We have used the hybridoma technique to prepare monoclonal antibodies to acetylcholine (ACh) receptor purified from denervated rat skeletal muscle. Both immunized rats and mice were used as sources of antibody-producing cells. BALB/c mice were immunized by two injections of either 0.5 μg ACh receptor in complete Freund's adjuvant or of 10-50 ng of receptor that was bound to cobrotoxin-Sepharose and treated with glutaraldehyde. Rats were immunized with four 1 μg injections of receptor over two months. In all cases, animals produced detectable serum antibodies to the ACh receptor. Spleen cells from immunized animals were fused with cells from a mouse myeloma line, NS-1, and cultured in a medium that selected for hybrids. Anti-ACh receptor antibodies that were secreted into the culture medium by the hybrid cells were detected with a solid phase radioimmune assay that required only 1 ng of muscle receptor as a target antigen.

Anti-receptor producing hybridomas were detected at a low frequency (less than 1% of the hybrid cells), and six hybridoma lines that secrete anti-receptor were isolated and have been continuously cultured. Of these, three are derived from mouse spleen/NS-1 hybrids and secrete IgM, while three are rat/mouse hybrids that secrete IgG. Antibodies from all six lines did not distinguish junctional and extra-junctional forms of the rat muscle receptor, and did not cross-react with purified, solubilized *Torpedo* receptor in the solid phase assay.

Tumors that grew from mouse hybrid cells injected into host mice produced anti-receptor antibody in the sera of host animals, but symptoms of experimental autoimmune myasthenia gravis were not observed.

1648 MECHANISM OF MAGNESIUM INHIBITION OF TRANSMITTER RELEASE: IMPLICATIONS IN DEPOLARIZATION-SECRETION (D-S) COUPLING. M.D. Miyamoto and R.A. Previti*. Dept. Pharmacol., E. Tenn. St. Univ. Col. Med., Johnson City, TN 37601 and Dept. Physiol. Biophys., Univ. Vermont Sch. Med., Burlington, VT 05401.

At frog motor nerve terminals, endplate potential (e.p.p.) size is related to $[Ca]^4$, suggesting a co-operativity, with competitive antagonism by Mg(Dodge & Rahamimoff, J. Physiol. 193: 419, 1967). Cooke et al. (J. Physiol. 228: 459, 1973) indicate that the role of Ca in D-S coupling can be described by two steps, Mg competing with Ca at both steps. The present results reveal further details of the actions of Mg and Ca in D-S coupling.

Miniature e.p.p. frequency (F) was continuously recorded from single endplates of frog cutaneous pectoris, during eight changes in [Mg] from 0.03 to 15 mM (Ca constant at 1.8 mM). Results from 5 to 10 of these experiments were normalized and pooled for $[K]_o$'s of 2.5, 5, 8, 11 and 14 mM. The family of curves of F vs. $[Mg]^o$ showed a transition from little effect at 2.5 mM K to a hyperbolic relationship at 14 mM K. Since a similar hyperbolic relationship is found for e.p.p.s. vs. [Mg] (Dodge & Rahamimoff, 1967), this indicates that the mechanisms for spontaneous and nerve-evoked transmitter release are equivalent.

Plots of F vs. Ca/(1+Ca+Mg/3) for each $[K]_o$ revealed a family of curves with parallel slopes at low Mg. However, with high Mg there was a reversal in curvature, indicating that high Mg could also increase F. Curve fitting was based on the assumption that 4th power co-operativity for Ca held for all levels of K depolarization (as indicated by the parallel slopes at low Mg for all levels of $[K]_o$). Improvement was made using a two stage model (Cooke et al., 1973), whereby Ca and Mg compete for a voltage-dependent (ν) Ca channel (binding but no co-operativity),as well as at the intracellular releasing site (possibly vesicular and/or active site membrane). Thus,

$$F = A\left[\frac{Ca}{1/\nu+Ca+Mg/3}\right]^4 + A\left[\frac{\beta Mg/9}{1/\nu+Ca+Mg/3}\right]^2$$

A,β=constants
ν=f(K^+),
$0 \leq \nu \leq 1$.

According to this model, 1) 4th power co-operativity may hold, at the releasing site, regardless of the extent of membrane depolarization (ν); 2) the 'inhibitory effect' of Mg may be attributed to competition at intra- and extracellular sites and need not invoke a charge screening mechanism (Muller & Finkelstein, PNAS 71: 923, 1974); and 3) the increased F with high Mg may be explained by either a Mg action at the release site or at the mitochondria to inhibit re-uptake of residual Ca. (Supported by USPHS NS 12270 & 15089).

1649 DEVELOPMENT OF SYNAPTIC SPECIALIZATIONS ON CULTURED, NON-INNERVATED, MUSCLE CELLS AT SITES OF CONTACT WITH THE CULTURE DISH. F. Moody-Corbett* and M.W. Cohen (SPON: R. Chase). Dept. Physiol., McGill Univ., Montreal, Quebec.

Cultured muscle cells derived from the myotomes of 1-day-old Xenopus embryos develop discrete patches of ACh receptors which can be readily visualized by labelling the receptors with fluorescent α-bungarotoxin. Many of the patches form on the bottom surface of the muscle cells, facing the collagen-coated surface of the culture dish (1,2). In the present study we have found that some 80% of these receptor patches are also sites of cholinesterase activity as revealed histochemically.

Another characteristic feature of the neuromuscular junction is the strong adhesiveness between the pre- and postsynaptic membranes. Interestingly many of the ACh receptor patches on the bottom surface of the cultured muscle cells appear to be located at sites of adhesion with the culture dish. When the cultures are treated with high concentrations of dibucaine (0.5-2.5 mM) the muscle cells round up but often remain attached to the culture dish in a region which contains one or more ACh receptor patches. Furthermore in cases where the muscle cells have a number of processes, those processes without receptor patches tend to withdraw whereas those with receptor patches tend to remain attached to the dish. That the regions which remain attached are relatively adhesive is further emphasized by the observation that subsequent agitation can tear the rounded cells away, leaving behind only small muscle fragments and associated ACh receptor patches.

These results taken together with those of previous studies (3,4) emphasize that several synaptic specializations can develop on cultured amphibian muscle cells in the absence of innervation. The finding that ACh receptor patches on non-innervated muscle cells are often located at sites of contact with the culture dish also raises the possibility that surface interactions may be important in triggering, and in acting as a locus for, the generation of synaptic specializations.

1650 EFFECT OF AN EXOPEPTIDASE INHIBITOR ON ACETYLCHOLINE RELEASE FROM MOUSE MOTOR NERVE TERMINALS. James R. Musick. Dept. Physiol., Sch. Med., University of Utah, Salt Lake City, UT 84108.

Acetylcholine (ACh) release at the neuromuscular junction is accompanied by release of other molecules that react in assays for proteins and their derivatives. The proteinaceous molecules may be released as a consequence of secretion of exo- and endopeptidase enzymes from motor nerve terminals (Musick, J.R., Am. J. Physiol: Cell Physiol. 236 (5), 1979). Since it may be possible to infer a functional role for this phenomenon by observing the effect of its inhibition, an amino acid derivative known to inhibit cathepsin C was applied to the phrenic nerve-mouse diaphragm preparation and the effect on spontaneous ACh release was determined by electrophysiological methods. Exposure of preparations to 1.5 mM L-trytophanamide (Try-NH_2), which was 2 x K_i for inhibition of cathepsin C, produced the following reversible effects on signals, intracellularly recorded from the endplate region of diaphragm muscle fibers: 1. A 20 mV depolarization of the muscle fiber resting membrane potential (RMP) (-80 to -60 mV). 2. A more slowly developing 50% drop in miniature endplate potential (MEPP) amplitude (2.0 to 1.0 mV), which was coincident with, 3. A 2.9-fold increase in the frequency of MEPPs (1.8 to 5.2 sec^{-1}).

The effects of the amino acid, L-Tryptophan (Try) were then compared to Try-NH_2 because the former compound is not known to inhibit cathepsin-C, but is a structural analogue of Try-NH_2. Try mimicked the effects of Try-NH_2 on the muscle cell RMP and MEPP amplitude but had an opposite effect on MEPP frequency. While Try-NH_2 increased MEPP frequency ca. 2-fold, the same concentration of Try (1.5 mM) reversibly reduced MEPP frequency by 26% (from 1.15 to 0.85 sec^{-1}). It is therefore concluded that the Try-NH_2-induced increase in MEPP frequency is due to its additional amide linkage. Hence, this effect may be due to inhibition of exopeptidase activity at the neuromuscular junction. These results suggest a regulatory function for the proteinaceous molecules released in association with ACh from motor nerve terminals. Assuming that some of these molecules are formed as a consequence of exopeptidase activity, inhibiting the production of a small protein derivative by Try-NH_2 could block feedback inhibition of spontaneous ACh release, and thus imply that these molecules normally regulate ACh release from motor nerve terminals.

1651 PROPERTIES OF SINGLE CHANNELS IN TISSUE CULTURED SKELETAL MUSCLE. D. J. Nelson* and F. Sachs* (SPON: B. Bishop). Dept. of Pharmacology, SUNY at Buffalo, Buffalo, NY 14214.

Using the technique of Neher et al. (Pflug. Arch. 375: 219, 1978) we have recorded the currents produced by single nicotinic channels in tissue cultured chick skeletal muscle cells. In myotubes, the single channel conductance, when activated by suberyldicholine in Hanks' solution, had a positive temperature coefficient, so that the conductance increased from approximately 50 pS at 17°C to 115 pS at 36°C. We saw no evidence of a levelling off of conductance with increasing temperature as reported by Fischbach and Lass (J. Physiol. 280: 527, 1978). The conductance values are consistent with the values obtained by noise analysis on normal and vinblastine treated cultures (Sachs and Lecar, Biophys. J. 17: 129, 1977; Nature 246: 214, 1973).

Histograms of the open channel durations were exponential implying a Poisson process of channel closing. The time constants with suberyldicholine activation were about 25 msec at 17°C and 6 msec at 36°C. The activation enthalpy, based on Arrhenius plots was about 10 kcal/mole. Confirming the results on frog endplate, different agonists appear to open the channels for different periods of time. However, the enthalpy of activation decreases with decreasing closing rate, implying a significant entropy increase between the open state and the transition state. (Supported by HL 21294, NS 13194 and the Muscular Dystrophy Association.)

1652 EFFECTS OF Ca^{++}, Ba^{++}, AND Sr^{++} ON THE KINETICS OF TRANSMITTER RELEASE AT THE FROG NEUROMUSCULAR JUNCTION UNDER CONDITIONS OF NORMAL QUANTAL CONTENT. Barry S. Pallotta and Karl L. Magleby. Dept. Physiol. & Biophysics, U. Miami Sch. Med., Miami, FL 33101.

