential secretion of oxytocin and vasopressin. (Supported by NIH #AM-01940 and AM-20337).

1512 EFFECTS OF INDIVIDUAL HOUSING ON DIMETHYLTRYPTAMINE AND TRYPTAMINE IN RAT BRAIN AND ADRENAL GLANDS. Robert Harrison* and S. T. Christian, Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294.

Sensitive GC/MS assays have been developed for quantification of picogram amounts of tryptamine (TA) and N,N-dimethyltryptamine (DMT). Using this method, TA and DMT were measured in single brains and adrenal glands taken from 120 day old male Sprague-Dawley rats. Known amounts of α, α, β, β-tetradeuterated TA (DTA) and α, α, β, β-tetradeuterated DMT (DDMT) were added to tissue samples prior to deproteinization and delipidization under acid conditions. The amines were extracted from the basified mixture with methylene chloride and derivatized with heptafluorobutyryl imidazole according to Benington, Christian and Morin (J. Chromatog. 106:435, 1975). The derivatized products of this reaction were taken up in 1 ml methylene chloride and washed with distilled water. Microliter portions of this mixture were found suitable for analysis of the heptafluorobutyryl derivatives of TA, DTA, DMT and DDMT. Determinations were carried out on a Hewlett-Packard 5985 GC/MS equipped with a Supelco 4' glass column containing 2% SP-2250 on 100-120 mesh Chromosorb W-HP. Quantification was obtained by a comparison of ratios of ion densities of fragments specific for the heptafluorobutyryl derivatives of TA, DTA, DMT and DDMT from both pure standards and tissue extract.

These data indicate that DMT and TA are elevated in both brain and adrenals from animals that were individually housed for 28 days. If the animals are individually housed for 60 days, there is a decrease in the level of DMT from brain and adrenal while TA in these tissues remains elevated. This effect is enhanced considerably in younger animals. Further aspects of these phenomena are currently being investigated.

This work was supported in part by Intramural Faculty Research grant #82-6607.

1513 ELEVATIONS IN PLASMA CORTICOSTERONE IN RATS IN RESPONSE TO CONSUMPTION OF CONCENTRATED SUCROSE SOLUTIONS. Robert P. Hart*, Gary D. Coover, Allan Shnerson*, Dept. of Psychology, Northern Illinois Univ., DeKalb, IL 60115, and William P. Smotherman, Dept. of Psychology, Oregon State Univ., Corvallis, OR 97331.

In Exp. 1, male hooded rats were given a 23% w/W sucrose solution or a choice between this sucrose solution and tap water after 36 hr of water deprivation. Sucrose consumption was completed within the first 15 min of the 120-min session, and was associated with a marked elevation in plasma corticosterone level (to 50 μg/100 ml within 60 min) that remained elevated for the 120 min. The sucrose-water choice group consumed water after consuming sucrose, and exhibited a more rapid decline in corticosterone concentration during the interval between 60 and 120 min after the initiation of sucrose consumption. These data suggest that ingestion of concentrated sucrose solution facilitates pituitary-adrenal activity through dehydrational consequences that continue after sucrose consumption is terminated unless subsequent water intake rehydrates the animal. As a test of this dehydration hypothesis rats in Exp. 2 were deprived of water for 2, 24 or 48 hr and then consumed a sucrose solution (23% w/W). The three groups consumed the same amount of sucrose solution, and thus varied in degree of ultimate dehydration in accordance with hours of prior water deprivation. While all groups showed elevations in plasma levels of corticosterone, higher and more prolonged elevations occurred for the 24 than the 2, and for the 48 than the 24, hr deprived rats. As a further test of the dehydration hypothesis, rats in Exp. 3 consumed one of six concentrations of sucrose solution (ranging from .120 to 1.166 moles/liter) or one of two concentrations of glucose solution (.470 or 1.166 moles/liter) after 36 hr water deprivation. Increasing the concentration of sucrose resulted in a decrease in amount consumed and an increase in plasma corticosterone concentration. Glucose consumption produced similar effects, though more weakly than equimolar sucrose solution consumption. These data suggest that dehydration from consumption of highly concentrated sugar solutions inhibits further drinking and produces corticosterone elevations. The effect of rapid, acute dehydration on corticosterone levels is surprising considering the minimal effects of water deprivation per se on corticosterone levels and the interpretation of pituitary-adrenal activation as a sign of psychological stress.

1514 A POSSIBLE NEUROSECRETORY PATHWAY UTILIZING SUBSTANCE P (SP) IN THE HYPOTHALAMUS OF THE NORTH AMERICAN OPOSSUM. Raymond H. Ho and Carol Laxson*, Dept. Anat., Sch. Med., The Ohio State University, Columbus, O., 43210.

A very dense plexus of SP immunoreactive (SPI) fibers and terminals is present in the external layer of the median eminence (ME) in the human, monkey, domestic fowl and opossum, but not in the rat, guinea pig, mouse or frog. The location of these SPI terminals is suggestive of a regulatory role for this peptide in anterior pituitary function. Antibodies raised in rabbits against synthetic SP were used in the indirect antibody PAP method to localize SPI on 10μm coronal and sagittal sections of opossum brains that were fixed by intracardiac perfusion with Bouin's fixative. A SPI fiber pathway was observed that projected to the ME. This fiber bundle begins to form in the medial preoptic area and courses caudally and ventrally adjacent to the III ventricle toward the ME. SPI perikarya were observed scattered among the beaded SPI fibers in the medial preoptic region. These observations suggest that the SPI perikarya in the preoptic area are the cells of origin of the SPI projection. In addition, SPI cell bodies were also seen in the arcuate nucleus. These cells may also contribute to the SPI plexus observed in the ME. The specificity of immunostaining was established in control experiments in which anti-SP serum pretreated with an excess of SP failed to demonstrate the aforementioned structures on adjacent sections. We conclude that the SPI fibers and terminals in the ME of the opossum can be traced to the preoptic and the arcuate nucleus regions where SPI containing perikarya were observed. (Supported by the Snyder Fund and The Graduate School of The Ohio State University.)

1515 IMMUNOCYTOCHEMICAL IDENTIFICATION OF MELATONIN BINDING MATERIAL IN THE PINEAL GLAND OF THE RAT. W. R. Holloway*, L. J. Grota, and G. M. Brown. Dept. Psych., Sch. Med., U. Roch., Roch., N. Y. 14642, and Dept. Neurosci., McMaster U. Hamilton, Ont., Canada.

Using an immunohistochemical technique (Cell Tiss. Res., 1975, 162:141; Endocr., 1978, 102:63) we have localized a saturable binding material for melatonin (Mel) in the pineal gland (PG) of the rat. A quantitative double antibody procedure with anti-Mel (A-Mel) as the first antibody and FITC-labeled IgG as the marker was used. Fluorescence Intensity (FI) was measured with a Cadmium Sulfide photosensor.

PG from adult male rats (n=6) sacrificed 1.5 hr after lights-on showed successive increases in FI when 0, 10 ng, and 1000 ng Mel/ ml were added to A-Mel before incubation. Adding 5 mg Mel/ml failed to increase FI above this level, showing saturation of the binding material. An estimate of the proportion of the binding material occupied by endogenous Mel, 0.30, was determined by dividing the FI for 0 Mel by the maximum FI from the saturation curve. Using this method, a diurnal change in the proportion of receptors occupied by Mel was found; the degree of binding increased progressively through the lighted portion of the day, reaching a maximum value of 1.0 shortly after lights-out. For this sampling point, the highest FI occurred when 0 Mel was added to the antibody. FI decreased when Mel was added. Thus, a daily rhythm of Mel binding in the PG exists,evidenced by changes in the proportion of the receptor population occupied by endogenous Mel.

Initial studies to determine the specificity of the binding element show that it binds both Mel and N-acetyl-serotonin (NAS). Sections of PG from rats (n=4) killed 1.5 hr after lights-on were incubated with antibody containing either Mel or NAS (1000 ng/ ml). When an antibody which binds both Mel and NAS (A-NAI) was used, each indoleamine caused an increase in FI. When A-Mel, which binds only Mel, was used as first antibody, only Mel increased FI.

In conclusion, this procedure provides a means of visualizing and quantifying Mel receptors in the PG. The application of this method to the study of Mel binding in other tissues will be discussed.

1516 THE EFFECT OF ANTEROVENTRAL 3RD VENTRICLE REGION LESIONS ON OSMOTIC STIMULATION OF VASOPRESSIN RELEASE BY THE ORGAN CULTURED RAT HYPOTHALAMO-NEUROHYPOPHYSEAL SYSTEM. Alan Kim Johnson and Celia D. Sladek. (SPON: Fred W. Mis). Dept. of Psychology, Univ. of Iowa, Iowa City, IA 52242, and Depts. of Neurology and Anatomy, Univ. of Rochester Sch. of Medicine, Rochester, NY 14642.

Rats with electrolytic lesions of the anteroventral 3rd ventricular (AV3V) region of the hypothalamus exhibit hypernatremia and chronic drinking deficits in response to hypertonic NaCl. These findings are suggestive of impaired osmoreception. The organ-cultured rat hypothalamo-neurohypophyseal system (HNS) previously has been shown to release vasopressin (VP) in response to osmotic stimuli. The ventral portion of the region damaged by AV3V lesions is included in the HNS explant. Thus, these studies were initiated to evaluate the osmotic response of HNS explants which were obtained from rats previously prepared with AV3V lesions.

Following electrolytic ablation of the AV3V region or sham lesioning and a 2 wk recovery period, HNS explants were removed from 5 AV3V lesioned rats and 6 sham lesioned rats. The explants were maintained in organ culture for 4 days. On the third day in culture, increasing the osmolality of the culture medium from 295 to 315 mOsm/kg H_2O by the addition of NaCl resulted in a 2.5 fold increase in VP release from the sham lesioned explants, but did not significantly alter VP release from the AV3V lesioned explants. On the subsequent day in culture, acetylcholine (10^{-5}M) stimulated VP release from 4 of the 5 AV3V lesioned explants as well as the sham lesioned explants. These data suggest that the osmoreceptors which are involved in controlling VP release from the organ cultured HNS may be located in the region anterior to the ventral 3rd ventricle.

1517 ACTIVITY OF TUBEROINFUNDIBULAR DOPAMINERGIC NERVES DURING SURGES OF PROLACTIN AND LUTEINIZING HORMONE. C.A. Johnston, K.T. Demarest and K.E. Moore. Dept. of Pharmacol. & Toxicol., Michigan State Univ., East Lansing, MI 48824.

The purpose of the present study was to estimate the activity of tuberoinfundibular dopamine (DA) nerves during and after the elevation of serum concentrations of prolactin and luteinizing hormone (LH) which occur in normal female rats on the afternoon of proestrus, and which can be induced in ovariectomized rats by injections of estrogen. The activity of different DA neuronal systems was estimated by measuring the accumulation of DOPA 30 min after the injection of a DOPA decarboxylase inhibitor, 3-hydroxybenzylhydrazine (NSD 1015, 100 mg/kg, i.p.). The DOPA content was determined using a radioenzymatic assay in the median eminence (ME), striatum (ST) and neurointermediate lobe of the pituitary (NIL), regions containing terminals of the tuberoinfundibular, nigrostriatal and tuberohypophyseal DA neuronal systems, respectively.

Female rats which had at least 2 consecutive 4 or 5 day estrous cycles prior to the experiment were sacrificed by decapitation at appropriate times during the cycle. DOPA accumulation did not change in any brain region on the morning of diestrus, metestrus, or proestrus. DOPA accumulation in the ME significantly increased in the late evening of proestrus and on the morning of estrus. Much smaller but temporally related changes were also noted in ST and NIL.

Ovariectomized rats were injected with estradiol benzoate (5 µg/kg, s.c.) for 4 days. On the fifth day a surge of prolactin and LH was induced in half of these animals by an injection of 0.5 mg/kg estradiol benzoate at 1000 hr; the control group received injections of corn oil vehicle. DOPA accumulation was determined at 800, 1200, 1800, 2400 hr on day 6 and at 800 hr on day 7. There were no changes in DOPA accumulation in ME, ST, or NIL of the control group. Although the serum concentrations of prolactin and LH in the experimental group increased on the afternoon of day 6, DOPA accumulation was significantly increased selectively in ME only on the morning of day 7. Thus, the increased accumulation of DOPA in ME occurs 6-16 hr after the peak of the serum concentration of the hormones. This delayed activation of tuberoinfundibular DA neurons is consistent with previous studies in which prolactin concentrations in serum or CSF were elevated by pharmacological means. These results suggest that the normal and simulated surges of prolactin and LH are not the result of a reduction in the activity of tuberoinfundibular DA neurons, but that the elevation of serum concentrations of prolactin, and possibly LH, appear to cause a delayed increase in the activity of these nerves. (Supported by USPHS grant NS 9174.)

1518 IN VITRO EVIDENCE FOR MULTIPLE OSCILLATORS IN THE CHICK PINEAL GLAND. Charles A. Kasal*, Wim du Bois*, Michael Menaker, J. Regino Perez-Polo. Dept. Zool., Univ. Texas, Austin, TX 78712 and Dept. Human Biological Chemistry and Genetics, Univ. of Texas Medical Branch, Galveston TX 77550.

In Vitro studies done by us and others on chick (Gallus domesticus) pineal glands demonstrate that N-acetyltransferase, the enzyme involved in melatonin synthesis is under the control of a self sustained circadian oscillator located in the pineal gland. Cultured chick pineal glands maintained in constant darkness (DD) exhibit a persistant rhythm of NAT activity with peaks occuring approximately 24 hours apart and a phase which closely approximates that seen in vivo. These findings clearly suggest that the pineal gland contains one or more oscillators that can function independent of innervation and external time cues.

In the present study we asked whether the organ integrity is essential for maintenance of this rhythm in culture. Chicks raised from one day of age in a light-dark cycle of 12 hours of light (LD 12:12) were sacrificed at three weeks of age and pineals were removed and placed into culture. Glands were bisected along the sagittal plane and each of the halves were placed into separate culture flasks. Respective halves were retrieved simultaneously during sampling. Examination of the first and second day in culture in DD revealed rhythm in NAT activity similar to that seen in whole-gland preparations with high levels occuring during the projected night of the birds prior light-dark cycle. Maintaining the organ culture in a continued LD cycle for two days and then releasing into DD again revealed a persistant rhythmicity in NAT during the third and fourth day in culture.

The persistance of rhythmicity in each section of the pineal gland demonstrated that the whole gland is not necessary for the production of a circadian rhythm and that the pineal gland contains at least two, if not more, self sustained oscillators which may function independently to produce a circadian rhythm. The issue of possible multiplicity of oscillators will be addressed in experiments entailing cultures of dissociated pineal cells.

1519 ANDROGEN CONCENTRATING CNS REGIONS OF THE SOUTH AFRICAN CLAWED FROG, XENOPUS LAEVIS: AUTORADIOGRAPHY WITH DIHYDROTESTOSTERONE. Darcy B. Kelley, Dept. Psychology, Princeton University, Princeton, N.J. 08544

Androgen concentrating regions in the CNS of X. laevis were mapped autoradiographically with the non-aromatizable androgen, dihydrotestosterone (DHT). One week after castration, five male frogs were injected with 200 uCi (0.0003 mg) of ^{3}H-DHT (1,2,4,5,6, 7,16,17-^{3}H-DHT, 200 Ci/mM). Frogs were sacrificed two hours later and the horizontally sectioned brains processed for steroid autoradiography. Control and experimental slides were exposed for 4, 6, or 8 weeks, developed, lightly stained with cresyl violet acetate and scanned for labelled cells (criterion: 5x background). After DHT injection the following brain regions contain labelled cells: anterior pituitary, posterior thalamus (TH), laminar nucleus of the torus semicircularis (TOR), dorsal tegmental area of the medulla (DTAM), principal nucleus of cranial nerve V, motor neurons of cranial nerve IX-X and large and small neurons in the ventral columns of the rostral spinal cord. These DHT results are compared to previously reported (Kelley et al., J. Comp. Neur., 164: 47, 1975; Morrell et al., J. Comp. Neur., 164: 63, 1975) labelling patterns following testosterone (T) or estradiol (E) injection into males below.

	TEL	APOA	VIN	TH	TOR	DTAM	IX-X
E	X	X	X	X	X	-	-
T	-	X	X	-	-	X	X
DHT	-	-	-	X	X	X	X

The limbic telencephalon (ventral striatum, ventral septum, rostral amygdala) contains labelled cells after E but not after T or DHT injection. The anterior preoptic area and ventral infundibular nucleus contain labelled cells after T or E injection but not after DHT. The TH and TOR contain labelled cells after DHT or E but not after T injection. Preliminary studies indicate that long term T treatment of castrated males will prevent labelling with ^{3}H-E in APOA, VIN, TH and TOR, but not in TEL. These results suggest that the TEL cannot aromatize T to E and thus differs from other E concentrating nuclei. The DTAM and IX-X nuclei contain labelled cells after T and DHT, but not after E. Many hormone concentrating brain nuclei have been implicated in control of reproductive behaviors. Both T and DHT are effective in restoring sex behavior to castrated males; E is not. The hormone differences in labelling patterns described here may in part explain the different effects of androgens and estrogen on male sex behavior.

1520 SEROTONERGIC REGULATION OF RHYTHMIC CORTICOSTERONE SECRETION IN THE RAT. T. Kepic*, R. Morgan*, J. P. Allen and C. F. Rowlands. Peoria Sch. Med., Peoria, IL 61605 and Southwest Foundation for Research and Education, San Antonio, TX

Serotonin is known to affect ACTH secretion in mammals. The suprachiasmatic nucleus (SCN) of the hypothalamus is rich in serotonin and presumably modulates the rhythmic secretion of hormones including corticosterone (B). We studied the effect of SCN ablation or the administration of 5,7-dihydroxytryptamine (5,7-DHT), a serotonin neurotoxin, on diurnal B secretion. This was accomplished by either destroying the SCN bilaterally using a radio frequency lesion generator or injecting 150 µg of 5,7-DHT in 30 µl of an ascorbic acid-saline vehicle intraventricularly at diestrous in groups of 160 gm female Sprague Dawley rats. Animals given 5,7-DHT were pretreated with protriptyline (20 mg/kg, ip) to prevent uptake in norepinephrine neuron terminals. Data from the two experimental groups were compared to those obtained from sham-operated controls or following the intraventricular injection of the ascorbic acid-saline vehicle in protriptyline treated controls. Three weeks following neurosurgery, the rats were decapitated and trunk blood collected at 0700 hr (AM) or 1600 (PM) and B measured by radioimmunoassay. There was no significant difference in the mean plasma B concentration between those with SCN lesions compared with the 5,7-DHT treated group at either the AM or PM periods. There was no significant difference between the AM and PM mean plasma B levels in each experimental group. The actual AM and PM levels in both experimental groups were significantly higher ($P < 0.05$) and lower ($P < 0.01$) respectively, than in the two control groups which had the normally expected diurnal difference in plasma B levels. We conclude that the effect of either SCN destruction or administration of a serotonin neurotoxin had a similar effect. These observations support the hypothesis that a serotonergic influence from the SCN is involved in the regulation of the circadian secretion of corticosterone in the rat.

1521 ONTOGENY OF CATECHOLAMINE-NEUROPHYSIN INTERACTIONS IN THE RAT HYPOTHALAMUS. H. Khachaturian* and J.R. Sladek Jr. (SPON: J.P.J. Maurissen). Dept. Anat., Sch. of Med. & Dent., Univ. of Roch., Rochester, N.Y. 14642.

The development of the magnocellular, hypothalamo-neurohypophysial system of the rat was investigated with a combined fluorescence-immunocytochemical approach for the demonstration of monoamines and neuropeptides (McNeill T.H. & Sladek J.R., Jr., 1978, Science 200:72-74). This technique is particularly useful for the study of ontogenetic events, because due to possible timing heterogeneities among littermates, precise correlation of different neuron systems is difficult unless they are simultaneously examined in each animal.

Norepinephrine (NE) is known to influence vasopressin secretion. This may indicate an important functional relationship between NE terminals, as seen with fluorescence microscopy and peptidergic neurons of the supraoptic (SON) and paraventricular (PVN) nuclei. Furthermore, the appearance during the late gestational period of neurosecretory material and catecholamine (CA) varicosities in SON and PVN raises questions regarding the time of establishment as well as the nature of functional relationships during development.

Brains from embryonic and early postnatal rats, ages 16, 17, 18, 20, 21 and 22 days postcoitus (dpc) and 1, 4, 7, 14, 21, 28 and 35 days postnatal (dpn) were processed for formaldehyde-induced fluorescence of CA. Alternate sections to those taken for fluorescence were stained immunocytochemically, using anti-rat neurophysin (RNP, provided by Dr. A. Robinson). RNP was visualized in the neuronal perikarya of SON and PVN on 17 and 18 dpc, respectively; the majority of immunoreactive cells stained very lightly, with a few cells staining darker. The numbers of darker staining perikarya, axons and dendrites increased with age in both nuclei, up to 28 dpn and remained essentially the same through 35 dpn. A few CA varicosities were also observed in the SON and PVN on 17 and 18 dpc, respectively. The density of CA varicosities in SON and PVN increasd up to 14 dpn, beyond which there were only subtle differences among the remaining ages studied. The distribution of CA varicosities in SON and PVN began to resemble the adult pattern as early as 4 dpn, became more apparent on 7 dpn and was well established by 14 dpn with CA varicosities frequently encountered in close juxtaposition to the magnocellular neurosecretory neurons. The appearance of neurosecretory material in SON and PVN much earlier than the establishment of varicosity-cell contacts might indicate a trophic influence of the magnocellular neurons upon the ingrowing NE axons.

1522 THE PARTIAL PURIFICATION OF PROTHORACICOTROPIC HORMONE (PTTH) FROM THE TOBACCO HORNWORM, *MANDUCA SEXTA*. Timothy G. Kingan* and R. W. Newburgh.* (Spon: Duncan P. Taylor) Dept. of Biochem. & Biophys., Oregon State Univ., Corvallis, OR 97331.

The insect protein hormone prothoracicotropic hormone (PTTH) has previously been partially purified from a Lepidopteran, *Bombyx mori* (Ishizaki and Ishikawa, Biol. Bull. 1967, 133: 355-368; Yamazaki and Kobayashi, J. Insect Physiol. 1969, 15: 1981-1990). We report here the partial purification of this hormone from the tobacco hornworm, *Manduca sexta* (Lepidoptera: Sphingadae). Hormone activity has been followed throughout purification with a larval bioassay (Gibbs and Riddiford, J. Exp. Biol. 1977, 66: 255-266). Material for purification was obtained from the powdered heads of wandering stage (5th instar) larvae. The 2% NaCl/0.1 mM phenylthiourea extract was heat coagulated, with the activity remaining in the supernatant. Extracts were subsequently fractionated with ammonium sulfate, fractionally precipitated with acetone, and then chromatographed on Sephadex G-100. Active fractions were pooled for ion-exchange chromatography on DEAE-Sephadex in 0.1 M Tris-HCl, pH 7.90, with linear gradients of NaCl. Active fractions were pooled, dialyzed, lyophilized, and then subjected to flat-bed isoelectric focusing in a granulated gel. Hormone activity co-eluted with ovalbumin (45,000 daltons) from a Sephadex G-75 column. Material was quantitatively absorbed by DEAE-Sephadex with greater than 90% of the activity recovered by elution with buffer containing 0.1 M NaCl. Isoelectric focusing indicated that activity is recoverable from at least two slightly acidic pI's.

623 IMMUNOCYTOCHEMISTRY OF RAT PINEAL GLAND USING ANTISERA GENERATED AGAINST ANTIOVULATORY ANALOGS OF LRF. Karl M. Knigge, Diane T. Piekut*, and Shirley A. Joseph*. (SPON: Mary Ann Romagnano). Dept. Anat., Univ. of Rochester Sch. Med., Rochester, NY 14642.

Ongoing studies indicate that the pineal gland secretes (both in vivo and in vitro) a non-indolic substance which inhibits LRF-induced release of pituitary LH. This pineal anti-LRF factor exhibits immunological characteristics which suggest that its structure may provide antigenic determinants similar to those of LRF itself; partially purified preparations of this factor cross-react with certain LRF antisera and both pinealocyte cell bodies and/or processes stain immunocytochemically with these antisera. A considerable number of analogs of LRF have been synthesized which are effective antiovulatory compounds; 2 of the most potent analogs are [D-Phe^2, D-Trp^3, D-Phe^6]-LRF ("B-2") and [Ac-Pro^1, D-Phe^2, D-Trp^3, D-Trp^6]-LRF ("K-43"). Antisera were generated against these analogs using a bisdiazotized benzidene conjugation to bovine serum albumin. Cross-reactivity with LRF was examined by RIA procedures and immunocytochemical characteristics were studied by comparing the staining of median eminence and pineal gland. Antisera to analog K-43 recognized LRF and stained cells in the pineal gland; antisera to analog B-2 also stained cells in the pineal but did not recognize LRF. These results focus attention upon the N-terminal portion of the pineal anti-LRF substance with particular reference to positions 1 and 2.

Supported by grants from the National Science Foundation (No. NS:PCM78-16123) and the Ford Foundation (No. 780-0616).

625 3α-Androstanediol as an Inhibitor of Reproductive Function in the Immature Female Rat. Ilze Kraulis*, Sally J. Naish* and K.B. Ruf (SPON: F. Ervin), Dept. Ob. Gyn., McGill University, Montreal, Canada.

Immature female rats treated with 10 µg estradiol benzoate (EB) at 1200 h on d 23 and stimulated with 1 mg progesterone (P) 72 h later respond with a gonadotropin (GT) surge (Caligaris et al., Endocrinol., 55: 97, 1972) which may lead to ovulation. Aromatizable, but not ring A-reduced androgens, can effectively be substituted for EB in this system (Kraulis et al., Endocrinol. 103: 1822, 1978). As shown in the Table below, the ring A-reduced androgen, 5α-androstane-3α, 17β-diol (3α), 6 mg/100 g, can completely eliminate the estrogen-induced GT surge, if given 30 min before EB.

	EB only	EB/P	3α/EB/P	3β/EB/P
LH /ng/ml)	58±29	1089±215	21±16	600±93
FSH /ng/ml)	393±78	2178±489	349±107	1597±309
(4-5 animals per group)				

Implantation on d 21 of silastic capsules of the 3α-, but not of the 3β-diol, led to signs of hypopituitary hypogonadism in 51-d-old rats as indicated by small-for-weight pituitaries as compared to blank implanted controls (4.63±0.28 vs 7.56±0.75 mg), ovaries (21.02±9.96 vs 39.88±2.60 mg), and uteri (145±32 vs 248±21 mg). This inhibitory effect on the reproductive system may be reversible, since upon removal of the capsules (d 51) 4 out of the 6 animals were successfully impregnated. These studies suggest that the 3α-diol, a prominent product of the immature rat ovary (Eckstein et al., Endocrinol., 94: 224, 1974) may serve as a natural inhibitor of sexual maturation during the prepubertal period. (Supported by MRC grant MA-6235).

1524 CONNECTIONS OF HYPOTHALAMIC NEUROSECRETORY NUCLEI WITH VISCERAL SENSORY STRUCTURES IN THE BRAINSTEM OF THE RAT. Edward Tongju Koh* and Juarez A. Ricardo* (SPON: W.J.H. Nauta). Dept. of Psychology, Massachusetts Institute of Technology, Cambridge, Mass. 02139 and Dept. of Anatomy, Harvard Medical School, Boston, Mass. 02115.

Recent reports have shown that the paraventricular nucleus of the hypothalamus (pa) receives direct input from both the caudal portion of the nucleus of the solitary tract (nts; Brain Res. 153:1) and the parabrachial region (pb), and projects directly back to these structures. In view of pa's role in releasing antidiuretic hormone (ADH) and oxytocin (OXY), such relations of pa may represent mechanisms by which information from vagal and glossopharyngeal receptors modulates neurohypophysial effects on the body's fluid status and triggers adenohypophysial responses to some types of stress. In the present study, the anterograde autoradiographic and retrograde horseradish peroxidase (HRP) tracing techniques were used to further examine this neural system.

HRP injected into either the caudal portion of the nts or pb labeled neurons in pa. In both series, the population of labeled neurons lies within parvocellular portions of pa, avoiding the magnocellular regions which occupy its lateral borders (Brain Res. 108:187). At the caudal pole of the nucleus the population extends laterally away from the third ventricle and establishes continuity with a group of labeled neurons within the posterior fornical nucleus (pfo; J. comp. Neur. 128:181), an accessory neurosecretory cell group which lies dorsal to the fornix.

Tritiated leucine and proline injected into either the caudal part of the nts or pb labeled a continuous region including both pa and pfo. Within pa, tracer substance is again heavily concentrated within parvocellular territories, with little labeling above background levels in magnocellular regions.

All of the projections described are bilateral, with uncrossed components which are heavier than their crossed counterparts.

The present findings suggest that pa's interactions with visceral sensory structures are mediated by its parvocellular regions and perhaps also by pfo, with which it shares both afferent and efferent visceroceptive connections. In the light of evidence that the hypophysial projections of pa arise chiefly from its magnocellular portions (Brain Res. 88:403), the axons it sends to nts and pb are probably not collaterals of the hypothalamo-hypophysial tract. However, pfo also projects into this tract, meaning that its projections to visceroceptive brainstem nuclei may well arise from neurons which also send their axons to the pituitary. This notion is strengthened by reports that antibodies to ADH and OXY bind within pathways to nts and pb (Anat. Rec. 190:349; SNS 4:1316). (Supported by USPHS grants NS 06542, MH 25515 and 5 T05 GM 02220, and by Fellowship Award 04-75/0167 to J. A. R. from the Fundação de Amparo à Pesquisa do Estado de São Paulo, Brazil.)

1526 THE ANTERIOR PITUITARY DOPAMINE RECEPTOR; A MULTIPLE SUB-SITES COMPLEX. F. Labrie*, T. Di Paolo*, B. Gagné*, J.P. Raynaud* and J.R. Boissier* (SPON: J.F. Estable-Puig). MRC Group in Molecular Endocrinology, CHUL, Québec, G1V 4G2, Canada, and Centre de Recherches Roussel-UCLAF, Romainville, France.

Since it is well documented for a large series of hormones (and also some neurotransmitters) that the response of a target tissue is largely dependent upon the level of specific tissue receptors, it becomes important to gain a detailed understanding of the characteristics of binding to the dopamine (DA) receptor. In order to avoid interference by possibly different properties of pre- and post-synaptic receptors in the central nervous system, our studies were performed using a tissue containing exclusively post-synaptic DA receptors, the anterior pituitary gland. In agreement with previous observations in brain and pituitary, DA agonists were more potent than antagonists to displace [^{3}H] apomorphine binding from bovine anterior pituitary membranes while the opposite was true for [^{3}H] haloperidol and [^{3}H] spiroperidol binding, such data being compatible with two states of the DA receptors. However, when the potent DA agonist [^{3}H] RU24213 (N-n-propyl-N-phenylethyl-β-(3-hydroxyphenyl) ethylamide hydrochloride) was used as ligand, the pattern of displacement was RU24213 > haloperidol > (+) butaclamol > spiroperidol = (-) butaclamol while dihydroergocryptine, apomorphine and DA were inactive up to 10^{-4}M, this specificity being highly antagonistic. Moreover, the specificity of binding of another potent DA agonist, [^{3}H] dihydroergocryptine was closer to that of antagonists than agonists. The presence of multiple subsites was also clearly indicated by the ligand-specific potency of each unlabeled drug, the presence of biphasic curves, the extension of many displacement curves over many orders of magnitude and the variable maximal levels of displacement obtained. The present data show that the specificity of binding to a probably pure population of postsynaptic dopaminergic receptors does not correlate necessarily with the pharmacological agonistic and antagonistic properties of the ligand used. Such findings clearly indicate that the DA receptor exists as a multiple subsites complex and that some of these subsites (at least five, specific for each dopaminergic drug used) may not be linked to a biological function.

1527 EFFECT OF SYSTEMIC MORPHINE ON AMYGDALOID SEROTONIN CONTENT AND SERUM LEVELS OF LUTEINIZING HORMONE. Joan M. Lakoski and Gerald F. Gebhart, Dept. of Pharmacol., Univ. of Iowa, Iowa City, IA 52242.

Ascending serotonergic projections to the amygdaloid nuclei and hypothalamus have been implicated in the regulation of the secretion of luteinizing hormone (LH). Recent evidence defines a role for these serotonergic pathways in the depression by opioids of LH release in the rat (Maughan et al., Brain Res. 155:413, 1978). To evaluate the role the amygdaloid nuclei might play in the depression of serum levels of LH, the effect of acute parenteral administration of morphine (MOR) on levels of serotonin (5-HT) in 8 amygdaloid and 1 hypothalamic area was examined and correlated with MOR's effect on serum LH.

Male Sprague-Dawley derived rats maintained on a 12:12 light-dark cycle (lights on 0700 hr) were non-stressfully injected with MOR (20, 7.5, or 1 mg/kg), naloxone (NAL; 1 mg/kg), MOR plus NAL (7.5 + 1 mg/kg), or saline I.P. at 0800-0900 hrs. Animals were decapitated 60 minutes after injection and the brain tissue was rapidly removed, frozen and stored at -80°C. Blood from the decapitated trunk was collected, the serum separated, and stored at -80°C. Samples were punched from the following 8 amygdaloid nuclei (584 μ dia) and 1 hypothalamic area (508 μ dia) from frozen coronal brain sections and assayed for 5-HT employing an enzymatic-isotopic method (Saavedra et al., JPET 186:505, 1973): medial, cortical, basolateral, lateral posterior, central and the cortical, basolateral and lateral posterior caudal amygdaloic nuclei and the hypothalamic ventromedial nucleus (VMN). Serum LH was determined using a double antibody radioimmunoassay method (NIAMDD). Control serum LH levels (28.7 ± 2.4 ng/ml, n=15) were depressed by MOR in a dose-related manner. Serotonin content in the amygdaloid nuclei and VMN after MOR administration did not significantly differ from control levels of serotonin at any of the MOR doses employed. These data suggest the amygdaloid nuclei may not be the primary site of opioid regulation of LH secretion by ascending serotonin pathways. Supported by NIH grant NS 12114.

1528 DISCRETE LESIONS OF THE DORSAL ROSTRAL PONS PREVENT ACTH INCREASES AFTER HEMORRHAGE. Alan M. Lefcourt*, David G. Ward, Helen Santana*, Virginia S. Rudrow* and Donald S. Gann. The Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.

The region of the locus coeruleus has been implicated in the ACTH response to hemorrhage, but alternative pathways have not been excluded. Electrical stimulation of this area leads to changes in release of ACTH (Endocrinol. 99:1220, 1976; Fed. Proc. 38:1200, 1979) and neurons in the same area respond to decreases in venous return (Fed. Proc. 37:743, 1978). However, stimulation of more lateral and medial regions also lead to changes in ACTH (Fed. Proc. 38:1200, 1979), and the lateral pons receives projections from the solitary nuclei (J. Comp. Neurol. 181:421, 1978). To determine whether the region of the locus coeruleus is essential for the ACTH response to hemorrhage, bilateral electrolytic lesions (11 cats) or sham lesions (3 cats) were placed chronically in the pons of 14 anesthetized cats. Four days later the animals were anesthetized with chloralose/urethane and four hours later were hemorrhaged 15 ml/Kg/3 min. Arterial blood samples were collected over 3 min periods for 30 min beginning 6 min before hemorrhage and were assayed for ACTH by RIA. Responses were analyzed by analysis of variance. Data were grouped both according to the presence or absence of responses of ACTH and according to whether the lesions included the locus coeruleus bilaterally. Both methods for categorizing the data led to identical groups as shown:

ACTH pg/ml

	before Hem		after Hem				
	-6 min	-3 min	3 min	6 min	9 min	15 min	21 min
sham (n=7)	59±16	69±18	126±28	125±22	125±11	124±20	114±20
lesion(n=7)	73±11	66±9	61±10	43±4	61±11	75±11	90±22

The sham group includes sham lesions or lesions of areas surrounding the locus coeruleus and shows a significant response of ACTH to hemorrhage ($P<0.05$). In contrast, the lesion group includes bilateral lesions of the region of the locus coeruleus and shows no response of ACTH ($P>0.5$). The common overlap of the lesions in the lesion group is a region of less than 1 mm^3 that is within an area from which stimulation leads to changes in ACTH. The region includes the area of the ventral locus coeruleus and of the locus subcoeruleus that contains neurons responding to decreases in venous return, and an area immediately dorsal. The present data indicate that, under the conditions of the experiments, a discrete region within the locus coeruleus and locus subcoeruleus is essential for the response of ACTH to a 15 ml/Kg hemorrhage. (Supported in part by NIH grants AM14952 and GM7031).

1529 TESTOSTERONE EFFECTS ON ENZYMES IN CENTRAL AND PERIPHERAL TARGET SITES IN Tfm MUTANT MICE. V.N. Luine, N.J. MacLusky* and B.S. McEwen. Rockefeller University, New York NY 10021.