Under conditions of low quantal content repetitive stimulation leads to an increase in the amount of transmitter released with each nerve impulse. Following repetitive stimulation, evoked transmitter release decays towards pre-stimulation levels with a multiexponential time course. Four individual components of the decay have been identified on the basis of time constants: two components of facilitation (time constants approximately 50 and 300 msec), augmentation (7 sec), and potentiation (tens of seconds to minutes). Under conditions of low quantal content the second component of facilitation and augmentation have been identified pharmacologically with Sr^{++} and Ba^{++}. Sr^{++} increases the magnitude and time constant of decay of the second component of facilitation, while Ba^{++} selectively increases the magnitude of augmentation. The purpose of our experiments was to determine whether facilitation, augmentation and potentiation can be observed under conditions of normal and increased quantal contents, and whether Sr^{++} and Ba^{++} still retain their selective effects under these conditions.

End-plate potentials (EPPs) were recorded extracellularly from the frog sartorius nerve-muscle preparation. Quantal content was changed by altering $[Ca^{++}]_o$, and curare was used as required to prevent contraction.

Using a variety of stimulation patterns, four components of the EPP amplitude decay were observed with time constants similar to those observed at low quantal content. For a train of 10 impulses at 10 Hz the time course of the change of EPP amplitudes during and following stimulation was similar in 0.3 mM Ca^{++} and 1.8 mM Ca^{++}. However, at 7.2 mM Ca^{++}, EPP amplitudes first increased, then decreased during the conditioning train. The depression of release then recovered with a 4-6 sec time constant. Although increasing $[Ca^{++}]_o$ greatly increased quantal content, the magnitudes and time constants of the two components of facilitation, after correcting for depression, were little affected over this 24-fold range of Ca^{++} concentrations.

The selective effects of Sr^{++}, although present, appeared to decrease with increasing quantal contents, while the magnitude of augmentation was still increased by Ba^{++}.

These results suggest that the processes which affect transmitter release at low quantal content are also present and have similar kinetic properties under conditions of higher quantal contents. The differential effects of Sr^{++} and Ba^{++} suggest that some of the underlying factors affecting these processes are different.

1653 TWO CLASSES OF ACETYLCHOLINE RECEPTORS ON CULTURED MUSCLE CELLS DISTINGUISHED BY DETERGENT EXTRACTION. J. Prives*, M. P. Daniels, F.M. Neal*, H-C Bauer*, S. Penman*, C.N. Christian*. (SPON: B.K. Schrier). NIH, Bethesda, MD 20205 and Dept. of Biology, M.I.T., Cambridge, MA 02139.

Cultures of embryonic myotubes were extracted with 0.5% Triton-X 100 under conditions that removed membrane lipids and soluble proteins. The intact myotube cytoskeleton remained attached to the substrate. Two populations of AChR, labelled with (^{125}I) α-bungarotoxin (α-btx) were distinguished by different rates of detergent extraction.

In newly formed muscle cells, AChR are diffusely distributed on the myotube surface, and totally extracted at a rapid rate by detergent (T 1/2 <1 min.). Further differentiation of cultured myotubes is marked by aggregation of surface AChR and the appearance of a subpopulation of AChR resistant to rapid detergent extraction. Quantitative fluorescence microscopy of rhodamine α-btx labelled muscle cells indicated that diffusely distributed AChR were rapidly extracted by detergent whereas a major proportion of AChR in aggregates was retained with the myotube cytoskeleton. Medium conditioned by the neuronal cells NG108-15 increased the number of AChR aggregates per myotube, and increased the proportion of AChR retained after brief detergent extraction.

These observations suggest that the decreased lateral mobility of AChR found in aggregates may be associated with the anchorage of AChR to the myotube cytoskeleton. In marked contrast, the freely mobile AChR which are diffusely distributed on the cell surface at the initial stages of postfusional differentiation, show no comparable anchorage.

We propose that anchorage of AChR to the muscle cytoskeleton underlies the spatial organization of AChR during development and innervation.

1654 CHANGES IN PROPERTIES OF THE ACETYLCHOLINE RECEPTOR DURING DEVELOPMENT OF RAT SKELETAL MUSCLE. C. Gary Reiness* and Zach W. Hall, Dept. of Physiology, UCSF, San Francisco CA 94143.

Acetylcholine receptors (AChRs) at the neuromuscular junction of adult skeletal muscles differ from the receptors that occur on the extrajunctional surface of embryonic muscle in having a faster metabolic turnover time, a higher density in the membrane and distinct immunological properties. High density clusters of AChRs appear at sites of neuromuscular contact in rat muscle by embryonic day 16 (ED 16) while the extrajunctional receptors (EJRs) initially present persist until after birth (ED 22) and disappear during the first two weeks postnatally (for review, see Fambrough, Physiol. Rev. 59, 165, 1979). As a first step in identifying the molecular changes in AChRs that underlie physiological changes, we have followed the changes in turnover time and immunological properties that occur during development.

AChR turnover was measured by following the loss of ^{125}I-α-bungarotoxin bound to AChR in situ. We compared by autoradiography the turnover of clustered AChR and EJR in embryonic diaphragm. At ED 17 AChR in clusters found at sites of acetylcholinesterase staining have a turnover rate that is close to that of EJR ($t_{\frac{1}{2}}$=32h v 24h), but by ED 20 turnover in the clusters is significantly slower. At birth the half-time of turnover of clustered receptors is nearly the same as for receptors in adult muscle, while the turnover time for EJR is unchanged.

The immunological properties of receptors in developing muscle were analyzed using a serum from a patient with myasthenia gravis that contained antibodies that recognize unique determinants on EJR (Weinberg and Hall, PNAS 76, 504, 1979). Under appropriate conditions the extent of reaction with this serum was directly proportional to the fraction of receptor in muscle extracts with the immunological properties of embryonic EJR. Analysis of both diaphragm and total carcass muscle showed that adult AChR was first detectable at postnatal day 5 (PD 5), and became an increasing fraction of the total receptor number over the next 10 d. Whether receptors with the immunological properties of adult AChR were present at earlier times could not be determined because of the large amount of EJR in the muscles.

We conclude that ACh receptors clustered at sites of neuromuscular contact in rat become stable at about the time of birth. The immunologically adult form of the receptor can first be detected at PD 5 but may be present earlier. (Supported by grants from NIH, the Muscular Dystrophy Association, and a fellowship to C.G.R. from the Muscular Dystrophy Association).

1655 MEMBRANE STRUCTURE AND PHYSIOLOGY OF AN IMMATURE SYNAPSE. Mary B. Rheuben and Ann E. Kammer. Dept. of Biology, The Pennsylvania State Univ., University Park, PA 16802 and Div. of Biology, Kansas State Univ., Manhattan, KS 66506.

During development of the flight muscles of the moth Manduca sexta, synapses are formed de novo on maturing fibers. In the last week of pupation, increasingly large junction potentials can be recorded. Intracellular recordings were made from fibers of the dorsal longitudinal muscles, each bundle of which is innervated by a single separate motor neuron, and measurements made of endplate potential amplitude and time course, and response to multiple stimulation. Samples were then removed and prepared for thin section, freeze-fracture, and scanning microscopy. Early in the last week, we record small, long duration synaptic potentials that fatigue readily. Junctions are characterized by having postsynaptic structures seen either as small patches of particles on the external leaflet in freeze-fracture or small areas of electron dense membrane opposite the nerve in thin section. The membrane of the nerve terminal is specialized into plaque-like areas similar to those in adult junctions but smaller; there are irregular clusters of large particles in the center of the plaques in the cytoplasmic leaflet. In thin section the plaque area is seen as a region where the nerve membrane parallels the postsynaptic membrane, and the cluster of particles is in the same location as the presynaptic dense body or active zone. There are a few scattered or clumped, large round particles that lie both within the postsynaptic patches and adjacent to them. They appear to correspond to desmosome-like structures in thin section. Like similar structures found in other developing synapses, they may function in attachment of nerve to muscle and glial cell to muscle during the initial stages of apposition. Glial cells have a large volume of cytoplasm above the nerve terminal; they are beginning to form the processes that penetrate the muscle and curve around the nerve extensively in the adult. There is a difference in the complexity of structure from one end of a junction to another, with the greatest development of postsynaptic and glial processes at the end first contacted by the nerve. Junctions formed by a particular motor neuron are relatively uniform in length and complexity. Differences are seen between the populations of muscle fibers innervated by different neurons. On the basis of anatomical and physiological evidence, the developing muscle fibers are electrically coupled. Further development consists of increase in size and quantity of the pre- and postsynaptic structures and glial specializations.

1656 ULTRASTRUCTURAL EVIDENCE OF MOTOR AXON RETRACTION DURING MATURATION OF RAT SOLEUS MUSCLES. Dan A. Riley. Dept. of Anatomy, U.C.S.F., San Francisco, California 94143.

Soleus muscle fibers of immature rats are polyneuronally innervated. Multiple motor axons converge upon the single endplate of each fiber. All but one of the multiple inputs per endplate are completely eliminated during the second postnatal week, generating the mature pattern of unineuronal innervation. My previous light microscopic studies of silver stained material indicated that terminal axonal branches are eliminated either by retracting from the endplate and absorption into the parent axon or by sloughing in situ and Schwann cell phagocytosis (Brain Res. 134: 279, 1977). In the present study, these mechanisms were examined further by electron microscopy of serial thin sections of soleus muscles from 7- to 15-day-old rats. The majority of the axonal profiles examined exhibited morphological features consistent with a scheme of retraction without marked degeneration. Axons interpreted as retracting were found between the neuromuscular junctions and the nearest intramuscular nerve bundles occupied by the parent axons of the transient terminal branches (a total distance of 20-40 μ). The retreating axon was characterized by a slender proximal shaft containing normally organized neurotubules and neurofilaments and terminating in a distal bulbous enlargement. The terminal swelling contained mostly closely packed 50 nm clear vesicles, a few dense core 100 nm vesicles (these are ubiquitous in developing axons), some larger irregular membranous sacs and mitochondria. The axoplasm of the bulb was generally electron lucent, except for flocculent material which probably represented depolymerized neurotubules and neurofilaments. Other than an occasional dense mitochondrion, there was a remarkable paucity of degenerating debris. Evidence of sloughed processes was sparse. Axons with fragmented plasma membranes and very densely clumped axoplasm and mitochondria were rarely (<1% of the nerve fibers) encountered in the nerve bundles. The identity of these profiles was not known, but some could have been skeletomotor because a vesicle-laden terminal swelling with dense axoplasm was found in a small nerve bundle. Despite extensive searching, dense degenerating boutons were never seen at the synapses. Sloughing apparently accounts for very little of the axonal loss. However, the real contribution of this mechanism may have been masked by a rapid rate of degeneration and removal of the not yet myelinated processes. The present results indicate that the majority of the transient terminal axonal branches retract rather than degenerate in situ.

1657 FURTHER ELECTROPHYSIOLOGICAL STUDIES OF NEUROMUSCULAR TRANSMISSION IN THE ANIMAL MODEL OF MYASTHENIA GRAVIS. Donald B. Sanders and Yong I. Kim* (SPON: R.N. Johnson). Dept. of Neurology, Univ. of Virginia Sch. of Med., Charlottesville, VA 22908

Neuromuscular transmission defects were examined in forelimb flexor digitorum longus (FDL) muscles from rats with experimental autoimmune myasthenia gravis (EAMG), produced by immunization with an initial subcutaneous injection of 50μg Torpedo acetylcholine receptor protein (AChRP) and a booster injection of 10 to 15 μg AChRP given two weeks or more before the experimentation.