The testicular feminization mutation (Tfm) in mice is a mutation on the X chromosome conferring an insensitivity to testosterone (T) action in target organs. Affected mice show deficiencies in cytosol androgen receptors (Attardi et al., Endo 98: 864, 1976; Gehring et al., Nature New Biol. 232:106, 1971) and in the response of a number of enzymes to T in peripheral target sites (Ohno et al., Clin. Gen. 1:35, 1970).

We have examined the response of enzymes in central and hypophyseal sites to androgen as well as confirmed previous work in peripheral targets. Normal Balb/C and Tfm males were castrated and received s.c. implants of Silastic capsules containing cholesterol or T. Five days later they were sacrificed and cerebral cortex (Ctx), whole hypothalamus, preoptic area and amygdala (HPA), pituitary and kidney were removed and homogenized. The following enzymes were measured: monoamine oxidase (MAO) in Ctx and HPA; glucose-6-phosphate dehydrogenase (G6PDH) and lactate dehydrogenase (LDH) in pituitary; and G6PDH and alcohol dehydrogenase (ADH) in kidney.

In the brain, MAO activity in the HPA from normal males was increased approximately 20% by T. T was without effect on MAO in the HPA from Tfm males. In the Ctx, a brain region which contains far fewer T receptors than the HPA, T administration did not alter MAO activity in either normal or Tfm males. Kidney ADH activity was dramatically increased, approximately 6-fold, in normal males, but activity in T treated Tfm's was unchanged. G6PDH activity in the kidney also increased after T in normal but not Tfm mice. The change in normal males, approximately 30%, was modest compared to the ADH change. T effects on pituitary enzymes were not noted in either normal or Tfm mice.

The ability of T to increase activities of ADH and G6PDH in kidney and MAO in the HPA of normal but not Tfm mice led us to measure these enzymes in intact normal and intact Tfm mice. Kidney ADH levels were higher in intact mice, but G6PDH and MAO were identical in the two groups.

While further experiments are needed to clarify the hormonal regulation of G6PDH and MAO, it is clear that the response to T is abnormal in Tfms. Results with MAO are important because this is the first central enzyme shown to be androgen resistant in the Tfm, and it may provide a marker for exploring how alterations in levels of central androgen receptors may affect androgen sensitive neurochemical events in neuroendocrine regulation.

1530 MELATONIN SPECIFICALLY INHIBITS PITUITARY RESPONSIVENESS TO LH-RELEASING HORMONE. Jeanne E. Martin and Carol Sattler.* Department of Pharmacology, Washington University Medical School, St. Louis, Missouri 63110.

Previous studies from this laboratory have shown that the pineal indole melatonin (MEL) can suppress the neonatal rat pituitary LH and FSH responses to LH-releasing hormone (LHRH). The present study has examined the specificity of MEL inhibition for the gonadotropins by measuring the effects of MEL on thyrotropin-releasing hormone (TRH) induced release of TSH and prolactin (PRL) and on basal release of TSH, PRL, and GH by pituitary cells in culture. Neonatal rat anterior pituitary cells were dissociated with collagenase and hyaluronidase and cultured for 22h. At the time of use, the dispersed cells were washed with fresh medium and incubated for 3h in control medium or medium containing TRH (0.1-1000 nM) or LHRH (1-1000 nM) either alone or in the presence of MEL (10 or 1000 nM). Medium concentrations of TSH, PRL, GH, and LH were determined by double antibody radioimmunoassay with the use of materials supplied by the NIAMDD. As previously, MEL (10 nM) significantly ($p<0.01$) suppressed LH release by all concentrations of LHRH with inhibition of the response ranging from 17-56%. This concentration of the indole consistently produces maximal suppression of both LH and FSH responses to LHRH. By contrast, MEL at a 100-fold greater concentration (1000 nM) had no effect on either TSH or PRL release induced by any dose of TRH. In the absence of releasing hormones, medium LH increased only about 50% over zero-time values during the 3h incubation whereas the levels of TSH, PRL and GH increased 200-300%. While this apparent spontaneous secretion of TSH and GH was not affected by MEL (1000 nM), the indole has consistently induced a slight (16-18%), but significant ($p<0.05$), suppression of PRL release. These findings reveal that MEL inhibition of releasing hormone-induced pituitary secretion apparently is specific for LHRH. The data suggest, however, that MEL may also exert a regulatory effect on PRL secretion by the pituitary gland. (Supported by The Population Council).

1531 CNS ACTIVITY DURING THE ESTROUS CYCLE OF THE RAT. J. F. Masken and R. J. Morgan. Dept. Physiol. and Biophys., Colo. State Univ., Fort Collins, Colo. 80523.

Sprague-Dawley rats were implanted with chronic electrodes in the amygdala, pre-optic area, and arcuate nucleus-median eminence region in order to learn about electrical communication in the limbic system during the estrous cycle. Electrical signals were recorded simultaneously for ten minutes of each half-hour between 10:00 h and 15:30 h on each day of the estrous cycle. These signals were analyzed for amount and direction of signal traffic between pairs of electrodes and for transmission times between pairs of sites. Signal traffic from the amygdala to the preoptic area lasts longer and takes longer en route during the "critical period" on the day of proestrus than at other times of the cycle. This is statistically significant at $p < 0.0002$ and implies a change in the signal pathway during this time. These data also imply that the arcuate-nucleus median eminence is probably not directly involved in initiating the release of gonadotropin-releasing hormone as a key event in the estrous cycle in the rat.

1532 EFFECTS OF GAMMA-AMINOBUTYRIC ACID (GABA) ON LORDOSIS BEHAVIOR AND DOPAMINERGIC ACTIVITY IN ESTROGEN PRIMED SPAYED FEMALE RATS. Marilyn Y. McGinnis*, John H. Gordon and Roger A. Gorski (Spon: M. Krieger). Dept. Anat. Sch. Med. UCLA, Los Angeles CA 90024.

To examine alterations in lordosis behavior (measured by the lordosis quotient: LQ) and dopaminergic function as they relate to changes in GABA activity, two drugs which alter GABA function were studied: picrotoxin, a GABA receptor blocker, and hydrazinopropionic acid (HPA) which elevates endogenous GABA levels. Because spayed female rats show low LQ's when primed with estrogen only, a suppression of lordosis would not be detected. Therefore, septal lesioned (SL) rats were used for detecting decreases in lordosis behavior as they show high LQ's after treatment with estrogen only. Also the estrogen-primed SL rat is a useful model in that it is known to have lower dopamine (DA) turnover and higher GAD activity than sham-operated (Sham) controls. To test whether alterations in GABA were correlated directly with changes in LQ, spayed SL and Sham rats were primed with estradiol benzoate (EB: 2µg/day for 3 days) and tested for behavior on the fourth day before and after bilateral infusion of drugs directly into the substantia nigra. SL rats received picrotoxin or saline; Sham rats received HPA or saline. In SL rats, the LQ was suppressed 30 min after picrotoxin but was again elevated by 120 min post infusion. Conversely, HPA resulted in a moderate increase in the LQ at 30 min and reached high levels by 120 min. The LQ was again low by 360 min post infusion demonstrating that the effect was reversible. Saline had no effect on behavior. In experiment II, SL and Sham rats were primed with EB and infused with the drugs as in Experiment I, but were sacrificed at the time the maximal behavioral effect had been observed in order to determine the effects of these same drugs on DA activity. Tyrosine hydroxylase (TH) activity and DA and homovanillic acid (HVA) levels were measured. No effect on TH activity was found, but Sham rats receiving HPA infusions had lower DA and HVA levels compared to those receiving saline, and SL rats receiving picrotoxin infusions had higher DA and HVA levels than those of saline controls. SL saline infused rats also showed decreased DA and HVA levels relative to Sham saline infused animals. Thus, these three variables tend to be related in a particular way: when DA is low and GABA is high, the LQ is high, and conversely, when DA is high and GABA is low, the LQ is also low. These results support the concept of a GABA inhibitory neuronal feedback system which modulates DA turnover and perhaps plays a critical role in the neural control of lordosis behavior.

1533 PINEAL, TESTES, ADRENAL AND THYROID DATA IN INSULIN DEFICIENT RATS AFTER INJECTIONS WITH ANTERIOR HYPOPHYSEAL EXTRACT. M. Evelyn McNeill, Carl R. Morgan* and Everett C. Simpson*. Depts. of Anat. (Sch. Med.) and Biology, East Carolina University, Greenville, N. C. 27834.

In conjunction with an investigation of the pancreotropic effect of anterior hypophyseal extract (beef), we have initiated a study of the effects of this extract on other endocrine tissue with particular interest focused on the pineal - testes axis. Male Sprague-Dawley rats (18), made insulin deficient with i.v. injection of 2% alloxan, 40 mg/kg body weight, were paired with 18 normal rats of comparable weight. Half of the alloxan-diabetic rats and half of the normal rats were injected (2 ml, s.c.) daily x 14 with a crude alkaline extract of beef anterior hypophysis. On day 14 the animals were weighed, bled, anesthetized with Diabutal (60 mg/kg) and perfused with 10% formalin for light microscopic observations or with 0.25 Karnovsky's fixative for EM observations. The pineal, testes, adrenals and thyroid were harvested from alloxan-diabetic (AD), alloxan-diabetic plus extract (AD+E), normal (N) and normal plus extract (N+E) groups. The initial body weight, final body weight, wet weight of the pineal, testes, adrenals and thyroid were recorded in gms. Statistical analysis of the numerical data was carried out with an electron desk computer (Sharp Compet 364 P-II) using magnetic cards containing programs for multiple analysis of variance.

Group & Number	$\bar{x}$ Initial Body Wt. Gms.	$\bar{x}$ Final Body Wt. Gms.	$\bar{x}$ Pineal Wt. Gm.	$\bar{x}$ Testes Wt. Gms.	$\bar{x}$ Adrenal Wt. Gm.	$\bar{x}$ Thyroid Wt. Gm.
AD(n=8)	229	234	.00128	3.17	.06789	.01808
AD+E(n=9)	220	239	.00117	3.18	.14049	.01813
N(n=9)	219	257	.00189	3.51	.05691	.01990
N+E(n=9)	219	284	.00203	3.14	.12304	.02838
	$p>.05$	$p<.01$	$p<.01$	$p>.05$	$p<.01$	$p<.01$

Comparison of the mean testes weights for the 4 groups revealed no significant differences. Pineal weights in groups AD and AD+E were both significantly different from groups N and N+E ($p<.05$). In addition adrenal weights in groups N and AD were significant at the $p<.05$ level from groups N+E and AD+E. The only significant difference ($p<.05$) found in the thyroid weights was confined to the N+E group. Group comparisons were determined by the Neuman-Keul analysis.

1534 INHIBITION OF MELANOCYTE-STIMULATING HORMONE SECRETION BY NALOXONE IN AMPHIBIANS. S. P. Mennin* and L. C. Saland. Dept. Anat., Sch. Med., Univ. of New Mexico, Albuquerque NM 87131

It has recently become apparent that opiate peptides interact with several neuroendocrine systems. In view of the similarities between the proposed control mechanisms of prolactin in mammals and melanocyte-stimulating hormone (MSH) in amphibians we undertook a series of experiments to determine if opiate peptides were involved in the control of MSH secretion. Pars intermedia secretory cells contain MSH, beta-lipotropin, endorphins, and adrenocorticotrophic hormone, which may be present in the same secretory granule and released simultaneously. Melanophore changes may therefore be a valid biologic assay in amphibians for release of opiate peptides. Naloxone hydrochloride (20mg/kg, Endo Laboratories) was injected into the dorsal lymph sac of light adapted frogs at hourly intervals for three hours. Animals were placed on a dark background after the first injection, and the melanophore index (MI) was determined (Hogben and Slome, 1931, Proc. Roy. Soc. B, 108:10). The mean MI of naloxone injected frogs (2.1 ± 0.2) (mean $\pm$ S.E.M.) was significantly lower than control MI's (3.1 ± 0.1) after one hour and remained significantly less for three hours (naloxone: 2.1 ± 0.1, control: 4.1 ± 0.1). Naloxone also prevented the transient lightening observed routinely after handling. In contrast, the MI of animals already dark adapted and treated with naloxone was not significantly different from that of control dark adapted frogs at any time up to four hours. Ultrastructural examination of intermediate lobes from frogs moved from light to dark backgrounds and treated with naloxone revealed cellular characteristics of light adaptation. Controls acquired the endoplasmic reticulum and Golgi zone expansions typical of dark adaptation. These data support a role for endogenous opiates in amphibians. The data further indicate that naloxone may enhance the neural inhibition of MSH release. We suggest that an opiate-receptor dependent mechanism may modulate hypothalamic control of pars intermedia peptides. (Supported by a grant from NSF PCM 78-16224 and R-3002 from University of New Mexico.)

1535 RELEASE OF α-MSH-ACTIVITY FROM ISOLATED RAT NERVOSA-INTERMEDIA (NI) FOLLOWING ELECTRICAL STIMULATION AND IONIC CHANGES. H. J. Mitchell* and J. V. Milligan. Dept. of Physiology, Queen's University, Kingston, Ontario K7L 3N6.

Release of α-MSH from rat pituitary is thought to be under inhibitory control by the hypothalamus. This hypothesis is based on indirect evidence. We tested the theory directly using a modification of the in vitro procedure first described by Mikiten (1967). The NI were separated from the pars distalis with a bent needle using 10X magnification. The total time from decapitation of the rat to the end of tissue isolation did not exceed 40 sec. One or more isolated rat NI were skewered on a #22 stainless steel hypodermic needle and set up so that field stimulation (40 Hz, 80 V, 1.75 msec, bipolar cathodal pulses) could be applied every other minute. Incubation media was Krebs Ringer bicarbonate supplemented with 1% BSA and 2% glucose. A pH of 7.4 was maintained by gassing with a humidified gas mixture of 95% O_2-5% CO_2. The tissue and media content of α-MSH were determined by a sensitive bioassay (100 ± 30 pg in 50 µl) modified from Tilders et al. (1975). Total α-MSH ranged from 2.0 to 5.3 µg/NI. Spontaneous release was followed for periods of 120 minutes with media changes every 10 min. After a maximum of 30 minutes a steady release ranging between 0.1% and 1.0% of the total α-MSH (0.5% average) was observed. This is much smaller than values reported by others. Electrical stimulation during a 10 minute period promptly produced either a small but significant increase or a small decrease in release (0.7-2.0 fold). Incubation in low Na^+ (25 mM), produced by equiosmolar substitution with sucrose, caused a prompt decrease (.27-.13 of control values) in α-MSH release. Electrical stimulation produced a doubling, on the average, of this release. When Ca^{++} was reduced to 15% of normal, by omitting the appropriate amount from the medium, the release decreased to about 0.4 of the control value and electrical stimulation caused a further drop to about 0.2 of the control value. We cannot exclude the possibility of a direct effect of the ionic changes upon the pars intermedia cells. However, we suggest that our isolated in vitro preparation of rat NI is being tonically stimulated by both spontaneous inhibitory and excitatory nervous activity. In control circumstances the inhibitory activity predominates. Modification of the ionic environment would appear to preferentially affect the activity of either excitatory or inhibitory nerves allowing the respective single effect to be seen more clearly.

Supported by MRC (Canada) and Queen's University.

1536 EFFECTS OF PERINATAL ACTH-NALOXONE TREATMENT ON LH LEVELS, AND PHYSICAL AND BEHAVIORAL DEVELOPMENT. H. Monder, N. Yasukawa*, S. D. Michael* and J. J. Christian*. Dept. Biol. Sci., S.U.N.Y. Binghamton, Binghamton, NY 13901.

A previous study from this laboratory (Life Sci. 22: 1381, 1978) implicated opioid receptors in the role of ACTH in reproductive maturation. Rate of maturation is an important factor in the control of rodent populations. The detrimental effects of high population densities are transmitted to the young even if the parents are removed from the population. In order to determine if a naloxone sensitive ACTH system mediates these effects, pregnant mice were treated with ACTH extract and Naloxone from about 5 days prior to parturition. ACTH injections were continued in the mothers to 5 days postpartum.

Observations of physical development, such as body weight, age of eye opening and vaginal opening were made. LH levels in trunk blood at 60 days of age were measured. Behavioral observations included ability and time for turning over for pups after being placed on back at 3 days of age; squares crossed in an open field task at 32 days of age; and latency to react to heat on a hot plate at 50 days of age.

ACTH treated animals showed a lower body weight from parturition to sacrifice at 60 days of age. Eye opening and vaginal opening were delayed in these animals and LH levels were depressed in the blood samples taken when the animals were sacrificed. These effects were not observed in the offspring of animals treated with both ACTH and naloxone. Open field activity was depressed in the naloxone treated group, but not in the offspring of mothers treated with both ACTH and naloxone. Latency on a hot plate at 50 days of age was significantly reduced by the naloxone treatment, while ACTH had no effect.

ACTH has not been shown to pass the placental barrier. Therefore, a separate class of ACTH mediated receptors, probably in the mother, may affect reproductive development of the fetus. These receptors may be preferentially blocked by naloxone, preventing the ACTH-induced delay of maturation. Naloxone also affects locomotor as well as nociceptive systems, while ACTH does not affect the development of these systems. The interaction of ACTH and naloxone on square crossing activity in the open field may be due to changes in the emotional reactivity of the animals. This research was supported by NICHHD 10515.

1537 COINCIDENCE MODELS AND HAMSTER PHOTOPERIODISM. L. P. Morin. Dept. Psychol., Dartmouth College, Hanover, N.H. 03755.

The external coincidence model of photoperiodic time measurement predicts that the testes of male hamsters which have experienced prolonged exposure to long days will always atrophy in the absence of photic stimulation. Three experiments were designed to test this prediction. Groups of reproductively mature male hamsters entrained to a long photoperiod were subjected to one of a variety of light cycle phase shifts followed several days later by blinding. Across all experiments, full gonadal atrophy occurred in 100% of the animals (N=58) not experiencing a shift or experiencing a phase advance, but failed to occur in 44% of animals (N=27) experiencing a 4 hr phase delay maintained for 10 days prior to blinding. A decrease or increase in the period of the circadian locomotor activity rhythm was an after-effect of a phase advance or delay, respectively. Animals with atrophied testes showed relative compression of the nocturnal locomotor activity phase regardless of the type of phase change. The fact that blinding does not necessarily lead to gonadal regression cannot be easily explained by the external coincidence model. Both gonadal size and wheelrunning patterns in blind hamsters are lighting history dependent. The data are consistent with an internal coincidence explanation of hamster photoperiodic time measurement.

1538 RELEASE OF ACTH AND β-LPH BY HUMAN ANTERIOR PITUITARY CELLS IN VITRO. G.H.Mulder* and D.T. Krieger, Mount Sinai School of Medicine, Division of Endocrinology, New York, N.Y., 10029

Collagenase dissociation of postmortem (6-36 hrs) normal human anterior pituitary tissue yields viable (65-95% Trypan Blue exclusion) cells that were used in the study of the regulation of ACTH, β-EP and β-LPH release. Two or more cell columns from one batch of pituitary cells were superfused simultaneously according to our previously published method (Endocrinology 100, 1143, 1977). Effluent was collected at 2 min intervals and assayed by RIA for ACTH, β-EP and β-LPH, using antibodies specific for ACTH, for β-EP+β-LPH and for β-LPH. We have previously shown that such human cells release ACTH in a log.dose-response fashion after stimulation with a rat hypothalamus extract (NIH-HME), that ACTH release can be inhibited by glucocorticoids and that such ACTH release represents active secretion (8th Neuroscience Meeting 1978). Serotonin at 5 x 10^{-6}M increased ACTH release to 3-4 times basal levels (n=5). Norepinephrine at 5 x 10^{-6}M and Dopamine at 10^{-6}M had no effect (n=5 and n=3). AVP at 20-40 mU/ml doubled to tripled ACTH release (n=4). In all cases cited, release of β-EP+β-LPH was not affected by the substances that increased the release of ACTH. Recovery of ACTH, β-EP or β-LPH, all added at 2 x 10^{-10}M, was 70-80, 70-85 and 60-70% respectively. In experiments with rat pituitary cells, both rat NIH-HME and AVP stimulated the release of both ACTH and β-EP+β-LPH, indicating that the methodology of the superfusion system was not the cause of our inability to detect concomitant release of these peptides by human cells in vitro. In contrast, a partially purified human hypothalamus extract (5M acetic acid extraction followed by Sephadex G-50 chromatography) is the only substance thus far found to stimulate the release of human β-EP+β-LPH, though dose-response curves have not yet been constructed. The main component (+ 90%) of the released β-EP+β-LPH was β-LPH; little or no stimulation of β-EP release was observed, indicating that there was little or no conversion of β-LPH to β-EP. These results indicate that, contrary to our earlier findings, it is possible, using a human hypothalamus extract, to induce concomitant secretion of ACTH and β-LPH by human anterior pituitary cells in vitro.

*present address GHM : Dept. of Pharmacology, Free University Amsterdam, the Netherlands.

1539 THE EFFECT OF HIPPOCAMPAL LESIONS ON THE HYPOTHALAMIC-PITUITARY-THYROID-TARGET ORGAN AXIS. Helen M. Murphy and Cyrilla H. Wideman, John Carroll Univ., Cleveland, OH 44118, Donald W. Long*, Consolidated Biomedical Laboratories, Columbus, OH 43216, and Thomas S. Brown*, DePaul University, Chicago, ILL 60614.

Two experiments were conducted in an attempt to ascertain the effect of hippocampal lesions on the hypothalamic-pituitary-thyroid-target organ axis. In the first experiment total T_4 (RIA), total T_3 (RIA), cholesterol, triglycerides and albumin were measured in animals with hippocampal lesions (H) and in cortical control (C) and normal animals (N). The H animals had significantly less total T_4, significantly lower serum cholesterol levels and significantly lower triglyceride levels than control animals. There were no significant differences in total T_3 or serum albumin levels. In the second experiment total T_4, total T_3, free T_4 (RIA) and TSH (RIA) were measured in H, C and N animals as well as in thyroidectomized animals (T) and animals made hyperthyroid (I) by means of thyroxine injections. The H animals had significantly less total T_4 than C, N and I animals. The T group was significantly lower than all of the other groups. The H animals were not significantly different from C and N animals in total T_3, but were significantly lower than I animals and significantly higher than T animals. The H group had significantly less free T_4 than the C, N and I groups. The T animals were significantly lower than the other groups. Animals with hippocampal lesions were not significantly different from C and N animals in plasma TSH concentrations. The H animals had significantly more TSH than the I group and significantly less TSH than the T group. T_4 (RIA) to T_3 (RIA) ratios were calculated for all five groups. The H group was significantly lower than the C, N and I groups and significantly higher than the T group. The results of the two experiments present a paradox. From the total T_4 and free T_4 tests it would appear that H animals may be tending toward hypothyroidism. From the cholesterol and triglyceride tests it would appear that these animals may be tending toward hyperthyroidism. It is hypothesized (particularly from the TSH results and the calculation of the T_4:T_3 ratios) that animals with hippocampal lesions have an increased utilization of thyroid hormones. This hypothesis could explain many of the behavioral studies in which animals with hippocampal lesions resemble hyperthyroid animals.

(Rat TSH standard was provided by NIAMD.)

1540 DIFFERENTIAL CHANGES IN VASOPRESSIN IN SPECIFIC HYPOTHALAMIC NUCLEI AND CIRCUMVENTRICULAR ORGANS AFTER PROGRESSIVE DEHYDRATION. A. Negro-Vilar* and W. K. Samson* (SPON: J. M. Lipton). Dept. Physiol. Univ. of Tx. Hlth. Sci. Ctr. at Dallas, TX 75235.

Increased extracellular osmolarity after water deprivation (WD) is a well known stimulus for vasopressin (AVP) release. Taking advantage of a highly sensitive radioimmunoassay for AVP combined with microdissection techniques, we have analyzed the sequential changes in AVP in specific brain areas, in the posterior pituitary (PP) and in the serum of rats after 1-7 days of WD. Serum AVP increased progressively up to 3 days after WD, was still high by 5 days and declined to low levels by day 7 of WD. AVP in the PP declined steadily to values below 10% of controls by day 7 of WD. AVP levels in paraventricular (PVN), suprachiasmatic (SCN) and arcuate (ARC) nuclei, declined slightly by 3 days and clearly fell below control levels by day 7. ME levels of AVP were also diminished after 7 days of WD. Levels of AVP in the SON remained unaltered throughout the 7 days of WD. AVP was also measured in the organum vasculosum lamina terminalis (OVLT), subfornical organ (SFO) and in the pineal gland. Changes in these circumventricular structures mirrored the changes in serum AVP, i.e. high values were seen at 3-5 days of WD and by 7 days levels had returned to low control values. To determine if the increased AVP content in the OVLT after 3 days of water deprivation was due to an increased delivery of AVP from the SCN, bilateral lesions were generated in this nucleus. Preliminary results suggest that SCN lesions reduced AVP levels in the OVLT in normally hydrated rats. It was also found that AVP levels in the OVLT did not increase 3 days after WD. If confirmed, these results would suggest that the AVP in terminals of the OVLT may originate in SCN cell bodies. The decline in serum AVP levels by day 7 of WD may reflect an exhaustion of AVP stores as indicated by the drop in AVP in the PP, PVN, ARC, ME and SCN. The lack of change in AVP levels in the SON even after 7 days of WD is puzzling, and suggests that these nuclei may play a role different from that of the PVN in the release of AVP. The increase in AVP levels seen in the circumventricular organs may be a passive reflection of peripheral AVP levels or may represent an epiphenomenon of some central action of the hormone. (Supported by NIH AM10073 and HD09988 and the Ford Foundation).

1541 QUANTIFYING SEXUAL BEHAVIOR IN FEMALE HAMSTERS. Nancy L. Ostrowski and Ralph G. Noble*. Dept. Psych. Rensselaer Polytechnic Institute, Troy, N.Y. 12181.

Females of many mammalian species display a vaginal orienting response to tactile stimulation of the perineum during coitus. This response aids the male in achieving intromission and successfully impregnating the female. A system for measuring this response in the female hamster has been developed.

The measurement system: The lateral component of this response can be measured using a technique which simulates tactile stimulation during coitus. Application of repetitive stimulation to an anatomically defined region results in a lateral displacement toward the point of contact. The magnitude of the reflex is a linear function of the log of the amount of force applied (ranging from .009 - 66.8 g of force), with the mean interobserver reliability (R) typically greater than .90.

The response: This lateral displacement response can only be obtained from females in the lordosis posture. This measure will discriminate among "receptive" females. Those which are active sexual participants display a greater amount of displacement than either (a) females mated to 30 or more intromissions and ejaculations, or (b) pregnant females which show lordosis. The magnitude of the response increases rapidly during the early stages of the estrus period; it decreases gradually toward the end of the estrus period and can be used to predict the termination of estrus.

Other manipulations which are known to alter the neuroendocrine state of an animal also produce changes in magnitude of this response including inescapable foot shock, morphine, ethanol, naloxone and voluntary exercise.

It is suggested that this measure may reflect subtle changes in the neuroendocrine status of the "receptive" female, changes which are not usually detected by other currently used measures.

1542 THE ONTOGENY OF THE LHRH NEUROSECRETORY SYSTEM IN THE ALBINO RAT: AN IMMUNOCYTOCHEMICAL STUDY. C.M. Paden* and A.J. Silverman (SPON. D. Micco). Rockefeller University and Dept. Anat., P&S, Columbia University, New York, NY 10032.

A study on the ontogeny of the LHRH neuroendocrine system was carried out on fetal and neonatal rats (Charles River, CD). Both male and female brains from 18 day fetuses to 20 day neonates were studied. Fetal brains were fixed by immersion in Bouin's solution; neonates were perfused with Bouin's solution and fixation continued by immersion for 48 hr. Brains were cut at 50um on a Vibratome, sections washed in PBS and incubated sequentially with: (1) rabbit antiserum to LHRH (48hr); (2) sheep anti-rabbit globulin serum (60min); (3) the PAP complex (90min) and (4) DAB-H_2O_2 (15min). All sera contained 0.4% Triton X 100. After immunostaining sections were mounted on glass slides, counterstained with cresyl violet and coverslipped. Specificity controls were performed on paraffin sections.

On day 21 of fetal life (day 1=day of sperm plug, and birth occurs on day 23) there is a dense fiber plexus around the organum vasculosum lamina terminalis (OVLT); only a few isolated fibers were present in the median eminence (ME) at this time. The number of LHRH positive axons in both structures increased throughout the first postnatal week, though the increase was more dramatic in the ME.

In the neonatal rat, LHRH cell bodies have been observed in the medial preoptic area at the level of the OVLT and in the n. of the tract of the diagonal band. Perikarya measured 10-12um in diameter and the majority had a single dendritic process extending for 60 to 250um. Some of these dendrites branched approximately 100um from the cell body. Although no LHRH neurons were observed in the arcuate nucleus of the neonatal rat, our antiserum does stain LHRH neurons in this region in the neonatal monkey in similarly prepared tissue sections.

By using Vibratome sections we have been able to enhance the immunostaining of LHRH fibers and perikarya in the perinatal rat. Furthermore the use of thick sections aids in observing the dendritic arborization of these neurosecretory neurons.

1543 FURTHER CHARACTERIZATION OF PINEAL MONOLAYER CULTURES. J. Parr* V.D. Rowe Veterans Administration Medical Center, Kansas City, Missouri 64128, and Univ. of Kansas Medical Center, K.C., KS.

Monolayer cultures of cells derived from neonatal rat pineal glands have been shown to share certain characteristics with the pineal gland in vivo and in organ culture. In particular, serotonin N-acetyltransferase (NAT) activity is markedly stimulated by norepinephrine (NE) and by dibutyryl cyclic AMP (dBcAMP). These cultures, however, have been found to differ from organ explant cultures in at least 3 important respects: (1) Despite the many-fold increase in NAT activity with NE and dBcAMP stimulation, no formation of N-acetylserotonin or melatonin from either tryptophan or serotonin could be demonstrated. (2) Stimulation of NAT activity was potentiated by serum in a dose-dependent fashion. (3) L-propranolol was found to cause a small but significant stimulation of NAT activity, and this stimulation could be blocked by cycloheximide and actinomycin D. These differences may reflect the effect of the absence of neuronal influence on the developing pineal.

1544 THE TEMPORAL RELATIONSHIP BETWEEN ESTROGEN-INDUCIBLE PROGESTIN RECEPTORS IN THE BRAIN AND THE TIME COURSE OF ESTROGEN ACTIVATION OF MATING BEHAVIOR. B. Parsons*, N.J. MacLusky*, L. Krey, D.W. Pfaff and B.S. McEwen. Rockefeller Univ., New York NY 10021

Estradiol (E_2) has been shown to induce progestin (P) receptor synthesis in those areas of the brain which mediate sexual behavior, the mediobasal hypothalamus (MBH) and the preoptic area (POA). In this study, we explored the temporal relationship between inducible P receptors in the MBH-POA and pituitary (PIT), and the time course of estrogen activation of mating behavior.

Ovariectomized (OVX) female rats received Silastic capsules of E_2. Animals either were given mating tests after progesterone (P), or were sacrificed. Radioimmunoassay (RIA) indicated that plasma E_2 levels were 40.0 ± 4.6 pg/ml at 12h, and remained constant. Initial receptivity was seen after 18h (LQ=22 + 10). LQ's increased between 18 and 48h, approaching maximal levels (LQ=78 ± 13). In both MBH-POA and PIT, an increase in ^{3}H-R5020 cytosol binding was seen at 12h. When receptivity is first observed (18), inducible P receptors are 26% maximal. Increases in ^{3}H-R5020 binding were seen at 24, 36 and 48h, reaching maximal levels at 48h.

OVX females which had been implanted with E_2 capsules for 7 days had their capsules removed. All animals either were tested with E_2 and E_2 + P, or were sacrificed. At time 0, animals tested with E_2 and E_2 + P gave LQ scores of 98 and 100, respectively. Thus E_2 alone may induce full receptivity as measured by the LQ score. Behavior without P showed a more rapid decline than behavior with P. LQ's decreased progressively at 12, 24, and 36h, reaching 10% (+P) and 1% (-P). Receptivity was not seen at 48, 72 or 120h. In the MBH-POA and PIT, a decrease in ^{3}H-R5020 binding was observed at 12h. We analyzed mathematically the time course of decay of E_2 inducible P receptors. The half life of the inducible P receptor, a first order process, is 24.7h in MBH-POA, and 26.6h in PIT. When receptivity is last observed (36h), ^{3}H-R5020 binding was 34% maximal. RIA indicated that plasma E_2 had declined to ADX-OVX levels (6.8 ± 1.0 pg/ml) within 12h.

Three observations suggest a complex, non-linear relationship between inducible P receptors and sexual receptivity. 1) Continuous estrogenic stimulation for 7 days results in LQ's of 100 in the absence of P. 2) While the decay of inducible P receptors follows first order kinetics, the complex decay of mating behavior clearly does not. 3) Receptivity is first observed when inducible P receptors in brain are 26% maximal; sexual receptivity is last observed when inducible P receptors are 34% maximal. A threshold level (25-35% maximal) of P receptors in the MBH-POA of the rat brain thus appears to be a good index of the competency to express feminine sexual behavior.

1545 EFFECTS OF PREOPTIC AND HYPOTHALAMIC STIMULATION ON SERUM LEVELS OF TESTOSTERONE AND CORTISOL IN INTACT AND GONADECTOMIZED MALE RHESUS MONKEYS. A. A. Perachio, J. G. Herndon*, M. Alexander and D. C. Collins*. Yerkes Regional Primate Research Center, Emory University, Atlanta, Georgia 30322.

Recent evidence has suggested that, in the rhesus monkey, social aggressive behavior may be correlated with fluctuations in blood concentrations of gonadal and adrenal steroids. Electrical stimulation of specific regions of the hypothalamus and preoptic area can be effective for eliciting both aggression and the release of prolactin and gonadotrophin (luteinizing) hormone. The purpose of the present experiments was to investigate the effects of electrical stimulation of the preoptic area and medial basal hypothalamus of unanesthetized male rhesus monkeys on testosterone and cortisol as measured in RIA of serum samples obtained through chronically implanted venous catheters. A single set of stimulus parameters (0.4 mA, 1.0 msec, 50 Hz, 10 sec/min trains) was used for all subjects and all stimulus sites. These parameters had been determined in preliminary experiments to be suprathreshold for producing manifest behavioral responses. Stimulation was delivered unilaterally through a monopolar electrode arrangement for 60 min. Blood samples were taken 30 min prior to and just before the onset of stimulation. Samples were obtained at 15, 30 and 60 min following stimulation onset and at 30 min intervals for two hours post-stimulation. Positive hormonal responses were observed as 30-500% increases in serum concentration of cortisol or testosterone during stimulation over the mean of the two pre-stimulation values. Stimulation of the medial basal hypothalamus in both castrated and intact males produced increments as great as 2 to 5 fold in levels of both testosterone and cortisol. In castrated males the time course of change of both hormones was parallel. Increases in steroid levels in some instances remained elevated for more than 2 hours post-stimulation. Of the 40 tested sites that were histologically verified to be located in the preoptic area or hypothalamus, most effective sites were found in the POA (15%) and VMH (12.5%), with additional active sites located in the SCH, ARC, LH and AHA. Negative sites, from which no response was obtained, were located in the MB, DMH, SEPT and OC. Behavioral observations were conducted during stimulation of some of the same sites while the animal was able to move freely in a social situation. Some, but not all, sites from which testosterone and cortisol release could be elicited also supported stimulation-bound aggressive behaviors. The magnitude of the hormonal response to hypothalamic and/or preoptic stimulation was equivalent to or greater than the elevation in testosterone that occurred after episodes of social aggression. 1546 THE AFFERENT CONNECTIONS OF THE SUPRACHIASMATIC NUCLEUS: A HORSERADISH PEROXIDASE STUDY. Gary E. Pickard. Dept. Anat., College of Physicians & Surgeons,Columbia Univ., N.Y.,N.Y. 10032

The region of the hypothalamus that includes the suprachiasmatic nuclei (SCN) is known to be responsible for the entrainment of endogenous circadian rhythms to the external light-dark cycle. It has been shown that the SCN receives an input from the retina, the ventral lateral geniculate nucleus, and the midbrain raphe, however the precise anatomical location and morphlogical characteristics of these neurons are unknown.

The afferent connections of the SCN of the female hamster were examined using the method of retrograde transport of horseradish peroxidase (HRP). A 30% solution of HRP in 0.05 M Tris (pH 7.6) was iontophoretically applied to the SCN using 20-30 um (OD) micropipettes by a positive current of 2 uamps for 2-5 min. After a survival period of 24-72 hr, animals were perfused with 0.9% saline followed by 2.0% glutaraldehyde in 0.1 M phosphate buffer (ph 7.4). During the saline perfusion, both eyes were removed and the retinae were dissected from the choroid and pigment epithelium. The retinae were briefly fixed in 1.5% glutaraldehyde and rinsed in phosphate buffer. HRP in retinal whole mounts and 60 um thick frozen sections of the brains was demonstrated histochemically using tetramethyl benzidine.

HRP injected into the SCN was taken up by retinal ganglion cell terminals and transported to the retina. Labeled ganglion cells were large, relatively few in number and displayed no outstanding regional localization. After correcting for shrinkage resulting from fixation and histochemical procedures, the ganglion cell somata were estimated to average about 17 um in diameter. 3-4 proximal processes could often be followed a short distance from the labeled cells and entered the inner plexiform layer at a wide angle. Control injections into the optic chiasm resulted in the labeling of all sizes of retinal ganglion cells.

The ventral lateral geniculate nucleus (vLGN) was also labeled after HRP injections into the SCN. Labeled neurons were more often found in the lateral magnocellular subdivision, although the parcellation into magno- and parvocellular regions is not distinct in the hamster. There were 2-3 times more labeled cells ipsilateral vs. contralateral to the injection. The dorsal-caudal aspect of the vLGN contained the majority of labelled cells. Many large neurons were often clustered near the boundary between the dorsal and ventral LGN which is demarcated by traversing vessels.

HRP was also transported to neurons in the midbrain. Labeled cells were distributed bilaterally in the periaqueductal gray and in the dorsal and medial raphe nuclei.

Evidence exists that suggests all these afferent systems to the SCN modulate endogenous circadian rhythms. (Supported by a Fellowship from the Pharmaceutical Manufacturers Association).

1547 RELATIONSHIP OF DOPAMINE TURNOVER IN THE MEDIAN EMINENCE TO DOPAMINE CONCENTRATION IN HYPOPHYSIAL PORTAL PLASMA AND PROLACTIN RELEASE. Nancy S. Pilotte, Gary A. Gudelsky, and John C. Porter, Depts. Ob/Gyn. & Physiol., Green Ctr. for Reprod. Biol. Sci., Univ. of Texas Southwestern Med. Sch., Dallas, TX, 75235.

The release of prolactin from the pituitary gland is influenced by several substances, e.g., anesthetic agents and dopaminergic compounds. In the present study, we compared serum prolactin concentrations in urethane- or pentobarbital-anesthetized male rats with turnover of dopamine in the median eminence and concentration of dopamine in hypophysial portal plasma. The serum prolactin concentration in rats anesthetized with pentobarbital was 47 ± 7 ng/ml (mean and SE), whereas that in rats anesthetized with urethane was 16 ± 3 ng/ml. Inasmuch as the secretion of prolactin from the anterior pituitary gland is under tonic inhibitory control of dopamine released from tuberoinfundibular neurons, we examined the question whether the difference in serum prolactin concentrations in rats anesthetized with pentobarbital or urethane reflected differences in the release of dopamine from hypothalamic neurons. The effects of these anesthetic agents on the release of dopamine from tuberoinfundibular neurons were assessed by measuring the dopamine concentration in hypophysial portal plasma and dopamine turnover in the median eminence. Dopamine was determined in acidified extracts of plasma or median eminence fragments using a radioenzymatic procedure. Pituitary stalk blood was collected for 1 hr from rats anesthetized with urethane (1.5 g/kg, ip) or pentobarbital (40 mg/kg, ip). The dopamine concentration in hypophysial portal plasma from urethane-anesthetized rats was .49 ± .11 ng/ml, and was significantly greater than that in rats anesthetized with pentobarbital (.11 ± .03 ng/ml). The α-methyltyrosine (αMT)-induced decline of dopamine in the median eminence was used in the evaluation of dopamine turnover, using urethane- or pentobarbital-anesthetized male rats. The animals were injected with αMT (250 mg/kg, ip) 1 hr or 2 hr prior to removal of the median eminence. Anesthetized rats which were injected with 0.15M NaCl served as controls. The dopamine concentrations in the median eminence of saline-treated rats anesthetized with urethane or pentobarbital were the same. In addition, at no time after inhibition of dopamine synthesis with αMT did concentrations of dopamine in the median eminence of urethane- or pentobarbital-anesthetized rats differ significantly, indicating that the turnover of dopamine in the median eminence of these two groups of animals was similar. These results are suggestive that the release of dopamine from tuberoinfundibular neurons into pituitary stalk blood is greater in rats anesthetized with urethane than in rats anesthetized with pentobarbital, and are indicative of an inverse relationship between the dopamine concentration in hypophysial portal blood and the release of prolactin from the pituitary gland. Furthermore, it would appear that dopamine turnover in the median eminence is not necessarily an accurate index of the release of dopamine from those tuberoinfundibular neurons which secrete dopamine into hypophysial portal blood.

1548 THE LH-RELEASING ACTION OF N-METHYL ASPARTATE IS REVERSIBLE AND IS DEPENDENT ON ARCUATE HYPOTHALAMIC NEURONS. M.T. Price, J.W. Olney, M. Anglim*, V. Mitchell* and S. Buchsbaum*. Washington University School of Medicine, St. Louis, MO 63110.

Recently we reported that subcutaneous (sc) administration of a subtoxic dose (25 mg/kg) of N-methyl aspartate (NMA), a potent excitotoxic analog of glutamate and aspartate, to 25 day old male rats, induces a rapid elevation of serum luteinizing hormone (LH). The locus of NMA action is suprasellar, since NMA does not release LH from pituitary *in vitro* (Schainker and Cicero, Neurosci. Abstr. 4, 355, 1978). In toxic sc doses, NMA selectively destroys arcuate hypothalamic neurons (AH) which are thought to play a role in LH regulation. We have proposed that both the AH neurotoxic and LH releasing actions of NMA stem from specific interaction of NMA at excitatory receptors on the dendrosomal surfaces of AH neurons, the assumption being that irreversible depolarization underlies one phenomenon and reversible depolarization the other. Findings reported here further characterize the LH releasing action of NMA as rapid in onset, brief in duration, reversible and AH-dependent.

LH levels reach peak values 7½ min following NMA administration sc and return to base line within 30 min. Reversibility of the LH releasing action was explored by sacrificing groups of rats for LH determination 7½ min following either a 1st, 2nd, 3rd or 4th sc injection of NMA, the first 3 injections being at consecutive hourly intervals and the 4th being 24 hrs after the 3rd. The LH response to the 1st NMA injection was typical (12.7 times control values) but to the 2nd and 3rd was moderately and markedly attenuated respectively. The LH response to the 4th injection was the same as to the 1st. Thus, although repetitive stimulation of the pathway at hourly intervals reduces its response capacity, it is restored to normal after a 24 hr interval. We suspect this pattern reflects a transient depletion of LHRH stores with replenishment after a 24 hr rest period.

To further clarify the role of AH neurons in NMA-induced LH release, we destroyed approximately 80% of the neurons in AH by administering glutamate to neonatal rats, then challenged them with 25 mg/kg NMA at 25 days of age. LH levels in these animals 7½ min after NMA challenge did not differ from controls. It appears therefore, that AH neurons are a crucial part of this LH release pathway. This and other evidence, including the finding that alpha-aminoadipate, a specific antagonist of NMA excitation,blocks both the AH neurotoxic and LH releasing actions of NMA (Olney et al., Neurosci. Abstr. 1979), argues compellingly that the LH releasing action of NMA is not only AH dependent but stems from specific interaction of NMA with excitatory receptors (aspartergic?) on the dendrosomal surfaces of AH neurons. Supported by NIH grants DA-00259, MH-14677, NS-09156, a Huntington's Chorea Fdn. grant and RSD Award MH-38894 (JWO).

1549 BIOCHEMICAL AND PHYSIOLOGICAL EFFECTS OF UNPREDICTABLE AND PREDICTABLE STRESSFUL STIMULATION IN RATS. Carolos M. Quirce* and Mauricio Odio* (SPON: Roger P. Maickel). School of Pharmacy, University of Costa Rica, San Jose, COSTA RICA.

The biochemical and physiological effects of both unpredictable and predictable schedules of physical immobilization were determined in adult, male Sprague-Dawley rats. Both schedules were tested in isolated and group-reared animals; the total number of test sessions was also varied (15, 25, 36). Plasma levels of glucose and corticosterone were found to be significantly elevated for up to 48 hours after the last immobilization session in animals on the unpredictable schedules, but were essentially normal in those on the predictable schedules. In contrast, plasma levels of free fatty acids were significantly elevated in all animals on unpredictable schedules, but were significantly lowered in animals on the predictable stress schedules. Adrenal gland hypertrophy and relative decreases in total body weight gain were both greater in animals subjected to unpredictable stress schedules, as compared to those on predictable schedules. These findings suggest that elevations in biochemical and physiological stress markers can be achieved preferentially through the use of unpredictable schedules of stimulation. In contrast, predictable schedules appear to evoke a type of habituation or adaptation of stress marker levels.

1550 SYNTHESIS OF ACTH BY RAT NEURONAL CELL CULTURES. Richard J. Robbins*, Leonard P. Kapcala*, Richard H. Goodman*, and Seymour Reichlin. Dept. Med., Endocrine Div., New England Medical Center Hospital, Tufts University School of Medicine, Boston, MA 02111.

ACTH has been demonstrated by radioimmunoassay and immunohistochemistry in many areas of the brain including the amygdala, hypothalamus, hippocampus,midbrain and brain stem. Studies of brain ACTH after hypophysectomy have given contradictory results leaving unresolved the question as to whether ACTH can be synthesized by neurons themselves. In this experiment we determined serially the ACTH content of monolayer cell cultures derived from amygdala cells of day 1 neonatal rats. The amygdala was chosen for study because it is one of the limbic structures containing and regulating ACTH, our laboratory has shown somatostatin synthesis in these cell cultures and Pacold et al. had shown IR-GH production in amygdaloid cell cultures. Cells were dissociated by trituration and Papain-DNA-ase treatment, and the cultures maintained in a modified Eagles media with 10% heat inactivated horse serum at 35.5°C in 5% CO_2 in high humidity. The media were changed three times a week and the cells harvested at various times in distilled deionized water (DD) and sonicated. The initial cell suspension contained 80 pg of IR-ACTH/dish by radioimmunoassay and there was a progressive increase in cellular content up to day 23 when content was 257 pg/dish. This IR-ACTH exhibited parallelism to the standard curve. At no time was IR-ACTH release into the media shown. To demonstrate incorporation of precursor amino acid into ACTH ^{35}S-Met was incubated with day 14 cultures in Met-free media for 4 hrs. followed by 14 hrs. in normal media, or for 18 hrs. in normal media. The cells were harvested in DD water, sonicated, the extracts immunoprecipitated with anti-ACTH anti-serum and chromatographed on SDS gels which were analyzed by autoradiography. Each of the incubations gave rise to several bands, one of which was similar in mobility to $ACTH_{1-39}$. These findings are interpreted to indicate that amygdala neurons have the capacity to synthesize ACTH independent of the pituitary.

51 TWO EXCITABLE NEURONAL ELEMENTS IN THE PINEAL GLAND OF THE RAT: FURTHER EVIDENCE FOR A HABENULO-PINEAL PATHWAY. Oline K. Rønnekleiv*, Martin J. Kelly*, Wolfgang Wuttke* (SPON: D.L. Tomko) Western Psychiatric Institute & Clinic (OKR), Dept.of Physiology (MJK), Univ.of Pittsburgh Sch. of Med., Pittsburgh, PA. 15261, and Max-Planck Inst. for Biophysical Chemistry (WW), D-3400 Goettingen, W. Germany.

Recently we observed, using electron microscopy, degeneration of nerve terminals in the pineal following habenula lesions (Rønnekleiv & Møller, Exp.Brain Res.,in press). It was earlier believed that these central fibers running from the habenula and posterior commissures do not make synaptic contact in the pineal. We decided to further elucidate the nature of the central neural connection and the excitability of the pineal cells using conventional single unit recording techniques. Stimulating electrodes of Wood's metal (40-60µm tip) were placed in the habenula area of female rats. Extracellular AC recordings were made through glass-insulated tungsten electrodes (1-5µm, 8-14MΩ) placed in the pineal by penetrating the sagittal sinus from above. Throughout the recording period, single anodal pulses of 50-200 µsec duration and of 0.001-0.1mA strength were delivered to the habenula complex. Two distinct populations of pineal cells were found, 23 silent cells which were driven by habenula stimulation and 114 spontaneously active cells. In the former case 17 of the silent cells (median latency of 1.2msec) showed a positive-negative potential in response to habenula stimulation, and 6 of the 23 silent cells (∿1msec latency) showed only a positive potential of 1-2msec duration. The remaining cells (114) could not be driven by habenula stimulation but exhibited spontaneous activity with firing frequencies varying from less than 1Hz to greater than 100Hz with a median firing frequency of 10Hz. These experiments clearly demonstrate a direct habenulo-pineal fiber pathway and furthermore show that there are neuronal elements in the pineal which are only activated by habenula stimulation (∿17%). In view of the recent findings showing a direct peptidergic pathway from the suprachiasmatic nucleus (SCN) to the habenula complex (Sofroniew & Weindl, Am. J. Anatomy 153:391, 1978), our findings would indicate that a more direct innervation of the pineal by the SCN is possible than what had been proposed earlier. We do not know if the spontaneous activity is of pinealocyte origin since neurons have not been identified in the pineal, but intracellular recordings will reveal the nature of this activity and whether it is coupled to the secretory function of the pinealocyte.

OKR was an Alexander Von Humboldt Fellow and MJK an NIH Fellow at the Max-Planck Institute.

1552 PROJECTIONS TO THE LATERAL MEDULLA FROM THE MIDBRAIN AND PONS IN THE CAT. James D. Rose. Dept. Psychol., Univ. Wyoming, Laramie, WY 82071.

Evidence from single unit recording and lesion-behavioral experiments has implicated the lateral medullary tegmentum in the mediation of estrous vocalization and afterreaction responses to genital stimulation in the female cat. The principal densities of estrogen-concentrating neurons in the cat brain, however, are in hypothalamic, preoptic, and limbic regions. The present study was aimed at identifying descending pathways through which the activity of estrogen target neurons could be transmitted to lateral medullary cells. Cats received pressure-injections of 0.1-0.2µl of horseradish peroxidase (HRP) in a 50% saline solution, in the lateral medulla near nucleus ambiguus. After a 1-3 day survival, the brains were processed to demonstrate retrogradely transported HRP by the method of Mesulam (J. Histochem. Cytochem., 1978). At supramedullary levels, labeled neurons were concentrated mainly in the pons and midbrain. In the pons, labeled cells were most abundant in the ipsilateral medial and lateral parabrachial nuclei, the Kolliker-Fuse nucleus, and lateral tegmental field. Some nucleus raphe magnus neurons were also labeled. In the midbrain, the periaqueductal gray contained labeled neurons distributed widely, but unevenly along its rostro-caudal extent. The relative abundance of labeled central gray neurons varied substantially between animals. Labeled midbrain neurons were also found, in lesser numbers, just lateral to the central gray and in the oculomotor, trochlear and Edinger-Westphal nuclei. In non-midline midbrain regions most labeled neurons were ipsilateral to the injection site. Only a small number of labeled neurons, these in the lateral and periventricular hypothalamus, were found in the diencephalon. In view of variability of retrograde labeling of central gray neurons, electrophysiological verification of a medullary projection from this region was also undertaken. Central gray cells were antidromically-invaded in sufficient numbers by stimulation of the lateral or medial medulla to indicate the presence of a quantitatively significant number of neurons with descending axons. The existence of the central gray projection to the lateral medulla provides a potential route for activity of estrogen-concentrating neurons to be transmitted to neurons involved in vocal and other estrous reflexes, since some central gray neurons in the cat are estrogen-concentrating cells, and since the central gray receives a strong projection from the ventromedial hypothalamic nucleus, which contains numerous estrogen-concentrating cells.

Supported by NIH Grant NS-13748.

1553 DIURNAL VARIATION IN PITUITARY SENSITIVITY TO LHRH. K.B. Ruf, and J. McElhone*, Dept. Ob/Gyn., McGill Univ., Montreal H3A 1A1 Canada.

Gonadal steroids and LHRH itself have been recognized as the main modulators of the sensitivity of pituitary gonadotrophs. Recently, Caffrey et al (PSEBM 159,444,1978) reported that the neuropeptides oxytocin and vasopressin synergize with LHRH at the level of the anterior pituitary gland. Since it is possible that gonadotropin release is affected by additional brain peptides (some of which may be released in episodic manner), diurnal variations in pituitary sensitivity were investigated. In order to standardize the steroid milieu, groups of 5 adult female rats, ovariectomized for one month, were given estradiol benzoate (20 µg) at either 0700 h (AM), 1200 h (PM I) or 1700 h (PM II) colony time. Exactly 72 h later, 200 ng (D-Ala^6-des-Gly-NH$_2$^{10})-LHRH-ethylamide was injected i.v. and the LH and FSH response monitored over 4 h. Additional groups of 5 rats were pretreated with Dexamethasone phosphate (Dex. 100 µg/100 g b.w. i.p.) at -22h and -4 h. Results, expressed as areas under the respective curves and subjected to 2-way ANOVA are tabulated below:

Hormone measured	Treatment applied	AM	PM I	PM II
LH	LHRH	74*	100	80*
	Dex/LHRH	53*	72*	80*
FSH	LHRH	61*	100	71*
	Dex/LHRH	63*	78	74*

(Figures refer to areas under curves as percentage of PM I-response to LHRH; * denotes $p < 0.05$ compared to 100% response).

The results indicate that the sensitivity of the gonadotrophs is not governed solely by gonadal steroids and the administered LHRH, but shows marked diurnal variations which can be abolished by pretreatment with Dex. The nature of the factor(s) influenced by the glucocorticoid (ACTH, endorphins, half-life of LHRH, adrenal progesterone/DOC?) is under investigation. (Supported by grant MA-6235 from the Canadian Medical Research Council).

1554 CHROMATOGRAPHIC AND BIOLOGIC COMPARISONS OF THE LUTEINIZING HORMONE RELEASING HORMONE (LHRH) FOUND IN THE ORGANUM VASCULOSUM LAMINA TERMINALIS (OVLT) AND MEDIAN EMINENCE (ME). W. K. Samson*, and S. M. McCann. Dept. Physiol., Univ. of Tx. Hlth. Sci. Ctr. at Dallas, TX 75235.

LHRH is present in the OVLT and ME of the male (7.42 ± 3.30 pg/µg extracted protein, n = 10;25.06 ± 2.53, n = 9, respectively), ovariectomized female (3.01 ± 0.43, n = 11; 18.73 ± 3.27, n = 12), and random cycle female (3.04 ± 0.20, n = 40; 25.43 ± 1.04, n = 40) rats. In order to compare the physical properties of the LHRH in both structures, acid extracts of pooled tissue punches from the OVLT, ME and a punch of tissue surrounding the OVLT, as well as synthetic LHRH, were chromatographed on G-25 Sephadex (1.2 x 96.0 cm) using 0.2N acetic acid. Column fractions were measured for LHRH content by RIA. In two separate experiments the elution profiles of LHRH were seen to be similar for OVLT and ME extracts and the decapeptide. In the second experiment extracts of tissue surrounding the OVLT, including stria terminalis and preoptic area, revealed a similar elution pattern. Bioassay of LHRH activity in extracts of ME and OVLT tissue was conducted in cultures of both dispersed male rat anterior pituitary cells and an enriched gonadotropin fraction from 18 day old female rat pituitaries. In both systems extracts of rat cerebral cortex failed to stimulate LH or FSH release, while extracts of OVLT and ME tissues were capable of stimulating gonadotropin release with a similar dose response profile as that of the synthetic decapeptide.

We then examined the temporal fluctuations in LHRH content in these areas at 1000 hr and 1600 hr on all four days of the estrous cycle. Both ME and OVLT displayed marked temporal fluctuations in LHRH content throughout the estrous cycle with highest levels found in the ME at the 1000 hr sampling, and a precipitous decline between 1000 hr and 1600 hr on proestrous, however, the OVLT contained highest LHRH levels in the afternoons, particularly on proestrus and estrus and precipitous declines occurred between 1600 hr of estrus and 1000 hr of metestrus, and between 1600 hr of proestrus and 1000 hr of estrus.

In summary we have demonstrated the physical and bioassayable similarities of the LHRH residing within the OVLT and the ME and have seen a fluctuation in tissue LHRH content which is disparate between the two areas. These observations suggest either a phase shift in the delivery or release of LHRH by these structures or the possible existence of an entirely separate release mechanism within the two structures. (Supported by AM 10073 and HD09988 and HD07062).

1555 CHRONIC GLUCOCORTICOID ADMINISTRATION ALTERS AXON SPROUTING IN THE RAT HIPPOCAMPAL FORMATION. Stephen W. Scheff, Donald R. Thorne‡ Georgia Sasvary‡ Larry S. Benardo* and Carl W. Cotman. Dept. Psychobiology, Univ. California, Irvine, CA 92717.

The hippocampus has been widely used to study plasticity in the CNS. Previously we demonstrated that the sprouting reaction in the dentate gyrus of the hippocampal formation could be altered with pharmacological doses of a glucocorticoid, hydrocortisone. In the present study we tested whether or not chronic changes in the levels of glucocorticoids which more closely approximates physiological conditions might also alter this sprouting response. Thus, we examined the response of various hippocampal afferents following a unilateral lesion of the entorhinal cortex in control and hormone treated animals.

Young adult animals were adrenalectomized six to ten days prior to a subcutaneous implantation of a pellet containing a specified concentration of corticosterone utilized for chronic glucocorticoid replacement. Adrenalectomized animals were maintained on levels of corticosterone which corresponded to those in naive young rats. In addition animals were maintained on levels which were approximately twice those present in control animals. Five days following implantation the animals were subjected to unilateral removal of the entorhinal cortex. The brains were examined for changes in septal input by means of AChE staining and for changes in the commissural-associational fiber plexus by means of the Holmes fiber stain. Control animals showed a sprouting response in agreement with previous results. It was found that animals maintained at the high levels of corticosterone showed significantly less sprouting than controls and animals maintained on low levels of hormone. Astrocytes appeared markedly hypertrophied in the high level group.

The present findings support our previous results with the administration of hydrocortisone. These findings suggest that steroid hormones may regulate synaptogenesis in the mature brain. Moreover, these results may provide a clue for understanding the mechanism underlying changes in synaptogenesis in aged animals. Previously we found that axon sprouting is reduced in aged rats and that glucocorticoids are elevated in these animals. The elevated glucocorticoids may be responsible for reduced sprouting in the aged animals. (Supported by research grant AG 00538)

1556 DECREASED DOPAMINE TURNOVER IN THE MEDIAN EMINENCE IN RESPONSE TO SUCKLING IN THE LACTATING RAT. Michael K. Selmanoff and Phyllis M. Wise*. Department of Physiology, University of Maryland, School of Medicine, Baltimore, Maryland 21201.

The effects of suckling on the turnover of dopamine (DA) and norepinephrine (NE) were studied in terminal projection fields of the tuberoinfundibular (median eminence, ME) and nigrostriatal (caudate nucleus, CN) dopaminergic neurons. Lactating rats with their litters were received between 1 and 5 days postpartum from the supplier. On day 9 postpartum the litters were culled to 8 pups and the mothers fitted with indwelling right atrial cannulae under ether anesthesia. On day 10 postpartum pups were removed from their mothers for 4 hours and then returned. The onset of suckling was operationally defined as the time when 6 or more of the 8 pups started suckling. This occurred with a latency of 1-5 minutes from the time of pup return. After 30 minutes of suckling fresh litters were substituted to ensure continuation of the stimulus from 30 to 60 minutes.

Catecholamine turnover was assessed by using the synthesis inhibitor α-methyl-para-tyrosine (αMPT). The drug was administered in acidic diluent (pH 5.2-6.5, 0.5-1.2ml volume) via the indwelling catheter (300mg/kg body weight) and the animals killed at 0, 30 and 60 minutes thereafter. The ME and CN were microdissected and DA and NE concentrations determined by radioenzymatic and protein assays. Trunk blood was collected and serum prolactin levels determined by double-antibody radioimmunoassay.

Two protocals were employed. In one, αMPT was administered 30 minutes after the onset of suckling, and in the other, at the same time the pups were returned. In both situations the results were similar. Comparison of the rates of DA depletion after αMPT in suckled and non-suckled mothers revealed a decrease in ME DA turnover in the suckled mothers. In contrast, dopamine turnover in the CN was not affected by suckling. Similarly, NE turnover in suckled mothers did not differ from non-suckled mothers in the ME. These results are consistent with the hypothesis that dopamine is a physiological prolactin inhibitory factor mediating suckling-induced prolactin release. (Supported in part by NIH grants NS-14611, HD-02138 and HD-00435).

1557 ESTROGEN NULLIFIES LORDOTIC REFRACTORINESS TO PROGESTERONE IN SPAYED RATS. B.D. Shivers, R.E. Harlan* and R.L. Moss. Dept. Physiol., Univ. Texas Health Sci. Ctr., Dallas, TX 75235

Experiments were conducted to investigate the interaction between estrogen and progesterone in the display of feminine sexual behavior. Spayed rats received 5mm Silastic capsules containing 17β-estradiol (E_2) and sc injections of progesterone (P;2.5mg) or oil (O) at 1200h, and were tested at 18-2000h for lordotic responsiveness (LR) as measured by the lordosis quotient (LQ) in 20-mount tests (lights off: 13-2300h). Results are reported as mean LQ±1 SEM (N). A preliminary study revealed that in rats exposed to E_2 for 27 h, P given 24 h after capsule removal (1200h) could not facilitate LR (at 18-2000h) [P:32±10 (11); O:21±6 (10)]. In Experiment 1, E_2 capsules were removed 48 h after implantation at 0900h; P or O was injected at 1200h on this and the following day; and the rats were tested at 18-2000h on both days. Results indicate that while the first P injection facilitates LR, the rats are refractory to a second P injection given 24 h after the first [O,O:36±9; 21±9 (11); P,P:88±6; 6±3 (11); P,O:97±3; 2±2 (9); O,P: 43±11; 54±12 (10)]. In Experiment 2, E_2 capsules were left in vivo throughout the experiment. P or O was injected at 1200h on the third and fourth days after implantation and the rats were tested at 18-2000h on both days. Results show that a second P injection 24 h after the first can facilitate LR if E_2 capsules are present [O,O:47±14; 64±12 (10); P,P:98±1; 98±1 (10); P,O: 96±2; 66±12 (10); O,P:59±12; 100±0 (9)]. In Experiment 3, E_2 capsules were either left in vivo or removed 3 h before or 1, 11 or 20 h after the first P injection (given at 1200h). Results suggest that for the second P injection (given 24 h later) to facilitate LR, E_2 capsules must be in vivo either for longer than 1 h, with 11 h sufficing, following the first P injection or for longer than 52 h, with 62 h sufficing [second test: E_2 removed 3 h before P:37±14 (6); 1 h after P:18±7 (10); 11 h after P:90±3 (10); 20 h after P:99±1 (9); E_2 not removed:99±1 (6)]. Experiment 4 was conducted to distinguish between these two possibilities. E_2 capsules were left in vivo 62 h with the E_2 present for either 1 or 11 h after the first P injection. Results show that the presence of E_2 for 11 h, but not 1 h, following the first P injection permits the second P injection to facilitate LR [second test: E_2 removed 1 h after P:49±16 (8); 11 h after P:97±2 (7)]. In summary, the results of the present experiments (a) reveal that 5mm E_2 capsules must be in vivo for longer than 27 h for P injected 24 h later to facilitate LR; (b) demonstrate the lordotic refractoriness developed in response to sequential P injections; and (c) establish that E_2 must be present longer than 1 h, with 11 h sufficing, following the first P injection for a second P injection given 24 h later to facilitate LR. 1558 THE ONTOGENY OF THE MAGNOCELLULAR NEUROSECRETORY SYSTEM OF THE MOUSE. A.J. Silverman and R. Goldstein*. Dept. Anat., P&S, Columbia Univ., New York, NY 10032.

Four aspects of the development of the supraoptic (SO) and paraventricular (PV) nuclei of the mouse were studied: (1) appearance of neurophysin (NP) immunoreactivity; (2) axonal outgrowth to neural lobe (NL) and median eminence (ME); (3) synaptogenesis in SO and (4) dendritic growth of NP positive neurons. Light microscopic immunocytochemistry on 6 um paraffin and 50um vibratome sections and electron microscopy were used. Adult females were placed with males at 1700 hr and checked for sperm plugs at 0800 hr the following day; this equals day 1/2 of gestation. NP positive perikarya were first seen on fetal day 13 1/2 either in the presumptive SO or in migration to the SO from the ependymal wall. No positive axons were observed in either the brain or NL. A substantial increase in the no. of positive cells in the pricipal SO was seen on day 14 1/2; this is also the first day on which NP axons were seen in the NL. These fibers were only present in the lateral aspect of the gland. Days 14 1/2 and 15 1/2 were similar except for the appearance of NP in cells of the dorsal and retrochiasmatic SO. Day 16 1/2 marks the appearance of NP cells in the PV, mainly in the dorso-medial aspect. By day 17 1/2 NP axons are evenly distributed in the NL and are present in the zona externa of the ME. By this time all cells in the SO are NP positive. This is not true of the PV; appearance of NP positive cells occur throughout the remainder of gestation and the first week of neonatal life.

Synapses were almost completely absent in SO just prior and after birth (18 1/2 day = 0.07/250um^2; day 1 neonate = 0.26 ± 0.19/250um^2) compared to the adult (13.03 ± 1.0/250um^2). These first synapses were on the dendrites. There is a significant increase in the no. of synapses by day 5 (1.77 ± 0.45/250 um^2) which continues on day 15 (6.8 ± 0.62/250um^2). Synaptogenesis is complete on day 24 (10.04 ± 0.8/250um^2). On day 5 axo-somatic as well as axo-dendritic synapses are present. By day 15 axo-axonic synapses appear. On the day of birth, very little dendritic arborization can be seen in thick, immunostained sections. There is a progressive increase in dendritic complexity from birth to day 24 post-natal.

Supported by USPHS (HD 10665) grant, a Sloan Fellowship and an Irma T. Hirschl Career Scientist Award to A.J. Silverman.

1559 DRINKING, VASOPRESSIN SECRETION, AND ACTH SECRETION INDUCED BY INTRACRANIAL ANGIOTENSIN. J.B. Simpson, M. Reed, L.C. Keil, T.N. Thrasher, and D.J. Ramsay. Dept. of Physiology, University of California School of Medicine, San Francisco, CA 94143

178 male Long-Evans rats were stereotaxically implanted each with one 26-33 ga cannula system. On the fifth and sixth days following surgery, each rat received an intracranial injection of 5 ng Ile^5-angiotensin II (AII)/0.5 ul/10 sec. Water intakes for the following 30 min were measured. On the seventh day, following the same injection procedure, each rat was decapitated at 60 sec following AII administration. Trunk blood was collected for subsequent measurements of arginine vasopressin (AVP) and ACTH by radioimmunoassay. Nissl-stained sections were prepared showing the cannula track from each brain.

Rats were assigned to either of two principle groups: ventricular loci or tissue loci. Differentiation was made on whether the cannula ruptured lateral or third ventricular ependyma at its tip or along its trajectory. Ventricular loci were: lateral; dorsocaudal third; rostrodorsal third; mid (D/V) third; ventral third; and optic recess. Cannulae not perforating ependyma were classified according to the tissue surrounding the cannula tip.

Drinking (4 ml or more) and elevated plasma AVP (8 pg/ml or more vs. control of 2.4 pg/ml) followed anatomically different distributions. Drinking and increased AVP were observed at subfornical organ, lateral ventricle and rostrodorsal third ventricle. Drinking but not increased AVP was found in ventral third ventricle and optic recess. Increased AVP but not drinking was found in diagonal band and medial preoptic area. Neither drinking nor increased AVP was found in corpus callosum, fornical commissure, septum (medial, lateral, triangular and fimbrial nuclei), lateral preoptic area, anterior hypothalamus, supraoptic nuclei, and dorsocaudal third ventricle. Increased plasma ACTH was not found to occur reliably following AII at any tissue or ventricular locus tested.

These results indicate that AII may or may not provoke drinking independently of enhanced AVP secretion. Previous results (Simpson and Mangiapane, 1978) have shown likewise that drinking may or may not be provoked independently of a primary increase in arterial pressure. Application of AII unilaterally to the supraoptic nuclei did not provoke AVP secretion, suggesting that AII does not act there. It was also found that application of AII to those loci positive for drinking and/or AVP secretion did not provoke increased ACTH secretion. At the subfornical organ, the only tested site which is accessible to circulating AII, application of AII causes drinking, increased arterial pressure, and increased secretion of AVP. Such data, then, suggest different central sites of action of AII at which drinking and/or AVP secretion and/or increased arterial pressure may be provoked. Supported by NIH grant AM 06704.

1560 NORADRENERGIC CONTROL OF VASOPRESSIN RELEASE BY THE ORGAN CULTURED RAT HYPOTHALAMO-NEUROHYPOPHYSEAL SYSTEM. Celia D. Sladek and John R. Sladek, Jr. Depts. of Neurology and Anatomy, Univ. of Rochester Sch. of Medicine and Dentistry, Rochester, NY 14642.

It is well established that the supraoptic nucleus (SON) receives a rich noradrenergic innervation, but contradictory evidence exists as to the role of norepinephrine (NE) in the control of vasopressin (VP) release. The organ cultured rat hypothalamo-neurohypophyseal system (HNS) has been used as an *in vitro* system for investigating the effect of NE on VP release. Each of these organotypic explants includes the SON, median eminence, and neural lobe. It has been shown previously that the HNS releases VP at a constant rate *in vitro*, and releases VP in response to acetylcholine and other stimuli. In this study, NE inhibited VP release from 3-day cultured HNS explants. Addition of 10^{-5}M NE to the culture medium reduced VP release to 56±7% of control VP release. Addition of NE (10^{-5}M) concurrently with acetylcholine (10^{-5}M) inhibited cholinergic stimulation of VP release. These data are consistent with previous observations of inhibition of electrical activity of supraoptic neurons by NE (Barker et al., Science 171:208, 1971; Sakai et al., J.Pharm. Exp.Ther. 190:482, 1974).

HNS explants were examined for formaldehyde-induced catecholamine (CA) fluorescence before and after 1,3 and 5 days in culture. A rich pericellular pattern of CA varicosities were observed in the SON prior to culture. Pericellular fluorescent varicosities persisted in the SON in explants maintained 1 or 3 days in culture, but were not detected after 5 days. Microspectrofluorometric analysis of the fluorescence persisting in 3-day cultures confirmed the presence of CA. Thus, agents inhibitory to VP release are endogenous to the HNS explant at least through day 3 of culture.

These data indicate that the noradrenergic input to the SON is inhibitory to VP release. Noradrenergic afferents may transmit information from cardiovascular volume and baroreceptors. Additionally, the effect of NE on acetylcholine stimulation of VP release suggests that noradrenergic control mechanisms may modulate VP release in response to osmotic and other control mechanisms for VP release.

1561 EVIDENCE FOR BRAIN HORMONE CONTROL OF LONG-DAY-INDUCED MATURATION IN A TERRESTRIAL MOLLUSC. Phillip G. Sokolove and Elinor J. McCrone*. Dept. Biol. Sci., UMBC, Catonsville, MD 21228.

Maturation of the reproductive tract of the terrestrial slug, *Limax maximus* is photoperiodically controlled: Long days (LD 16:8) promote growth of the hermaphrodite gonad and of the accessory sex organs such as the penis and albumen gland. Animals kept on short days (LD 8:16) fail to mature sexually regardless of age. (Sokolove and McCrone, J. Comp. Physiol. 123:317 1978). Results of implantation experiments suggest that reproductive tract development is controlled by a "maturation hormone" (or hormones) produced by the *Limax* CNS. Slug "brains" (circumesophageal ring of 9 fused ganglia) were removed from maturing animals that had been exposed to LD 16:8 lightcycles for 13-15 weeks. These were implanted in the haemocoels of immature recipient slugs that were hatched in the laboratory and had seen only LD 8:16. Host slugs were replaced on short days, and, when their reproductive tracts were examined 9-10 weeks later, all were found to be maturing. In contrast, only immature tracts were found in control slugs that received muscle implants or were sham operated. In another experiment, short-day recipients were implanted either with brains from long-day (maturing) donors, or with brains from short-day (immature) animals. Reproductive tract development was later found in hosts receiving long-day brains but not in those receiving short-day brains. The presumptive neuroendocrine factor thus appears to be synthesized and/or secreted only by the brains of animals exposed to long days.

Supported in part by grants from NSF (BNS78-01408) and NIH (MH-27948).

1562 EFFECT OF INTRAVENTRICULAR ANGIOTENSIN II AND BRADYKININ ON RELEASE OF ANTERIOR PITUITARY HORMONES IN THE RAT. M. K. Steele, A. Negro-Vilar* and S. M. McCann. Dept. Physiol., Univ. of Tx. Hlth. Sci. Ctr. at Dallas, TX 75235.