Results show: (1) Miniature end-plate potential (MEPP) amplitude was reduced to 25 to 50% of control values; (2) The resting membrane potentials and MEPP frequency were unchanged; (3) End-plate potential (EPP) and MEPP amplitudes were reduced the same amount; (4) The waveform of indirectly elicited muscle action potentials (APs) was normal; (5) Curare sensitivity of EAMG muscles was markedly augmented as measured by twitch tension reduction; application of 4-aminopyridine restored the reduced twitch tension of curarized muscles; (6) The carbamylcholine-induced depolarization of EAMG end-plates was found to be significantly less than that seen at normal end-plates; (7) The mean number of ACh quanta released per nerve impulse in Mg^{++}-blocked preparations was not significantly different from control values.

These studies confirm that the major defect of neuromuscular transmission in EAMG results from postsynaptic abnormalities at the end-plates, presumably secondary to reduction in the number of functional ACh receptors, and support the concept that EAMG is primarily a postsynaptic disorder. EAMG in rats serves as a reasonable model of human myasthenia gravis in which a similar defect of neuromuscular transmission is present.

1658 AN ACETYLCHOLINE RECEPTOR AGGREGATION FACTOR IS RELEASED BY SYMPATHETIC AND SPINAL CORD NEURONS. A.E. Schaffner,* R.L. Schnaar,* Z. Vogel,* and M.P. Daniels. NHLBI, NIH, Bethesda, MD 20205

Neuromuscular synapse formation is characterized by a redistribution of acetylcholine receptors (AChR) which results in receptor localization at the postsynaptic region of the muscle plasma membrane. Recently it was reported that neuroblastoma x glioma hybrid cells which form synapses with cultured muscle cells release a factor which increases the number of AChR aggregates on cultured striated myotubes, independent of new receptor synthesis (1). We now have evidence for release of such a factor by neurons in primary cell cultures.

Coculture of rat superior cervical ganglion (SCG) cells for 4 days with rat myotubes resulted in a 5.8 fold increase in the number of AChR aggregates per myotube (A/M) over control cultures which contained myotubes alone. The A/M was determined by staining cultures with tetramethylrhodamine labeled α-bungarotoxin (TMR α-BT) and counting fluorescent patches and myotubes. Incubation of myotube cultures for 24 hrs with conditioned medium (CM) from SCG cultures grown in L-15 medium without bicarbonate and containing only neurons ("adrenergic condition") caused a 1.8-2.6 fold increase in A/M over cultures which received control medium. Four day incubation with this medium yielded a 2.9 fold increase. CM from SCG cultures grown in bicarbonate buffered medium, allowing growth of glial cells ("cholinergic conditions"), caused a 3.4 fold increase in A/M. However, CM from SCG glial cells cultured without neurons did not increase the A/M in myotube cultures. AChR on myotubes were stained with TMR α-BT before application of CM from "adrenergic" cultures. This resulted in a 2.1 fold increase in the A/M, indicating that the factor caused incorporation into aggregates of AChR already on the muscle cell surface. Receptor aggregation activity was not blocked when myotubes were exposed to 100 μg/ml cycloheximide; thus the factor was effective in the absence of protein synthesis. Six day chick embryo spinal cord cells were fractionated on a Metrizamide density gradient and 3 fractions maintained in culture. CM from a fraction with a high ratio of choline acetyltransferase to lactate dehydrogenase activity (CAT/LDH) caused a 2.4 fold increase in A/M while fractions with low CAT/LDH activity caused only a 1.3-1.5 fold increase.

Studies in progress may indicate whether release of an aggregation factor is limited to cell types which can form cholinergic synapses.

1659 A STUDY OF THE MOTOR NERVE ENDING AS A DRUG RECEPTOR FOR DIVALENT CATION AGONISTS-A RE-EVALUATION OF THE TRADITIONAL MASS ACTION APPROACH. E.M. Silinsky. Dept. Pharmacol.,Northwestern Univ. Med. Sch., Chicago, IL 60611.

Studies on the activation of depolarization-secretion coupling by divalent cations have generally relied upon the mathematical framework of Henri-Michaelis-Menten (HMM) enzyme kinetics.Such an interpretation assumes that the responses mediated by the activating cations (e.g. Ca^{++},Sr^{++}) are in accordance with the principle of mass action,whereby receptor occupation by the agonist provides a direct measure of the response. Recent results suggest however, that the binding site for Ca^{++} at the motor nerve ending behaves more in the fashion of a drug receptor (e.g. Silinsky, Brit. J. Pharm.63:485, 1978). Implicit in this pharmacological interpretation is that the full agonist, Ca^{++} may produce a maximal response with only a small percentage of the binding sites occupied and in turn leave 'spare receptors'. This study was undertaken to determine if spare Ca^{++} binding sites are present at motor nerve terminals.

Experiments were made on isolated frog cutaneous pectoris nerve-muscle preparations using conventional electrophysiological methods. Lanthanum (La^{+++}) in micromolar concentrations has been shown to antagonize irreversibly evoked transmitter release by obstructing Ca^{++} entry into nerve endings. Such an effect has been confirmed in this study. In addition, however, a small elevation in the extracellular Ca^{++} concentration in the presence of La^{+++} caused an immediate, forceful increase in evoked transmitter release. It can be demonstrated that this effect of Ca^{++} is not due to displacement of La^{+++} by Ca^{++} nor to the effect of Ca^{++} on events that follow entry of the ion into the nerve terminal. The simplest explanation appears to be that increasing the external Ca^{++} concentration surmounts the La^{+++} antagonism by 'mopping-up' spare external receptor sites for Ca^{++}. If this interpretation is correct then the following should hold: a) The partial agonist, Sr^{++} (which must occupy a large fraction of binding sites to support transmitter release), would be irreversibly antagonized by La^{+++} and an increase in the external Sr^{++} concentration should not restore transmitter release;b) Comparison of equal levels of transmitter release evoked in the presence of Ca^{++} and Sr^{++} should provide an affinity constant for Sr^{++} that is similar to the value determined for Sr^{++} as an antagonist of Ca^{++}-mediated release. The observed behaviour is in accord with these predictions.

These results suggest that spare receptors for Ca^{++} exist at frog motor nerve terminals and demonstrate that the mathematical approach of modern drug receptor theory is more appropriate than HMM kinetics when studying the agonist effects of divalent cations on transmitter release.

1660 DEVELOPMENT OF SKELETAL MUSCLE AND ACETYLCHOLINE SENSITIVITY IN THE ABSENCE OF INNERVATION. G. S. Sohal, R. K. Holt and Tony L. Creazzo*. Dept. Anat., Sch. Med., Medical College of Georgia, Augusta GA 30912.

An attempt to understand the role of nerve fibers on the development of skeletal muscle and on its acetylcholine sensitivity is being made by examining the superior oblique muscle of the duck embryo in which contact by the trochlear nerve is experimentally prevented. Trochlear nerve fibers normally reach the muscle on day 10 of incubation and the muscle at this time is primarily composed of myoblasts and a few myotubes. In order to destroy the trochlear nucleus dorsal midbrain lesions were made on day 7 of incubation by using electrocautery. The absence of the trochlear neurons and fibers was verified both from the histological serial sections of the midbrain and from silver-esterase preparations of the muscle. The control muscle on day 18 is composed of myotubes and myofibers and the motor endplates are morphologically identifiable with cholinesterase stain. Our limited observations based on a few samples of the aneurogenic muscle processed so far indicate that the overall muscle mass is greatly reduced as compared to the control on day 18. Muscle appears to be comprised of mainly myoblasts with a few myotubes. No cholinesterase deposits could be observed at this time. On day 24 the striated appearance of the muscle fibers at the light microscope level is apparent. Large deposits of cholinesterase mainly located in the belly of the muscle were also seen on this day. Ultrastructural localization of such deposits is being currently sought. The appearance, distribution and content of acetylcholine receptors in the anuerogenic muscle is currently being examined.

1661 A STUDY OF THE PRE- AND POSTSYNAPTIC REACTIONS OF A POTENT AGONIST OF THE NICOTINIC RECEPTOR. C. E. Spivak*[1], E. X. Albuquerque[1], R. S. Aronstam*[1], M. E. Eldefrawi*[1], and B. Witkop[2]. Dept. Pharmacol. & Exptl. Therap.,[1]Univ. MD, Sch. Med., Baltimore, MD 21201 & Lab. Chem.,[2] NIAMDD, NIH, Bethesda, MD 20205 .

(+)-Anatoxin (ATX), a stable toxin in the presence of junctional acetylcholinesterase (AChE), is a bicyclic tertiary amine having potent agonist activity as revealed by our initial electrophysiological studies. ATX was shown by biological assay on frog rectus abdominis muscle to be 10-fold more potent than carbamylcholine. Frog sartorius endplates rapidly depolarized to about −45 mV in 5 μM ATX. This was accompanied by the disappearance of miniature endplate potentials (mepp) and was followed by spontaneous repolarization that continued for 50 min at a rate of about 0.6 mV/min. Upon washing, mepps returned in about 20 minutes. ATX caused no alteration of the time course of the endplate current (epc), and at high concentrations, i.e., 1 μM, it depressed the peak amplitude of the epc without, however, changing the epc's voltage and time-dependent properties. At these concentrations, when 90% reduction in epc peak amplitude was recorded, there was no change in the equilibrium potential, which is similar to that of the natural agonist acetylcholine (ACh). Iontophoretically applied to the endplate region, ATX induced an inward current whose similarity to that of ACh disclosed that the single channel conductance and lifetime were unaltered. The two agents, ACh and ATX, applied to the same endplate region using a double-barreled micropipet disclosed, however, a slower onset and offset for ATX as compared to ACh, this effect being mostly related to the inability of AChE to hydrolyze ATX. Because of its depolarizing action, the toxin markedly decreased the amplitude of the miniature epcs while producing a marked presynaptic effect, increasing the rate of release by several fold during iontophoretic application of ATX. At similar concentations, ATX inhibited 90% of the binding of [^{3}H] ACh to the membrane bound ACh receptor isolated from the electric organ of the Torpedo ocellata. ATX reduced the rate as well as equilibrium binding of [^{125}I] α-bungarotoxin. ATX also blocked the binding of [^{3}H] 3-quinuclidinyl benzilate (50 pM) to muscarinic acetylcholine receptors from rat brain with an IC_{50} of 20 μM. In conclusion the reaction of ATX with the nicotinic receptor appears remarkably similar to that of ACh. Since ATX does not change the properties of the single channel, it is suggested that neither diffusion nor hydrolysis of transmitter plays a major role in the ultimate transmitter action. Thus, ATX promises to serve as a most important tool for the study of the nicotinic receptor. (Supported in part by USPHS Grant NS-12063.)

1662 ANTICHOLINERGIC EFFECT OF AMANTADINE IN MOTOR NERVE TERMINALS P.C.Su, M.D., W.D. Niemi, PhD* and A.D. Rosen, M.D. Division of Neurology, SUNY at Stony Brook, N.Y., Dept of Phisology, Columbia University, N.Y.

Amantadine is an effective antiparkinsonism agent especially for the symptom of tremor and rigidity. The mode of action has been suggested that Amantadine causes release of donamine (Grelak, et al, Science 169:203, 1970). Due to loss of dopaminergic neuron in parkinsonism such a mechanism probably plays little role. We have, hence studied the effect of Amantadine on cholinergic nerve terminals and our results indicate that Amantadine possess significant anticholinergic effects in motor nerve terminals.

We used in vitro mouse phrenic nerve-diaphragm preparations. Intracellular recording of membrane potentials (MP); endplate potentials (EPP) and minature endplate potentials (MEPP) were made by glass microelectrode filled with 3M Kcl. The EPP's were obtained by nerve stimulation in high megnesium Kreb's soloution or in glycerol treated muscles. At least 100 to 150 EPP's were recorded on FM tape along with 60 to 100 MEPP's in each muscle fiber. Off-line analysis using an IBM 360/44 was used. The analysis includes the quantal content, probability of release (p) and available store (n). The quantal content were determined by direct methods using the ratio of mean amplitude of EPP's and MEPP's after correlation of non-linear response of EPP. The p and n were determined assuming binominal distribution of quantal release and according to formula given by Johnson and Wernig (J. Physiol. 218:757, 1971).

Amantadine at 50 uM and 150uM concentration significantly reduce the amplitude of EPP and MEPP to 60% and 90% of control respectively. The muscle membrane potentials were depolarized from -78 mV to -58 mV at 150 uM concentration and the depolarization was not noticeable at 50 uM concentration. Quantal content evokes at 1 Hz showed a 50% to 60% reduction at 150uM and a 15% to 20% reduction at 50 uM. No change in the p and n were noted. The effect on quantal content has slow onset which usually takes 60 minutes, whereas the effect on amplitude of EPP and MEPP is rapid and complete within 10 minutes. The time course of reduction in quantal content is quite similar to muscle membrane depolarization. We susnect that reduction in quantal content might be caused by the depolarization of presynaptic nerve terminals.

Based on our findings and others (Nastuk, et al, Nature 264: 76, 1976), we propose that anticholinergic effect of Amantadine both presynaptically and postsynaptically accounts for its action in antiparkinsonism.

1663 BINDING OF ANTI-SYNAPTIC VESICLE ANTISERUM TO NERVE TERMINALS IN VERTEBRATE SKELETAL MUSCLE. Randall J. von Wedel, Joshua R. Sanes, Steven S. Carlson & Regis B. Kelly. Dept Biochem. Biophys. Univ. Calif. San Francisco, CA 94143

Antibodies directed to specific components of motor nerve terminals would be valuable molecular probes of presynaptic function, such as transmitter release, at the neuromuscular junction. Recent success in obtaining purified cholinergic synaptic vesicles from the electric organs of Narcine brasiliensis (Carlson et al., 1978) has enabled us to raise anti-synaptic vesicle antibodies in rabbits, and to demonstrate by indirect immunocytochemical techniques that antibodies in Rabbit Anti-Synaptic Vesicle Antiserum (RASVA) bind to nerve terminals in rat, chick and frog skeletal muscle. Cryostat sections were incubated with a mixture of RASVA and rhodamine-conjugated α-bungarotoxin (α-BTx) and then with a fluorescein-conjugated second antibody (goat anti-rabbit IgG). Appropriate filter combinations allowed us to excite and view fluorescein or rhodamine selectively and thus to compare the distribution of the immunohistochemical stain with that of α-BTx, which binds tightly and specifically to the acetylcholine receptors that are clustered in the postsynaptic membrane of the neuromuscular junction. Antiserum stained a variety of membranes, but most intensely stained were small patches on the muscle fiber surfaces, which could be identified as neuromuscular junctions because they also stained with rhodamine α-BTx. The RASVA-stained structures were identified as nerve terminals on the basis of their size, shape and position, and because they were absent from denervated muscle. After adsorption of RASVA with vesicle-free membranes from Narcine electric organ, nerve terminals stained intensely, but axons on the nerve or in intramuscular nerve branches did not stain well, nor did the cytoplasm of motor neuron somata. Thus, antiserum distinguishes terminal from preterminal portions of motor axons. It is particularly fortunate that antibodies in RASVA bind to nerve terminals in frog skeletal muscle, for it is in frog muscle that the best evidence has been obtained for the exocytosis hypothesis of transmitter release. This hypothesis predicts that antigens on vesicles should be hidden from antibodies applied to whole muscle, but exposed when vesicles fuse with the plasma membrane during stimulation.

1664 PRESYNAPTIC EFFECTS OF CHRONIC ADMINISTRATION OF NEOSTIGMINE ON NEUROMUSCULAR TRANSMISSION. David F. Wilson and Ted. W. Klein*. Dept. Zoology, Miami University, Oxford, OH 45056.

Previous investigations on rats have demonstrated presynaptic effects of neostigmine treatment using high dosages (1.0 mg/Kg/day) but the dosage dependency of this effect is uncertain. In the present study the presynaptic effects of daily treatment of rats with neostigmine at 0.88 mg/Kg/day for 7-10 days was compared with rats treated with 0.44 mg/Kg/day for 7-10 days, and control rats. Intracellular recording techniques were used to examine end-plate potentials (EPPs) and miniature end-plate potentials (MEPPs) in the rat diaphragm cut muscle preparation. Quantal release was determined by the direct method. The binomial parameters store and probability of release were examined. Neostigmine treatment with 0.88 mg/Kg/day reduced quantal release of the first EPP by 60%, the statistical store by 59% and the mobilization rate by 65%. The probability of release and facilitation properties of the nerve were not significantly affected. Neostigmine treatment with 0.44 mg/Kg/day did not significantly affect any of the presynaptic parameters. These results suggest that chronic treatment of Myasthenic patients with anticholinesterases normally does not lead to alterations in transmitter release unless high dosages are administered.

1665 IMMUNOHISTOCHEMICAL LOCALIZATION OF ACETYLCHOLINE RECEPTORS ON RAT MYOTUBE SURFACE WITH MONOCLONAL ANTIBODIES. Riley C. Yu, D.P. Richman* and C.M. Gomez*, Department of Neurology and Brain Research Institute, University of Chicago, Chicago, IL 60637.

Progress towards understanding neuromuscular conduction at the molecular level has been greatly aided by studies of binding properties of cholinergic ligands to membrane receptors using biochemical and morphological techniques. We have used anti-acetylcholine receptor (AChR) antibodies secreted by cloned hybridomas produced by fusion of a myeloma cell line with spleen cells from animals immunized with purified Torpedo AChR (Gomez, et al., Biochem. Biophys. Res. Com., 1979, in press). Dissociated cells from leg muscle of new-born Wistar rats were first preplated for myoblast enrichment before being seeded on collagen-coated coverslips and nourished with regular muscle culture medium. AChR appeared on the membrane surface as the myoblasts fused to multinucleated myotubes which manifested spontaneous contraction and cross-striations. Application of concentrated supernatant from one clonal hybridoma culture, followed by labeling with goat anti-rat IgG conjugated with fluorescein or with peroxidase resulted in stained patches only on the myotube surface. The background mononucleated cells showed no staining. These patches were thought to be indicative of specific AChR sites, because no staining was found in similar experiments with cultures preincubated with alpha bungarotoxin (α-Btx). When mature and fully developed, each myotube showed 2-3 ring-shaped patches of AChR staining located in the central portion of the myotube. On young myotubes, however, staining revealed numerous small, round patches, some of which were distally located on the myotubes. A similar staining pattern has also been observed with antibody from another hybridoma, but was not blocked by α-Btx. Antibody from two other hybridomas stained the myotube surface with a totally different pattern of numerous, scattered small spots. We are investigating further the identity of these surface receptors by providing neuronal input combined with electrophysiologic analysis in these myotube cultures. Antibodies from clones which showed negative results in our immunohistological experiment may still possess affinity to mammalian AChR which is not located on the membrane surface. This is suggested from an early observation (Gomez, et al., 1979, Fed. Proc. 38:1421) that one of these monoclonal antibodies produced experimental myasthenia when injected into animals intravenously. The specificity provided by monoclonal antibodies combined with the great sensitivity of immunohistochemical analysis in a tissue culture system has proved a valuable tool in our effort to understand the development and fine structure of AChR at the molecular level.

1666 A FURTHER EXAMINATION OF FACILITATION OF TRANSMITTER RELEASE AT THE FROG NEUROMUSCULAR JUNCTION. J. E. Zengel & K. L. Magleby. Dept. of Anat., Emory Univ., School of Med., Atlanta, GA 30322 and Dept. of Physiol. and Biophysics, Univ. of Miami, School of Med., Miami, FL 33101.

There are a number of differences in the literature concerning the kinetic properties of facilitation of transmitter release. Mallart & Martin (1967) and Magleby (1973) were able to approximate the increase in transmitter release during short trains of repetitive stimulation at the frog neuromuscular junction using a linear model of facilitation. Younkin (1974), on the other hand, developed a power facilitation model to describe transmitter release in the frog. More recently, Balnave & Gage (1977) were unable to describe data they obtained from the toad neuromuscular junction with a linear facilitation model, but used instead a two-step kinetic model. In all of these previous studies the data were analyzed without correcting for changes in transmitter release that might arise from augmentation and potentiation, two processes with time constants longer than facilitation that also act to increase transmitter release during and following repetitive stimulation. We have reexamined several models of facilitation, taking into account the effects of augmentation and potentiation.

End-plate potentials (EPP's) were recorded from the frog sartorius nerve-muscle preparation under conditions of low quantal content (0.4-0.6 mM Ca, 5 mM Mg). The nerve was conditioned with short trains of impulses (10-40 impulses at 10-100/sec), then tested with single impulses applied at varying intervals after the conditioning stimulation. The decay of the testing EPP amplitude was corrected for the contributions of augmentation and potentiation and estimates of facilitation were obtained assuming three models: a linear model, such that

$$F = F_1^* + F_2^*$$

where F is facilitation and F_1^* and F_2^* are the factors responsible for the first and second components of facilitation; a power model, such that

$$F = (F_1^* + F_2^* + 1)^q - 1.$$

where q is the power relating the factors responsible for facilitation to facilitation; and a multiplicative model, such that

$$F = (F_1^* + 1)(F_2^* + 1) - 1.$$

Both the power and multiplicative models of facilitation could describe the effect of repetitive stimulation on facilitation of transmitter release; the additive model consistently gave poorer fits to the data. Supported by NIH grant NS 10277.

NEURONAL CIRCUITS AND PATTERN GENERATION

1667 BIOGENIC AMINE ACTIONS ON LIMULUS CARDIAC GANGLION NEURONS. George Augustine, Raymond Fetterer and Winsor Watson III*. Depts. of Zoology, Univ. of Maryland, College Park, MD 20742, Michigan State Univ., E. Lansing, MI 48824, and Univ. of New Hampshire, Durham, NH 03824.