Angiotensin II (A II) and Bradykinin (BK) have been localized within the hypophysiotrophic area of the rat (Correa, et al. Neurosci. Abstracts 1280, 1978; Fuxe, et al. Neurosci. Letters 2: 229, 1976). Although the physiological significance of these peptides is as yet unclear, their predominence within the hypothalamus may suggest an endocrine function. We therefore proceeded to evaluate the possible role of A II and BK on pituitary hormone release in ovariectomized rats bearing chronically implanted third ventricular cannulae. On the day prior to testing, silastic cannulae were inserted into the jugular vein. On the test day, blood samples were taken from the unrestrained, conscious rats according to the following schedule: 2 pre-drug samples 30 min apart; post-drug samples at 5,15,30,60 and 120 min. Infusions of saralasin, an A II blocker, preceeded A II infusion by 30 min and an additional blood sample was taken just prior to A II administration. Control animals were infused with the saline diluent. In the A II experiments, water intake was monitored throughout the testing period.

Results: Infusion of 5 µg A II significantly reduced plasma LH at 15,30,60 and 120 min. Prolactin levels were also reduced at these time points as well as at the 5 min sample. Intravenous A II (5 µg) had no significant effect on LH. However, prolactin levels were increased at the 5 min sample, returning to baseline by 15 min. No consistent effects were observed on GH, TSH or FSH release. Infusions of saralasin (25 µg) attenuated the A II-induced LH suppression and totally blocked the decrease in prolactin levels.

BK infusion (5 or 25 µg) resulted in a dose-related increase in GH levels at 30 and 60 min. No effects on LH or prolactin concentrations were seen.

Current research is investigating whether A II and BK act directly upon the pituitary or via the hypothalamus to produce these endocrine effects. (Support by NIH AM10073, HD09988 and HD05492).

1563 DIVERSITY OF DISTRIBUTION OF CORTICOTROPIN AND β-LIPOTROPIN IN HYPOTHALAMUS AND ANTERIOR PITUITARY. Ludwig A. Sternberger*, Thurma V. McDaniel* and Shirley A. Joseph* (SPON: Leo G. Abood). Ctr. Brain Res. and Dept. Anatomy, Univ. Rochester Sch. Med., Rochester, NY 14642.

With the PAP method two antigens in the same paraffin or vibratome section can be stained in consecutive reaction sequences, using diaminobenzidine as electron donor for peroxidase in the first sequence to obtain a brown color, and chloronaphthol in the second sequence to obtain a blue color. No removal of the immunoreagents is necessary between the two sequences even though anti-immunoglobulin and PAP are used in each. Anti-ACTH 1-24 and 1-39 stained fibers in the dorsomedial nucleus and fibers and perikarya in the arcuate nucleus. Fibers were distinct from those containing somatostatin, vasopressin and luteoliberin. Anti-ACTH 17-39 failed to stain these areas even though all anti-ACTH sera used stained cells in the pars intermedia (PI) and pars distalis (PD). Antiovine β-lipotropin (LPH, courtesy of Dr. C. H. Li) stained in the PI the same cells as the various anti-ACTHs, yielding mixed color reactions. Anti-LPH and anti-ACTH 1-39 stained in the magnocellular system and the internal zone of the median eminence the same cells and fibers as vasopressin, again giving mixed color reactions. Pars nervosa was either unstained or weakly stained with anti-LPH or anti-ACTH 1-39. No hypothalamic LPH reactivity was seen outside the magnocellular system. Anti-ACTH 17-39 and 1-24 failed to stain the magnocellular system. In the PD separate cells were stained brown and blue when pairs of antisera to prolactin, growth hormone, luteinizing hormone and ACTH were applied, except for a few cells that stained both for growth hormone and luteinizing hormone. Mixed colors were obtained in the PI when pairs of anti-LPH and various anti-ACTHs were used in sequence. However when anti-ACTH 1-24 was followed by anti-LPH, separate cells stained brown and blue in the PD. On the basis of mixed color reactions the PD cell reactive with anti-LPH was identified as a glycoprotein-containing cell. The data suggest that ACTH-like peptides in various areas of brain may not always be identical to ACTH and that ACTH or β-LPH precursors are not necessarily coded by the same genes in different areas of brain and pituitary.

1564 TYROSINE INJECTION LOWERS SERUM PROLACTIN LEVELS IN CHRONICALLY RESERPINIZED RATS. Alan F. Sved*, John D. Fernstrom & Richard J. Wurtman MIT, Cambridge, MA 02139.

Work in our laboratory has indicated that catecholamine synthesis depends, in part, on the availability of the precursor amino acid, L-Tyrosine (TYR). Since dopamine neurons play a major role in the inhibitory control by the hypothalamus of pituitary prolactin (PRL) release, we tested the effects of TYR administration on serum PRL levels. However, previous work has suggested that nigro-striatal dopamine neurons release more dopamine in response to TYR injection only following treatments that increase dopamine turnover. Therefore, we also tested the effects of TYR in chronically reserpinized rats. The injection of TYR (200 mg/kg ip) to male Sprague-Dawley rats had no effect on serum PRL levels. In contrast, TYR (200 mg/kg ip) significantly reduced serum PRL levels in chronically reserpinized rats (2.5 mg/kg twice daily for 4.5 days) (vehicle 138±16 ng/ml; TYR 67±7 ng/ml; $p<.05$) 1 hour after its injection. That this effect is mediated via increased hypothalamic dopamine release is suggested by the concomitant increase in hypothalamic levels of the dopamine metabolites dihydroxyphenylacetic acid (DOPAC; +300%, $p<.05$) and homovannylic acid (HVA; +54%, $p<.05$) following TYR injection. TYR injection to non-reserpinized rats did not alter hypothalamic DOPAC or HVA levels. These studies demonstrate that a physiologic variable dependent upon catecholaminergic neurons can be affected by the availability of the catecholamine precursor, TYR. Furthermore, they suggest that TYR may be a useful treatment for lowering chronically elevated PRL levels found in hyperprolactinemia.

1565 **EFFECT OF MUSCIMOL ON PROLACTIN GROWTH HORMONE AND TSH SECRETION IN THE CONSCIOUS MALE RAT.** **C.A. Tamminga, M. Szabo & L.A. Frohman, NIH, NINCDS, Bethesda, MD 20205 and Michael Reese Hospital, University of Chicago, Chicago, Ill.**

The role of GABA in the regulation of anterior pituitary hormone secretion has been incompletely studied. Results of pharmacologic studies have varied depending on the GABA drug used, route of administration and type of animal preparation. In the present studies, estrogenized male rats with indwelling intraatrial cannulae were used. Catheters were implanted at least 3 days prior to testing and estradiol valerate (1.25 mg/kg) was administered 3-14 days before each experiment. On the day of the experiment, extension catheters were attached to the indwelling cannula, the animals placed in individual cages, and a 45 min period of accommodation allowed. Muscimol (1.5 mg/kg) was administered i.v. to the conscious rats while blood samples were drawn into heparinized syringes at specified intervals prior to and following the drug. The samples were centrifuged and the plasma frozen for subsequent radioimmunoassay. Prolactin (PRL), growth hormone (GH) and TSH were measured by double antibody radioimmunoassay. Plasma PRL response to muscimol described a biphasic curve. An initial elevation which peaked at 5-10 min was followed by a subsequent prolonged suppression at 30-60 min. The PRL elevation was blocked by both haloperidol and picrotoxin pretreatment, whereas the PRL suppression occurred even with haloperidol blockade. GH secretion was not altered in the animal preparation either in the conscious rat or in urethane anesthetized animals. TSH briskly rose following muscimol in the conscious rat, however, was blocked by urethane anesthesia. GABA could alter pituitary hormone secretion through a direct effect of GABAergic pathways on hypothalamic regulatory hormones or through an indirect effect on another neurotransmitter possibly dopamine which regulates pituitary function.

1566 IS ACETYLCHOLINE A RELEASING HORMONE: EVIDENCE FOR MUSCARINIC RECEPTORS IN ANTERIOR PITUITARY. Richard L. Taylor* and David R. Burt. Dept. Pharmacol. Exptl. Ther., U. Md. Sch. Med., Balto., MD 21201, U.S.A.

One of the clearest pieces of evidence that dopamine must have direct effects on the pituitary as a prolactin-inhibitory factor was the demonstration of dopamine receptors there by binding studies. Two recent reports of cholinergic effects on the anterior pituitary in vitro (Vale et al., 1976, In Hypothalamus and Endocrine Functions, Plenum, p. 397; Pawlikowski et al., 1978, Neuroendocrinol. 26:85) led us to look for muscarinic receptors in the pituitary by binding of [^{3}H]quinuclidinyl benzilate (QNB), a potent and specific muscarinic antagonist. We have detected [^{3}H]QNB binding sites in membranes of sheep anterior pituitary whose characteristics are closely similar to those reported for muscarinic receptors in other tissues. They have an equilibrium dissociation constant in the 20-40 pM range, a rate constant for association at 37°C of about 2×10^8 $M^{-1}min^{-1}$, a rate constant for dissociation at 37°C of about 4×10^{-3} min^{-1}, and the expected specificity for a variety of cholinergic and other drugs. Since there is no established cholinergic or other innervation of the anterior pituitary, the presence of typical muscarinic receptors there, assuming that they are functional, suggests that acetylcholine reaches the tissue through the hypophyseal portal circulation and that it may thus act as a releasing hormone or otherwise regulate pituitary function. An alternative possibility is that there is a minor cholinergic innervation of the vasculature, which contains all the receptors. Histological examination of receptor localization is needed for a definitive answer, but a vascular or innervation-related localization in the anterior pituitary is argued against by the fact that both the posterior pituitary (with a known innervation and heavy vascularization) and lower infundibular stem have less concentrations of [^{3}H]QNB binding sites than the anterior pituitary by at least a factor of two. The concentration of apparent muscarinic receptors in the sheep anterior pituitary (5-7 pmol/g wet weight) still is relatively low compared to receptors for thyrotropin releasing hormone (20 pmol/g wet weight) or dopamine (20-30 pmol/g wet weight) in the same membrane preparations or compared to muscarinic receptors in similarly prepared membranes from sheep whole hypothalamus (25-30 pmol/g wet weight) or median eminence (10-15 pmol/g wet weight). These regional differences may explain in part the failure of most investigators to detect the physiological correlates of our biochemical findings. Relatively prominent effects of muscarinic agents at the hypothalamic level in vivo could obscure any direct effects at the pituitary level. (Supported in part by U.S.P.H.S. grant MH-29671 to D.R.B.)

1567 FURTHER STUDIES OF LESIONS OF THE MEDIAL PREOPTIC NUCLEUS (MPN) ON THE CONTROL OF LUTEINIZING HORMONE (LH) RELEASE IN FEMALE RATS. E. Terasawa, S.J. Wiegand, L.V. Rubens* and W.E. Bridson*. Wis. Reg. Primate Res. Ctr., Univ. of Wis., Madison, WI 53706

Previously we have reported that the MPN, a small periventricular structure located immediately caudal to the organum vasculosum lamina terminalis is indispensable for the cyclic release of LH in the female rat. In the present study, effects of MPN lesions on I) the estrogen (EB)-induced daily surge of LH and on II) LHRH content in the medial basal hypothalamus (MBH) following injections of EB and P, were determined. Regular cyclic rats housed under standard lighting conditions were ovariectomized 4-6 wks after brain lesions, and 2 wks later were given ovarian hormones. Circulatory LH and hypothalamic LHRH were measured by RIA. (I) Small electrolytic lesions were placed in 4 loci of the suprachiasmatic area. Lesions of MPN and suprachiasmatic nucleus (SCN) induced persistent estrus. Lesions in the locus anterior to MPN (VPC) and lesions in the locus between MPN and SCN (ASR) as well as sham lesions did not abolish estrous cyclicity. However, after ovariectomy and 50 µg EB, the daily surge of LH evident at 1730 on days 1 and 2 in sham controls was blocked in all lesioned groups. After 1.5 mg P on day 3, a surge of LH comparable to that of sham controls was induced in VPC and ASR lesioned groups, and an attenuated surge was seen in SCN lesioned groups. MPN lesioned groups did not respond to P. (II) Lesions were made in the MPN and in VPC with partial damage to MPN. MPN lesions, but not VPC lesions, abolished estrous cyclicity. After ovariectomy, lesioned animals and controls were treated with 5 µg EB (day 0). On day 2 at 1000 half of the animals in each group were decapitated, tissue blocks from the MBH were removed for LHRH, and trunk blood was collected for serum LH. Remaining animals received P on day 2 and were sacrificed at 1730. MBH content of LHRH in controls decreased from 1000 to 1730 ($p<0.001$) with a concomitant increase of serum LH. However, LHRH contents in both MPN and VPC lesioned groups were well below those of controls at 1000 and 1730 ($p<0.001$), despite the facts that MPN lesions entirely abolished the P-induced LH surge while VPC lesions partly attenuated it. It is concluded that the P-induced LH surge can be blocked only by MPN lesions, while the EB-induced daily surge of LH can be eliminated by lesions anywhere in the suprachiasmatic region, suggesting that the neural mechanism mediating the facilitatory action of EB is diffusely organized. Reduction of LHRH content in the MBH is caused not only by MPN lesions, but also by VPC lesions, indicating that the LHRH neuronal system is also diffusely organized in the vicinity of the MPN. Thus, the neural component sensitive to P in the MPN may be the key factor for the cyclic release of LH. (NIH RR00167)

1568 MODULATION OF HIPPOCAMPAL EXCITABILITY IN ADULT CASTRATED AND OVARECTOMIZED RATS. Timothy J. Teyler, Michael Foy* and Richard M. Vardaris. Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272 and Kent State University, Kent, Ohio 44240.

We previously demonstrated the modulating effects of 100 pM concentrations of 17-beta-estradiol (E_2) and testosterone (T) on in vitro slices of normal adult rats (Vardaris and Teyler, Neurosci. Abs., 1978, 4, A1145). In normal males and proestrus females E_2 enhanced the amplitude of an extracellular population spike from the CA1 area of the hippocampal slice. In non-proestrus females T enhanced the amplitude of the same monosynaptic responses. This differential responsivity to physiologically appropriate levels of gonadal steroid may reflect sexual differentiation in the hippocampus as is suggested by the presence of androgen and estrogen receptors in the embryonic brain (Vito & Fox, Neurosci. Abs., 1977, 3, A359; Science, 1979, 204, 517) or it may result from the priming effect of plasma gonadal steroids.

To investigate this question adult rats were castrated or ovarectomized prior to testing with 100 pM E_2 and T. After allowing two days for plasma gonadal steroid levels to decline, hippocampal slices were prepared and were tested to both E_2 and T in an ABA design. Electrophysiological measures were taken at 10 and 20 minutes following addition of steroid to the bathing ringer solution. CA1 excitability to monosynaptic stimulation of stratum oriens displayed the same properties as seen in the gonadally intact animals. That is, E_2 enhanced the amplitude of the population spike in the castrated male. T enhanced the same response in the ovarectomized female. A tendancy was also noted for T to depress responsivity in castrated males and for E_2 to depress responsivity in ovarectomized females.

These data are consistent with the hypothesis that hippocampal modulation by gonadal steroid hormones reflects sexual differentiation of hippocampal tissue rather than a response to circulating levels of hormone. The rapid onset of the steroid effect, within 10 min, may suggest a membrane effect of the steroid and is similar to the effect of E_2 on hypothalamic cells (Dufy et al., Neuroendocrin., 1976, 22, 35). These results indicate that steroid fluxes modulate the excitability of the rodent hippocampus and may do so by acting upon sexually differentiated neurons. (NSF grants BNS-77-28497 and BNS-78-23947 (TJT)).

1569 EFFECTS OF ESTRADIOL ON CATECHOLAMINE SYNTHESIZING ENZYMES, LUTEINIZING HORMONE (LH) AND PROLACTIN IN THE OVARIECTOMIZED RAT. Harriet Tobias*, Laurence Carr and James Voogt*. Dept. Pharmacol., Univ. Louisville, Louisville, KY 40232 and Dept. Physiol., Univ. Kansas Medical Center, Kansas City, KS 66103.

Hypothalamic catecholamines have been postulated to play a role in the effects of estrogen on LH and prolactin release. In the present study the actions of estradiol benzoate (EB) on tyrosine hydroxylase (TH) and dopamine-B-hydroxylase (DBH) activity were studied to determine their relationship to the plasma levels of LH and prolactin. Female Sprague-Dawley rats ovariectomized 3-4 weeks previously were injected with 10 µg EB or oil and decapitated 1, 2, or 3 days later. The medial basal hypothalamus (approx. 30-90 µg protein) was dissected and assayed for TH and DBH activity. Trunk blood was assayed for LH and prolactin by radioimmunoassay. Injection of EB caused a significant decrease in LH levels 1 day later but LH returned to control (untreated) levels on the second day. LH levels decreased again on the third day. Plasma prolactin increased steadily over the first two days and remained elevated on the third day. TH activity was increased 1 day after injection of EB but returned to control level on the second day. The release of LH appeared to be inversely correlated with TH activity throughout the 3 day period whereas no consistent correlation with prolactin levels could be demonstrated over the same time period. DBH activity remained unchanged except for a significant decrease 2 days after administration of EB. The results suggest that the effects of EB on LH release may be mediated by selective alteration of TH activity in the hypothalamus.

1570 INACTIVATION OF BRAIN CYTOSOL GLUCOCORTICOID RECEPTOR BY ATPase. Andrew C. Towle* and Paul Y. Sze (SPON: B. E. Ginsburg). Dept. of Biobehavioral Sciences, Univ. of Connecticut, Storrs, CT 06268.

Na^+-K^+-ATPase from porcine cerebral cortex inactivates the glucocorticoid binding capacity of 104,000 x g soluble preparations from rat hippocampus and liver. Pre-incubation of the hippocampus preparation at 30°C in the presence of ATPase (10 u/ml) results in a rapid loss of specific ^{3}H-triamcinolone binding, with a half-life of approximately 10 min. The ability of ATPase to inactivate the glucocorticoid receptor is dependent on the concentration of the enzyme, requires magnesium, and is inhibited by ouabain. The unbound receptor is sensitive to inactivation, whereas the steroid-bound receptor is unaffected. The inactivation results in a loss of the binding capacity rather than an alteration of the binding affinity for the steroid. Similar inactivation by ATPase can be obtained in liver cytosol preparations.

Alkaline phosphatase is known to inactivate the glucocorticoid binding capacity of rat liver cytosol preparations (Nielsen et al., PNAS, 74, 1398, 1977). This effect of alkaline phosphatase has also been demonstrated with hippocampal glucocorticoid receptor in our study. Similar to ATPase, alkaline phosphatase produces its effect only on unbound receptor, and the inactivation reflects the decrease of binding capacity rather than binding affinity, in both liver and brain preparations.

Since ATP is a substrate of alkaline phosphatase as well as ATPase, the inactivation of glucocorticoid receptors by the two enzymes may have a similar mechanism. Nielsen et al. proposed phosphorylation-dephosphorylation of receptor protein as a regulatory process on the basis of the phosphatase effect. Alternatively, as suggested by the ATPase effect, it may be ATP instead of protein-bound phosphate that is required for receptor binding activity.

1571 THE EFFECT OF DARK PULSES ON THE CIRCADIAN RHYTHM OF LOCOMOTOR ACTIVITY IN HAMSTERS MAINTAINED IN CONSTANT LIGHT. Fred W. Turek and Gary B. Ellis*. Northwestern Univ., Evanston, IL 60201.

An important approach in the elucidation of formal properties of circadian systems has been the characterization of how a free-running rhythm is altered following a brief perturbation. In the most commonly used paradigm, organisms free-running in constant darkness are exposed to a single light pulse, and the resulting phase shift of the rhythm is measured. The interpretation of phase response curves generated from such studies is at present the theoretical basis for the entrainment of circadian systems by environmental signals. Despite the theoretical importance attached to phase response curves generated via light pulses on a background of constant darkness (DD), little is known about the effects of dark pulses on a background of constant light (LL).

To assess the response of the circadian rhythm of wheel-running activity to dark pulses, 22 male golden hamsters maintained in LL were exposed to a 3h dark pulse at various circadian times. The dark pulses were administered at 3 wk intervals through 150 days of LL. The effect of the dark pulse on the activity rhythm depended upon the phase relationship between the dark pulse and the rhythm. Dark pulses occurring either late in the subjective night or early in the subjective day had little effect on the activity rhythm. In contrast, dark pulses occurring either late in the subjective day or early in the subjective night consistently altered the rhythm in one of three ways: 1) The rhythm was phase advanced 0.5-2.0h (this should be contrasted to the phase delays occurring in response to light pulses administered at this circadian time during maintenance in DD); 2) A new component of activity, in phase with the dark pulse, was induced and lasted for up to 4 cycles before fusing with the main bout of activity; 3) The activity rhythm was split into two distinct components within a day after the pulse.

While only 2 of 22 hamsters showed splitting the day after a dark pulse, splitting did eventually occur in 12 other animals. As in other reports on splitting, the 2 components stabilized at a 180° antiphase relationship, and the steady-state period of the split condition was always shorter than the period of the rhythm prior to splitting. Once the activity rhythm was split, subsequent dark pulses had little effect. Hormonal manipulations (castration, pinealectomy, melatonin treatment) which have been found to alter rhythmicity under other experimental conditions, were also without effect on splitting.

The present study indicates that dark pulses on a background of LL perturb the circadian system in a different manner than light pulses on a background of DD. The use of dark pulses to perturb circadian rhythmicity may be a useful tool in examining the formal properties of circadian systems. (NIH-HD-09885).

1572 BABOON CORTICOSTERONE: SUBSTANTIAL BRAIN BINDING OF A 'MINOR' ADRENAL GLUCOCORTICOID. Barbara B. Turner, Elaine M. Smith*, and Bernard J. Carroll*. Mental Health Res. Inst., Univ. Mich., Ann Arbor, MI 48109

In primates the predominant glucocorticoid secreted by the adrenal is cortisol. The concentration ratio of corticosterone to cortisol in plasma is usually less than 0.10. The ratio of corticosterone to cortisol in post-mortem brains (tissue concentration) has been reported to be higher than that of plasma. We wished to examine the extent to which disproportionate brain concentrations are reflected regionally in cytosol binding and nuclear binding in the primate brain.

Subjects were 4 baboons (Papio cynocephalus) being used in acute experiments. Under pentobarbital anesthesia, following 6-8 hrs of surgical stress, the baboons had blood samples withdrawn via femoral catheters. They were then immediately perfused with cold dextran-saline via the internal carotid arteries. The brains were quickly removed and then dissected at 4°C. Tissues for cytosol preparations were homogenized in Tris-EDTA buffer (10ml/g); following centrifugation, free steroid was removed by dextran-charcoal adsorption. Tissues for nuclear binding were homogenized in the absence of detergent, and the crude pellet repeatedly washed prior to final centrifugation through dense sucrose. Dried extracts, both cytosol and nuclear, were chromatographed on LH-20 columns. Cortisol and corticosterone fractions were quantitated by radioimmunoassay, taking into account sample recovery values.

The mean plasma values for corticosterone (B) and cortisol (F) were 3.1 $\pm$ 0.7 and 41.1 $\pm$ 5.7 respectively, yielding a B to F ratio of .075. The tissue concentration of B + F in the brain regions studied (preoptic-septum, hypothalamus, amygdala, hippocampus and cortex) was found to be about 8 picomols/mg protein, with the pituitary being somewhat higher. The ratio of B to F in tissues ranged between .2 and .4 in all regions, a marked increase over the plasma ratio. The cytosol binding of both B and F was found to range between 250 and 500 femtomoles/mg protein in the 8 regions examined. The ratio of B to F bound in cytosol was 0.5 or greater in all regions, with the lowest ratio observed in the thalamus and the highest in the pituitary (1.2) and hippocampus (1.6). In brain nuclei, the ratio of B to F was relatively uniform in the pituitary and the 5 brain regions, ranging between .50 and .75.

For both cytosol and nuclear binding the ratio of corticosterone to cortisol is at least .50, and in the majority of brain regions examined, the principal glucocorticoid bound is not cortisol, but rather corticosterone.

1573 DOES GLIAL CELL ENCLOSURE OF NEURAL LOBE NEUROSECRETORY ENDINGS INHIBIT HORMONE RELEASE? C.D. Tweedle, and G.I. Hatton, Depts. Anat. & Psychol. & the Neuroscience Program, M.S.U., E. Lansing, MI 48824.

It has been noted previously in electron micrographs that neurosecretory axons in the neural lobe of the rat are sometimes completely surrounded by the cytoplasm of pituicytes, specialized glial cells. In an earlier ultrastructural morphometric study (Anat. Rec. 193, 707), we found that the number of such "enclosed" neurosecretory axons significantly decreased with water deprivation (24 h) and reappeared with subsequent rehydration (24 h) in the rat. This indicates that pituicyte enclosure of the neurosecretory axons is greatest during periods of low hormone release. To further analyze the relationship between neurosecretory endings and pituicytes, serial thin section analysis was carried out on the rat neural lobe. The data obtained to date indicate that, while neurosecretory axons are often only transiently wrapped in pituicyte cytoplasm (for .5-2.5 μm), numerous examples could be found where the neurosecretory axons actually terminated within the pituicyte cytoplasm. In these latter cases, in serial cross sections, the neurosecretory axons gradually attenuated and disappeared. During this process, the contents of the neurosecretory endings only rarely appeared degenerative and no unusual appearance of the surrounding pituicyte cytoplasm was noted. Synaptoid contacts between enclosed axons and pituicytes were occasionally seen.

The present finding that neurosecretory axons can frequently be observed to actually terminate within pituicyte cytoplasm plus previous observations that the number of enclosed neurosecretory axons is highest with low hormone release suggest to us that pituicyte enclosure is involved in the inhibition of hormone release. One possible mechanism of this inhibition could be an alteration in the ionic milieu of the extracellular space around the enclosed neurosecretory axon by the pituicyte. (Supported by NIH BGRS funds and NIH grant NS 09140.)

1574 ANGIOTENSIN II SPECIFIC BINDING SITES IN RAT BRAIN. Mark van Houten*, Ernesto L. Schiffrin*, Johannes F.E. Mann*, Barry I. Posner* and Roger Boucher* (SPON: R. Hirsh). Depart. of Medicine, McGill University, and the Institut de Researches Cliniques de Montréal, H3A 2B2.

The existence of brain angiotensin II (AII) receptors is well established. In the present study quantitative light microscopic radioautography (LMR) was used to determine the location of specific binding sites for blood-borne AII in the rat brain.

Ile^5-AII was monoiodinated (specific activity of 1.5 mCi/μg) as described by Freedlander and Goodfriend (Handbook of Radioimmunoassay, 1979), and 1.5 X 10^8 cpm was injected intracardially into anaesthetized male rats. Three minutes later brains were perfused with Ringer's lactate followed by Bouin's fixative solution. Four micron sections of brain were prepared for LMR.

Radioautographic reactions occurred over the choroid plexus and all the circumventricular organs (CVO) deficient in blood-brain barrier: organum vasculosum of the lamina terminalis (OVLT), subfornical organ (SFO), median eminence (ME) and area postrema (AP). ^{125}I-AII binding sites were concentrated in the deep center of the SFO, the medial palisade zone (MPZ) of the ME, and as "hot spots" about cells in the vicinity of blood vessels in the AP. Radiolabeling by ^{125}I-AII in the center of the SFO was 2.5-3 times greater than labeling in the other CVOs, which exhibited similar overall reaction intensities. Grain densities over all other regions of the central nervous system did not differ from background.

Femoral vein infusion of sar^1-ala^8-AII (10nM/Kg/min) 30 minutes prior to and during the injection of ^{125}I-AII reduced by 72-94% the radioautographic reaction caused by ^{125}I-AII over the CVOs, but reactions over the choroid plexus were unchanged. In prior experiments sar^1-ala^8-AII infusion caused an initial rise in blood pressure that rapidly returned to normal for the duration of the infusion, and completely blocked AII-induced blood pressure elevation. Infusion of an isomolar dose of des-asp^1-ile^8-AII was somewhat less effective in blocking ^{125}I-AII binding, and $ACTH^{1-24}$ was non-inhibitory.

These results demonstrate the presence of AII specific binding sites in the SFO and OVLT, regions thought to mediate central effects of blood-borne AII on drinking, and in the AP, which has been implicated in AII stimulation of central pressor activity. AII specific binding sites in the MPZ of the ME implicate AII in the control of hypophysiotropic function, perhaps in the secretion of vasopressin and/or serotonin.

1575 PUTATIVE ANDROGEN AND ESTROGEN RECEPTORS IN EMBRYONIC RAT HYPOTHALAMUS. Christine C. Vito, Sarah E. Bates* and Thomas O. Fox. Dept. of Neuroscience, Children's Hospital Med. Ctr., and Dept. of Neuropathology, Harvard Medical School, Boston, MA 02115

Sexual differentiation of brain occurs during a critical period of development which includes late embryonic and early neonatal ages of mice and rats. The organizational influences of gonadal steroids upon a non-differentiated neural substrate occur during this period. We reported previously that adult-like estrogen receptors (Vito & Fox, Science 204:517-519, 1979) and androgen receptors (Fox, Vito & Wieland, Amer. Zool. 18:525-537, 1978) exist in late embryonic and early neonatal mouse hypothalamus (HPOA).

Embryonic and neonatal rat HPOA also contain adult-like androgen and estrogen receptors. By DNA-cellulose (DC) affinity chromatography, we detect macromolecular hormone-binding activities in cytosols of rat HPOA as early as embryonic-day 15 (E15; vaginal plug = E0, birth = E21,22). Androgen- and estrogen-binding activities, respectively, from embryonic, neonatal and prepubertal rat HPOA adhere to DC and exhibit elution maxima in the 140 and 220 mM range of a NaCl elution gradient. These elution characteristics are typical of receptors from mouse HPOA and kidney. Heat activation ($22^{o}C$-$24^{o}C$) improves the detection of these rat androgen- and estrogen-binding activities by DC over previous levels (Vito & Fox, Neurosci. Abstr. 3:359, 1977). Embryonic and neonatal rat estrogen-binding activities saturate at ^{3}H-estradiol concentrations < 10nM and are competed by 100-fold excess nonradioactive diethylstilbestrol; androgen-binding activities saturate at ^{3}H-dihydrotestosterone (purified by high-performance liquid chromatography) concentrations < 10nM and are reduced > 90% by 10-fold excess non-radioactive testosterone. These indicators of hormone-binding affinities are similar to those observed for perinatal mouse estrogen and androgen receptors.

We have measured the detectable concentrations of putative androgen and estrogen receptors in rat HPOA. At E17, E18 and E19, estrogen receptor increases from 1.2 to 5.1 x 10^{-17} moles/mg HPOA (4-fold) and ranges from 11.6 to 13.0 x 10^{-17} between postnatal-day 4 (P4) and P21; androgen receptor increases from 0.3 to 0.7 x 10^{-17} at E17-E19 (2-fold) and from 0.8 to 3.2 x 10^{-17} between P4 and P21 (4-fold). At E16, E17 and E18, mouse HPOA contains 4.5 x 10^{-17} moles estrogen receptor/mg HPOA which increases only 2-fold by P21; while it contains 0.3 x 10^{-17} moles androgen receptor which increases 2-fold by P4 and 4-fold more by P21.

1576 IN VIVO AND IN VITRO STUDIES OF PINEAL-THYROID RELATIONSHIPS. Jerry Vriend*, Karl M. Knigge and Shirley Joseph*. Department of Anatomy, University of Rochester School of Medicine, Rochester, New York 14642.

Experiments with the golden hamster have demonstrated a dramatic influence of the pineal gland on the hormones of reproduction. Equally dramatic effects of the pineal gland can be demonstrated on thyroid hormones, particularly thyroxin. Depriving the hamster of light by bilateral orbital enucleation resulted in reduction of plasma thyroxin and an elevation of pituitary TSH. These changes were reversed by pinealectomy. Melatonin injections in either male or female hamsters resulted in significant depression of thyroxin concentrations. The depression obtained by melatonin injections was impaired by pinealectomy or subcutaneous implants of melatonin. In vitro experiments were designed to test the effects of pineal extracts on TRH induced TSH release by dispersed pituitary cells. An extract of bovine pineals was subjected to G-25 sephadex separation and the resulting fractions tested for their effects on TRH induced TSH release. Up to 80% inhibition of TRH activity was demonstrated with one of the fractions. Equal or greater inhibition of TRH activity was obtained in experiments with synthetic somatostatin (10^{-9}M). Melatonin at high doses (10^{-6}M) resulted in only 24% inhibition of TRH activity. These results suggest that the pineal gland, together with hypothalamic releasing factors, is involved in control of pituitary TSH secretion.

1577 THE EFFECT OF SEROTONIN ON PROLACTIN RELEASE IN NORMAL AND PITUITARY STALK SECTIONED RHESUS MONKEYS (MACACA MULATTA). W.B.Wehrenberg*, D.E.McNicol*, A.G.Frantz*, and M. Ferin* (SPON: J.L. Antunes) Dept. Ob/Gyn and Medicine, College of Physicians and Surgeons, Columbia University, New York, New York 10032

Biogenic amines have an important role in the regulation of prolactin (PRL) secretion. While we have reported that L-dopa, a dopamine precursor, can suppress PRL release in rhesus monkeys by a direct action on the pituitary, the site at which serotonin acts to stimulate PRL release is generally considered to be hypothalamic. In the present experiment we compared the effects of serotonin on PRL release in monkeys in which the pituitary gland was isolated from direct hypothalamic influences by pituitary stalk section and in normal monkeys. Pituitary stalk section had been performed under direct visualization via a transorbital approach and a silastic barrier was placed between the cut ends of the pituitary stalk to prevent revascularization. Serotonin was administered i.v. at doses of 50, 500 and 5000 µg to 4 normal and 3 stalk sectioned female rhesus monkeys. PRL concentrations were determined by radioimmunoassay. Basal PRL concentrations were elevated in stalk sectioned monkeys as compared to normal animals (34 ± 5 vs 3 ± 1 ng/ml, mean ± SEM), as a result of the loss of inhibitory hypothalamic influences. In normal animals, a 50 µg dose of serotonin did not induce a change in PRL concentrations. Following the administration of 500 µg PRL increased within 5 min from 3 ± 1 to 22 ± 6 ng/ml; there was an even greater response to 5000 µg of serotonin as PRL increased from 4 ± 2 to 82 ± 27 ng/ml within the same time interval. In both groups, PRL concentrations decreased within 10 min and reached baseline 50 - 60 min after the injection. Interestingly, serotonin administration resulted in an increase in PRL in stalk sectioned animals as well. Although a dose of 50 µg was ineffective, 500 µg and 5000 µg increased PRL from 27 ± 6 to 57 ± 10 ng/ml and from 30 ± 6 to 75 ± 26 ng/ml, respectively. Peak concentrations were reached after 5 min with the 500 µg dose and after 20 min with the 5000 µg dose.

These results confirm that serotonin releases prolactin in the normal rhesus monkey. Since serotonin induces a similar prolactin release in stalk sectioned monkeys, the results also suggest that this neurotransmitter, like dopamine, may mediate release of PRL by an effect on the pituitary.

Supported by NIH HD 10813 and 5P30 HD 06132

1578 EFFECTS OF CERVICAL STIMULATION ON PITUITARY AND PLASMA PROLACTIN AND HYPOTHALAMIC CATECHOLAMINES IN PREPUBERAL RATS. D.W. Weiss and V.D. Ramirez. Dept. of Physiol. and Biophys., Univ. of Illinois, Urbana, IL 61801.

A single cervical stimulation (CS) induces a marked increase in prolactin (PRL) in the 24 but not in the 22 day old rat. Catecholamines (CA), particularly dopamine (DA) are involved in the control of PRL secretion. In this study, CA levels in the median eminence (ME) and the medial basal hypothalamus (MBH), together with plasma and pituitary PRL levels were measured in prepuberal rats.

Female rats 26, 28, and 32 days of age, (14 hr/10 hr light/dark cycle) were CSx1 min. The stimulation was done at 20:00, 1 hour after the lights were turned off and 2 days after artificial vaginal opening. A control (CTL) group was handled in the same manner but not CS. Immediately following, and at intervals of 2, 4, 6, and 12 h groups of 4 animals were sacrificed by decapitation. Plasma and pituitary PRL were measured by radioimmunoassay, while CA were measured with a radioenzymatic assay.

As the CTL rats matured from 26 to 32 days of age, the mean ME-DA content across the entire 24 hr period more than doubled, while the MBH-DA and MBH-NE values decreased 42 and 48% respectively. The mean ME-NE content in the 26 and 32 day old rat were higher than those in the 28 day old rat.

In the 32, but not in the 26 or 28 day old CS rat, a 4 fold increase in plasma PRL was observed after 24 hours. No changes in plasma PRL were seen in any of the CTL rats for the entire 24 hr period. An 87% decrease in the ME-DA content was also seen in the 32 day old rat 6 hrs after CS which recovered to the initial value 18 hrs later. This decline was not observed at any other ages in either the CS or CTL groups. The MBH-DA values did not significantly change in any of the animals during the 24 hr period and the ME-NE content did not change in any of the 26 or 28 day old groups. In the 32 day old CS animal, the ME-DA content significantly decreased, while the ME-NE content significantly increased. In the 32 CTL rat, the ME-NE content increased.