The Limulus cardiac ganglion is a small neural network which generates the rhythmic heartbeat of this animal. It is known that a variety of biogenic amines alter the activity of this ganglion, but the cellular basis of their effects is unknown. We have therefore examined the effects of several amines on the physiological properties of cardiac ganglion neurons. The Limulus cardiac ganglion is composed of 100-400 neurons of two functionally different types. Pacemaker cells are spontaneously active neurons which generate the heartbeat rhythm, and follower cells are motorneurons which are postsynaptic to the pacemakers and innervate the cardiac muscle. Standard intracellular electrophysiological techniques were used to monitor the membrane potential of these two types of neurons. Most experiments were performed on the follower cells, which are larger and consequently more readily examined with intracellular electrodes. Bath application of octopamine (OCT), dopamine (DA), epinepherine (EPI) or norepinepherine (NE) produced increases in the frequency of bursting activity of follower cells. OCT was the most effective, increasing burst frequency by 120% (± 14% S.E.M.) at a concentration of 10^{-7} M. The excitatory effects of all four amines was reduced by the α-adrenergic antagonist phentolamine (10^{-5} M). In addition to their excitatory effects, DA and NE produced a transient inhibition of burst rate. This transient inhibition was blocked by the serotonin antagonist metergoline (10^{-5} M). Changes in follower cell burst frequency were a consequence of corresponding changes in pacemaker cell activity. Recordings from pacemaker neurons during amine treatment showed that the frequency of spontaneous action potentials increased, accompanied by a small (less than 5 mV) depolarization of membrane potential. A transient decrease in pacemaker action potential rate was observed with DA or NE perfusion. In addition to their effects on pacemaker cells, these amines also directly influence follower cell activity. DA and NE produced transient hyperpolarizations of follower cell membrane potential (up to 20 mV at 10^{-6} M), and OCT depolarized these cells (less than 10 mV at 10^{-6} M). These effects are not due to alterations in the synaptic input on to these cells, for they occurred in preparations where synaptic activity was blocked by addition of Co^{++} or Mg^{++}, or removal of Ca^{++}. Thus these biogenic amines are active on both types of neurons which comprise the Limulus cardiac ganglion.

1668 SUPPRESSION OF THE ACTIVITY OF SECONDARY IMPULSE INITIATION SITES BY THE ACTIVITY OF A PRIMARY INITIATION SITE IN RHYTHMICALLY ACTIVE NEURONS. Ronald L. Calabrese. Dept. of Biology, Harvard University, Cambridge, MA 02138.

The heart interneurons of the leech ventral nerve cord are normally active in rhythmic impulse bursts. Recent experiments indicate that this impulse burst rhythm is endogenous in origin (Calabrese, 1979, J. Exp. Biol., in press). The majority of the heart interneurons possesses impulse initiation sites in each segmental ganglion through which their respective axons pass and each of these initiation sites is capable of producing rhythmic impulse bursts endogenously. At any given time however, only one of an interneuron's initiation sites is rhythmically active, the others are apparently suppressed. The active initiation site is usually the one in the ganglion where the interneuron's cell body is located (Primary Initiation Site) and the activity of the other sites (Secondary Initiation Sites) is expressed only if the axon of the interneuron is severed or the primary site's activity is suppressed by injected hyperpolarizing current.

Experiments were performed to determine how the Primary Site suppresses the activity of the others. Two consistent observations emerged:

a) The free run period of the Primary Initiation Site's rhythmic activity is smaller than that of the Secondary Initiation Sites.

b) Intercalated impulse bursts from the Primary Initiation Site resets the rhythm of the Secondary Initiation Sites by phase delaying their next impulse burst.

From these observations the hypothesis was developed that suppression is accomplished through cycle by cycle reseting of the Secondary Initiation Sites impulse burst rhythm by the faster rhythm of the Primary Initiation Site. This hypothesis was tested directly by intercalating regular trains of impulse bursts from the Primary Initiation Site into the Secondary Initiation Sites' impulse burst rhythm. If the period of the intercalated bursts was greater than the free run period of the Secondary Initiation Sites suppression was not accomplished but if it were smaller then suppression was complete.

1669 NONLINEAR ANALYSIS REVEALS CRITERIA FOR INTRINSIC OSCILLATIONS IN "BURSTING"NEURONS. N. T. Carnevale, Dep't. Neurol., Scho. Med., SUNY, Stony Brook, N.Y. 11794.

Certain features are common among neurons which display an intrinsic slow oscillation of membrane potential: a steady-state inward current associated with a negative slope conductance (NRC), and a depolarization-induced slow outward current (Sci 186:932 (74)). However, the exact circumstances under which oscillations will arise have remained unclear; for example, not all cells with an NRC oscillate, and some question has arisen whether an NRC is even a prerequisite for oscillations. (Br.Res. 94:161 (75), Neuro-Sci.Abstr. #565 (78)). Detailed models of oscillating neurons, while elegant, are cumbersome and have tended to obscure critical features of the interaction between these membrane current components. To delineate the conditions which must be met in order for oscillations to occur, and to determine the factors which underlie distinguishing characteristics of the oscillations, a model which incorporates the slow outward and NRC-associated inward current was studied.

This model led to a set of non-linear differential equations which describe a phase space in which changes of the state of the model are analogous to movement along paths (trajectories) of "rapid" or "slow" motion (Andronow et al., Theory of Oscillators, p. 660 (Pergamon, 1966)). Piecewise linear analysis of these equations, confirmed by analog computer simulation, demonstrated several points clearly, including the following: 1, the oscillation requires an NRC, which must persist throughout the accelerating portion of the depolarizing phase of the oscillation; 2, increased leak conductance can abolish the oscillation; 3, the inward and outward currents remain partially activated throughout the oscillatory cycle; 4, a too rapidly activating outward current can prevent oscillations; 5, the reversal potential of the slow outward current must be hyperpolarized relative to the NRC region, or else inactivation of the inward current must play a dominant role in the repolarizing phase of the oscillation. This model also nicely illustrated the mechanism by which polarizing currents influence the frequency and amplitude of the oscillation. The conclusions drawn from the piecewise linear analysis serve as the basis for quantitative criteria for the prediction of oscillations in the more general non-linear model and in the real cell.

1670 A SIMPLE VERTEBRATE LOCOMOTOR MODEL: "FICTIVE SWIMMING" IN THE IN VITRO LAMPREY SPINAL CORD. A.H. Cohen and P. Wallén.* Dept. of Physiol. III, Karolinska Institute, 114 33 Stockholm, Sweden.

Little is known of the cellular organization of vertebrate central pattern generators (CPG's). Swimming in fish is a complex motor behavior which is produced by CPG's in the spinal cord (Grillner et al., Brain Res., 109:255-269, 1976). The undulatory body movements of fish result from a specific activation pattern consisting of a strict alternation between the two sides of a single segment and a constant phase coupling between successive segments (Grillner, Exp. Brain Res., 20:459-470, 1974).

To investigate the spinal pattern generator for locomotion in detail, we have used an in vitro preparation consisting of the isolated spinal cord of Icthyomyzon unicuspis. 50-60 segments were dissected out along with the notochord and surrounding membranes. The tissue was maintained in cooled aerated lamprey Ringers (pH = 7.4). Curare was added to prevent the small amplitude movements sometimes produced by the residual muscle tissue. Low concentrations of D-glutamate or L-DOPA were used to induce swimming movements, following the technique of Poon in the lamprey "myotome" preparation (submitted and cf. Teräväinen and Rovainen, J. Neurophysiol., 34:990-998, 1971). The ventral root (VR) discharges were monitored with suction electrodes in the conventional manner.

In the presence of D-glutamate and curare the isolated cords were capable of generating efferent activity having all the characteristics of normal swimming. 1) There was strict alternation between two roots of a single segment. 2) The duration of a burst of a VR increased linearly with the cycle duration, as is the case in intact fish. 3) The latency between bursts in successive roots increased linearly with cycle duration, i.e. there was constant phase coupling between the segments. To date, a piece of cord consisting of as few as 6 segments could produce this pattern, although such reduced pieces may be unstable.

The fibers ensuring the phase coupling were found to be highly distributed, as aspects of the coordination were preserved even after extensive transverse lesions including 80% of the cord width. The location of the lesion had effects on the coupling, but no region was found to be essential. Microstimulation of many different regions could affect the structure of the cycle. In addition, the alternation between the roots of a single segment was not disrupted by longitudinal lesion of 1-4 segments in the midline region.

This is the first preparation in which a complete locomotor pattern has been produced by a portion of an isolated vertebrate central nervous system maintained under in vitro conditions. Moreover, the efferent pattern can be highly stable and show all the essential features of the normal pattern.

1671 DRIVER POTENTIALS ISOLATED IN CRUSTACEAN CARDIAC GANGLION CELLS BY LIGATURING. I. M. Cooke* and K. Tazaki* (SPON: J. E. Bardach). Békésy Lab. of Neurobiology, U. of Hawaii, Honolulu, HI 96822.

Crab (Portunus sanguinolentus) cardiac ganglion neurons exhibit 20 mV, 200 msec, TTX-resistant, Ca-dependent, depolarizing responses to depolarizing pulses (J. Neurophysiol., in press). We now report these 'driver potentials' (DPs) in another crab, Thalamita crenata, and in the lobsters, Panulirus penicillatus and Homarus americanus. Ligaturing experiments provide evidence that DPs are intrinsic responses and arise at a site near the soma separate from the site for impulse initiation, which is a distance of 1 mm or more along the initial axon segment. In Homarus, a ligature was placed between the anterior bifurcation and one of the most anterior cells (1 or 2); extracellular electrodes were positioned on each side of the tie, and intracellular electrodes recorded from the anterior cell and the cell at the bifurcation (Cell 3). All electrodes remained in place while the ligature was tightened. All impulse activity ceased anterior to the ligature while uninterrupted bursting activity continued posterior to it. Current-passing confirmed interruption of the electrotonic connection between Cell 3 and the anterior cell. Depolarizing current passed into the anterior cell elicited a DP, but no impulses. TTX caused no change in amplitude and a slight increase in duration of the mechanically isolated DP. In Portunus, intra- and extracellular electrodes were maintained in place while tightening a ligature midway between the anterior and posterior large cell groups. Posterior to the tie, small cell bursting remained; corresponding synaptic responses and slow depolarization, recorded in a large cell, occasionally led to DPs, but there were no posterior large cell impulses. Electrotonic pathways between anterior and posterior cells were blocked, but not those among anterior cells. Anterior to the ligature, all small cell activity ceased, while large cells showed spontaneous pacemaker potentials leading to 'escape' firing or to DPs driving impulse bursts. Depolarizing pulses elicited DPs with bursts. These observations provide evidence that DPs: 1) probably are a property of most crustacean cardiac ganglia; they may correspond to 'plateau potentials' observed in decapod stomatogastric ganglia; 2) represent an intrinsic response of individual neurons and are not dependent on neuronal interaction; 3) are generated in or between the soma and the impulse initiation zone; 4) can occur independently of impulse initiation mechanisms; 5) are not greatly distorted by the presence of $3X10^{-7}$M TTX, thus supporting the extension of TTX observations to normal functioning.

1672 DETECTION OF RECURRING PATTERNS IN SPIKE TRAINS. Judith Dayhoff and George Gerstein. Dept. Physiology, University of Pennsylvania, Philadelphia, Pa. 19104

Repeating patterns in nerve spike trains could be important for information transfer in the nervous system. Patterns could be generated in response to internal stimuli occurring at times unknown to the experimenter. Thus, it is appropriate to search for patterns of firing which occur frequently but at unspecified times in the spike train. Such patterns might not be seen with an autocorrelogram or with other traditional spike train methods. We have developed a new pattern detection method based on comparing a series of template patterns to the spike train. This method differs from our previously presented method (Dayhoff and Gerstein, Neurosci. Abst. 4: 380(1978)) because it is able to detect frequently occurring spike patterns which are approximately the same each time they occur but can have extra spikes superimposed on the pattern. These extra spikes could be due to background noise or a variation in the pattern.

Our new pattern detection method tests whether a temporal pattern occurs more frequently than expected in a random model. The random model used is a shuffled version of the data spike train. The patterns detected consist of an arbitrary number of spikes. The computer program does not require a priori specification of a template pattern; it chooses a series of several hundred templates from the spike train, and tests to see if each occurs more than expected at random. The test is achieved by comparing each template pattern to every place in the data spike train and to every place in a number of shuffled versions of the spike train. In each comparison, extra spikes in the template or in the spike train are ignored. Those patterns which match the data spike train considerably more often than they match the shuffled spike trains are identified as patterns which occur unusually often in the data.

Results of analysis of both simulated and experimental data will be presented. Simulated spike trains containing known patterns were analyzed in order to assess the pattern detection sensitivity of the method. The experimental data analyzed consists of crayfish and cat spike trains.

1673 MODEL CIRCUIT FOR THE CONTROL OF MOTOR NEURON ACTIVITY PATTERNS IN DROSOPHILA FLIGHT. W. O. Friesen and R. J. Wyman. Dept. Biol., Univ. of Virginia, Charlottesville, VA 22901 and Dept. Biol., Yale Univ., New Haven, CT 06520.

Each fiber of the fibrillar flight muscles of Drosophila melanogaster is innervated by a single motor neuron. Recordings from individual muscle fibers have revealed that motor neurons innervating different fibers of a single muscle fire cyclically, with each motor neuron firing once per cycle. Of the six possible firing sequences for the four motor neurons innervating the ventral fibers of the DLM (units c, d, e and f) two, c-e-d-f and c-f-d-e, are preferred. Subsequent to antidromic stimulation of one motor neuron, firing in the others is inhibited for tens of milliseconds and the phase of the activity cycle is shifted. To account for these results Harcombe and Wyman (J. Neurophysiol. 40:1066-1077, 1977) proposed that the motor neurons innervating the DLM form an inhibitory circuit in which each neuron inhibits each of the others and that this mutual inhibition is greatest between c-d and between e-f.

To determine whether this circiut can account for motor neuron firing patterns observed during Drosophila flight, we have constructed an equivalent circuit with electronic neural analogs (neuromimes). These neuromimes were designed by Lewis (Proc. Inst. Elect. Engrs. 56:931-949, 1968) and have been employed in previous modeling studies of neural networks (Friesen and Stent, Biol. Cybernetics 28:27-40, 1977). The Lewis neuromimes mimic the Hodgkin-Huxley parameters describing large-scale voltage fluctuations at the neural impulse initiating zone and can model both excitatory and inhibitory synaptic interactions. We provided four neuromimes with common excitatory input and adjusted thresholds so that each had a 6 Hz free-running impulse frequency. We then connected each neuromime to each of the other three by way of their inhibitory inputs, setting synaptic time constants to 30ms and synaptic amplitudes such that inhibition between those neuromimes modeling motor neuron pairs c-d and e-f was twice that of the other connections, since quantitative physiological data for these parameters is lacking.

This neuromime network produced cyclic activity patterns closely resembling those observed in Drosophila flight muscles, confirming the prediction that a mutually inhibitory circuit can account for the physiological firing patterns. The preferred motor neuron fixing sequences observed in Drosophila were also the sequences most frequently observed in modeling experiments. Finally, by producing additional impulses in individual neuromimes, the phase of the neuromime activity pattern was shifted as during physiological experiments.
Supported by NIH research grant 14965.

1674 THE PRIMARY ACOUSTIC STARTLE CIRCUIT IN THE RAT. D. S. Gendelman* and M. Davis. Dept. of Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06508

The latency of the acoustic startle reflex in the rat is 6-7 msec., measured from tone onset to the beginning of the electromyographic response in the forepaw (Ison et al., Physiol. Behav., 1973, 10, 1035-1039). This extremely short latency indicates that only a few synapses could be involved in the primary acoustic startle circuit. Acoustic startle is being used as a model system for studying habituation, sensitization, pre-pulse inhibition, classical conditioning, fear or anxiety, and drug effects on behavior. Hence, the delineation of the exact acoustic startle circuit would provide critical information for further study in all of these areas.

Because of this, we have investigated the possible neural connections between the cochlear n., which receives the primary afferent input, and the reticulo-spinal tract, which most probably represents the final motor pathway of startle. Unilateral, single pulse electrical stimulation of specific ventral points within the nucleus reticularis pontis caudalis, the cell bodies which form the reticulo-spinal tract, elicit short latency, startle-like responses in unanesthetized rats. Bilateral lesions of these points abolish acoustically elicited startle responses. Reaction product from horseradish peroxidase iontophoresed into these points is found in the nuclei of the lateral lemniscus, which are known to be innervated by the cochlear nuclei. Unilateral, single-pulse stimulation of the nuclei of the lateral lemniscus elicit short latency startle-like responses. Bilateral lesions of these nuclei attenuate or abolish acoustically elicited startle. Latencies of electrically elicited startle become shorter as electrodes are placed progressively further down the circuit.

Simultaneous presentation of electric and acoustic stimuli elicit startle amplitudes greater than the sum of each presented alone. Temporal interactions between acoustic and electrical stimuli occur when one follows the other in time.

The data suggest that the primary acoustic startle circuit in the rat is: auditory nerve, cochlear nucleus, nuclei of the lateral lemniscus, nucleus reticularis pontis caudalis, spinal interneuron, lower motor neuron, muscles. Hence five synapses, plus the neuromuscular junction, are probably involved.

1675 NEURONAL BASIS OF THE SWIMMING RHYTHM IN TRITONIA.
Peter A. Getting, Paul R. Lennard and Richard I. Hume.
Department of Biological Sciences, Stanford University, Stanford, CA. 94305

The swimming rhythm of the marine mollusc, Tritonia diomedea, is a series of 2-20 cycles of alternating dorsal and ventral flexions. The central pattern generating network mediating swimming consists of at least three populations of cerebral premotor interneurons designated C2, dorsal swim interneurons (DSI), and ventral swim interneurons (VSI). The temporal firing pattern of these interneurons during a swim sequence was analyzed to elucidate neuronal mechanism involved in the initiation, maintenance, and termination of the swim pattern. Over the time course of a swim sequence, cycle period progressively increases. For a given preparation, oscillation terminates when the cycle period attains a maximal duration independent of the number of preceding cycles. Each swim cycle may be subdivided into three segments by the firing times of the three interneuron populations. Variation in the initial segment of each cycle accounts for 80 percent of the total increase in cycle period. The latter two segments remain relatively constant independent of cycle period. Cyclic bursting within the swim network is superimposed on a large average depolarization (10-15 millivolts) which slowly dissipates over the course of a swim sequence. Oscillation rate appears to be directly proportional to the level of tonic network excitation (e.g. cycle period decreases as tonic excitation increases).

Swim network oscillation is initiated by a tonic depolarization established by a transient sensory stimulus. Pattern generation is maintained as long as phasic positive feedback between C2 and the DSI is established during the initial and middle segments of each swim cycle. Positive feedback between C2 and DSI is required for maintenance of oscillation but is not required for the initiation of a swim sequence. During a swim sequence, dissipation of the tonic depolarization level decreases the likelihood of the positive feedback. Oscillation terminates when the tonic network excitation falls sufficiently to prevent C2/DSI positive feedback. A swim sequence ends on a weak dorsal swim interneuron burst corresponding to the last dorsal flexion of the behavior.

1676 RHYTHMICALLY OCCURRING SYNAPTIC POTENTIALS IN TRIGEMINAL MOTONEURONS EVOKED BY REPETITIVE CORTICAL STIMULATION
L.J. Goldberg and M. Tal,* Sch. Dent. & Dept. Anat., Sch. Md. UCLA, L.A., CA 90024.

Chewing, lapping and suckling are motor behaviors which have a strong rhythmic component. The guinea pig is used in this study as an animal model for the investigation of central nervous system pattern generators which may be responsible for the production of these rhythmically occurring jaw movements.

A single shock or short train of shocks delivered to the motor face area of the cortex of ketamine anesthetized guinea pigs evokes a brief jaw opening response. Intracellular recording in trigeminal motoneurons innervating the jaw opener and closer muscles reveals that the stimulus evokes membrane depolarization and spikes in jaw opener, and a reciprocal hyperpolarization in jaw closer motoneurons. The latency from the cortical stimulus to the onset of the response is ≈ 10 msec and the duration ≈ 30 msec. The hyperpolarization in jaw closer motoneurons changes to a depolarizing potential with the injection of Cl^- and can be reversed by hyperpolarization of the membrane with current passed through the recording microelectrode. These results indicate that the hyperpolarization is postsynaptic. When the stimulus intensity is reduced to well below threshold to evoke a response to a single shock, continuous stimulation at frequencies of between 20 and 40 hz produces the following: the initial stimuli of the train do not evoke a response in the motoneurons; after a variable period of time, each succeeding stimulus gradually becomes more effective until a maximum level of response is reached. This is accompanied by a sustained jaw opening since each stimulus is producing depolarization and spikes in opener motoneurons and a simultaneous hyperpolarizing potential in closer motoneurons. In most instances a rhythmic pattern is then initiated; each successive stimulus becomes gradually less effective, the opener motoneuron spiking ceases, the hyperpolarization in the closer motoneurons diminishes, and the jaw returns to the original rest position. Stimulus effectiveness then cyclically waxes and wanes and rhythmic (≈ 2 hz) opening and closing of the jaw is produced. Cortical stimulation with the animal paralyzed evokes a similar pattern of synaptic response. The results suggest that, 1) a facilitatory mechanism is activated by the high frequency cortical stimulation which greatly increases the effectiveness of the motor cortex-trigeminal motoneuron pathway and, 2) a centrally mediated oscillation can be activated which rhythmically gates this facilitation of the pathway. These central mechanisms result in rhythmic jaw movements similar in basic form to those observed in chewing or lapping behavior.