In the 26 day old animal a significant decrease in pituitary PRL content, reaching a nadir by 4 hrs and recovering by 24 hrs, was observed in both the CS and CTL rats. In the 28 day old animal, this decrease was only observed in the CTL rat. In the 32 day CTL rat, no changes in pituitary PRL were observed, but a 2 fold increase was seen in the CS animals beginning 4 hrs and peaking 20 hrs later. It is concluded that complex interactions among factors such as CA, maturation and circadian elements regulates the induced PRL surge after CS.

1579 EFFECT OF REPRODUCTIVE STATUS ON MEAL PATTERNS AND ACTIVITY OF MALE AND FEMALE RATS. Freya Weizenbaum, Suzanne Lochner* and Amelia Bland*. Dept. Psych., V.P.I. & S.U., VA 24061.

Meal patterns and activity levels of female and male rats were determined. The rats were videotaped for 24 hours and feeding behavior and cage crossings (activity) were quantitated. Analysis of the behavior revealed that there are striking parallels in the ingestive patterns of estrous females and mated males on the day after ejaculation. Females in estrus decreased 24-hour food intake and body weight, and increased the number of small meals and motor activity, compared to diestrus. Mated males decreased 24-hour food intake and body weight in the 24-hour period after ejaculation, and there was an increase in the number of short meals and in the number of approaches to the food cup. Novel-Cage Control males (which were placed in an empty arena for a brief period on the mating day) exhibited different behavioral patterns. There was no consistent effect of the Novel-Cage treatment on 24-hour food intake or meal pattern, and body weight tended to rise. Both Mated and Novel-Cage Control males showed a depression in gross motor activity, although there was some indication that the circadian distribution of the decrease may differ in the 2 groups. Thus the meal pattern (nibbling) and food intake of Mated males and Estrous females are similar. The nibbling pattern is known to be under the control of estrogen in the female rat (PB 17:20, 1976). The behavioral parallels between the Mated male and the Estrous female suggest that a common endocrine mechanism may be involved, possibly aromatization of testosterone to estrogen increases as a result of the mating-induced rise in testosterone(HB 6:277, 1975).

1580 AFFERENT CONNECTIONS OF THE MEDIAN EMINENCE IN THE RAT. S.J. Wiegand and J.L. Price. Dept. Anat. and Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

Retrograde axonal transport of horseradish peroxidase (HRP) or ^{125}I-wheat germ agglutinin (WGA) was used to identify the cell bodies of origin of axons terminating in the median eminence (ME). The basal hypothalamus was exposed by a ventral approach through the soft palate and base of the skull. Pressure injections of HRP (10%, 0.02 to 0.04 µl) or WGA (1.9×10^8 CPM/ml, 0.1 µl) were made under direct visual control into the ME of male and female rats through glass micropipettes (tip diameter, 6 to 10 µm). After 6 to 24 hours animals were sacrificed. Brains were processed for HRP with tetramethyl benzidine and for WGA by autoradiography.

Following injections into the ME, retrogradely labeled cells are found in the arcuate nucleus (ARC) and the periventricular region, as well as in the paraventricular nucleus (PVN), to a lesser degree, the supraoptic nucleus (SON) and other magnocellular neurosecretory cell groups. In the periventricular region, labeled cells are restricted to an area extending from the rostral part of the ARC to the level of the anterior commissure, and are particularly concentrated in the zone medial to the PVN. In the PVN labeled cells are found in all parts of the nucleus, but are most densely aggregated in the smaller-celled dorsomedial part. A few cells are also found in the rostral preoptic area lateral to the organum vasculosum of the lamina terminalis (OVLT). Cells of the ventromedial nucleus of the hypothalamus are not labeled in cases where the injection of WGA or HRP was confined to the ME, but are labeled if the injection spread into the ARC.

In order to determine if a portion of the labeling observed after ME injections was due to the spread of HRP into the posterior pituitary control injections were made directly into this structure. Following these injections, the PVN, SON and all "accessory" magnocellular cell groups are very heavily labeled. Cells containing HRP reaction product are found in all parts of the PVN, but are most densely concentrated in the larger-celled anteroventromedial and posterodorsolateral parts of the nucleus. In these areas virtually every cell is labeled. Scattered cells in the periventricular region near the PVN also contain reaction product. However, cells in the ARC, the ventral part of the periventricular region near the ARC, and the preoptic region lateral to the OVLT are not labeled after injection of HRP into the pituitary.

1581 URINE EXCRETION FOLLOWING ADMINISTRATION OF NALOXONE, OXILORPHAN AND BUTORPHANOL. Guillermo A. Zeballos* and Alan B. Rothballer. Dept. Neurosurgery, New York Medical College, Valhalla, New York 10595.

The possibility that opioids play a role in the regulation of neurohypophysial peptide release is suggested by the presence of opiate receptors and enkephalinergic fibers in the neurohypophysis (Rossier et al, Soc. of Neuroscience, Abstracts 4: 414, 1978), and the well-known antidiuretic action of morphine. Moreover, the morphine analogues oxilorphan (OX) and butorphanol (BU) produce diuresis (Miller, Neuroendocrinology, 19: 241, 1975) and suppress the release of vasopressin which normally follows hypertonic stimulation (Basulto et al, Fed. Proc. 37: 815, 1978). To investigate the type of opiate receptor mechanism possible involved, we studied the interaction of those analogues with the known potent opiate antagonist, Naloxone (NAL) on water diuresis. Six groups of adult male rats were used: a. saline (SA)+SA. b. SA+OX. c. SA+BU. d. NAL+SA. e. NAL+OX. f. NAL+BU. Animals were kept in individual cages with water ad libitum. All drugs, dissolved in SA, or SA alone (0.2 ml./100 gbw.), were injected subcutaneously. 1.0 mg/100 gbw. of NAL or saline was given at the beginning of the experiment (time 0), and 30m. later, 0.9 mg/100 gbw. of OX or BU was administered. Urine was collected every 30m. and volume and osmolality were measured. At the end of the experiment, the rats were killed by decapitation. Blood was collected in cooled tubes to measure plasma osmolality and plasma AVP levels. Rats receiving OX or BU developed a higher diuresis and produced urine with osmolalities significantly lower than the ones receiving SA alone or NAL plus SA. At the end of the third hour following drug administration urine and plasma osmolalities (mOsm/Kg.) for each group were as shown below.

	SA.	OX.	BU.	
SA.	a. 1986±290	b. 679±24	c. 316±12	Urine
	284±1	294±2	290±2	Plasma
NAL.	d. 1540±670	e. 990±450	f. 439±240	Urine
	283±2	290±2	283±3	Plasma

These data confirm the diuretic effect of OX and BU, an effect not blocked by NAL which had no effect when given alone. Since the drugs BU and OX had effects opposite to that of morphine and not blocked by NAL they seem to be acting not as morphine agonists, but rather as antagonists. Moreover, they seem to be acting on antagonist receptors different from those with affinity for NAL. (OX and BU were kindly supplied by Bristol Lab. and NAL by Endo Lab.).

Supported by NIH Grant NS No. 06624.

NEUROETHOLOGY

1582 JAMMING AVOIDANCE BEHAVIOR IN A PULSE SPECIES OF ELECTRIC FISH: SENSORY ENCODING FOR A TEMPORAL PATTERN DISCRIMINATION. Curtis L. Baker, Jr. Dept. of Neurosciences, U.C.S.D., La Jolla, CA 92093.

South American pulse species of weakly electric fish change their frequency of electric organ discharges(EODs) to avoid jamming of their electrolocation sense by other fish at similar frequencies. If a "foreign" fish is at a lower frequency its pulses scan from negative to positive latencies with respect to the fish's EOD, resulting in a strong acceleration in EOD frequency. Pulses of another fish at a higher frequency scan from positive to negative latencies, evoking a weak acceleration or a deceleration.

Neurophysiological studies reveal four classes of burst duration coder (BDC) electroreceptors which respond to scanning stimuli. α-type cells respond to the inward current component of the EOD, βs to outward current, and γs and δs to both components. All of these types respond strongly to foreign pulses at near-zero latencies with respect to the EOD. In addition, the δ-type cells and a subclass, α_es, respond to foreign pulses at negative latencies.

A series of foreign pulses at fixed negative latencies evoke large EOD accelerations, while pulses at near-zero latencies result in decelerations or very small accelerations. If foreign pulses are briefly placed at a negative latency, then at a near-zero latency, a large acceleration results. Conversely, pulses at first a near-zero and then a negative latency result in decelerations or weak accelerations. These "latency-clamp" stimuli thus seem to mimic scanning situations, and furthermore suggest a theory for directional responses: pulses at negative latencies activate an excitatory (E) process (resulting in acceleration), while those at near-zero latencies activate an inhibitory (I) process (preventing response to the first, and/or causing deceleration); the process activated first then dominates the overall response.

There are two possible ways in which information from BDCs could be used to drive the E and I processes. One way is to exploit the differential sensitivity to different latencies: α_e and δ types could activate E, while α, β, and/or γ types activate I. Another mechanism would be to pool responses from all BDC types and allow weak responses to drive E, while very strong responses would activate I.

The latter hypothesis is supported by experiments in which pulses at fixed latencies are amplitude-modulated; small vs. large modulations result in directional responses very similar to those obtained from scans and latency-clamps.

1583 PATTERNS OF NEURONAL ACTIVITY CORRELATED WITH THE JAMMING AVOIDANCE RESPONSE IN EIGENMANNIA. Joseph Bastian and Walter Heiligenberg. Dept. of Zoology, Univ. of Oklahoma, Norman, Ok. 73019 and Scripps Institution of Oceanography, UCSD, La Jolla, Ca. 92093.

The Jamming Avoidance Response (JAR) of weakly electric fish consists of an alteration of an animal's electric organ discharge frequency due to the presence of an interfering electric signal having a frequency from 1 to 10 Hz different than the former. If the interfering frequency is the higher then the fish responds by lowering its frequency (-JAR) and the fish raises its frequency in the presence of a lower frequency foreign signal (+JAR). Recent behavioral studies have identified a simple set of stimulus conditions under which this behavior occurs. We have studied the responses of single electroreceptors and of neurons in the Posterior Lateral-line Lobe (PLL) and in the Torus Semicircularis (TS) using stimuli that cause the behavior as well as stimuli that are lacking key features necessary for the behavior.

Previously Scheich (J. Comp. Physiol. 113, 207-255, 1977), using more complex stimuli, described responses of a type of receptors, PLL cells and of TS cells which differed in response to stimuli which evoked opposite signed JARs. Our results, using sinusoidal stimuli, show that different response patterns in the same types of receptors and PLL cells are not needed for complete behaviors of either sign to occur, however certain TS cells always show patterns of activity contingent upon the sign of the JAR. These cells are shown to respond to phase differences in electrical stimuli impinging upon nearby regions of the body.

1584 DISCRIMINATION OF SIGNAL FROM NOISE IN THE ESCAPE BEHAVIOR OF COCKROACHES. Jeffrey M. Camhi and Mark R. Plummer*. Sect. Neurobiol. and Behav., Cornell University, Ithaca, NY 14853

The cockroach Periplaneta americana responds to gentle wind puffs by turning and running away from the wind source. The animal is sufficiently sensitive that it detects and escapes from the strike of a natural predator, the toad Bufo marinus, by sensing primarily or only the wind which the toad makes during its strike (Camhi et. al. J. Comp. Physiol. 128, 203-212, 1978). This sensitivity presents a problem for the cockroach: how is the signal (toad's wind) discriminated from noise (background wind)?

To complicate this problem further, we find that restrained cockroaches are most sensitive to wind puffs delivered during slow walking (mean threshold for a pause or startle response, 3 mm/sec; for a running response, 12 mm/sec). If such a cockroach had walked about freely, it would have generated a "relative wind" directed posteriorly whose speed would equal the forward walking speed. When walking slowly (3 steps/sec) this would be approximately 80 mm/sec. We re-introduced this relative wind to restrained cockroaches by creating a steady posteriorly-directed flow which, at the cerci, measured 80 mm/sec. The cockroach's mean threshold was unchanged in the presence of this large wind. Moreover, while recording the wind speed just behind one cercus, we noticed that every walking step of the ipsilateral rear leg produced a gust of wind of 1-30 mm/sec. In addition, in these experiments, we did not shield the cockroach from room air currents, in an attempt grossly to stimulate ambient winds of the native habitat (Camhi et. al. op. cit.). Room currents ranged generally up to 50 mm/sec, and could flow in any direction. Therefore, the cercal wind receptors of a walking cockroach are subjected to a large and complex wind field. This constitutes background noise which can be more than 25 times larger than the just-threshold signal.

Although the threshold wind puffs had low flow rates, their accelerations were higher than the range of accelerations contained within the noise (noise, 0-300 mm/sec^2; threshold for pause or startle, 300 mm/sec^2; threshold for running, 750 mm/sec^2). Using ramp wind stimuli of 40 mm/sec peak flow but variable acceleration, accelerations greater than about 800 mm/sec^2 consistently evoked escape running, whereas those of about 300-800 mm/sec^2 most often evoked a pause in walking. Also, the lower the acceleration, the greater the probability that the stimulus would not evoke any response. At the lowest acceleration so far tried, 120 mm/sec^2, no response was evoked on about 50% of the trials. These data, plus recordings in progress from giant interneurons of walking cockroaches, suggest that a wind accelerometer in the escape circuit assists the animal in discriminating signal from noise.

1585 A ROLE FOR NUCLEUS INTERCOLLICULARIS IN THE REPRODUCTIVE BEHAVIOR OF THE FEMALE RING DOVE. Jeffrey Cohen and Mei-Fang Cheng. Inst. Anim. Behav., Rutgers Univ., Newark, NJ 07102.

Autoradiographic studies (Martinez-Vargas et al., JCN 167: 83, 1976) have identified several estrogen-concentrating sites in the ring dove brain, including the n. intercollicularis (ICo) region in the midbrain. Our previous radiofrequency lesion study implicated the involvement of this region in the mediation of females' nest-coo behavior pattern, a species-typical courtship response involving an oblique posture, wing-flipping and coos. The present studies further characterize the role of the ICo region in female courtship behavior.

The first study was designed to determine whether intracranial implants of estrogen in the ICo region could elicit female courtship behavior. A single cannula (30 gauge) containing crystalline estradiol-17β (E), estradiol benzoate (EB) or cholesterol (C) was placed unilaterally in the ICo region and the surrounding areas with the aid of a stereotaxic instrument in the females following bilateral ovariectomy. Behavioral results and histological verification of implant placement revealed that E and EB were most effective in eliciting nest-coo behavior when the implant was in the medial ICo region. Implants in other surrounding regions were not effective. None of these implants was effective in eliciting sexual crouch.

In the 2nd study, silver stain degeneration methods were used to determine efferent connections from the ICo region. Within the mesencephalon, dense degeneration was found in the ipsilateral ICo extending around Mld, and to the substantia griseas centralis. Degeneration was also observed in the contralateral ICo, with a few axons entering the Mld. Two sets of fibers may be discerned leaving the site of the lesions. One tract passes ventromedially from the ICo region, decussates under the medial longitudinal fasciculus and proceeds ventrally, staying medial to the locus coeruleus and lateral to n. decussationis brachium conjunctivorium. Some of these fibers appear to terminate in n. centralis superior, while others continue caudally and terminate in part in n. paramedianus. A second group of fibers leaves the lateral portion of the ipsilateral ICo, passing ventromedially around n. isthmi, pars parvocellularis and continues caudally on the tegmentum floor around n. pontis lateralis. Some of these fibers appear to decussate.

The estrogen implant study supports the implication of the ICo region and its connections in the mediation of the female's nest-coo behavior pattern. The degeneration study, however, did not provide a clear anatomical basis for the relationship between the ICo region and the known neural sites and pathways for vocalization.

1586 THE CENTRAL NERVOUS SYSTEM AND VOCALIZATION IN THE DOMESTIC CAT. N. C. de Lanerolle* (SPON: J. P. Flynn). Dept. Psychiatry, Univ. Yale Med. Sch., New Haven, CT 06508.

The vocalizations of the domestic cat are important in intraspecific communication. They are also expressions of emotion. Understanding the causation of vocalization can throw much light on these two aspects of species-typical behavior.

Studies by others on the domestic cat brain using either electrical brain stimulation or brain lesion techniques have implicated a number of brain regions in vocalization. However, the precise neuroanatomical pathways between these areas, or the inputs to or outputs from these areas remain unknown. The manner in which these areas influence vocalization has also not been investigated. With these questions in mind we have explored a region of the pons around the medial lemniscus using electrical brain stimulation combined with silver staining of degeneration from lesions placed at vocalization sites. Kanai & Wang (1962) had suggested that in the above region were sites on the final common path for all vocalization in the cat. The existence of such a common pathway for all vocalization has been disputed by workers on the Squirrel Monkey (Jurgens & Ploog, 1970). We found vocalization sites in and very near the medial lemniscus. The threshold current for evoked-vocalizations ranged from 0.05 mA to 0.2 mA, and in the majority of cats was below 0.1 mA.

The vocalizations evoked from these sites were similar to naturally produced (a) soft meows, (b) low frequency (2 KHz)calls of long duration (growls), (c) calls typically showing very dense and evenly distributed representations of resonant frequency elements which extend up to 8 KHz (protest meows). Hiss-like calls were evoked from some of these sites whereas purrs were never elicited. Very little overt behavior accompanied the vocalizations. Typically, the cat would be seated on its belly, tail drawn forward, ears up and facing forward to lateral, with pupils narrow rather than dilated. No non-vocal signs of escape or defensive threat (e.g., locomotion, piloerection, ear-flatten -ing or arching of the back) were associated with these sites. Such behavior without vocalization was observed at sites dorsal to the call site.

Descending projections from the call sites were followed to the lateral pontine nucleus; through the trapezoid area into the facial, ambiguus and inferior olivary nucleus. Ascending projections were traced to the ipsilateral inferior colliculus, the VPL nucleus of the thalamus, and in some instances to the periacqueductal central gray. It is argued that the vocalizations evoked from these sites are the result of the activation of a vocalization control mechanism, and not the indirect result of stimulating pain pathways.

1587 MUSCULAR CONTROL OF FREQUENCY AND DURATION OF ULTRASONIC VOCALIZATION IN THE LARYNX OF THE ECHOLOCATING BAT, EPTESICUS FUSCUS. Gary E. Durrant* and Roderick A. Suthers. Physiology Section, Med. Sci. Prog., Indiana Univ. School of Medicine, Bloomington, IN 47401

Eptesicus fuscus emits ultrasonic sonar pulses having a duration of one to several msec and repetition rates of up to 200 pulses per second. These downward sweeping FM vocalizations are emitted at intensities up to 110 dB SPL. We here report evidence regarding the mechanism by which echolocating bats are able to independently control the frequency and duration of an orientation sound, yet precisely coordinate these control mechanisms so that phonation occurs only when an appropriate tension exists on the vocal membranes, which are the source of the ultrasonic vocalizations. The frequency at which these membranes vibrate is primarily controlled by the three branches of the cricothyroid muscles. In short (5 msec) duration sounds, all three cricothyroid branches begin contracting prior to vocalization but stop contracting 10-12 msec before the start of phonation. The frequency of the downward FM sweep is controlled by the relaxation of these muscles. The cricothyroid muscle also adducts the vocal folds which are ventrocaudal to the vocal membranes and form the glottis. During the cricothyroid contraction prior to phonation, subglottic pressure (P_S) increases to a maximum of 40 cm H_2O due to the glottal constriction. When the cricothyroids relax, the P_S forces the vocal folds apart allowing air to flow between the vocal membranes and initiating phonation. The ventral thyroarytenoid muscle acts as a supplemental glottal constrictor which can operate independently from cricothyroid-generated constriction. This muscle starts to contract 55 msec prior to phonation and relaxes 16 msec before the start of phonation. When the duration of vocalization is increased, the relative timing of contractile activity in the three parts of the cricothyroid muscles vary. The ventral thyroarytenoid muscles also change the temporal relationship of their contraction relative to that of the cricothyroids. Since the ventral thyroarytenoid muscle has no effect on vocal membrane tension, it provides a means of controlling the duration of vocalization independently from its frequency. This supplemental glottal closure force can allow P_S to increase, resulting in more intense vocalizations, and it can prevent premature onset of phonation as P_S rises. Vocalizations appear to be terminated by the anterior and posterior cricoarytenoid muscles which are the arytenoid abductors and start to contract 5 msec before phonation starts. (Supported by NSF Grant BNS 76-01716).

1588 LEVELS OF FUNCTION IN RAT GROOMING BEHAVIOR. E. K. Freed* and H. J. Grill. (SPON: Steven E. Brauth). Dept. Psychol., Univ. Pennsylvania, Philadelphia, Pa. 19104.

Decerebrate rats initiate spontaneous bouts of effective grooming. Thalamic rats, with more brain intact, are much less effective in their grooming (Grill and Norgren '78). Thalamics perform grooming movements but do not correctly direct these to their fur. Our strategy was to define the components of grooming in intact rats and then to compare this normative data to that of chronic decorticate and decerebrate rats. Male rats, 8 intact, 4 2-stage supracollicular decerebrates (hand-held spatula transection) and 3 2-stage neodecorticates (aspiration) were used. Animals were observed in two conditions: spontaneous (no exogenous stimuli) and elicited (food; dirt on fur) grooming. Grooming bouts were timed and coded; half of the observations were videotaped for slow motion sequential analysis. Intact grooming consisted of 21 components, including 5 types of face-washing, differentiated on the basis of the forepaw's trajectory over the face; 13 categories for grooming various body areas with the mouth and/or forepaws; one category for hind leg scratching and 3 for shaking. Results show that both decerebrate (5.59) and decorticate (5.58) rats elicit fewer spontaneous bouts of grooming per a 45 min. interval than do intact animals (15.00). Decerebrate bouts last as long as 20 min. while those of intact rats rarely exceed 5 min., and and decorticates 1 min. Both decorticates and decerebrates display almost all components shown by intact rats; decerebrates show morphological differences in these components as well as components not displayed by the intact. Intact rats are likely to begin a sequence with face grooming, and to then alternate between the face and other body regions. Similarly, decorticate rats tend to begin with face grooming, but are only half as likely to move on to other body regions. Decerebrates, like intact rats, both begin at the face and show the alternating pattern. The basics of normative sequence remain in the decerebrate. These data suggest that neural mechanisms for sequencing grooming exist caudal to the diencephalon. Although decerebrates show postural anomalies and are often incapable of negotiating postural changes while maintaining a stable position, they do initiate postural transitions in grooming. Shorter decorticate bouts have been interpreted (Vanderwolf, Kolb, and Cooley '78) to indicate that the cortex may be important in selecting and initiating postural changes allowing grooming to continue. Since decerebrates attempt to make necessary postural transitions, and assemble grooming sequences like those of the intact, the deficit which decorticates show in combining components to form extended bouts appears not to be mediated by direct effects on the neurological substrates of either postural transition or grooming, but rather by some other deficit. (Supported by NIH AM 21397.)

1589 **EYE POSITIONS IN GOLDFISH SUGGEST CENTRAL MECHANISMS COUNTERACTING VISUALLY INDUCED TONUS ASYMMETRIES.** **Werner Graf* and Dietrich L. Meyer. Dept. of Histology and Neuroanatomy, University of Goettingen, D-3400 Goettingen, West Germany**

Freely swimming and restrained goldfish were exposed to different directions of light in a tube tank.Body and eye positions were determined by single frame videotape analysis.
When the tank is illuminated from the side a freely swimming fish tends to orient its dorsal side towards the light source (Dorsal Light Response,DLR). The amount of tilt depends on where visual and vestibular equilibrium sense balance each other out (v.Holst,Z.vergl.Physiol. 32, 60 - 120, 1950). Bilaterally labyrinthectomized fish tilt their bodies to an angle which corresponds to the angle of maximum light intensity.

A restrained animal turns its eyes towards the light source when a bodily response is prevented. Thus, the ipsilateral eye (w.r.t. direction of light) is deviated down, and the contralateral eye is deviated up.

This behaviour is observed in normal, as well as in bilaterally labyrinthectomized fish. Although lesioned animals display more pronounced eye deviations than normals, ocular displacements in lesioned fish never fully match the angle at which the light is directed towards them.

Ocular deviations observed in these experiments are less than the physiological range of eye movements.

Our data indicate that the DLR - model of v.Holst for bodily reactions cannot be employed for ocular responses. We conclude that mechanisms exist which counteract visually induced central asymmetries of tonus, and thus curb ocular counterrolls under the experimental circumstances described.

1590 STREAKING IN A STATE-PLANE: THE ANALYSIS OF STIMULUS PARAMETERS CONTROLLING THE JAMMING AVOIDANCE RESPONSE IN EIGENMANNIA. Walter Heiligenberg and Joseph Bastian . Scripps Institution of Oceanography,UCSD, La Jolla, Ca.92093 and Dept. of Zoology, University of Oklahoma, Norman, Okl. 73069.

Eigenmannia shifts its electric organ pacemaker frequency away from similar frequencies of other fish. This Jamming Avoidance Response (JAR) is driven by simultaneous modulations of phase and amplitude in electroreceptive afferences from the animal's sinusoidal electric organ discharges (EODs) beating against EODs of another fish. Modulations in phase and amplitude can be represented as graphs in a two-dimensional state-plane, and two classes of electroreceptors, T- and P-units, encode the two coordinates of this plane respectively. In addition to naturally occurring graphs, which characterize the beating of two sinusoidal signals, various computer generated artificial graphs were tested in order to determine the algorithm by which such graphs control the animal's electric organ pacemaker. It is demonstrated that short streaks in the state-plane alone can influence the pacemaker, and that the effect of a whole graph can be represented as the sum of the contributions of incremental streaks, i.e. line segments, which constitute this graph. The effect of a given graph upon the pacemaker can thus be written as its line integral in a vector field which characterizes the state-plane.

1591 NEURAL MODELLING OF PREY-PREDATOR INTERACTIONS IN FROG AND TOAD VISUOMOTOR COORDINATION. Rolando Lara*, Michael A. Arbib and Andrew Cromarty*. Center for Systems Neuroscience, Univ. of Massachusetts, Amherst, MA 01003.

Computer simulation is used to explore parameter-settings which will enable anatomically plausible neural networks to exhibit activity consonant with the behavioral and physiological findings of Ewert and Ingle. We model interaction between pretectum/thalamus and tectum, with the tectum represented as an array of tectal columns whose structure is abstracted from anatomical findings of Székely (Hdbk. Sens. Physiol., VII 3/B: 1-21, 1973). Simulation of a single tectal-column exhibits time-constant and synaptic settings which yield facilitation effects akin to those observed by Ingle (Science, 188: 1033-1035, 1975). These parameters extend to intercolumn connectivity to yield predictions on 'wormness'/velocity tradeoffs in the toad (Ewert, Naturwiss. Rundsch. 25: 1-11, 1972). Extending a model of Didday (Math. Biosci., 30: 169-180, 1976), we model thalamic-tectal interactions in offering an explanation of data of Ingle (Brain Behav. Evol. 1: 500-518, 1968) on choice between fly-like stimuli in frog, and of Ewert and von Wietersheim (J. Comp. Physiol. 92: 149-160, 1974) on thalamic modulation of tectal response to worm and 'antiworm' stimuli. [Research supported in part by NIH grant 1 R01 NS14971-01, Michael A. Arbib, P.I.]

1592 TEMPORAL ORGANIZATION OF SWIMMING ACTIVITY IN SARSIA TUBULOSA M. SARS (HYDROZOA). Janet L. Leonard* (SPON: Philippa Claude). Friday Harbor Laboratories, Friday Harbor, Washington 98250, and University of Wisconsin-Madison, Madison, Wisconsin 53706.

A quantitative ethological study of Sarsia medusae has been undertaken to establish what factors determine the timing of bouts of swimming in this animal. During the daytime undisturbed Sarsia in squaria alternate between periods of swimming by means of a series of bell contractions (swim bouts) and periods of quiet floating (pauses). Although the timing and duration of swim bouts and pauses can be very variable, the individual swimming contractions are initiated by an endogenous pacemaker. The behavior of Sarsia in aquaria was recorded over periods of six hours by a time-lapse videotape recorder. The videotapes were played back at normal speed and data were recorded onto a computer-compatible event recorder.

Three possible types of organization were considered in the analysis: 1) temporal organization, in which events occur with regular periodicity 2) serial organization, in which the duration of an event is a good predictor of the duration of some following event, and 3) no organization, in which both of the first two types are absent. Fourier analysis was used to detect temporal organization. Serial auto- and cross-correlation coefficients out to lags of 23 were calculated and plotted as correlograms to detect serial organization. Three parameters were used in the correlation analysis; swim bout duration, pause duration, and interonset interval (the length of time between starts of swim bouts).

For animals that were swimming less than 25% of the time, there was a remarkable similarity in shape between swim bout and interonset interval autocorrelograms. This means that swim bout duration determined the interonset interval. In more active animals pause durations were more important in determining when swim bouts would start, perhaps because of fatigue. The pauses in active animals may represent a necessary period of recovery before the animal can swim again.

Fourier analysis showed that the bulk of the power spectrum is always concentrated at frequencies lower than .030 cps. Some animals showed a strong rhythm with a frequency of .005-.025 cps. All other animals had their greatest peaks at frequencies very near zero. A given animal usually had a characteristic spectrogram shape for up to three days. This suggests that the way swim bouts and pauses are coupled may vary somewhat from individual to individual.

1593 MULTIMODAL DETECTION OF MOVING OBJECTS BY AN ELECTRIC FISH, STERNOPYGUS. Joanne A. Matsubara. Scripps Institution of Oceanography, UCSD, La Jolla, Calif. 92093.

Extracellular, single unit recordings from the posterior lateral line lobe (pLLL) were undertaken in a weakly electric fish, Sternopygus (Gymnotoidei). Sternopygus, like all other weakly electric fish, can electrolocate, i.e. they can detect objects which differ in impedance from the surrounding water. However, unlike all other wave-species tested, Sternopygus has no jamming avoidance response (JAR), yet can electrolocate even in the presence of electrical jamming signals.

Results indicate some pLLL units are bimodal; they respond to both electrical and mechanical stimulation. This is in accord with previous studies of the pLLL (Enger and Szabo, 1965). Evidence from this study suggests additionally that the behavioral relevance of such bimodal units is to encode movement of nearby objects. These units encode movement of objects by changes in their spike frequency, and such responses persist even after elimination of electrical and visual cues.

It is assumed that all fish receive information about moving objects in the water through the ordinary lateral line system (Dijkgraaf, 1967). In weakly electric fish, the lateral line lobes receive primary afference from both ordinary lateral line receptors (canal organs and free neuromasts) and specialized lateral line receptors (tuberous and ampullary electroreceptors). Hence, weakly electric fish possess two closely-related sensory systems with which they can monitor movement of objects in their environment. Since the presence of any object provides many different sensory cues, it is conceivable that the naturally-behaving animal will differencially rely upon the less ambiguous sensory aspects associated with its environment rather than "jammed" cues. This "selective attention" to mechanoreception may help Sternopygus to follow the motion of objects even in the presence of electrical jamming signals (Matsubara and Heiligenberg, 1978).

1594 PREOPTIC AND VMH LESIONS SEPARATE PROCEPTIVE AND RECEPTIVE COMPONENTS OF FEMALE SEX BEHAVIOR. Dennis A. Merkle* and Owen R. Floody. Bucknell Univ., Lewisburg, PA 17837.

Female sexual motivation can be expressed in distinct proceptive and receptive behaviors which function to initiate heterosexual contact and to facilitate male copulatory attempts, respectively (Beach, Horm. Behav., 7, 105, 1976). For example, ultrasonic vocalizations by estrous female hamsters are attractive to males and are produced most often before and after, but not during, male-female contact. In contrast, female lordosis clearly facilitates successful copulation and normally appears in response to tactile cues provided by a male just during close social contact.

The different roles played by hamster ultrasounds and lordosis in reproduction suggest that these behaviors depend on neural circuits that are at least partially distinct. To test this hypothesis, we studied the effects of preoptic area (POA) and ventromedial hypothalamic (VMH) lesions on female ultrasound production and lordosis. Whereas destruction of either area was expected to affect lordosis (e.g., Nance et al., Brain Res. Bull., 2, 307, 1977), previous studies implicate the POA, but not the VMH, in the control of reproductive vocalizations (Wada et al., Horm. Behav., 9, 141, 1977).

Ultrasound rates of ovariectomized, hormone-primed female hamsters were observed in tests with stimulus males and ultrasounds. The postoperative call rates of females with bilateral electrolytic lesions of the POA or VMH were compared with preop rates for the same females, and with postop rates of females subjected to sham lesions. POA lesions consistently caused decreases in rates of ultrasound production. In contrast, females with VMH or sham lesions showed no consistent postop change in call rate.

Lordosis responses were observed in tests with stud males. Females with VMH lesions showed consistent decrements in lordosis. Females with POA lesions were more similar to sham-operated controls, but tended to show increased lordosis durations in postop tests.

These results show that brain lesions can dissociate the proceptive and receptive behaviors of female hamsters. In particular, VMH lesions affected receptivity (lordosis), but not proceptivity (ultrasound production). POA lesions tended to affect both proceptive and receptive behaviors, but in opposite directions. These results, then, emphasize differences between the brain mechanisms for proceptive and receptive components of female sexual behavior.

1595 COPULATION ELEVATES PLASMA β-ENDORPHIN IN THE MALE HAMSTER. Michael R. Murphy, Donald L. Bowie*, & Candace B. Pert. NIMH, Bethesda, MD 20205.

In men, use of opiate drugs can cause depressed libido, delayed ejaculation and impotence. In opiate addicts, withdrawal can cause increased libido, premature ejaculation and spontaneous erection. We investigated the role of the endogenous opiates in sexual function by using a convenient animal model to (1) assay for changes in plasma β-endorphin during copulation, and (2) analyze the effects of opiate agonists and antagonists on mating behavior.

Male hamsters in one group were decapitated 30 sec. after their 5th ejaculation, during the refractory period. Hamsters in a 2nd group were decapitated 30 sec. after a non-ejaculatory intromission following their 5th ejaculation. Members of a 3rd group were decapitated after removal from their home cage. Blood was collected in EDTA (5ml) and bacitracin (500μg/ml), plasma obtained and β-endorphin was extracted by alumina absorption. Radioimmunoassay of plasma extracts resulted in non-detectable levels of β-endorphin ($<5x10^{-13}$M) in the unmated group. β-endorphin levels were at least 86 times higher ($4.3x10^{-11}$M, $p<.01$) in plasma collected following ejaculation. Levels in plasma collected after a non-ejaculatory intromission were slightly, but significantly, elevated ($1.6x10^{-12}$M, $p<.01$).

In other experiments the mating behavior of male hamsters was tested after injections of saline; 1, 2, 4, 8, or 16mg/kg of methadone; 2, 20, or 200mg/kg of naltrexone; or a combination of both drugs. Sixteen behavior patterns seen during mating were recorded on a computerized event recorder and analyzed with respect to frequency, total duration, latency and average duration. Methadone and naltrexone both caused a dose dependent reduction in libido, with the methadone effect being the most severe. Potency (ability to achieve erection and intromission) was greatly reduced by methadone (2mg/kg and higher) but was significantly increased by naltrexone (20mg/kg). Pretreatment with naltrexone blocked the effects of methadone; posttreatment reversed the effects.

These results show that β-endorphin is elevated following ejaculation, during the post-ejaculatory refractory period, and could be involved in the inhibition of mating during this period. The behavioral results further suggest that endogenous opiates may be involved in the control of sexual potency and libido in the male. Our findings with the hamsters are consistent with recent reports that in rats opiate peptides inhibit the mating of sexually vigorous males (Meyerson & Terenius; Gessa, et al.) and naltrexone induces mating in sexually inactive males (Gessa, et al.).

1596 BEHAVIORAL AND PHYSIOLOGICAL ASPECTS OF SOUND RECEPTION IN THE COCKROACH, GROMPHADORHINA PORTENTOSA. Margaret C. Nelson, Dept. of Neurobiol., Harvard Med. Sch., Boston, MA 02115

The giant Madagascar cockroach produces audible hisses in association with its courtship behavior. Two types of hisses, differing in amplitude modulation and temporal characteristics, occur in conjunction with 2 stereotyped behaviors performed by the male (Nelson, in press, J.C.P.&(1). These observations raise several questions: are these hisses used as communicative signals, affecting the female's behavior? If so, what is the sensory basis of reception of such signals? How closely is reception matched to the acoustical characteristics of the sound?

All hisses produced by this species contain a broad range of frequencies extending into the ultrasonic, but most of the sound energy is concentrated in 2 broad peaks at about 4-8 and 12-16 kHz. To determine the behavioral consequences of courtship hissing, I first silenced males by blocking the specialized spiracles, and then restored the acoustical component of hissing by playing recorded courtship hisses to mute males and females paired with them at the appropriate moments of courtship. The timing and frequency of several courtship displays were compared across 4 groups of animals: normal, sham-operated, mute (silenced, no playback) and playback (silenced, sound playback provided). The playback signal had a frequency cut-off of 16 kHz.