1677 ORGANIZATION AND GENERATION OF MOTORNEURON BURSTS DURING TRITONIA SWIMMING.
Richard I. Hume and Peter A. Getting. Dept. Biol. Sci., Stanford University, Stanford, CA 94305.

Escape swimming in Tritonia diomedea is characterized by alternating bursts of activity in two populations of antagonistic motorneurons, the Dorsal Flexion Neurons (DFN) and the Ventral Flexion Neurons (VFN). The basic swim pattern is generated by an identified network of premotor interneurons. Here we report on the temporal organization of the firing pattern in the flexion neuron pools, and on the synaptic interactions between the premotor interneurons and identified flexion neurons.

The VFN pool is relatively homogeneous. Swim bursts in VFNs are 1.5-3 seconds in duration and begin at virtually the same time in all VFNs. The DFN pool is made up of two major subpopulations. The DFN-A bursts are of long duration (3-5 seconds), have two frequency peaks per burst, and increase in duration as the swim cycle period increases. The DFN-A burst begins at a constant latency after the onset of firing in the VFNs. In contrast, DFN-B bursts are of shorter duration (2-3.5 seconds), have a single frequency peak, and do not increase in duration as cycle time increases. The latency from the beginning of a VFN burst to the onset of a DFN-B burst increases as cycle time increases, such that DFN-B bursts occur at nearly a constant phase in every cycle. Recordings from whole animal preparations indicate that cells in the DFN-B pool are responsible for generating most of the dorsal flexion movement.

Simultaneous intracellular recordings were made from identified pattern generator interneurons (C2, DSI, VSI) and identified flexion neurons in a search for monosynaptic connections. Monosynapticity was judged by 1) postsynaptic potential (PSP) at constant latency following a presynaptic spike 2) ability to affect postsynaptic potential by presynaptic polarization and 3) maintenance of postsynaptic potential in 2 1/2 times normal Ca, Mg sea water. By these criteria all three classes of interneurons make monosynaptic connections onto most flexion neurons. Some of the monosynaptic events are discrete EPSPs or IPSPs with a rise time of ≈ 50 msec, but many of the monosynaptic PSPs are very slow, with a rise time of greater than 500 msec. Many flexion neurons receive dual component PSPs from the DSI and/or the C2. The synaptic connections from the interneurons to the two classes of DFNs are distinctly different. As an example, C2 excites DFN-A cells but inhibits DFN-B cells. No monosynaptic connections were observed from flexion neurons to interneurons, nor among flexion neurons. The identified monosynaptic connections from C2, DSI, and VSI appear to be sufficient to account for much of the temporal organization of flexion neuron activity during a swim.

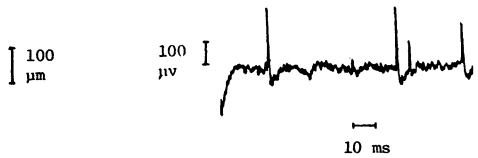
1678 

PARALLEL RECORDING OF SINGLE UNIT ACTIVITY IN VIVO.
Michael Kuperstein* and Douglas Whittington* (SPON: H. T. Hermann). Dept. Psychol., M.I.T., Cambridge, MA 02139.

We have developed a high-density fixed-array multimicroelectrode for monitoring extracellular neural activity in vivo. The PRONG (Parallel Recording of Neural Groups) can be used to simultaneously record from neighboring neurons along any 2 mm extent of brain tissue that is accessible within 7 mm of the surface. It is fabricated using microelectronic technology and consists of a linear array of recording sites fixed on a hair thin substrate (20 μm thick, 2 mm long). In the prototype, an electrochemically etched molybdenum substrate supports gold leads insulated with photoresist. The leads start at contact pads at the top of the PRONG and end in a wedge-shaped area containing an array of 20 recording sites (100 μm spacing) at the bottom tip of the PRONG. The shunt capacitance is about 3 pf. The area of the exposed recording sites can be varied during fabrication from 40 to 120 μm^2, and each site is plated with platinum black. For implantation, the PRONG is supported by a connector fixed to a microdrive. The connector springloads each of the contact pads of the PRONG with thin beryllium copper wire.

The PRONG has been used to record single units in cat visual cortex with 250 μv amplitude spikes with a signal to noise ratio of 10:1.

New versions of the PRONG with more recording sites and a thinner active area are under construction.
(Research supported by NIH grants 5 R01 EY00676 and 1 T31 GM07484.)



1679 DIAMETRIC PATTERN ENSEMBLES IN NEURONAL INTERSPIKE INTERVALS DURING SEVERAL BEHAVIORAL STATES IN THE CAT. T.J. Marczynski and L.L. Burns* (SPON: L. Isaac). Dept. Med. Pharmacology, Univ. of Ill. Med. Center, Chicago, Ill. 60612.

The activity of single cells was recorded chronically in awake freely moving animals from the centromedian-parafascicular (CM-Pf) area of the cat thalamus using fine wire semimicroelectrode bundles. Neuronal spike trains were analyzed by a pattern detection technique which made inequality statements about consecutive interspike intervals; an interval was either longer (+) or shorter (-) than the previous interval. Thus a consecutive series of (+) and (-) signs was generated which corresponded to the interval lengths of the neuronal spike train. A movable window of variable size then moved through the spike train one sign at a time tabulating occurrences of patterns 3 through 6 signs in length. The number of occurrences of each pattern encountered was compared to the expected occurrence calculated from a theoretical model which assumes independence (Brudno and Marczynski Brain Res. 125: 65, 1977). Chi-squared tests of significance were used for all comparisons. Patterns which were emitted more often than predicted by the theoretical model and those which were suppressed, i.e. appeared significantly less often than predicted, were both seen in the data and often constituted an ensemble, or idiosyncratic profile of patterns for a particular behavioral state.

Many neurons were found which, in paired sets of data, showed diametric tendencies; patterns emitted in one behavioral state were significantly suppressed in another and vice versa. Several neurons showed this type of behavior during slow wave sleep (SWS) and quiet wakefulness; other neurons were diametric during SWS and paradoxical sleep. Still other neurons were diametric during various phases of motor behavior. Some of the patterns in an ensemble did not show diametric changes; in many cases only a few patterns would reverse. In many instances diametric shifts would occur without changes in the mean firing rate.

The results suggest that neurons may increase the signal-to-noise ratio in certain pathways by actively suppressing certain temporal patterns below their chance occurrences. Even a small diametric shift in these patterns would constitute a highly significant signal against an otherwise noisy backround. The observed neuronal behavior is comparable to an anacoluthon, a change in syntax to achieve rhetorical effect, hence we propose to term this neuronal behavior anacoluthic.

1680 DIRECT PROJECTION OF PAUSER NEURONS TO NYSTAGMUS-RELATED PONTOMEDULLARY RETICULAR BURST NEURONS. Charles H. Markham, Shozo Nakao* and Ian S. Curthoys*. Dept. Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

Pauser neurons (PNs) which exhibit a tonic discharge ceasing prior to and during saccades, have been suggested to be important in the control of saccadic eye movements. The present study aims to demonstrate the role of PNs in vestibular nystagmus and to provide evidence that they project to and produce inhibitory effects in a class of reticular burst neurons which inhibit contralateral abducens motoneurons at the quick phase (BINs) (Hikosaka et al. Exp. Brain Res. 33:337-352, 1978).

Extracellular spike discharges of single PNs were recorded in the raphé nucleus near the rostral pole of the abducens nucleus during nystagmus in alert cats rendered pain-free by extensive local anesthesia. Abrupt cessation of PN tonic discharges during the slow phase was coincident with the onset of the negative field potential in the ipsilateral BIN area which preceded BIN burst activity at the quick phase. Microstimulation (less than 20μA) of the PN area using glass micropipettes suppressed burst activities of BINs.

Antidromic activation of PNs from the BIN area was examined. Of 54 PNs, 48 were antidromically activated from the ipsilateral BIN area. The spike latencies ranged from 0.3 to 1.2 msec (mean 0.75 msec). Fourteen neurons were also activated antidromically from the contralateral BIN area. Antidromic activation of PNs was further studied by systematic tracking with the stimulating microelectrode in saggital (L 0.5) and transverse (P 7.5) planes through the ipsilateral BIN area. There were two or three low threshold foci (less than 30μA) which were separated by nonresponsive sites. The effective sites were found mostly in the BIN area (around 0.5 mm lateral from the midline, and 1.0 to 3.0 mm deep from the floor of the fourth ventricle), indicating axonal branching in this area.

During intracellular recording of BINs, microstimulation of the PN area induced a hyperpolarization with latencies ranging from 0.7 to 1.5 msec (mean 1.0 msec) which were inverted into depolarizing potentials by passing hyperpolarizing currents. This indicates that the hyperpolarizations are monosynaptic IPSPs. The IPSPs induced on stimulating the PN area could explain IPSPs found in the same BINs during the slow phase of nystagmus.

It is concluded that burst activity of BINs may be caused by release of the direct inhibition from PNs (disinhibition).

1681 RAPID KILLING OF SINGLE NEURONS BY ILLUMINATION OF INTRACELLULARLY INJECTED DYE. John P. Miller and Allen I. Selverston. Biology Dept., UCSD, La Jolla ,Ca., 92093.

We have approached questions of neuronal function and connectivity with a new technique for rapidly killing all or part of single identified neurons. To examine the effect of removing one cell from a circuit, the lobster stomatogastric ganglion was used. This ganglion generates two motor patterns, and the connectivity of the 30 neurons it contains has been well worked out.The cell to be killed was first filled with the dye Lucifer Yellow CH via intracellular iontophoresis. The dye itself had no effect on the resting-, action-, or post synaptic potentials, or on the input resistance in any of the cells from which we recorded. To kill the dye-filled cell, the ganglion was illuminated with high intensity blue light. (This dye absorbs at 426 nm and fluoresces brilliantly at 540 nm, allowing visualization of the cell during the illumination.) Within 5 min. of illumination, the membrane potential of the cell depolarized to zero, all psp's onto follower cells disappeared, and action potentials were no longer observable on the cell's peripheral axon. Electron microscopy showed cytoplasmic vacuolization, mitochondrial disruption, and general membrane fragmentation in such dye-filled and irradiated cells. No structural or physiological damage was detectable in unfilled cells.

This method has been used to test our understanding of the circuitry underlying pattern generation by the ganglion. Elimination of a neuron predicted to be crucial to pattern coordination (such as the AB interneuron) causes disruption of the output pattern. Elimination of cells with roles predicted to be less crucial causes little disruption of ongoing activity.

In order to demonstrate the extent to which a dye-filled cell is damaged when only a portion of it is illuminated, one segment of a crayfish lateral giant axon was filled iontophoretically with Lucifer Yellow. After irradiation of a small portion (6%) near the center of the axon for 10 min., conduction of action potentials was blocked at this central point. However, the un-irradiated portions could still conduct action potentials. Thus, elimination of a fraction of a single neuron's dendritic tree may now be possible through a combination of this method and microbeam irradiation.