Both muting and playback had significant effects on the outcome of courtship. Silenced males spent significantly more time in the early phases of courtship, and without playback achieved significantly fewer copulations than males in control groups; the receptive behavior of females paired with them was significantly reduced from normal levels. In contrast, when silenced males did receive playback, they achieved near-normal levels of copulation, and females paired with them showed normal levels of receptive behavior. Thus I conclude that acoustic stimulation is a necessary feature of G. portentosa's social behavior.

To investigate the physiological basis of sound communication I recorded from the thoracic connectives of minimally dissected animals while playing both pure-tone and filtered noise stimuli. This revealed up to 4 interneurons which were driven by farfield sound stimulation, with the best frequencies ranging from 4 to 7 kHz. In the natural hiss this is the frequency range that contains the most energy. These preliminary data suggest that some neural elements involved in sound reception are tuned to the high-energy portion of the hiss's sound spectrum, in agreement with the observation that a playback signal lacking the higher-frequency components of the hiss was very effective in eliciting normal courtship behavior from females.

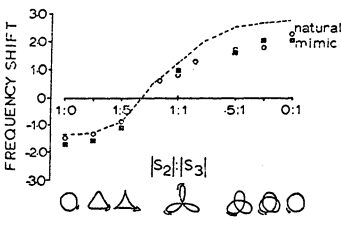
1597 THREE'S A CROWD: THE RESPONSES OF EIGENMANNIA TO MULTIPLE JAMMING ARE PREDICTABLE. Brian Partridge and Walter Heiligenberg Scripps Institution of Oceanography, UCSD, La Jolla, Ca. 92093

Most species of electric fish shift their electric organ pacemaker frequency away from potentially jamming signals, and a number of studies have investigated the behavior and its neuronal basis (e.g. Bullock et al., J.C.P. 77:1-48, 1972). With the exception of a brief mention by Bullock et al., however previous studies have examined the effect of only a single jamming stimulus whereas Eigenmannia normally live in groups and must constantly be subjected to the electric discharges of several neighbors.

We have extended the model proposed by Heiligenberg and Bastian (abstr., this vol.) to predict Eigenmannia's response to multiple jamming stimuli. Close matching between predicted and observed responses provides independent confirmation of the model since it was originally developed to explain results from experiments with only single jamming stimuli. In the model, we represent the fish's EOD and jamming stimuli as vectors in the complex plane and draw resulting graphs of modulation of phase (H) and amplitude (S) of the combined signal in a 2-D state-plane. Shape of the graphs and their direction of rotation provide quantitative predictions for fishes' behavior during multiple jamming. Behavior of Eigenmannia in both intact and curarized conditions is in close agreement with that predicted (see fig. left: dashed line shows predicted values.)



Previous work has shown that Eigenmannia does not require an internal representation of its own EOD to produce correct JARs. Contrary to earlier assumptions, our results demonstrate that fish also do not need to determine the separate DFs of jamming stimuli since attributes of the combined signal provide sufficient information for correct JARs.

1598 DIRECT HEATING OF MOTHER RATS CURTAILS MATERNAL NEST BOUTS. Rodney J. Pelchat, Barbara Woodside*, and Michael Leon*. Dept. Psych., McMaster Univ., Hamilton, Ontario, Canada.

Croskerry, Smith and Leon (Nature, 273: 299, 1978) have suggested that thermal cues limit nest bout duration in rats. We tested this hypothesis by directly heating either the ventrum, core or preoptic area of dams soon after nest bout initiation and measuring the time to nest bout termination. Ventral and core heating significantly reduced nest bout duration. However, termination of the bout was not concurrent with an acute, localized rise in temperature in either area but seemed to require time for temperature elevation in other areas as well. Diathermic heating of the preoptic area terminated bouts very rapidly. Therefore, thermal factors are sufficient to terminate nest bouts. Continuous recording of maternal temperature also suggests that thermal factors play a greater role in nest bout termination late in lactation (Day 10 after parturition) than early in lactation (Day 4). These data support a model that proposes the additivity of acute (eg. litter size and age, dam size, nest insulation, ambient temperature) and chronic (eg. elevated body temperature during lactation) factors in the control of maternal nesting.

1599 INHIBITION OF SHOCK-FACILITATED AGGRESSION IN FEMALE HAMSTERS BY SEPTAL STIMULATION. Michael Potegal, Alan Blau*, Rosemary Sweeney* and Murray Glusman. Dept. Behavioral Physiology, N.Y. State Psychiatric Institute, New York, NY 10032.

In order to evaluate the full potency of septal stimulation to inhibit intraspecific aggression in the hamster (Potegal et al, Soc. Neurosci. 4:364, 1978) we have modified our experimental procedure to maximize the frequency and intensity of aggression. We have found that septal stimulation will inhibit attacks by female Syrian golden hamsters (which are more aggressive than males in this species) even when these attacks are facilitated by foot shock.

Our subjects were retired breeders which were ovariectomized to eliminate the variability in aggressiveness accompanying the estrous cycle. Under our test conditions aggression levels of ovariectomized females are not different from those of intact, non-estrous, animals (cf. Floody and Pfaff, JCPP 91:443, 1977). Subjects were then screened for high aggressiveness and implanted with bipolar septal electrodes. After recovery from implantation they were presented in their home cages with non-aggressive female target hamsters prepared in standard fashion (Potegal et al, Soc. Neurosci. 4:364, 1978). Current values of 100 pps, 0.1 msec stimulation (82-370μA) that were sufficient to prevent the initiation of "spontaneous" (unshocked) aggression also proved sufficient to immediately stop already ongoing "spontaneous" aggression.

In subsequent daily sessions subjects were placed in a small shock chamber with a target animal and given ten 2 mA, 0.5 sec foot shocks at 30 sec intershock intervals (cf. Shipley & Kolb, JCPP 91:1056, 1977). Control sessions, C, (with no septal stimulation) preceded and followed experimental sessions, X, (with continuous septal stimulation at current values sufficient to inhibit "spontaneous" aggression) in the sequence: CCCXXC. To date, subjects have attacked following 50% of C session shocks for a mean of 18.6 sec of attack/session; in X sessions subjects have attacked following only 7.5% of the shocks for a mean of 1 sec of attack/session.

Subsequent flinch-jump tests of foot-shock pain thresholds show that septal stimulation at aggression-inhibiting current levels has had no effect to date on pain thresholds (mean control jump thresholds = 0.91 mA, mean stimulation-accompanied threshold = 0.90 mA). As in our earlier study, septal stimulation did not produce electrographic seizure activity in the septum and did not affect sunflower seed acceptance. It thus appears that septal stimulation is a potent and relatively specific inhibitor of intraspecific aggression in hamsters. (Supported by an H.F. Guggenheim Foundation Grant)

1600 A CRUSTACEAN STATOCYST: STRUCTURAL SIMPLICITY AND POSSIBLE FUNCTION IN BEHAVIOR. R. D. Rose*, R. Tawil* and D. R. Stokes* (SPON: J. W. Manning). Dept. Biol., Emory Univ., Atlanta, GA 30322

Paired statocysts occur in the telson of Cyathura polita (Crustacea, Isopoda, Anthuridae). Each statocyst is a hollow chitinous sphere (~140μm), containing a single concretion. Three pits, arranged to form the corners of a triangle, occur in the ventro-medial floor of the interior cyst wall. A single hair protrudes from each of these pits and penetrates the concretion. Each of the pits on the internal floor of the cyst corresponds with a nodule on the external wall of the cyst. Each nodule contains a central pore from which a process emerges. A branch of nerve 1, a posterior extension of the ventral nerve cord, contacts this nodular region, and presumably carries sensory input from the cyst to higher centers. The small number of elements in each cyst as well as the way in which they are morphologically coupled may be functionally significant. Penetration of the hairs into the solitary concretion insures that contact will be maintained, and the triangular placement of the hairs may, by vector addition of the shearing forces produced on each hair, provide information on both magnitude and direction of the shearing force generated by displacement of the concretion.

Functional static input may be important to the burrowing habit of this benthic animal. Lesion studies involving ablation of one or both cysts as well as several different control lesions have been performed and the effects of these lesions on behavior have been examined. Two separate paradigms have been used: one tested the ability of the animal to maintain an upright posture, the other tested burrowing efficiency. Cyathura is metastable, the center of gravity being above the dorso-ventral midline of the animal. Postural control, therefore, is an active process. Bilaterally lesioned animals show the greatest deficits in both experimental situations, unilateral lesions produce intermediate results, and control lesions produce only slight deficits.

Animals lacking one or both statocysts have difficulty in maintenance of posture, periodically falling to one side or onto their back; a few show no behavioral deficiencies. In some cases all burrowing activity is abolished; in others the animals discontinue burrowing after the head and anterior thoracic segments penetrate the substrate. These results suggest that other sensory structures are also involved in these behaviors. Vision may play a role since some bilaterally lesioned animals cease burrowing once their eyes are beneath the substrate surface.

1601 EVIDENCE FOR FEATURE DETECTION IN CORTICAL AUDITORY NEURONS OF SQUIRREL MONKEY. David Symmes, John D. Newman, and Shozo Kojima.* Lab. Dev. Neurobiol., NICHD, Bethesda, MD 20205.

Previous reports on response characteristics of cortical cells selective for one or a few natural calls in a test series have left at least two explanatory hypotheses untested. One hypothesis ("call detector") suggests that an array of unique acoustical properties activates the cell through temporal facilitation, giving rise to a response only after all elements have been added sequentially. A second and less pontifical idea is that cortical cells respond to unique, short-lasting acoustic fragments wherever and whenever such fragments occur in natural vocalizations ("feature detector"). We have tested these hypotheses by examining the role of temporal facilitation in well-timed, stable responses to vocalizations presented under optimal conditions. Active short fragments (usually less than 100 msec.) were identified within intact vocalizations and presented in an isolated manner by deletion of remaining parts. No evidence of temporal facilitation was found, and in fact many cells exhibited stronger responses to isolated fragments. This finding suggests that temporal inhibition may be common and serve to sharpen feature boundaries. Our results do not favor the view that individual "grandperson" cells encode the meaning of species-specific vocalizations, at least in primary auditory cortex.

1602 NEUROETHOLOGICAL STUDIES OF SWIMMING IN APLYSIA BRASILIANA.
K. von der Porten and H. Pinsker. Marine Biomedical Institute, and Dept. Physiol. & Biophys. and Psychiat. & Behav. Sci., UTMB, Galveston, TX 77550.

Aplysia brasiliana swim by bilateral parapodial flapping with a rostro-caudal metachronal wave. Video tape records of freely swimming animals provide a noninvasive monitor of two components of this behavior, the period and metachronal offset. Changes in temperature affect the period (1.7 sec at 21°C to 3.1 sec at 12°C) but not the metachronal offset (0.5 sec at both temperatures). This results in a change in phase relationships between anterior and posterior oscillations at different temperatures and suggests that the period and metachronal wave have different underlying mechanisms.

Peripheral nerve lesions established that the anterior, middle and posterior parapodial nerves are necessary and sufficient for normal flapping with the anterior nerve playing the major role. Synchrony of flapping in the two parapodia is abolished by lesions of the pedal commissure, but bilateral removal of the pleural ganglia has no effect. Bilateral lesions of the cerebro-pedal connectives totally abolish swimming, but tonic stimulation of this pathway via a cuff electrode produces normal parapodial flapping for as long as the stimulus is maintained. Thus the command to swim originates in the cerebral ganglia but a neuronal oscillator for parapodial flapping is located within each pedal hemiganglion.

Phasic bursts of efferent activity in large units are recorded by implanted cuff electrodes during swimming in unrestrained animals. These bursts are synchronous in the anterior, middle and posterior nerves, despite the metachronal offset in the parapodial oscillations. Reducing the temperature produces a significant decrease in conduction velocity of large efferent units which will increase the offset in time of arrival of the efferent volley at the anterior and posterior parapodia. Therefore the lack of any effect of cooling on the metachronal offset suggests that neuronal conduction time distal to the cuff does not contribute substantially to this component. Phasic bursts of descending activity in large units are also recorded from the cerebro-pedal connectives during swimming.

Isolated brain studies support the hypothesis of a central pattern generator. Although difficult to trigger, phasic bursts of large efferent spikes alternating with bursts of smaller efferent spikes can be seen in some preparations, due to an overall reduction in number of contributing units. The increase in signal-to-noise ratio in isolated brains should make it possible to analyze single unit activity with existing spike separation techniques (Camp and Pinsker, 1979). (This research was supported by NSF grants BNS 76-17480 and 77-25584 to H.P.).

NEUROMUSCULAR JUNCTION

1603 REVERSIBLE ACCUMULATION OF ACETYLCHOLINE RECEPTORS DURING THE DEVELOPMENT OF AN AMPHIBIAN NEUROMUSCULAR JUNCTION IN CELL CULTURE. M. J. Anderson* and F. G. Klier* (SPON. A. Selverston) Salk Institute, San Diego, CA. 92112

Cells from the myotomal muscle and neural tube of the embryos of Xenopus laevis were grown together in culture. Over a period of 1-2 days after adding the nerve cells to established muscle cultures, discrete acetylcholine receptor accumulations could be detected along the path of nerve-muscle contact after staining with tetramethylrhodamine-labelled α-bungarotoxin. Sequential observations on individual muscle cells over a period of 16-20 hours revealed a progressive formation and growth of discrete acetylcholine receptor aggregates at sites of nerve-muscle contact. Examination of identified nerve-contacted cells in the electron microscope further revealed that the larger regions of receptor accumulation corresponded to sites of extensive synaptic differentiation. These regions of cell-contact contained clusters of synaptic vessicles, post-synaptic membrane thickening and an intercellular specialization of the basal lamina. When such cells became denervated, either spontaneously or as a result of severing the developing neurite, the dense receptor accumulations along the nerve decreased in area or disappeared entirely within 16-20 hours. On the basis of these observations it is concluded that aggregates of junctional acetylcholine receptors remain dependant upon some continuing action of the nerve at these early stages of synaptogenesis.

1604 CALCIUM DEPENDENCE OF EVOKED TRANSMITTER RELEASE AT VERY LOW QUANTAL CONTENTS AT THE FROG NEUROMUSCULAR JUNCTION. Roberto Andreu* and Ellen F. Barrett. Dept. Physiol. & Biophys., Sch. Med., Univ. of Miami, Miami, FLA 33101.

At the frog neuromuscular junction a double logarithmic plot of evoked transmitter release vs. extracellular $[Ca^{2+}]$ has an average slope of nearly 4 at low release rates, suggesting that 4 Ca^{2+} might be necessary to activate a release site (Dodge & Rahamimoff, 1967). However, Crawford (1974) reported that when evoked release rates are lowered still further, the relationship between release and extracellular $[Ca^{2+}]$ changes rather suddenly from fourth power to linear. We reexamined the Ca dependence of evoked transmitter release at very low release rates using surface neuromuscular junctions of the frog cutaneous pectoris muscle. The average quantal content (m) of the end-plate potential was reduced to very low levels (between 0.002 and 1) by reducing bath $[Ca^{2+}]$ and adding 2 mM Mn^{2+}, 4 mM Co^{2+} or 10 mM Mg^{2+}. We found that when the motor nerve was stimulated at low frequencies (0.5 - 2 Hz) in Mn^{2+} or Co^{2+} m was proportional to the fourth power of extracellular $[Ca^{2+}]$ down to the lowest m values we could measure, 0.002 to 0.003. Together with Dodge and Rahamimoff's earlier results, this result suggests that some step in the transmitter release pathway has a steep, nonlinear dependence on bath $[Ca^{2+}]$ over more than 3 orders of magnitude of evoked release rate. When 10 mM Mg^{2+} was added to the bath, the lowest m values were markedly higher than the fourth power prediction. Increasing the stimulus frequency to 5 - 20 Hz progressively increased both m and the rate of 'background' release during the interstimulus interval. In the range of low quantal contents studied here, frequency enhancement of both evoked and background release was more pronounced in 10 mM Mg^{2+} or 4 mM Co^{2+} than in 2 mM Mn^{2+}. These results suggest that Mg^{2+} and possibly Co^{2+} are weak activators of transmitter release, so weak that their activating abilities are evident only when normal Ca^{2+}-activated release is greatly reduced. This frequency-dependent enhancement of low release rates in Mg and Co probably accounts for the difference between our and Crawford's results. Supported by NIH grant NS 12404.

1605 THE PARTIAL PURIFICATION OF A NEURONAL FACTOR WHICH AGGREGATES MUSCLE ACETYLCHOLINE RECEPTORS. Hans-Christian Bauer*, Mathew P. Daniels, Sandra Fitzgerald*, Paul Pudimat*, Joav Prives* and Clifford N. Christian*. (SPON: John D. Newman). NIH, Bethesda, MD 20205.

Medium conditioned by contact with NG108-15 clonal neuroblastoma x glioma hybrid cells contains a factor which increases the number of acetylcholine receptor (AChR) aggregates on cultured myotubes (Christian et al. 1978, PNAS 75: 4011-4015). A factor with this activity is also found in the cytoplasmic fraction of the hybrid cells and in the cytoplasmic fraction of embryonic rat brain. AChR aggregation activity was not found in the cytoplasmic fraction of adult rat brain. The AChR aggregation activity of hybrid cell conditioned medium or the cytoplasmic fraction of hybrid cells was concentrated by ultrafiltration, loaded on a Sephacryl S-300 column and eluted in 50mM Tris HCl buffer as a fraction with a molecular weight of from 150,000 to 200,000 daltons. At neutral pH, 80% of the protein in this active fraction bound to a DEAE cellulose column, and AChR aggregation activity was eluted in a linear NaCl gradient at an approximate salt concentration of 300 mM. Further separation on a Sephacryl S-200 column resulted in detectable aggregation activity at 4 μg of protein per ml, indicating purification of the starting material of over 10 fold. In addition, a factor which depressed the number of AChR aggregates on cultured myotubes was separated from the aggregation activity. Part of the receptor aggregation activity in conditioned medium bound to concanavalin-A sepharose and was eluted by α-methylmannoside. Hence a neuronal factor which aggregates myotube AChR appears to be a large, negatively charged glycoprotein.

1606 THE EFFECTS OF PARTIAL DENERVATION AT BIRTH ON THE DEVELOPMENT OF MOTOR UNITS AND MUSCLE FIBERS IN RAT LUMBRICAL MUSCLE. W.J. Betz, J.H. Caldwell*, and R.R. Ribchester*. Dept. Physiol., Univ. Colo. Med. Sch., Denver, CO 80262.

At birth, rat lumbrical muscle fibers are polyneuronally innervated, but by three weeks of age the adult pattern is reached, in which each muscle fiber is innervated by a single motor axon. The loss of polyneuronal innervation through elimination of some synapses results in a reduction in the size of individual motor units innervating the muscle (from about 120 at birth to about 85 in mature muscles). We were interested in knowing to what extent this normal reduction in motor unit size depends upon competition between motor neurons. The lumbrical muscle can be partially denervated at birth in such a way that (in about 1/4 of the muscles) a single motor axon is left innervating the muscle. Partial denervation was accomplished by cutting the lateral plantar nerve; the remaining motor axons to the muscle traveled in the sural nerve. After the animals matured, the number of remaining motor units was determined by in vitro twitch tension recordings. The muscles were then frozen, sectioned, stained, and muscle fiber diameters were measured with a camera lucida attachment. In single motor unit muscles, the number of large diameter muscle fibers provided an estimate of motor unit size. In such cases, the remaining motor unit matured in the absence of competing influences from other motor axons. We measured the size of the single remaining motor unit in 23 such muscles. The mean size (117) was nearly the same as in newborn muscles, which suggests that the normal reduction in motor unit size is the result of competitive interactions between motor axons.

Since the lumbrical muscle at birth contains only 50-60% of the adult number of muscle fibers, we were also interested in the extent to which postnatal production of muscle fibers depends upon the presence of motor axons. To measure this, we counted the total number of muscle fibers in muscles with different numbers of remaining motor units. The results showed the following: 1) In muscles totally denervated at birth, few or no additional muscle fibers were produced. 2) In muscles with only 8 remaining motor units (normal is about 12) mature muscles contained the normal adult number of muscle fibers. 3) The overall relationship between the number of muscle fibers and the number of remaining motor units could be described with reasonable quantitative accuracy by a simple model.

1607 TESTOSTERONE EFFECTS ON CHOLINE ACETYLASE AND ACETYLCHOLINESTERASE IN THE XIIth CRANIAL NERVE AND SYRINGEAL MUSCLES OF THE ZEBRA FINCH. W. Bleisch, V. Luine, F. Nottebohm and B. McEwen. Rockefeller University, New York NY 10021.

The syrinx is the organ of song production in passerine birds and is innervated by the tracheosyringealis branch of the XIIth cranial nerve. In many passerines, song is an important component of male sexual behavior, and it disappears following castration. Recent work shows that the syringeal muscles and the motor neurons which innervate them contain protein receptors for testosterone (T) which are specific and show high affinity (Arnold et al., J. Comp. Neurology 165:487, 1976; Lieberburg & Nottebohm, J. Gen. & Comp. Endo., in press). That these receptors may regulate function in the male Zebra Finch (ZF) is suggested by changes in syringeal weight and acetylcholinesterase (AChE) activity which occur when circulating levels of T are changed (Luine et al., Soc. Neuro. Sci. Abstracts 4:371, 1978).

In this study, we have examined the effects of altered circulating T levels on the tracheosyringealis nerve by measuring nerve choline acetylase (ChAc) and AChE. We have further explored the effects of T on syringeal muscle AChE using sucrose density gradient analysis. Adult male ZFs were castrated and implanted one week later with Silastic capsules containing cholesterol (C) or T. Four to 5 weeks after castration, nerve ChAc levels declined by 34% (from 3678 ± 229 μmoles/gm protein/hr. in intacts to 2444 ± 434 in C treated castrates). AChE levels decreased by 60% (1817 ± 207 μmoles/gm protein/hr. to 734 ± 93). T replacement for 3 to 4 weeks restored AChE activity (1741 ± 323) and partially restored ChAc (3299 ± 176). A similar pattern was observed for AChE and ChAc activities in syringeal muscle.

As in other vertebrates, sucrose density gradient centrifugation of ZF muscle homogenates revealed three peaks of AChE activity. In ZF, these occur at approximately 16 S (the H form) 10 S (M) and 4.5 S (L). Syrinx, larynx and hyoid muscles were homogenized in 1 M NaCl, .5% Triton X-100, .2mM EDTA, 50 mM sodium phosphate, pH 7.2, and applied to a 5 ml. 5-20% sucrose density gradient and centrifuged at 45,000 rpm (189000 x g) for 9 hours. In the syrinx, the L peak predominated strikingly, whereas the activities in the H and L peaks were more similar in the larynx and hyoids. Syringeal AChE was analyzed in intact birds and in castrates treated with T or C in Silastic capsules, as above. In contrast to the marked effects of T depletion on both total and specific AChE, no gross changes in the distribution of AChE activity between the three peaks was observed after castration. (Supported by PHS Grants HD12011 and MH18343, and by RF70095 from the Rockefeller Foundation.)

1608 The Effects of Ca^{++}-Deprivation on Accumulations of Acetylcholine Receptor at the Developing Neuromusclar Junction. Robert J. Bloch* and Joe Henry Steinbach. Neurobiology Laboratory, The Salk Institute, San Diego, Ca. 92112.

One of the earliest events in the formation of the neuromuscular junction is the accumulation of a high density of acetylcholine receptor (AChR) in the postsynaptic membrane. In order to determine what forces are involved in maintaining and maturing these primitive synaptic structures, we have subjected intact muscles excised from rats at different stages of development to disruptive treatments, and, in particular, to removal of Ca^{++}. Sternomastoid muscles were excised and pinned out on plastic dishes. AChR was visualized using a tetramethyl-rhodamine derivative of α-bungarotoxin (R-αBt). Removal of Ca^{++} was accomplished either by culturing in Dulbecco-Vogt modified Eagle's medium prepared free of Ca^{++}, or by using medium buffered with the Ca^{++} chelator, EGTA. When muscles from 16 day embryonic rats were treated for 6 hours at 37° in medium containing decreased concentrations of free Ca^{++} (<200 μM), extensive loss of AChR accumulations was observed. This loss was independent of whether staining with R-αBt was performed before or after incubation in Ca^{++} depleted medium. Muscles deprived of Ca^{++} carried on control levels of protein synthesis. Physically damaging muscles did not cause loss of AChR accumulations. Thus, Ca^{++} deprivation, while it disperses AChR accumulations at the newly formed neuromuscular junction, does not appear to do so by damaging muscle. As a function of developmental time, junctional AChR accumulations become increasingly resistant to the effects of Ca^{++} deprivation. This was already observable with neonatal sternomastoid muscle and was complete by 3 weeks after birth. Our results suggest that newly formed AChR accumulations at the developing neuromuscular junction are less stable than accumulations at mature junctions, and that stabilization occurs relatively rapidly after formation of the junction.

1609 PERTURBATION OF CONFORMATIONAL EQUILIBRIA OF THE MEMBRANE-BOUND CHOLINERGIC RECEPTOR OF TORPEDO INDUCED BY NONCOMPETITIVE ANTAGONISTS. Norman D. Boyd* and Jonathan B. Cohen. Dept. of Pharmacol., Harvard Med. Sch., Boston, MA 02115

The nicotinic cholinergic receptor in postsynaptic membranes isolated from Torpedo electric tissue has been shown to exist in two interconvertible conformations, one binding acetylcholine (AcCh) with low affinity and associated with channel activation (R_{Lo}) and a second binding AcCh with high affinity (R_{Hi}, desensitized conformation). In order to determine the mechanism by which noncompetitive antagonists cause receptor desensitization, we have measured their effects on receptor conformational equilibria in the absence and presence of [^{3}H]-AcCh. In the absence of ligands the fraction (F) of AcCh binding sites existing in the high affinity conformation was equal to 0.17 ± .02, while noncompetitive antagonists caused a concentration dependent stabilization of R_{Hi}. The maximal perturbation (F_{max}) and the ligand concentration (C_{50}) producing a half-maximal perturbation was dependent on the ligand employed. For proadifen C_{50} = 10 μM, F_{max} = 0.78; for histrionicotoxin (HTX), C_{50} = 15 μM, F_{max} = 0.31; and for 2-propanol, C_{50} = 0.8 M, F_{max} = 0.91. Since HTX produced only a small conformational perturbation, its effects on the actions of proadifen and 2-propanol were examined. HTX antagonized the conformational perturbation caused by proadifen alone, while the effects of HTX and 2-propanol were additive. The apparent competition between proadifen and HTX indicate that the receptor perturbation induced by the aromatic amine in the absence of cholinergic ligands results from ligand binding to a specific site, presumably the site identified by equilibrium binding of [^{14}C]-meproadifen (E. Krodel et al., Mol. Pharmacol. 15: 294, 1979). The additivity observed with HTX and 2-propanol indicate a different mode of action for 2-propanol.

The high affinity receptor conformations stabilized by the different noncompetitive antagonists and by AcCh were characterized by: the rate constant for receptor reisomerization upon removal of the stabilizing ligand (k_{rec} = 2.7 x 10^{-3} sec^{-1}); the dissociation constant for [^{3}H]-AcCh (K_{Hi} = 1 nM); the rate constant for the dissociation of [^{3}H]-AcCh-receptor complexes (k_{dis} = 4.3 x 10^{-2} sec^{-1}). On the basis of these criteria a unique high affinity receptor conformation is defined for all stabilizing ligands that is independent of the mechanism of stabilization. 1610 A CORRELATION BETWEEN THE APPEARANCE OF 11 - 19 NM INTERMEMBRANE PARTICLES AND ACETYLCHOLINE SENSITIVITY IN XENOPUS EMBRYONIC MUSCLE. Paul C. Bridgman* and Allan S. Greenberg* (SPON: Y. Nakajima). Dept. Biol. Sci., Purdue Univ., W. Lafayette, IN 47907

The onset of acetylcholine (ACh) sensitivity can occur with surprising speed in Xenopus embryonic muscle (Blackshaw and Warner, Nature 262: 217, 1976). To establish whether ACh receptors (AChRs) in Xenopus are incorporated into the sarcolemma in a physiologically active state or "activated" after incorporation, we correlated ACh sensitivity with the initial appearance of putative AChR (11 - 19 nm) intermembrane particles (IMPs). These studies were conducted both in vivo and in vitro.

In vivo electrophysiological studies confirm previous work (Blackshaw and Warner, 1976; Kullberg, et al, Dev. Biol. 60; 101, 1977) which indicates that the onset of ACh sensitivity in Xenopus embryos occurs between Nieuwkoop and Faber stages 19 and 24. Embryos from which intracellular recordings had been taken were freeze-fractured. We have been able to observe a direct temporal correlation between the appearance of 11 - 19 nm IMPs and ACh sensitivity. Embryos (st. 19 - 24) which did not exhibit ACh sensitivity had particle sizes distributed normally, around a mean value of 8.2 ± 0.3 nm (n = 7). Embryos with sensitivity (st. 20 - 27) had particle size distributions that were skewed to the right because of the increase in number of 11 - 19 nm IMPs. This had the effect of shifting the mean IMP size towards a larger average value (9.7 ± 0.2 nm; n = 13).

We have performed similar experiments on cultured myotome cells, dissociated from state 13 - 17 embryos. Cells were impaled with microelectrodes and tested iontophoretically for ACh sensitivity. Cells gained sensitivity between the corresponding stages 20 - 24 similar to that observed in vivo. Cells tested were photographed for later identification and then processed for freeze-fracturing. Preliminary results from these identified cells indicate that only cells with ACh sensitivity contain large numbers of 11 - 19 nm IMPs. We tentatively conclude that the appearance of 11 - 19 nm IMPs may occur almost simultaneously with the appearance of ACh sensitivity. This lends further support to the present notion that 11 - 19 nm IMPs represent AChRs. In addition, these results suggest that AChRs are physiologically active soon after, if not immediately following, incorporation into the sarcolemma.

1611 MORPHOLOGY AND ELECTROPHYSIOLOGY OF DYSTROPHIC CHICKEN MUSCLE. Joan S. Bryan* and Michael S. Letinsky. Dept. Physiol., Sch. Med. UCLA, Los Angeles, CA 90024.

Alterations in the morphological and electrophysiological properties of a small wing muscle, the extensor digitorum II, (EDII), have been examined in chickens with inherited muscular dystrophy ranging in age from 5 to 48 wks ex ovo (dystrophic line 455 and control line 454 obtained from Dept. of Avian Sciences, U. of Cal., Davis). These are new dystrophic and control lines with high hatchability and early onset of dystrophy.

We have shown that the EDII is a homogeneously fast twitch muscle having extensive pathological changes at the earliest age examined histologically (7 wks) including: extensive variation in muscle fiber diameter, muscle fiber hypertrophy, increased numbers of muscle fiber nuclei, many of which are centrally located, muscle fiber splitting and increased muscle connective tissue.

For electrophysiology the EDII was removed and continuously perfused with oxygenated chicken ringer,Hepes buffered to pH 7.2 at 21±1 deg.C. Muscle fiber resting potentials from control birds aged 6 to 34 wks were normally distributed with a mean of -77mV and did not change with age. Resting potentials from dystrophic muscle fibers (5 to 48 wks) were bimodally distributed with one mode at -78 mV and another mode at -58 mV. In dystrophic muscle resting potentials began diverging markedly from normal levels at 9 to 11 wks of age. In control chickens from 6 to 13 wks there was a decrease of about 30% in mean input resistance (from 1.3 to 0.8 Mohm) which correlated with about a 40% increase in mean muscle fiber diameter (from about 26 to 35 microns). Fiber diameter increased more rapidly in dystrophic muscles during this period; but in spite of this relative hypertrophy, dystrophic muscle fiber input resistance increased to 225% to 280% of control. A large jump in input resistance occurred in dystrophic muscle at about 7 to 9 wks (from .85 to 2.5 Mohm). Muscle fiber membrane time constants in normal chickens aged 6 to 14 wks averaged about 8 ms and were shorter than time constants in dystrophic fibers of this age range which increased from 18 to 28 ms. Miniature endplate potentials (Mepps) were recorded using intracellular electrodes placed close to endplates located using Hoffman modulation contrast optics. At all ages examined Mepp frequency was lower at dystrophic than at normal endplates. At 5 wks ex ovo Mepp frequency at dystrophic endplates (2.4 per min) was only 45% of the control frequency (5.4 per min); and although Mepp frequency increased with age in dystrophic muscles, it was still only 72% of control by 13 wks (11 per min in dystrophics vs 15 per min in normals). It is significant that this neuronal difference existed prior to functional muscle pathology observed here. Supported by grants from PHS (NS 14417) and from the Muscular Dystrophy Association of America.

1612 SURFACE SPECIALIZATIONS ASSOCIATED WITH HIGH DENSITY ACCUMULATIONS OF ACETYLCHOLINE RECEPTORS IN EMBRYONIC CHICK MUSCLE. Thomas G. Burrage* and Thomas L. Lentz. Section of Cell Biology, Yale Univ. School of Medicine, New Haven, CT 06510.

Staining with horseradish peroxidase-labeled α-bungarotoxin (HRP-α-Btx) reveals small patches of high density accumulations of acetylcholine receptors (AChR) on uninnervated surfaces and at sites of early nerve contact in myogenic cells of embryonic chick latissimus dorsi muscle in vivo (Jacob and Lentz, J. Cell Biol., in press). This study was undertaken to characterize the morphological specializations of these regions of high receptor density using different heavy metal stains. Latissimus dorsi muscles from 10 to 19 day old chick embryos were viewed by electron microscopy after glutaraldehyde and/or osmium fixation and combinations of heavy metal stains. The surface morphology of myogenic cells is demonstrated by osmium tetroxide fixation, uranyl acetate (UA) staining en bloc, and UA and lead citrate poststaining. A sparse, discontinuous external coating representing the precursor of the basement membrane is present on some of the myoblasts and early myotubes. Also, discrete, local specializations similar in location and extent to the HRP-α-Btx stained patches are present on the surfaces of the myogenic cells. These regions usually appear as small elevated ridges 0.1 to 0.5μm in width. The external surface of the patches is coated with a layer of amorphous to very fine textured material sometimes separated from the plasmalemma by a thin clear space. On the internal surface and coextensive with the external layer, dense material is applied immediately adjacent to the plasmalemma. A network of 60A filaments is contiguous with the dense material. The extraneous coating of these patches as well as the submembranous density is stained with ethanolic phosphotungstic acid (E-PTA) and bismuth iodide. E-PTA also stains a prominent band beneath the submembranous density and separated from it by a space. The specialized regions are usually widely separated on uninnervated surfaces of myogenic cells. At sites of early nerve-muscle contact, patches are more numerous and larger. Often the external coating extends a greater distance into the extracellular space forming bridges with a sparse coating on the surface of growing nerve fibers. In more highly developed junctions, the external layer and submembranous density occupy the entire postsynaptic region. This study reveals the presence of external and internal specializations at regions of high AChR density and at sites of initial nerve-muscle contact. These specializations may be involved in the localization or positioning of AChR in the membrane or contain components which establish these areas as preferential sites of nerve contact. (Supported by the Osserman Fellowship of the Myasthenia Gravis Foundation and NSF Grant BNS 78-13729).

1613 COATED VESICLES IN CULTURED MYOTUBES CONTAIN ACETYLCHOLINE RECEPTORS. S. Bursztajn and G.D. Fischbach. Dept. of Pharmacology, Harvard Medical School, Boston, Mass. 02115.

Chick myotubes and spinal cord explants were cocultured on glass coverslips. After myoblasts had fused to form myotubes, spinal cord slices cut from 12 day embryonic cords or isolated neurons dissociated from 8 day ciliary ganglia were added to the muscle cultures. Two to four days later, nerve-muscle synapses were located (within 3 to 5μm) by focal extracellular recording. Electrophysiologically identified sites of transmitter release were photographed at high magnification (X900) and the surrounding area was photographed at low power (X150). Synapses were relocated after the cells were fixed and embedded in Epon 812. They were circled with a diamond object marker (50μm in diameter) and this region was cut out and remounted. A striking feature of the identified synapses was the accumulation of coated vesicles in the muscle cytoplasm near the postsynaptic membrane. In several instances coated vesicles opened on the cell surface and appeared to contribute to the postsynaptic density. In some sections coated vesicles appeared to fuse with or bud off from dilated ampula of the "T" system. Serial sections showed that the postsynaptic membrane was dense and that small clear synaptic vesicles were clustered in the opposed nerve process. Morphometric analysis revealed that there was a 5.5 fold increase in the number of coated vesicles at functional synapses, compared to nonsynaptic nerve-muscle contacts. Coated vesicles did not appear to fill with HRP and ferritin even if these extracellular tracers were present for 3 hrs prior to fixation. This suggests that at least some coated vesicles in myotubes are involved in exocytosis.

The possibility that coated vesicles contain acetylcholine (ACh) receptors was investigated with HRP-αBTX conjugates, after the cell membranes were "permeabilized" with saponin according to the procedures described by Ohtsuki et al. (Biol. Cellul., 31:119-126, 1978) and Fambrough and Devreotes (J. Cell Biol. 237-244, 1978). The histochemical HRP reaction yields a fine precipitate that can be localized with a high degree of resolution. Treated cells were not stained with uranyl acetate. Reaction product was seen over some but not all of the coated vesicles. Reaction product was also found in segments of Golgi cisternae. No staining was evident in control cultures preincubated in unconjugated αBTX or curare. These results suggest that ACh receptors are inserted into the plasma membrane via coated vesicles.

1614 THE SIZE OF MOTOR UNITS DURING POSTNATAL DEVELOPMENT OF LUMBRICAL MUSCLE. J.H. Caldwell*, W.J. Betz, and R.R. Ribchester* (SPON: A.R. Martin). Dept. Physiol., Univ. Colo. Med. Sch., Denver, CO 80262.

The number of muscle fibers innervated by individual motor neurons (motor unit size) was measured in lumbrical muscles of rats aged 0-28 days, during the period of elimination of polyneuronal innervation. Motor unit sizes were determined from twitch tension measurements combined with muscle fiber counts made from histological sections of the muscles. The relative tensions contributed by individual motor units declined from about 25% of the total tension at birth, to about 9% at 28 days of age. Intracellular recordings showed that part of this decrease reflected the elimination of synapses from polyneuronally innervated muscle fibers.

During the same period, however, new muscle fibers were produced. The total number of muscle fibers present increased from about 550 fibers at birth to about 950 fibers in mature muscles. These two processes were offsetting: some synapses were eliminated (from polyneuronally innervated fibers) while simultaneously others were formed de novo (on newly produced muscle fibers). Quantitative measurements showed that for the first ten days after birth, there was little change in motor unit size. Thereafter production of new muscle fibers ceased, and with the final elimination of synapses from polyneuronally-innervated muscle fibers, motor unit size decreased to the adult level. It is concluded that during early postnatal development, a lumbrical motor neuron maintains a nearly constant number of synapses, but extensively reorganizes its synaptic field, retracting synapses from some muscle fibers, while forming new synapses with other fibers.

1615 THE EFFECT OF TEMPERATURE ON MEPP AMPLITUDE DISTRIBUTIONS AT THE MOUSE DIAPHRAGM. C.G. Carlson*, C.G. Muniak*, and F. Llados* (SPON: C. Edwards). Dept. of Physiology, Upstate Medical Center, Syracuse, NY 13210

Kriebel, Llados, and Matteson (J. Physiol. 262, 1976) observed a class of small spontaneous potentials (subminiature endplate potentials, s-MEPPs) in muscle fibers of the mouse diaphragm. These s-MEPPs are generally 1/10 to 1/15 the amplitude of normal amplitude MEPPs (major mode MEPPs, m-mode), and are relatively resistant to the depressive effects of Botulinum toxin on spontaneous frequency. In these experiments we determined the effect of low temperature on the relative frequencies of s-MEPPs and m-mode MEPPs.

Between 11 and 30°C, the overall MEPP frequency (s-MEPPs and m-mode MEPPs combined) showed a positive temperature dependence (c.f., Liley, J. Physiol. 132, 1956). The MEPP frequency increased from about 0.5 sec^{-1} at 15°C to 1.4 sec^{-1} at 25°C. At temperatures above 20°C, the MEPP distributions were similar to those observed at higher temperatures (32-40°C). MEPP amplitudes 1 to 4 times the s-MEPP showed distributions that skewed towards the smaller MEPP amplitudes (the "skew class"). MEPP amplitudes 5 to 20 times the s-MEPP showed distributions that were bell-shaped (the "bell-shaped" or m-mode class). Below 16 to 17°C, the s-MEPPs and corresponding "skew class" of MEPPs virtually disappeared in relation to the number of MEPPs in the bell-shaped part of the distribution. This indicates that in the range of temperatures from 11-25°C, the frequencies of s-MEPPs and "skew class" MEPPs are more sensitive to a reduction in temperature than the frequency of the larger MEPPs in the "bell-shaped" class. Although the MEPPs at lower temperatures (11-18°C) were slower in time course than MEPPs at higher temperatures (23-27°C), there was no obvious effect of temperature on either the s-MEPP or m-mode MEPP amplitude.

In some cells an optimal temperature for the release of s-MEPPs was seen between 25 and 30°C. This is consistent with the observation that the percentage of s-MEPPs at 32-34° was greater than at 38°C. These results provide further evidence that s-MEPPs and m-mode MEPPs are released by relatively independent mechanisms. (Supported by NIH Grant #11-1524D)

1616 THE EFFECT OF A SODIUM IONOPHORE, MONENSIN, ON NEURO-MUSCULAR TRANSMISSION. Milton P. Charlton, Brian J. Farnell* and Harold L. Atwood. Zoology Dept., University of Toronto, Toronto, Canada, M5S 1A1.

Mounting evidence indicates that intracellular Na^+ may play a role in modulating the secretion of transmitters at synapses. Increases in intracellular Na^+ caused by Na^+ pump inhibitors (Proc.Roy.Soc.B, 170,381-399), prolonged stimulation (Br.Res., 100, 198-204), direct injection (Br. Res., 134, 367-371) or loading by liposomes (P.N.A.S.USA, 75, 5214-5216) can result in increases in both spontaneous and evoked release. In this study Na^+ loading was attempted by the use of a carboxylic Na^+ ionophore, Monensin (Mon), which shows moderate selectivity against K^+ and very little complexation with Ca^{++} (Ann.Rev. Biochem., 45, 501-530). Mon (3-7uM) caused an increase in excitatory post synaptic potentials (EPSP) of up to 250% within 15 min of application to crayfish opener, stretcher and abdominal extensor muscles (12-15°C). EPSP's were not increased by Mon in saline containing only 1/3 [Na^+]. It is therefore likely that Mon is effective by increasing intracellular [Na^+]. The effect of the ionophore was reversible following washout but return to normal transmission took longer than the initial facilitation.

The effect of Mon on spontaneous release of transmitter was tested in the frog cutaneous pectoralis muscle by recording miniature endplate potentials (mepps). The frequency of mepps was increased by over 2000% during an 8 min application of Mon (6 uM, 21°C). Mepp frequency was still increased 1000% 13 min after washout of Mon. The membrane potential of muscle cells in either animal was not affected by Mon.

Compared to other techniques for Na^+ loading, the application of Mon is simple, rapid, reversible, does not involve poisons, does not require stimulation and can be used on cells of all sizes. The results confirm the observation that intracellular Na^+ can modulate transmitter release and indicate that Mon may be a valuable tool in the study of the mechanism of this phenomenon.

1617 SHIFTS IN THE MULTIPLE FORMS OF ACETYLCHOLINESTERASE IN CHICK EMBRYONIC SKELETAL MUSCLE IN VIVO AND IN VITRO. C. Michael Cisson, Carole H. McQuarrie*, Mark G. McNamee, and Barry W. Wilson. University of California, Davis, CA 95616

Experiments continue in our laboratory to understand the progression of development of multiple forms of acetylcholinesterase (AChE). The multiple forms in 11- and 18-day-old chick embryonic pectoral muscle and cultured muscle grown aneurally for 10 days were determined by centrifugation on a linear 5-20% sucrose gradient. Three forms were found in embryonic muscle in vivo: 7S (6.8±0.3), 11S (11.2±0.8), and 20S (20.4±0.6). The specific activity of AChE did not differ between 11- and 18-day-old muscle, but there was a shift in distribution of AChE activity among the three forms:

Embryo Age	% Total Activity 7S	11S	20S	N
11D	60.4±3.1	31.6±4.5	8.0±4.2	4
18D	46.9±4.4	19.7±2.7	33.5±3.9	4

Only the 7S and 11S forms were found in muscle cultured from 11-day embryos. 76.2±3.8% of the AChE activity was found in the 7S form and 23.8±3.8% in the 11S (N = 6). Newly synthesized AChE in DFP-treated cells initially appeared as a 7S form; a distinct 11S form did not appear until 2 hours after treatment.

The addition of two proteolytic enzyme inhibitors, pepstatin and phenylmethylsulfonyl fluoride, to the homogenization buffer (1 M NaCl, 0.5% Triton X-100, 50 mM Tris, 0.2 mM EDTA) did not alter the distribution of these forms.

AChE activity found in embryo plasma sedimented at 11S and that released into the muscle culture medium sedimented at 9S. In one experiment, a small amount of non-specific ChE appeared in 18-day-old muscle sedimenting at approximately 5.5S, 7.5S and 10S, and comprised 24% of the total ChE activity. Non-specific ChE was not detected in either 11-day embryo or cultured muscle.

The results reinforce the idea that there is a shift from smaller to larger molecular forms of AChE during development and synthesis and that functional innervation is required to maintain a 20S form in embryonic skeletal muscle. These findings will be compared to previous work from this lab examining electrophoretic multiple forms of AChE in chick muscle and plasma. (Supported in part by NIH grant ES 00202).

1618 DEVELOPMENT OF SYNAPTIC SPECIALIZATIONS AT SITES OF NERVE-MUSCLE CONTACT IN CULTURE: DEPENDENCE ON NERVE TYPE. M.W. Cohen and P.R. Weldon*. Dept. Physiol., McGill Univ., Montreal, Quebec.

In cultures of myotomal muscle and spinal cord (SC) derived from Xenopus embryos SC neurites can trigger the development of a high density of ACh receptors along the paths of nerve-muscle contact (1,2) and electron microscopy reveals the presence of typical synaptic specializations at many of the neuromuscular contacts (3,4). We have now examined whether neurites of dorsal root ganglia (DRG) and sympathetic ganglia (SG) interact with the cultured muscle cells in a similar fashion.

Muscle cells were plated at the same time as the nerve or shortly after the onset of neuritic outgrowth. After 2-4 days, when nerve-muscle contacts were apparent, ACh receptors were stained with fluorescent α-bungarotoxin in order to be able to visualize sites of high receptor density. Over 70% of SC-contacted muscle cells displayed some stain along the paths of contact whereas the corresponding values of DRG- and SG-contacted muscle cells were 9% and 5% respectively. Similar differences between SC- and SG-contacted muscle cells were also seen when both types of nerve were present together in the same culture chamber, thereby indicating that the SG explants did not adversely alter the culture medium. The few examples of stain associated with DRG- and SG-muscle contacts resembled the characteristic patches of stain seen on non-contacted muscle cells rather than the unique long bands of stain seen along some of the SC-muscle contacts. It is concluded that the accumulation of ACh receptors at SC-muscle contacts is triggered by a specific neural property which is lacking in the DRG and SG neurites.

Cultures containing muscle and DRG or SG explants were also examined by electron microscopy. Although the neurites approached to within 100 Å of the muscle cells synaptic specializations, particularly a thickened sarcolemma and an overlying basal lamina, were rarely observed at these nerve-muscle contacts. The much more frequent occurrence of these synaptic specializations at SC-muscle contacts (4) indicates that the SC neurites possess a specific property which is important for the establishment of synaptic contacts with muscle. This property is presumably the same as that which triggers ACh receptor accumulation at SC-muscle contacts.

1619 SYNAPSE FORMATION AT OLD AND DE NOVO ENDPLATE SITES. Ronald Ding* (SPON: A. D. Grinnell). Dept. Physiology, Sch. Med., UCLA, Los Angeles, CA 90024.

Re-innervation of old endplate sites and formation of de novo junctions at ectopic sites were studied in the cutaneous pectoris of Rana pipiens using electrophysiology and light microscopy. Each muscle fiber studied electrophysiologically was marked intracellularly with Chicago Blue 6B so that it could be identified later after staining the entire muscle for nerve terminals using nitroblue tetrazolium and for cholinesterase by the method of Karnovsky (J. Cell Biol. 23:217-232, 1964). Seven days or more after nerve crush, nerve terminal could be seen regrowing into and quickly filling old synaptic gutters. The nerve terminal had its fastest growth phase at postoperative times from 10 to 15 days. Up to 30 days after nerve crush, miniature endplate potential (mepp) frequency per unit length of nerve terminal was appreciably lower than normal. Preliminary evidence showed an initial increase in quantal content per unit length of terminal, followed by a decrease and then another increase. Data obtained at postoperative delays of 30 days or more in general showed that the staining pattern of nerve terminal, mepp frequency and quantal content per unit length of terminal were all roughly equivalent to normal.

In other animals when the nerve was transposed to an endplate-free region of muscle and the endplate-containing portion discarded, de novo synapse formation occurred in ectopic regions. Compared to normal of re-innervated junctions these de novo junctions were more branched, were not as consistently aligned with the long axis of the muscle fibers, and were associated with more but smaller cholinesterase spots per muscle fiber. This distinct morphology persists for as long as 2 years. Mepps, endplate potentials, and contractions were all first seen at 4 weeks postoperative. Physiological similarities and differences between these synapses and those observed at re-innervated endplates will be discussed.

1620 Differential Effects of Acetylcholine and Edrophonium on the Motor Nerve Ending. Kenneth L. Dretchen, R. Anthony Howard*, Frank G. Standaert, and Carolyn S. Rabe*. Dept. of Pharmacology, Sch. Med., Georgetown Univ., Washington, D.C. 20007.

The effects of acetylcholine and edrophonium on motor nerve endings were studied in the in vivo cat soleus nerve muscle preparation. Administration of edrophonium, 1.0 ug/kg i.a., resulted in the appearance of stimulus-bound repetitive activity (SBR) and druginduced activity recorded from the nerve. These neural responses were transmitted to the muscle; the former resulted in enhanced force of muscle contraction, the latter resulted in muscle fasciculations. The SBR persisted for 96 seconds and resulted in potentiation of contractile strength to 260% of control. Acetylcholine administered at 100 ug/kg i.a. also resulted in SBR and drug-induced activity though accompanied by a brief decrease in the force of muscle contraction. The SBR following acetylcholine persisted for only 15 sec. Pretreatment with tetrodotoxin, 30 ng/kg i.a., of 30 to 60 seconds duration, resulted in complete elimination of SBR and drug-induced activity following acetylcholine but only partial decreases is SBR, druginduced activity, and the enhanced contractile strength following edrophonium. Similar pretreatment with the calcium antagonists verapamil (10-100 ug/kg), D-600 (10-100 ug/kg) and $LaCl_3$ (0.1-10 ug/kg) resulted in dose-releated decreases in neural and muscle responses to edrophonium but had no effect on responses to acetylcholine. In order to study the interaction of these two compounds with cAMP, they were tested following administration of theophylline, a phosphodiesterase inhibitor. Theophylline (10-100 ug/kg) produced a dose-related increase in the neural and muscle response to edrophonium while it had no effect on responses to acetylcholine. It is concluded that the observed acetylcholine response probably results from a sodium depolarization of the motor nerve terminal while the edrophonium responses probably result from both a sodium depolarization and a cyclic AMP-mediated influx of calcium into the nerve ending.

1621 COMPARISONS OF THE IMMUNOLOGICAL PROPERTIES OF JUNCTIONAL AND EXTRAJUNCTIONAL RECEPTOR. D. S. Dwyer, R. J. Bradley and G. E. Kemp*. Neurosciences Program, University of Alabama in Birmingham, Birmingham, Alabama 35294.

Differences have been detected between junctional and extrajunctional acetylcholine receptor (AChR) from rats using serum from myasthenic patients (Weinberg and Hall (1979) PNAS 76:504). Titers against extrajunctional AChR were an average of 1.5 times higher than titers against junctional AChR. We have investigated this problem using three separate assays: inhibition of ^{125}I-α-bungarotoxin binding, conventional immunoprecipitation and a modified immunoprecipitation developed in this laboratory (for details see: Dwyer et al., Clin. Exp. Imm., in press). Characterization with serum from 10 patients has been conducted. Our data indicate no systematic differences between the two types of receptor when titers are compared. Several patients show slightly higher titers against junctional AChR; the reverse is also found.

Inhibition assays detect differences between receptor. Unlike previous reports (Almon and Appel (1975) Biochim. Biophys. Acta 393:66), we can measure inhibition with junctional receptor in 50% of patients tested compared to 90% able to inhibit against denervated AChR. Maximum inhibition of toxin binding has been measured as high as 75-80% with some sera. When saturation curves are plotted with percent inhibition vs. amount of serum, both the slope of the line and the maximal inhibition is in most cases greater against extrajunctional receptor. This suggests that there is antibody in most myasthenic sera that recognizes a determinant on extrajunctional AChR close to the toxin binding site.

We have also observed that a certain fraction, approximately 10-15%, of either junctional or extrajunctional AChR is not precipitated by myasthenic IgG even at saturating antibody concentrations. This phenomenon occurs even when the modified procedure is used, which corrects for antibody precluded from binding AChR by the toxin label. This appears to be a consequence of microheterogeneity of AChR itself. Whether this heterogeneity exists in intact membranes or whether it occurs as a consequence of tissue disruption is not known.

1622 MULTIPLE FORMS OF ACETYLCHOLINESTERASE IN QUAIL MUSCLE CELL CULTURE. M.R. Emmerling*, C.D. Johnson and B.H. Lipton*. (Spon: M.D. Bownds) Neuroscience Program, Depts. of Anatomy and Zoology, University of Wisconsin, Madison, WI 53706.

The presence of multiple molecular forms of acetylcholinesterase (AChE) was examined in muscle cell cultures derived from pectoral muscle of 9 day quail (Coturnix coturnix japonica) embryos. Muscle cells were scraped from tissue culture plates, homogenized in a 0.02 M borate buffer (pH 8.8) containing 1M NaCl and 0.5% Triton X-100. The homogenate was centrifuged for 30 min. at 45,000g, the soluble AChE in the supernatant collected and analyzed by velocity sedimentation on a linear sucrose gradient containing 0.02 M borate (pH 8.8), 1M NaCl and 0.5% Triton X-100. Assay of gradient fractions for AChE activity revealed three major peaks with sedimentation values of 21, 13 and 6.5 S. The 21S form made up to 15% of total AChE activity on the gradient. When fractions containing peaks of activity were re-run, they sedimented to their original position and gave rise to no new enzyme forms. Both culture medium and chick muscle cell cultures did not possess a large form of AChE or peaks of activity coincident with the quail forms.

AChE isolated from quail muscle in vivo was found to possess three forms which correspond to the forms present in cultured quail muscle cells. Experiments were performed to compare the in vivo and in vitro 21S forms. When the two enzymes were sedimented in gradients containing reduced NaCl concentrations (0, 0.2, and 0.4M), both showed a tendency towards aggregation as reflected in broader peaks and higher S values. In addition both 21S forms were collagenase sensitive and acquired an increased sedimentation value of 22S when treated with the enzyme. These observations indicate that the in vivo and in vitro 21S AChE are similar and suggest the presence of a collagen-like tail on the enzyme.

Studies are underway to ascertain the relationship of the 21S form to the neuromuscular synapse and synaptogenesis both in vivo and in vitro

1623 MECHANISM OF NEUROMUSCULAR BLOCK BY STREPTOMYCIN. Jerry M. Farley*, Chau H. Wu and T. Narahashi. Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

Aminoglycoside antibiotics are known to block neuromuscular transmission, but the mechanism of action is not clearly understood. Both pre- and postsynaptic blocking mechanisms have been implicated, but their relative contributions to the neuromuscular block have not been quantitatively determined. The effects of streptomycin on end-plate currents (EPC) were studied using the two microelectrode voltage clamp technique. Frog cutaneous pectoris muscles were used in all experiments. The EPC was decreased in amplitude by streptomycin at a concentration of 3×10^{-5} to 3×10^{-4}M. The linearity of the current-voltage relationship was not appreciably altered by streptomycin, although slight curvature might occur especially at large negative potentials. The EPC was slightly prolonged in time course; for example at -70 mV, the time constant of decay was increased from 1.31 to 1.54 msec by 3×10^{-4} streptomycin. No frequency dependent block was observed. The ED_{50} value for the block of EPC's under conditions of high quantal content was estimated to be 8.5×10^{-5}M. Under conditions of low quantal content in the presence of high magnesium and low calcium, 3×10^{-5}M streptomycin decreased the quantal content to 0.51 ± 0.03 (Mean ± SEM) of the control. At this concentration the miniature EPC was also decreased to 0.80 ± 0.04 of the control. We conclude that streptomycin blocks neuromuscular transmission by both pre- and postsynaptic effects. Under conditions of low quantal content the presynaptic block predominates. The characteristics of the presynaptic block resemble those of magnesium. The characteristics of the postsynaptic block resemble those of curare, and either the receptor or the ionic channel, or both are blocked. This study was supported by NIH grant NS14145.

1624 TRYPTAMINE-INDUCED ALTERATIONS OF ACETYLCHOLINE RELEASE AT A NEUROMUSCULAR JUNCTION. Richard N. Friedman* (SPON: R. Rahamimoff). Dept. Physiol. Hebrew Univ.-Hadassah Med. Sch., Jerusalem, Israel.

Tryptamine, which is endogenous in several invertebrate and vertebrate nervous systems, has a concentration-dependent, biphasic effect on excitatory endplate potentials (EPPs) evoked at a lobster neuromuscular junction where glutamate is the putative excitatory neurotransmitter. Tryptamine also reduced GABA mediated inhibitory postsynaptic potential amplitudes (Friedman, et al.).

In the present study, I used conventional electrophysiological techniques to examine the effects of tryptamine on cholinergic transmission in the frog sartorius nerve-muscle preparation bathed in a modified (0.4mM Ca^{++}) Ringer's solution. Tryptamine (0.1-0.5μM) caused an increase in EPP amplitudes. Since the average miniature EPP amplitude was virtually unchanged, it seems that the action of tryptamine is a presynaptic effect which increases the mean number of quanta liberated by the nerve impulse. Higher tryptamine concentrations (≥10μM) depressed average EPP amplitudes. Both effects were reversible upon washing. These results indicate that the effects of tryptamine at a cholinergic synapse are similar to those observed at presumably glutamatergic synapses of the lobster neuromuscular junction.

1625 ULTRASTRUCTURE OF LOBSTER NEUROMUSCULAR JUNCTIONS TREATED WITH BLACK WIDOW SPIDER VENOM. L.C. Fritz*, H.L. Atwood and S.S. Jahromi*. Rockefeller University, New York, NY 10021 and Dept. of Zoology, University of Toronto, Toronto, M5S 1A1 Ontario, Canada.

Lobster stretcher muscles were treated with black widow spider venom (BWSV) and the resulting physiological and morphological effects were examined. Application of BWSV causes potentiation of EPSP's and IPSP's and a massive increase in the frequency of spontaneous miniature EPSP's. With time, evoked potentials are abolished, miniature EPSP frequency decreases to zero, and the synapse becomes electrically quiet except for large slow spontaneous events ("giant minis") [Kawai et al, J. Gen. Physiol. (1972) 650-664]. The effects of BWSV on miniature EPSP frequency are abolished if Ca^{++} is replaced by Co^{++} in the bathing solution.

Lobster preparations were fixed for electron microscopy after intermediate (~ 15 min) and long (~ 1 hr) periods of BWSV exposure. Terminals treated for intermediate periods (while miniature EPSP frequency was still high) contained vesicles, but these vesicles were not localized to release zones as they are in control preparations. Furthermore, many instances of vesicle clumping and vesicle-vesicle fusion were seen. After long exposure to BWSV (after miniature EPSP frequency fell to zero), most terminals were depleted of vesicles, and large infoldings of the plasmalemma were evident. In addition, terminal mitochondria were grossly swollen.

The results suggest that BWSV causes an influx of calcium into the nerve terminal leading to vesicle dispersion, vesicle-vesicle fusion, vesicle exocytosis and mitochondrial swelling. "Giant minis" may be caused by the release of clumped or prefused vesicles. The morphological results are similar to those seen following BWSV treatment of vertebrate neuromuscular junctions, even though the effects in crustaceans are mediated by a different venom component than are the effects in vertebrates [Fritz et al, Soc. for Neurosci. Abs. (1978) 4, 369].

1626 β-Bungarotoxin Stimulates Acetylcholine Synthesis in Rat Diaphragm. Cameron B. Gundersen, Michael W. Newton*, Donald J. Jenden. Dept. Pharmacology, UCLA School of Medicine, Los Angeles CA 90024

β-Bungarotoxin (β-Btx) is a presynaptically acting polypeptide neurotoxin with Ca^{++}-dependent phospholipase A activity. We have observed that β-Btx (140 ng/ml) caused a large increase in tissue levels of acetylcholine (ACh) in rat hemidiaphragms. Relative to control values (1.3 pmol/mg wet wgt), a 100% increase in tissue ACh was measured within 45 min of toxin exposure of an unstimulated muscle in the absence of a cholinesterase inhibitor. Subsequent studies indicate that uptake of extracellular choline (Ch) and Ca^{++} are both necessary to produce the rise in tissue ACh content. Fan-shaped segments of hemidiaphragm (wet wgt: 50-90 mg) of 90-150 g male rats were treated for 30 min with β-Btx (140 ng/ml) in an eserinized (15 μM) Krebs-bicarbonate medium at 37°C. After three 10 min periods of indirect (10 Hz) stimulation and a final 15 min rest period the released ACh and the tissue ACh were assayed by gas chromatography mass spectrometry. When $[^2H_4]$-Ch (1 μM) was added to the Krebs medium, very little label was incorporated into ACh in either toxin treated or control diaphragms. This may be due to the dilution of labelled precursor by endogenous Ch, which is released by diaphragm at rates in excess of 1.0 pmol min^{-1}-mg wet wgt^{-1}. The average Ch concentration of diaphragm is 50 pmol/mg wet wgt. Using $[^2H_4]$-Ch (10 μM), 55 pmol of $[^2H_4]$-ACh (0.74 pmol per mg wet wgt) was retained by control preparations, while 249 pmol of $[^2H_4]$-ACh (4.1 pmol per mg wet wgt) was present in toxin treated samples. Total ACh levels (pmol/mg wet wgt) were 9.4 in toxin treated vs 2.3 in controls. Hemicholinium-3 (10 μM) blocked the increase in tissue levels of ACh caused by β-Btx and reduced stores to 0.7 pmol per mg wet wgt. When Ca^{++}-free Krebs supplemented with $SrCl_2$ (2 mM) or EGTA (1 mM) was used, β-Btx did not cause an increase in tissue ACh levels. Evoked ACh release in both the $SrCl_2$ and EGTA containing media was inhibited. We conclude that external sources of Ch and Ca^{++}, of which the latter may be necessary for the toxin phospholipase activity, are required for the increased ACh levels following β-Btx treatment of the rat diaphragm. (Supported by USPHS grants NS-05753 and MH-17691).

1627 ENHANCEMENT OF TRANSMISSION AT CHRONICALLY DISUSED NEUROMUSCULAR JUNCTIONS IN RATS: EVIDENCE FOR FUNCTIONAL END-PLATE ENLARGEMENT. G.L. Harris* and W.D. Snider* (SPON: J.N. Weakly). Dept. Physiol. Sch. Med., U. of N.C., Chapel Hill, N.C. 27514.

Recent histological studies have shown that chronic conduction block of a muscle nerve produces sprouting of the motor nerve terminal and an increase in end-plate size (Brown, M.C. and Ironton, R., Nature 265: 459, 1977., Pestronk, A., and Drachman, D.B., Science 199: 1223, 1978). If the junctional enlargement were functional, then one might expect a corresponding increase in the mean quantum content (m) and the frequency of spontaneous miniature end-plate potentials (m.e.p.p.s) both of which have been shown in the frog to be positively correlated with end-plate area (Kuno, M. et al., J. Physiol., Lond. 213: 545, 1971.). To test whether these parameters are increased following the elimination of muscle activity (disuse), we made comparisons of synaptic function between disused and normal (contralateral) soleus muscles in rats.

Muscle disuse was effected by implanting tetrodotoxin (TTX) impregnated silicone cuffs around the sciatic nerve. Conduction block was confirmed by the absence of the toe-spreading reflex on the cuff side. A quantal analysis and determination of m.e.p.p. frequency were made in excised muscle-nerve preparations after 8-9 days of conduction block. The muscles were pinned side by side in a chamber and superfused with an oxygenated, low calcium and high magnesium buffered saline solution. Records of 200 evoked end-plate potentials (0.5/sec) and approximately 50 seconds of spontaneous m.e.p.p.s were obtained alternately from disused and control fibers. For each muscle, 5-7 junctions were examined.

In the seven animals studied, the mean m value from the disused side was significantly greater than that from the control side ($P < 0.01$, by t-test for matched pairs), the average difference being 40%. In five animals from which m.e.p.p. data were obtained, the mean frequency was also significantly greater on the disused side ($P < 0.05$), the average difference being 80%. In five additional animals, the effect of a control cuff (no TTX) was similarly determined. No significant differences in m or m.e.p.p. frequency between the two sides were noted.

We conclude that chronic disuse leads to an increased evoked release of transmitter as well as an increased spontaneous release of quanta. This is consistent with the hypothesis that under such circumstances, the functional end-plate area becomes enlarged.

1628 ANALYSIS OF MINIATURE ENDPLATE CURRENTS IN THE FROG NEUROMUSCULAR JUNCTION UNDER PHYSIOLOGICAL CONDITIONS. Edward G. Henderson and Linda S. Reynolds*, Dept. of Pharmacol., U. Conn. Health Center, Farmington, CT 06032.

Frog sartorius and cutaneous pectoris endplate membranes were voltage clamped by standard techniques in normal phosphate buffered Ringer solution at room temperature (20-22°C). Under these conditions, peak miniature endplate current (mepc) amplitude as a function of holding potential (V_m) was found to be non-linear and discontinuous between negative and positive V_m's. In fact, average mepc amplitudes as a function of V_m (-20 to -100mV) could be fit by a straight line with an average slope of $1x10^{-8}$mho, while those between +10 and +60mV were fit by a different linear regression line of average slope $2.5x10^{-8}$mho. Extrapolation of the regression line for net outward current to negative V_m's predicted a reversal potential (V_r) between -15 to -30mV and an intersection with the net inward current curve at potentials more negative than -60mV. Extrapolation of the regression line for net inward current predicted intersection with the voltage axis at about +60mV. The mepc decay under these conditions was found to be voltage dependent in a fashion similar to that shown by others (i.e. $\alpha(-90mV)=0.40\pm.02msec^{-1}$; $\alpha(+40mV)=.92\pm.12msec^{-1}$). The addition of neostigmine ($3x10^{-6}$M) to the Ringer solution or prior exposure of the muscles to glycerol (400-500mM) produced linear mepc-Vm (-60 to -40mV) relationships with slopes between 3.2 and $4.7x10^{-8}$mho's with a typical reduced slope at more hyperpolarized V_m's. V_r's in neostigmine or glycerol treated preparations obtained by the intercept of regression lines were between -5 and -3mV. Endplate currents (EPC's) in Mg^{++}-treated muscles also provided linear EPC-V_m (-80 to +40mV) relationships with slopes of the order of $20x10^{-8}$mho's and an average E_R of -5mV. These results suggest for MEPC's under physiological conditions (i.e. when cleft acetylcholine concentration and frequency of release are low) that a discrete E_R is unobtainable and that inward and outward conductances are distinguishable. (Supported by NS12563.)

1629 SYNAPTIC EFFECTIVENESS AND MOTOR UNIT SIZE: EVIDENCE FOR PHYSIOLOGICAL PLASTICITY IN TRANSMITTER RELEASE AT NEUROMUSCULAR JUNCTIONS. Albert A. Herrera* and Alan D. Grinnell (SPON: Alison J. Longley). Dept. Biol., UCLA, Los Angeles, CA 90024.

An important factor in synapse elimination at the neuromuscular junction during development may be the extent to which a particular nerve terminal is supported by its soma. This level of support may affect both the ability of a terminal to withstand elimination and the efficacy of transmission by that terminal. The support each terminal receives may in turn depend on the total number of terminals supported by that soma, i.e., motor unit size. We have partially tested these hypotheses by assessing the effects of changing motor unit size on synaptic effectiveness.

The left sartorius muscle of anesthetized adult Rana pipiens was exposed, the sartorius nerve crushed, and a longitudinal cut made through the sartorius so as to remove the fibers in the lateral half of the muscle. When the motor axons regenerated, they would encounter only the intact medial half of the muscle, containing approximately half the normal number of fibers. Control operations, where the nerve was crushed but the muscle left intact, were also performed. After 8 - 11 weeks synaptic strength was tested in two ways.

First, we measured the tension of nerve-evoked twitches while lowering $[Ca^{++}]$ in the Ringer from normal (1.8 mM) to 1.0 or 0.6 mM. Reduction of tension occurs when all the junctions on some fibers fall below threshold. In a normal sartorius muscle, reducing Ca to 1.0 mM causes tension to drop to 42% of tension in 1.8 mM. Lowering Ca to 0.6 mM causes a drop to 5%. Control muscles in which the nerve was crushed followed by reinnervation of the whole muscle behaved similarly. However, the experimental muscles with reduced motor unit size showed enhanced synaptic strength (75% and 19% in 1.0 and 0.6 mM, respectively).

Secondly, to test if the release properties of these stronger terminals were inherently different, we measured quantal content in Ringer containing 0.3 mM Ca and 1 mM Mg. The junctions were marked by intracellular dye injection for identification and analysis of junctional morphology in the light and electron microscope. The experimental muscles showed an approximately 5-fold increase in the number of quanta released per 100 µm of terminal length as compared to normal muscles.

We conclude that there can be pronounced physiological plasticity in the release of transmitter at neuromuscular junctions, with motor unit size an important regulating factor. It is possible that competition between synapses on the same fiber, or other variables, will also prove to be important.

1630 ASYMMETRY IN THE ACETYLCHOLINE CHANNEL. Richard Horn, Malcolm S. Brodwick* and W. Daryl Dickey*. Dept. Physiol. and Biophys., UTMB, Galveston, TX 77550.

The quaternary lidocaine derivative QX-314 blocks open ACh channels in a voltage-dependent manner from the external membrane surface of frog muscle (Neher and Steinback, 1978). We have applied QX-314 to both internal and external membrane surfaces in order to determine if its blocking action is equivalent from each side. The thighs of neonatal rats were dissociated into myoblasts with 0.025% trypsin and grown under tissue culture conditions. The myoblasts fused to form multinucleate myotubes, which were treated with 10^{-8}M vinblastine to form 60-130 µm spherical myoballs. The myoballs were sucked onto the tip of a glass pipette, the membrane was ruptured, and the cell was internally dialyzed (Lee, K., et al., 1978). The internal and external solutions were approximately symmetrical, each containing 85mM Na aspartate, 150mM sucrose, 5mM HEPES. The external solution had 1.5mM $CaCl_2$, the internal 2mM EGTA. The adequacy of the internal dialysis was confirmed by the fact that the resting potential, Na channel reversal potential, and ACh reversal potential were all approximately 0 mV. In many cells the series resistance through the suction pipette was greater than the membrane resistance. Therefore a microelectrode was used to record membrane potential, V_m. The cells were voltage-clamped and ACh was applied iontophoretically. Both V_m ramps and V_m jumps were applied to the cell during the action of ACh. External QX-314 (0.1mM) produced a V_m and time-dependent block of the open ACh channel. Internal QX-314 (1.0mM) produced a frequency-dependent block of the Na channel without affecting current in the ACh channel. This result suggests that a barrier prevents internal QX-314 from reaching the same site in the ACh channel which QX-314 can reach from the external surface. Further work will determine if this barrier affects the movement of smaller cations through the channel. Supported by NS-13778 and CA-19017.

1631 SINGLE-CHANNEL CURRENTS OF ACETYLCHOLINE RECEPTORS IN CULTURED RAT MUSCLE. M. B. Jackson*, C. N. Christian* and H. Lecar* (SPON: R. E. Taylor). NIH, Bethesda, MD 20205.

Single-channel current fluctuations were observed for acetylcholine (ACh)-sensitive channels in cultured embryonic rat myotubes. The current measurements employed a 1-2 μ diameter extracellular electrode containing 1 or 10 μM carbamyl choline which was pressed against the cell membrane. Rectangular current-fluctuations caused by the agonist-activation of individual ionic channels were observed with a pipette-to-membrane seal resistance of 20 MΩ or greater. For 10-day old cultures, cells held at a membrane potential of -90 mV, gave current jumps of 4.4 pA at 22°C. Assuming a reversal potential of 0 mV, this leads to a value for the unit channel conductance of 49 pS. Open-channel durations are exponentially distributed, with a mean open time of 3.3 msec. As a convenient means of analyzing channel properties, the fluctuation records were processed by a Fourier transform program. The resulting power spectra were Lorentzian, and the open-channel durations could be extracted even for records so dense that individual-channel events are unresolvable. The surfaces of the myotubes were probed for variations in acetylcholine sensitivity. The regions of intense channel activity were correlated with regions of high receptor density as measured by fluorescence microscopy with rhodamine labelled α-bungarotoxin. The direct recording of ACh-sensitive single-channels together with the analysis of membrane noise, permits the quantitative mapping of the spatial distribution of ACh receptors and the characterization of the parameters of the ACh sensitive channels.

1632 MIGRATION OF SCHWANN CELLS AND WRAPPING OF NEURITES IN VITRO: A FUNCTION OF PROTEASE ACTIVITY IN THE GROWTH MEDIUM. Nurit Kalderon. The Rockefeller University, New York, N.Y. 10021.

Proteolytic enzymes activities associated with chick embryo spinal cord cells are studied in culture, in relation to the ability of these cells to invade, migrate and extend during the development of both the peripheral nervous system and the neuromuscular junction. It was found that dissociated spinal cord cells from 7-9 day old chick embryos produce a proteolytic enzyme, as determined by their fibrinolytic activity in culture. The proteolytic enzyme was identified as plasminogen activator. The relative spatial organization of the dissociated spinal cord cells was found to be directly related to the expression of their plasminogen activator activity. The neuron cell bodies aggregated in ganglia-like clusters, from these aggregates there was an extensive outgrowth of bundles of axons, and these bundles were wrapped by Schwann cells. This was determined both by EM ultrastructural analysis, and by tritiated thymidine labeling of cell nuclei. Neurons at this stage of differentiation for the most part do not divide whereas the Schwann cells do. When [^{3}H] thymidine was added to the cultures the nuclei of the wrapping cells were radiolabeled whereas the clusters of neurons did not incorporate any label. In cases in which the spinal cord cells were grown either in regular medium (supplemented with horse serum and chick embryo extract),or in medium in which plasminogen was eliminated, no plasminogen activator activity could be detected, and the cells displayed a random growth pattern. In these cultures the neurons were individually spread on a carpet of non-neuronal cells as previously described (Fischbach and Dichter, 1974; Dev. Biol. 37:100). It is possible to conclude from the data described above that Schwann cells migrate and wrap the growing neurites as a result of the presence of the proteolytic activity of plasmin. The plasminogen probably is activated by plasminogen activator produced by one of the cell types in the culture. Thus, to achieve wrapping of neurons by Schwann cells in culture, it is essential to have the expression of plasminogen activator activity.

It was suggested that the elimination of multiple innervation of the skeletal muscle is carried out by proteolytic activity (O'Brien et al., 1978; J. Physiol. 282:571). The role of the Schwann cell and the plasminogen activator activity in the formation of the neuromuscular junction will be discussed with respect to this observation.

1633 IMMUNOHISTOCHEMICAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE AT THE NEUROMUSCULAR JUNCTIONS OF RABBIT DIAPHRAM. K.-S. K. Kan and L.-P. Chao. Dept. Neuro., Reed Center, Sch. Med., UCLA, Los Angeles, CA 90024.

The innervation of skeletal muscle at the neuromuscular junction is known to be cholinergic. Since choline acetyltransferase (ChAc) catalyzes the synthesis of acetylcholine, high ChAc activity has been detected in the ventral horn, the ventral root and the nerves that innervate skeletal muscle. Until recently we have visualized ChAc in motor neurons of bovine spinal cord with an immunofluorescent method using guinea pig antiserum to purified bovine ChAc (Nature 250: 243, 1974). This antiserum cross-reacts with ChAc from rabbit brain and we have localized ChAc in the motor neurons of rabbit spinal cord (Brain Res. 146: 221, 1978) by the newer and more sensitive immunoperoxidase method. The present communication reports the localization of ChAc at the neuromuscular junction. Frozen sections of rabbit diaphram were stained histochemically for cholinesterase (ChE) using 5-bromoindoxyl acetate as the substrate. This yielded a blue deposit at the motor end plate. After this histochemical staining of ChE, the immunoperoxidase staining for ChAc was performed on the same section. The immunoperoxidase staining involved the sequential incubation of the sections with guinea pig antiserum to bovine ChAc, rabbit anti-guinea pig IgG and guinea pig peroxidase-antiperoxidase (PAP) (Brain Res. 146: 221, 1978). The brown reaction deposits of the complex of ChAc, antibody and peroxidase was visualized by incubation with diaminobenzidine in the presence of H_2O_2. This combination of histochemical staining for ChE and immunohistochemical staining for ChAc revealed blue motor end plates and brown nerve terminals. The ChE at the neuromuscular junction was localized mainly in post-synaptic structures while the ChAc was localized at the presynaptic nerve terminals. Similar presynaptic nerve terminals were observed when a silver stain was substituted for the immunoperoxidase stain. Supported by USPH Service Grant No. NS-11087 and BRSG from NPI of UCLA.

1634 DEPRESSANT EFFECTS OF MORPHINE AND MEPERIDINE ON NEUROMUSCULAR TRANSMISSION IN RAT AND HUMAN MYASTHENIC MUSCLES. Yong I. Kim,* James F. Howard* and Donald B. Sanders. Dept. of Neurology, Univ. of Virginia Sch. of Med., Charlottesville, VA 22908

The depressant actions of narcotic analgesics, morphine (MO) and meperidine (ME), on neuromuscular transmission were investigated in vitro in forelimb flexor digitorum longus muscles of normal rats and those with experimental autoimmune myasthenia gravis (EAMG) and in intercostal muscle biopsies from patients with myasthenia gravis (MG).

In the rat muscles MO and ME at concentrations from 8 to 80μM reduced the amplitudes of miniature end-plate potentials (MEPPs) and end-plate potentials (EPPs) in a dose-dependent manner. At equimolar concentrations (24 and 80μM), MO and ME produced a similar reduction in MEPP and EPP amplitudes. At maximum therapeutic concentrations (MO:0.03μM, ME: 0.7μM), both drugs showed little effect on neuromuscular transmission, but at 10 to 40 times the therapeutic concentration only ME produced an apparent neuromuscular depression. At very high concentrations (160μM), both drugs decreased the amplitude and maximum rates of rise and fall of APs, suggesting an effect on the ionic conductances of muscle membranes. Isometric twitch tension was significantly reduced by both drugs in muscles in which neuromuscular transmission was partially blocked by d-tubocurarine. The concentration of MO required to produce a given reduction of twitch tension was greater than that of ME. Similar depressant effects of MO and ME on neuromuscular transmission were found in muscles from rats with EAMG.

In intercostal muscles from patients with MG, both MO and ME depressed MEPP and EPP amplitudes in a dose dependent manner. Reductions in MEPP and EPP amplitudes were observed with 30μM MO and 70μM ME but the quantum content of evoked transmitter release was not altered, indicating that the major depressant action of MO and ME occurs postsynaptically. As in rat muscle, ME produced a greater neuromuscular depression than did MO. At 10 times the maximum therapeutic concentration, both drugs had no inhibitory effect. At 100 times the therapeutic concentration, MO (3μM) still had no inhibitory effect, but ME (70μM) significantly impaired the neuromuscular transmission.

These results demonstrate that meperidine has a greater depressant effect on neuromuscular transmission in vitro than does morphine, but that these effects are seen only at concentrations significantly greater than are achieved clinically. (Supported by NIH Grant NS-12905 and a center grant from the Muscular Dystrophy Association)

1635 DENERVATION CHANGES IN FROG NEUROMUSCULAR JUNCTIONS: FREEZE-FRACTURE STUDIES. Chien-Ping Ko. Lab. Neuropath. Neuroanat. Sci., NINCDS, Natl. Inst. Health, Bethesda, MD 20205.

Neuromuscular junctions of frog cutaneous pectoris muscle were freeze-fractured 1-14 days after cutting the nerve 3-5 mm from the muscle. The results confirmed earlier findings that structural changes in the presynaptic elements occur abruptly. In addition, it was found that Schwann cells after denervation possessed membrane ridges opposed to the junctional folds of the muscle.

During the first three days after denervation, neuromuscular junctions showed the normal 3-cell arrangement: muscle with junctional folds, axon and Schwann cell. No abnormalities were detected at the active zones or elsewhere in the presynaptic membrane (36 terminals with 880 active zones from 4 frogs). At 4-7 days, neuromuscular junctions had either (1) the usual 3-cell arrangement with normal appearing nerve terminals or (2) complete replacement of the nerve terminal by the Schwann cell. Occasionally, a few transitional stages were seen, in which processes interpreted to be portions of nerve terminals were surrounded by Schwann cells already occupying most of the junctional gutter. The scarcity of such transitional stages implies a rapid engulfment of nerve terminals by Schwann cells and abrupt changes in the membrane structures of nerve terminals if they occur at all before engulfment.

At 1-2 weeks after denervation, nerve terminals were no longer seen and the muscle did not contract when the nerve stump was stimulated. At this stage, Schwann cells still occupied the synaptic gutters, but now ridges appeared on the cytoplasmic leaflets of the Schwann cell membrane. Like the active zones of nerve terminals, these ridges lay directly over the junctional folds. However, no rows of particles marked these sites on the Schwann cell membrane. Examination of thin sections from paired muscles confirmed that Schwann cell processes form these ridges and that these ridges are over the junctional folds. However, no other specialized cytoplasmic structures or clustering of organelles in these regions of Schwann cells were found. Molding of the Schwann cell membrane to the contours of the junctional folds suggests attachment of the Schwann cell to the muscle or its basement membrane in the location to which nerve terminals are also thought to be attached.

1636 ACh RECEPTOR CHANNELS BEGIN TO OPEN WITHIN 10 μsec AFTER AGONIST IS APPLIED. Mauri E. Krouse*, Henry A. Lester, Menasche M. Nass, Jeanne M. Nerbonne*, Norbert H. Wassermann* and Bernard F. Erlanger* (SPON: W. F. Agnew). Division of Biology, California Institute of Technology, Pasadena, CA 91125 and College of Physicians and Surgeons, Columbia University, New York, NY 10032.

We have improved (by a factor of 10) our estimate of how rapidly acetylcholine (ACh) receptor channels begin to open after agonist appears nearby. Isolated Electrophorus electroplaques are arranged for transcellular recording. The innervated face is bathed in a solution of cis-Bis-Q (3,3'-Bis-[α-(trimethylammonium) methyl] azobenzene) which has no effect on receptors. Trans-Bis-Q is a potent agonist; a concentration of 350 nM activates half the receptors at the resting potential. Roughly half the cis-Bis-Q molecules are photoisomerized to the trans configuration within 1 μsec by a pulse of 440-nm light from a dye laser. Our methods can detect a depolarization caused by activation of 0.5-1% of the receptor channels. At 23° C and at a trans-Bis-Q concentration of 1 μM, this level of activation occurs within 10 μsec after the flash. This latency has a Q_{10} close to 3 and at lower [trans-Bis-Q], the latency increases as the inverse of the concentration. Thus, the minimum latency has the same concentration and temperature dependence on a μsec time scale as the channel opening rate, measured in relaxation experiments, has on a millisecond time scale. The data show that if there is an absolute delay involved in activation of receptor channels by agonist, this delay is less than 10 μsec at 23°C. Our agonist concentration jumps are still much smaller than the local ones that occur when the presynaptic nerve terminal releases a quantum of ACh into the synaptic cleft.

Further information is obtained from a second flash, which photoisomerizes trans-Bis-Q molecules bound to receptors (as well as Bis-Q molecules in solution). Since the cis configuration is a much weaker agonist, channels close rapidly and the electroplaque repolarizes. The observable latency for this repolarization is even less than for the depolarization due to the first flash.

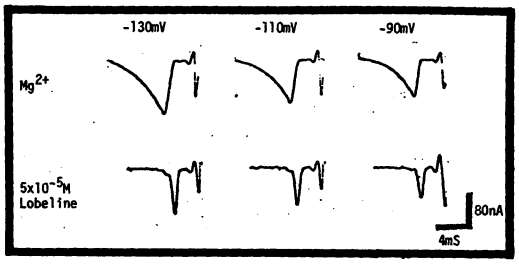
1637 THE ACTION OF LOBELINE ON THE ACETYLCHOLINE-ACTIVATED IONIC CHANNEL. Jeremy J. Lambert*, Linda S. Reynolds*, Robert L. Volle and Edward G. Henderson. Dept. Pharmacol., U Conn. Health Center Farmington, CT 06032.

Frog sartorius and cutaneous pectoris muscles were studied using conventional endplate voltage clamp techniques. Lobeline has previously been shown to cause neuromuscular blockade characterized by a non-depolarizing postsynaptic action (N.-Schmied. Arch. Pharmacol. 272:16, 1972). Unlike tubocurarine, lobeline enhances receptor desensitization (N.-Schmied. Arch. Pharmacol. 272:307, 1972). The half time of decay ($t_{½}$) of the endplate current (e.p.c.) in Mg^{2+} or tubocurarine-pretreated preparations was logarithmically related to holding potential (Vm) in the range -30mV to -130mV, being slower at more hyperpolarized potentials. In preparations pretreated with lobeline ($5x10^{-5}$M) the $t_{½}$ of the e.p.c. was shown to be independent of Vm (at -90mV, $t_{½}$ = 0.46± 0.03mS; at -130mV, $t_{½}$ = 0.45±0.02mS). When lobeline ($5x10^{-5}$M) was added to Mg^{2+} (11-14mM) pretreated preparations the amplitude of the e.p.c. at -90mV was 18.1±4.9% of control and $t_{½}$ was decreased in the range -90mV to -130mV. The dependence of $t_{½}$ on Vm was still evident but modified from that in Mg^{2+} alone (at -90mV, $t_{½}$ = .94±0.14mS; at -130mV, $t_{½}$ = 1.14±0.22mS). After a 15 min. wash with Mg^{2+}-Ringer (lobeline-free) the amplitude of the e.p.c. remained depressed but $t_{½}$ returned to control values. The reversal potential measured in the presence of lobeline alone was not different from values obtained in Mg^{2+} alone (-5 to 0 mV) however, the amplitudes of the e.p.c.'s for Vm in the range 0 to +40mV were more depressed than in the range 0 to -90mV. This data is consistent with an action of lobeline on the acetylcholine-activated ionic channel, as has been suggested for several other drugs. Lobeline may serve as a useful tool for elucidating the properties of the endplate channel and its interaction with the membrane electric field. (Supported by NS-07540 and NS-12563.)



1638 REGENERATION FOLLOWING MICRO-CAUTERY OF NEUROMUSCULAR JUNCTIONS OF NORMAL AND DYSTROPHIC MOUSE MUSCLES. Peter K. Law. Dept. Neurol., Jerry Lewis Neuromus. Ctr., Vanderbilt Univ. Sch. Med., Nashville, TN 37232.

Recovery of neuromuscular function after micro-cautery of the motor end-plate zone was studied in normal and dystrophic littermates of the 129/ReJ-dy mice. A fine platinum wire (5 mm long, 0.005" diameter) heated to about 400C by a needle-tipped soldering iron was applied to the middle third of the right soleus, which was cooled immediately with a flush of equilibrated Krebs-Henseleit solution at 22C. This procedure caused immediate neuromuscular dysfunction without disrupting the physical continuity of nerve and blood vessels into the muscle. The soleus was used because of its discrete, central end-plate zone and because its fibers ran longitudinally from tendon to tendon. Unoperated solei in the left legs served as controls. Mice were cauterized at 6 to 7 weeks of age and examined 3 months post-operatively.

Results were obtained from 10 dystrophic and 9 normal mice. Measurements were made in vivo at 37C. Cauterized and unoperated normal solei did not differ in indirectly evoked twitch and tetanus tensions. However, cauterized dystrophic solei produced only 62.8% of twitch, and 66% of tetanus tensions of their controls. Motor unit counts did not differ between cauterized and unoperated solei, regardless whether the preparation was normal or dystrophic. Cauterized normal myofibers were more depolarized (68 ± 5 mV, X ± SD) than unoperated normals (73 ± 4 mV). There is no difference in the mean resting membrane potentials between cauterized dystrophic (64 ± 8 mV), and unoperated dystrophic myofibers (64 ± 7 mV). There is no difference in contraction time and half-relaxation time between cauterized and unoperated solei. The results indicated that the dystrophic mouse exhibited less-than-normal neuromuscular regenerative capability after an acute lesion. (Supported by MDA, MDAC).

1639 AGONIST INDUCED MYOPATHY IS MEDIATED BY CALCIUM. John P. Leonard* and Miriam M. Salpeter. Section of Neurobiology and Behavior, Cornell University, Ithaca, New York 14853.

Inactivation of cholinesterases at mammalian neuromuscular junctions (nmj) produces extensive muscle "necrosis", which was first reported by Ariens et al. (Experientia 25:57-59, 1969). Fine-structurally this myopathy begins at the nmj with an increase in large diameter (>130nm) vesicles in the soleplasm, the dissolution of Z-disks, dilation of mitochondria, dilation of sarcoplasmic reticulum and often a highly specific contracture of the muscle under the endplate.

Biochemical studies have shown that a Ca^{++}-activated protease, which specifically removes Z-disks from isolated myofibrils in vitro, is present in mammalian skeletal muscle. (Busch et al. J. Cell Biol. 52:367-380, 1972). Since agonist causes specific Ca^{++} influx at motor endplates, (e.g. Evans J. Physiol, 240: 517-533, 1974; and Miledi, et al. J. Physiol. 268:32-33p, 1977) it was suggested that the myopathy after esterase inactivation may be due to Ca^{++} influx during the prolonged Ach lifetime (Salpeter et al. J. Neurocytol. 8:95-115, 1979). To test this hypothesis an isolated nerve muscle preparation of the mouse extensor digitorum longus (EDL) was used. The myopathy near endplates was first produced by esterase inactivation with diisopropylfluorophosphate (DFP) followed by nerve stimulation, and later mimicked by bath application of 10^{-4}M carbamylcholine (CCh) without esterase inhibitors. The extent of damage was assessed from the two most consistent morphological changes: vesiculation of the soleplasm and Z-disk dissolution. The damage produced in a muscle preparation maintained in vitro for 3 hours, depended on the relative time that CCh was present in the bath. The myopathy was prevented by inactivating the acetylcholine receptors (AChR) with 1μM α-bungarotoxin or with 5μM d-tubocurarine. The myopathy was also completely prevented by removing Ca^{++} from the CCh bath with 5mM EGTA, and partially prevented by adding .1mM D-600 (a specific Ca^{++} flux inhibitor) to the CCh bath. The myopathy was unaffected when Na^{+} was replaced by either Choline or Tris HCl.

These results favor the hypothesis that prolonged exposure to agonist produces a myopathy which mimicks one produced by esterase inactivation, is mediated by Ca^{++} and requires an unblocked AChR.

1640 A COVALENTLY BOUND PHOTOISOMERIZABLE AGONIST AT ELECTROPHORUS ELECTROPLAQUES: EQUILIBRIA, KINETICS, AND STOICHIOMETRY. H. A. Lester, M. E. Krouse# and M. M. Nass, Division of Biology, California Institute of Technology, Pasadena, CA 91125; N. H. Wassermann# and B. F. Erlanger#, Department of Microbiology, Columbia University, New York, NY 10032.

After disulphide bonds are reduced with dithiothreitol, trans-3-(α-bromomethyl)-3'-[α-(trimethylammonium)methyl] azobenzene (trans-QBr) alkylates a sulfhydryl group on receptors. The membrane conductance induced by this "tethered agonist" shares many properties with that induced by reversible agonists. Equilibrium conductance increases as the membrane potential is made more negative; the voltage sensitivity resembles that seen with 50 μM carbachol. Voltage-jump relaxations follow an exponential time course; the rate constants are about twice as large as those seen with 50 μM carbachol and have the same voltage and temperature sensitivity. With reversible agonists, the rate of channel opening increases with the frequency of agonist-receptor collisions; but with tethered trans-QBr, this rate depends only on intramolecular events. In comparison to the conductance induced by reversible agonists, the QBr-induced conductance is at least tenfold less sensitive to competitive blockade by tubocurarine and roughly as sensitive to "open-channel blockade" by QX-222.

Light-flash experiments with tethered QBr resemble those with the reversible photoisomerizable agonist, Bis-Q: the conductance is increased by cis → trans photoisomerizations and decreased by trans → cis photoisomerizations. As with Bis-Q, light-flash relaxations have the same rate constant as voltage-jump relaxations. Receptors with tethered cis-QBr have a channel duration severalfold briefer than with the tethered trans isomer. By comparing the agonist-induced conductance with the cis/trans ratio, we conclude that each channel's activation is determined by the configuration of a single tethered QBr molecule. The QBr-induced conductance shows slow decreases (time constant several hundred msec) which can be partially reversed by flashes.

The similarities suggest that the same rate-limiting step governs the opening and closing of channels for both reversible and tethered agonists. Therefore, this step is probably not the initial encounter between agonist and receptor molecules.

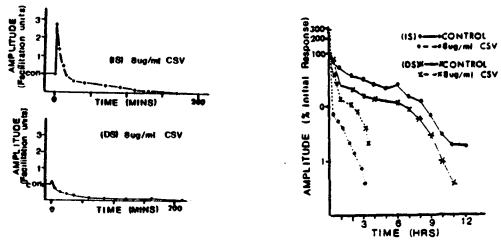
1641 COMPARISON OF THE EFFECTS OF CENTRUROIDES SCULPTURATUS VENOM ON FROG MUSCLE TWITCH TENSION DEVELOPMENT VIA INDIRECT (IS) (NEUROTRANSMISSION) OR DIRECT (DS) ELECTRICAL STIMULATION OF THE MUSCLE. Gesina L. Longenecker, Herbert E. Longenecker, Jr., and Barbara Beyers, Department of Pharmacology, College of Medicine, University of South Alabama, Mobile, AL 36688.

In preliminary twitch tension studies (Soc. for Neuroscience Abstracts, Vol. 4) with C. sculpturatus venom (CSV) a gradual rundown of the IS frog preparation over a period of many hours occurred. No systematic study of this observation was pursued, nor a directly stimulated (DS) control preparation examined. We have now extended our earlier observations in these directions. Isolated frog sciatic/sartorious nerve muscle preparations, dissected and mounted in Ringer's (2.5 mMK^{+}, 2.0 mM Ca^{++}, 114.5 mM Na^{+}) were used. CSV solutions (0.1 to 50 ug/ml) were made in the Ringer's. Either indirect (electrodes placed on sciatic nerve) or direct (electrodes placed bilaterally on the muscle at the plevic end) stimuli were adjusted to 125% of that voltage giving maximal twitch tension.

Twitch tension in both IS and DS preparations declined irreversibly to zero amplitude over a period of approximately 12 hours although after "initial rundown" both preparations exhibited an 'apparent' plateau of 3-5 hours. CSV added to either preparation substantially accelerated eventual twitch decline at all concentrations of venom studied. With IS, an initial several fold facilitation was followed by twitch block, whereas with DS, following barely perceptible facilitation (with lower concentrations only) twitch tension rapidly decreased. However, twitch tension declined considerably more rapidly with IS as opposed to the DS preparation at any dose of venom. Thus, CSV effect on neurotransmission contributes significantly to the eventual twitch block. Block of twitch in both preparations may be accounted for by known effects of CSV on active sodium permeability. Indeed, this effect alone probably accounts for the failure of the DS preparation.



1642 AMANTADINE AND ITS ANALOGS ON ENDPLATE CONDUCTANCE AND LIGAND BINDING AT THE NEUROMUSCULAR JUNCTION. M. A. Maleque*, J. E. Warnick, M. E. Eldefrawi* and E. X. Albuquerque, Dept. of Pharmacol. & Exper. Therap., University of MD, Balto. MD. 21201.

Amantadine (1-adamantamine) blocks neuromuscular transmission in a voltage-dependent manner, by reacting directly with the ionic channel of the acetylcholine (ACh) receptor. In this study amantadine and its N-alkyl substituted analogs: N-methyl- (ID 2), N-ethyl- (ID 3), N-(1-propyl)- (ID 4), N-(1-butyl)- (ID 6), and N,N-diethyl-amantadine (ID 27) and six bicyclo-octane compounds: 4-methylbicyclo [2.2.2] oct-2-ene-1-carboxylic acid (ID IIIb), 4-methyl-bicyclo [2.2.2] octane-1-carboxylic acid (ID Vb), 1-amino-4(1-propyl)-1,4-bicyclo [2.2.2] octane (ID 11), 1-amino-4(1-hexyl)-1, 4-bicyclo [2.2.2] octane (ID 16), 1-(amino-methyl)-4-methyl- (ID 33) and 1(N,N-dipropyl-aminomethyl)-4-methyl (1,4-bicyclo [2.2.2] octane (ID 36) were investigated on frog sciatic sartorius preparations. Amantadine and ID 2, 4, 6, 11, 27, 33 and 36 blocked indirectly elicited twitches while ID 4, 6 and 27 also potentiated directly elicited twitches and prolonged the muscle action potential. ID IIIb, Vb and 16 had no effect on twitches. Fifty percent blockade of the indirect twitch with amantadine occurred at 130 μM; at 12 - 15 μM for ID 2, 3, 4, 11 and 27; 50-55 μM for ID 6 and 36; and 100 μM for ID 33. Miniature endplate potential (m.e.p.p.) amplitude was reduced by amantadine (by 80% in 60 min) and by ID 2, 3, 4 and 27. Neither amantadine nor its analogs affected m.e.p.p. frequency or membrane potential. Amantadine and ID 2, 3, 4, 6, 11, 27, 33 and 36 caused a marked departure from linearity in the voltage-current relationship of the peak endplate current (EPC). This effect was clearly apparent at very negative membrane potentials. The voltage dependent peak EPC amplitude for amantadine and ID 2, 4 and 33 remained unattenuated at depolarized membrane potentials. Amantadine and ID 2, 3, 27 and 33 altered the voltage dependency of the falling phase of EPC and reduced the slope of the relationship between τ (of the EPC) and the membrane potential with subsequent reversal of the slope. Peak EPC amplitude and shortening of the falling phase of the EPC were concentration dependent. ID 4, 6, 11 and 36 decreased the voltage dependency of the falling phase at a low concentration (20-50 μM) but was voltage independent at a higher concentration (100 μM). Neither amantadine nor its N-alkyl substituted analogs and bicyclo-octane derivatives inhibited the binding of ^{3}H-ACh to its receptors but did inhibit competitively the binding of ^{3}H-perhydrohistrionicotoxin to the ionic channel of the ACh receptor with Ki for each compound equal to: amantadine, 60 μM; ID 2, 30 μM; ID 3, 15 μM; ID4, 40 μM; ID 6, 40 μM; ID 27, 15 μM; ID IIIb > 1mM; ID Vb, > 1 mM; ID 11, 200 μM; ID 16, 30 μM; ID 33, 600 μM; ID 36, 50 μM. It is suggested that amantadine and its analogs react with the ionic channel of the ACh receptor causing the appearance of two species of conductance, one where the channel is partially blocked (hyperpolarized state) and the other where the channel is in an open conformation (depolarized state). (Supported in part by USPHS Grant NS-12063 and the Dept. of the Army.)

1643 DISTRIBUTION OF ACHR IN DEVELOPING AND DYSTROPHIC MOUSE NEUROMUSCULAR JUNCTIONS. Julia Matthews-Bellinger* and Miriam M. Salpeter. (SPON: Lee Rubin). Neurobiology and Behavior, Cornell University, Ithaca, NY, 14853. Supported by NIH Grant NS 09315.

The microdistribution of the acetylcholine receptor at extensor digitorium longus (EDL) muscle endplates during normal postnatal development of mice (inbred strain 129/ReJ) was studied by EM autoradiography after ^{125}I-α-bungarotoxin (BTX) labeling. In adult mouse endplates the ACh receptive surface corresponds to a thickened region of the post-junctional membrane (pjm) at the crests of the junctional folds (Fertuck and Salpeter, J. Cell Biol. 69:144, 1976). The morphological maturation of the pjm during development was quantified by the ratios of the lengths of total pjm and thickened pjm to the length of the primary cleft midline (1°cleft). Approximately 50% of the 1°cleft is covered by Schwann cell extensions between day 1 and 5, whereas by 2 weeks axon terminals have expanded to occupy most of the cleft. Results are given in the Table:

age (#animals)	Genotype	Morophology: total pjm/1° cleft	Morophology: thickened pjm/1° cleft	^{125}I-α-BTX site density†: per μm^2 1°cleft	^{125}I-α-BTX site density†: per μm^2 thickened pjm
	normal (+/+)	$\bar{x}$ ± SD	$\bar{x}$ ± SD	$\bar{x}$ ± SD	$\bar{x}$ ± SD
1d(3)		1.14±.01	0.58±.08	0.63±.12	1.05±.13
5d(3)		1.23±.07	0.66±.03	0.67±.10	1.01±.12
2wk(2)		2.03±.13	0.73±.10	0.82±.11	1.13±.15
>4mo(3)		4.45±.79	1.34±.11	1.34±.11	1.00±.04
>4mo(2)	+/dy	4.32±.65	1.33±.12	1.76±.11	1.27±.08
>4mo(2)	dy/dy	1.42±.32	0.83±.23	0.96±.34	1.13±.17

The ratio of total pjm/1°cleft shows that junctional folds, absent at birth, develop over a period of several weeks. The length ratio of thickened pjm to 1°cleft also increases very gradually. ^{125}I-α-BTX site density per unit area of 1°cleft increases but per unit area of thickened pjm is constant throughout postnatal development. Furthermore, we found that these post-junctional specializations are comparable under axon and Schwann cell.

A single autosomal recessive mutation for "dystrophy" (dy) occurs in strain 129/ReJ. The endplate in adult dystrophics (dy/dy) is enlarged with minimal junctional folds, generally patchy distribution of thickened pjm and extensive subneural regions lacking recognizable thickened pjm and having greatly reduced ^{125}I-α-BTX binding. However per total area of thickened pjm whenever it occurs the ^{125}I-α-BTX binding density is that of normal adults in this strain.

†normalized to site density per thickened pjm in normal adult.

1644 EFFECTS OF PURIFIED CONUS GEOGRAPHICUS TOXINS G_1 AND G_{11} ON NEUROMUSCULAR ELECTROPHYSIOLOGY. Owen McManus* and James Musick (SPON: S. Stensaas). Dept. Physiology, Col. of Med., U. of Utah, Salt Lake City, UT 84108.

The electrophysiological effects of two purified peptide toxins (G_1 and G_{11}) isolated from the venom of the marine snail Conus Geographicus were investigated. The composition of the two peptides has been previously reported as: G_1 = Glu (Arg, His, Asn, Ser, Pro, Cys_4, Gly, Ala, Try) and G_{11} = Glu (Lys, His_2, Ser, Pro, Cys_4, Gly, Ala, Phe), and the LD_{50} in mice reported as 12 μg/KG (Gray, Luque, Olivera, Fed. Proc., 61: 2171, 1977; Cruz Gray, Olivera, Arch. Bioch. Biophys., 190: 2, 1978). The toxin was applied in all cases as an equal mixture of G_1 and G_{11}.

The toxin was applied to a 5 mm segment of ventral root from the bullfrog sciatic nerve in concentrations ranging from 5 μg/l to 1 mg/l. The nerve was stimulated distal to the site of toxin application and recording leads were placed on the ventral root proximal to the site of toxin application. After 25 min. exposure to toxin, the amplitude of the extracellularly recorded action potential was within 5% of the value predicted from a baseline extrapolation. The twitch tension developed by directly stimulated frog sartorius muscle was similar to control values after 25 min. exposure to toxin at 300 μg/l. These results indicate that even in high concentrations, G_1 and G_{11} have a negligible effect on action potential propogation in nerve or muscle.

The effects of G_1 and G_{11} on neuromuscular transmission were investigated in the mouse hemidiaphragm using intracellular recording techniques. While recording miniature endplate potentials (m.e.p.p.s.) the toxin was added to a static, directly oxygenated bath. Exposure to toxin concentrations between 220 μg/l and 475 μg/l caused a dimunition of m.e.p.p. amplitude until m.e.p.p.s. became indistinguishable from noise. Upon superfusion with control saline, m.e.p.p. amplitude increased, but this return to near control levels was significantly slower than the onset of effects. These results suggest that G_1 and G_{11} may act as receptor antagonists at the neuromuscular junction. The results do not rule out the possibility that G_1 and G_{11} act by altering the conductance of the subsynaptic membrane or by affecting presynaptic function.

Supported by NIH grant NS07938 from the U.S. Public Health Service, intramural funds from the U. Utah College of Medicine, and a U. Utah Graduate Research Fellowship.

1645 WHAT IS THE SITE OF ACTION OF MAGNESIUM ION AT THE MOTOR NERVE TERMINAL? STUDIES WITH ION-CONTAINING LIPOSOMES. A.M. Mellow, E.M. Silinsky and A.F. Boyne. Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

It has long been known that magnesium ion (Mg^{++}) is an effective inhibitor of the evoked release of transmitter from presynaptic nerve terminals. Mg^{++} is thought to act as a competitive antagonist of calcium ion (Ca^{++}), the physiological mediator of depolarization-secretion coupling. Both intracellular and extracellular sites for this antagonism have been proposed, but definitive evidence for either site remains lacking. The recent observations of Rahamimoff et. al. (PNAS, 75:5214, 1978) suggest that liposomes can be used to introduce ions directly into the cytoplasm of nerve terminals. We have utilized this technique to test the hypothesis that Mg^{++} has an intracellular site of action.

Sonicated liposomes containing either 80 mM $CaCl_2$ or 80 mM $MgCl_2$ were prepared from egg phosphatidylcholine according to standard procedures and were dialyzed in an Amicon ultrafiltration unit against a control Ringers solution which contained 0.3 - 0.4 mM $CaCl_2$ and 1 - 2 mM $MgCl_2$. The integrity of the liposomes and the extent of dialysis were assessed by the addition of $^{45}CaCl_2$ to the lipid dispersions prior to sonication. Liposome suspensions were perfused over isolated cutaneous pectoris nerve-muscle preparations of the frog and quantal content was measured at single end-plates using conventional electrophysiological techniques. Liposomes containing $CaCl_2$ produced a three to fourfold increase in quantal content over that seen in control Ringers solution. This effect is thought to result from the activation of the release mechanism by Ca^{++} which has been introduced directly into the nerve terminal (presumably due to an interaction between liposomes and the nerve terminal membrane). When liposomes containing $MgCl_2$ were applied to the preparations, no change in quantal content could be detected. These results suggest that when Mg^{++} is introduced directly into the nerve terminal cytoplasm, it is ineffective in antagonizing transmitter release. This study therefore supports the notion that the primary site of action of Mg^{++} is extracellular, presumably as a blocker of depolarization-induced Ca^{++} entry through the presynaptic membrane.

1646 MINIATURE ENDPLATE POTENTIALS DO NOT APPEAR TO BE COMPOSED OF SEVERAL SUBUNITS. Douglas C. Miller* and Karl L. Magleby. Dept. of Physiol. and Biophys., U. Miami Sch. Med., Miami, FL. 33101

It has been suggested that quanta of transmitter release, as represented by miniature endplate potentials (mepps), are made up of about 7 smaller subunits. Support for this hypothesis comes from the existence of a distinct class of small mepps usually about 1/7 the amplitude of the mean mepp amplitude, and from the presence in histograms of mepp amplitudes of multiple peaks, which often appear to occur at regular intervals (Kriebel et al. 1976 J. Physiol. 262:553; Wernig and Stirner 1977, Nature 269:820.

The autocorrelation function is a powerful test for regularly repeating events in sets of data. We have obtained the autocorrelations of histograms of mepp amplitudes from 27 cells and found no evidence for regularly recurring peaks, suggesting the absence of subunits. Mepps were recorded intracellulary from frog and mouse neuromuscular junctions; usually 2000-3000 mepps were recorded per cell. In data analyzed, resting potentials were usually stable within 2%, and mean mepp amplitude usually varied less than 5% throughout the course of the experiment. Since the autocorrelations of the mepp amplitude histograms indicated no evidence for a repeating pattern, the observed peaks in the histograms did not fall at regular intervals, as expected for the subunit hypothesis. We have previously suggested that random variation in the data could give rise to peaks on histograms (Miller et al. 1978, Nature 274:388).

To determine whether the autocorrelation technique could detect subunits we did correlations of histograms of simulated mepp amplitudes in which the mepps were composed of a mean of 7 subunits. Provided that the baseline noise did not exceed about ± 1/2 the mean subunit amplitude and that the standard deviation of the subunits did not exceed about 10% of the mean subunit amplitude, the autocorrelations of the simulated data clearly indicated the presence of regularly spaced peaks in the amplitude histograms. These results are consistent with these alternatives: 1) mepps are not composed of subunits; 2) mepps are composed of subunits but the standard deviation of the subunits is greater than about 10% of the mean subunit amplitude so they would not be detected by our method; 3) mepps are composed of subunits but the subunits are much smaller than previously proposed so they would be obscured by the noise in the recording system.

Simulated histograms constructed using the assumption that mepp amplitudes fall into a bimodal distribution, the small mode representing the class of small mepps and the larger mode representing the classical mepps, provided a good fit to experimental data. Supported by a Muscular Dystrophy Association fellowship to DCM and NIH grant NS10277 to KLM.

1647 MONOCLONAL ANTIBODIES TO THE NICOTINIC ACETYLCHOLINE RECEPTOR FROM RAT MUSCLE. Jeffrey Boone Miller* and Zach W. Hall. (SPON: M. Stryker). Department of Physiology, University of California, San Francisco, CA 94143