1682 TWO FIRING PATTERNS IN AN IDENTIFIED MOLLUSCAN NEURON. Mark W. Miller* and Matej Stepita-Klauco. (SPON: W.A. Wilson,Jr.) Department of Biobehavioral Sciences, U.Conn., Storrs, CT. 06268

Experiments have been conducted on an identified cell in the buccal ganglion of the land snail, Helix aspersa. The activity of this cell was recorded extracellularly with a suction electrode on the ipsilateral salivary nerve and intracellularly with single- or double-barrelled microelectrodes in the desheathed soma. This cell exhibited two distinct patterns of firing (I & II) which appear to be generated by two separate mechanisms.

Firing pattern I consists of trains of three to ten evenly spaced action potentials. Interspike intervals within a train range from 200 to 400 msec. and trains are separated by 2 to 10 seconds. Hyperpolarization of the cell reveals a pattern of incoming synaptic activity which appears to produce this firing.

Firing pattern II is an intense burst of action potentials which is always preceded by a prolonged period of hyperpolarization. These bursts typically consist of 12 to 20 action potentials and are separated by intervals ranging from 20 seconds to over 4 minutes. Patterns I and II are both eliminated in high Mg^{++}-low Ca^{++} bathing medium.

A pressure injection pulse of 5-HT applied to the hillock region of this cell elicited the entire sequence of events associated with firing pattern II. The presence of this response was time dependent, requiring a sufficient interval (approximately 3 min.) to elapse following the previous instance of firing pattern II. If an insufficient period was allowed to elapse, 5-HT produced only a biphasic response consisting of an early hyperpolarizing phase followed by a depolarization without generating pattern II. A similar situation was observed when hypolarizing current pulses were passed through the recording electrode into the soma. Such a hyperpolarization was always followed by a post-inhibitory burst of action potentials. On trials having a sufficient delay from the previous pattern II the rebound burst was immediately followed by production of another pattern II. As was the case with 5-HT, the interval since the previous occurrence of firing pattern II appears to determine whether pattern II will be generated or not.

Single pulses of ACh to the hillock region produced depolarizing responses which were excitatory at resting membrane potential. ACh responses did not trigger either of the firing patterns. We suggest that this Helix cell may provide an opportunity to study the generation of two rhythms and their interactions at the level of a single neuron.

1683 AUTORADIOGRAPHIC PROJECTIONS OF THE MIDBRAIN CENTRAL GRAY.
M.K. Sanghera, D.C. German, M. Mendershausen*, and R.S. Kiser.
Depts. of Physiol. and Psychiat., Univ. Tex. Health Sci. Ctr., Dallas, TX 75235.

The mesencephalic central gray area (CG) is not a functionally homogenous structure. For example, stimulation of the dorsal portion of the central gray produces aversive behavioral effects while the ventral portion, which contains the serotonergic dorsal raphe nucleus, has been implicated in stimulation-produced analgesia. Electrical stimulation of the lateral central gray has been shown to induce the lordosis reflex in the female rat, and luteinizing - hormone releasing hormone terminals have been located in this area. The present study examines autoradiographically the projections of these functionally different areas of the central gray. Iontophoretic injections of ^{35}S-methionine were made into the (1) dorsal CG (2) ventral CG and (3) lateral CG. Rats survived for 3 days. Following a 6 day exposure period, the tissue was developed, stained for Nissl and examined microscopically. From the dorsal CG injection site, extensive bilateral labelling was observed. The commissure of the superior colliculus was labelled both rostrally and caudally. Labelled fibres radiated laterally and ventrally in Weisschedel's radiatio grisea tegmenti. Intra-central gray projections went to the pretectal area and periventricular nucleus of the thalamus. From the ventral CG injection site caudal projections were seen bilaterally in discrete fascicles on the lateral edge of the central gray. Rostrally labelled fascicles coursed into the ventral tegmental area and the medial forebrain bundle. Light labelling was also seen in the periventricular nucleus of the hypothalamus. From the lateral CG, three rostrally projecting pathways could be identified. Heavy labelling was obtained in the commissure of the superior colliculus from the injection site to the pretectal area. Labelled fascicles were also seen to course ventromedially to ascend in the central tegmental tract to the region of the red nucleus and further rostral in the medial forebrain bundle. Labelling was seen as far rostral as the preoptic area. Finally, intracentral gray projections, mainly ipsilateral, ascended as far rostral as the N. parafasicularis and the ventral nucleus of the thalamus. These diverse projections from different parts of the CG may underlie the functional heterogeneity associated with this structure. (Research supported by BRS grants 5-S07-RR07175-03 and 5-S07-RR05426-16).

1684 IS THE NERVOUS SYSTEM A "BIT" OR A "BYTE" PROCESSOR?: AN EVALUATION OF THE MARKOV CHAIN LENGTH OF INTERSPIKE INTERVALS.
C. J. Sherry and W. R. Klemm. Dept. of Biol. Texas A & M Univ. College Station, Tx. 77843.

The times between adjacent action potentials (ISI) are usually treated from both a theoretical and practical standpoint (Biophy. J. 7: 391, 1967) as if they form a memory-less Markov chain (i.e. knowing the value of an ISI does not allow prediction of succeeding ISIs). Based on empirical observations of statistically significant changes in the occurrence of patterns involving as many as 13 sequential ISIs (Life Sci. 11: 441, 1972), we decided to test the hypothesis that ISIs form higher-order Markov chains. The first step was to have the computer determine if the first interval in a sequential pair was >, =, or < the next sequential interval and code this relationship as a +, 0, or - in the computer memory. The occurrences of these patterns were tallied into a series of conditional probability matricies where the sequential relationships were specified as probabilities in a 'digram' matrix for 2 symbols, 'trigram' matrix for 3 symbols, and 'quadgram' matrix for 4. We tested the hypothesis that the data were generated by a process utilizing a Markov chain of either 1st, 2nd, or 3rd order (a 3rd order chain, for example, implies that the probability of occurrence of an ISI depends on the probability of occurrence of two immediately preceding ISIs. For each of the matricies, we calculated the expected and empirically observed values in each cell to determine the Chi-square statistic (Theoret. Biol. 29:427, 1970). For 12 neurons in the rat cerebellar cortex, we found that 7 neurons required at least a 3rd order Markov chain to describe the spike train adequately. The remaining 5 neurons required at least a 2nd order Markov chain.

These data suggest that at least part of the information processing in the nervous system may be analagous to computerized 'byte' processing.

1685 MODELLING OF GANGLION CELLS IN A REALISTIC VERTEBRATE CONE RETINA.
R. Siminoff 705 Sycamore Terrace, DeWitt, N.Y. 13214

Prototypes of ganglion cells (GC) of vertebrate cone retinas require 4 specifications:

1. an informational flow diagram relating the flow of signals from cones to GCs. Two types of GCs are present- - tonic (t-) GCs formed by direct convergence of bipolar cells (BC) and phasic (p-) GCs formed by convergence of 2 types of BCs- - hyperpolarizing- and depolarizing-center BCs;

2. spatial organization of cones into unit hexagons (UH) which form repetitive units across the entire retina. A UH is a geometrical pattern consisting of a central cone and spectrally like-cones located at each of the 6 corners of the UH. Receptive fields (RF) of GCs result from converging UHs and RF sizes can be increased by adding rows of cones to the UH. At the GC level, RF organizations develop from convergence of all or parts of 7 overlapping central UHs with their accompanying surround UHs. Six variations are possible- - within the central and surround regions, spectrally like-UHs are present and, in one case, are the same for the 2 regions and, in the other case, are different and finally, within each region different overlapping UHs are present in each region. Besides p- and t-GCs, there are color-coded (C-) and non-color-coded (L-) types of GCs. The L-types are formed with all cones, regardless of spectral type, within a UH connecting to appropriate retinal elements and C-types are formed with the appropriate spectral type of cone within the UH;

3. weighted inputs (a_x) for each cone depend on electrical coupling of like-cones and/or stray light given by, $a_x = at_x + bu_x + cv_x + dw_x + - - - - -$, where t_x, u_x, etc are the number of cones located in the 1st, 2nd, etc rows from the central cone and a, b, etc are their respective weighting factors;

4. a polarization factor (X) relating the amount of polarization change produced in a given GC by hyperpolarization of a given cone, $X = a_x E(t)(Zd_i)f(g_i)$, where $E(t)$ is hyperpolarization of the cone as a function of time, Zd_i is the sum of synaptic delays in the path from the cone to the GC and $f(g_i)$ is a complex linear function of synaptic gains assuming linearity and modifications due to negative feedback from L-HCs to cones and electrical coupling between like-HCs.

The model can generate all known RF organizations of vertebrate retinal GCs. Proper manipulations of the various parameters generate GC types for any given species of vertebrate.

1686 CENTRAL GENERATION OF THE SCRATCH REFLEX IN THE TURTLE.
Paul S.G. Stein and Margaret L. Grossman*. Dept. of Biology, Washington University, St. Louis, MO 63130.

Scratching movements of a hindlimb can be elicited by tactile stimulation of specific regions of the shell of a turtle, Pseudemys scripta elegans, whose spinal cord is cut posterior to the forelimb enlargement at D2 (Valk-Fai and Crowe, J. Comp. Physiol. 125: 351, 1978 and in press). The present study has demonstrated that this scratch reflex is centrally programmed within the spinal cord of the turtle. These results are similar to those obtained with the scratch reflex of the cat (Berkinblit et al., J. Neurophysiol. 41: 1040, 1978).

In low spinal turtles with intact sensory input, the knee extensor muscle (KE), triceps femoris, pars femorotibialis, vastus medialis, was active during the protraction phase of the scratch and the hip retractor and knee flexor muscle (HR-KF), flexor cruris, pars flexor tibialis internus, was active after the termination of KE activity and during the retraction phase of the scratch. A scratch in response to a single tactile stimulus was either (i) a half cycle, i.e. just one KE burst, (ii) a full cycle, i.e. a KE burst followed by a HR-KF burst, (iii) several full cycles, or (iv) several full cycles and a half cycle. A small burst of activity in HR-KF was sometimes also seen during KE activity. In addition, during a few scratch episodes a burst of HR-KF activity was seen prior to the first onset of KE activity.

Sensory activity entering the spinal cord from the hindlimbs via dorsal roots was eliminated by bilateral dorsal rhizotomies of segments D7-S2. In addition, all inputs from the caudal segments were isolated from the hindlimb enlargement by a complete cut of the cord posterior to the S2 roots. The patterns of muscular activation during the scratch in these preparations were similar to those observed in turtles with intact sensory input. Moreover, when further total section of the cord was made posterior to either D8 or D9 and the cord posterior to the section removed, then a normal burst pattern of KE was observed in response to tactile stimulation.

Muscular paralysis with gallamine triethiodide (5 mg/kg, i.m.) was utilized as an alternate way of demonstrating the central program for the scratch. In these preparations, KE motor neuron activity was recorded from the femoral nerve and HR-KF motor neuron activity was recorded from the flexor tibialis nerve. Tactile stimulation in these immobile preparations elicited neural activities, "fictive scratching", whose patterns were similar to the muscular activities observed in preparations with moving limbs.

Supported by NSF Grant BNS78-13038.

1687 BIOGENIC AMINES AND REGULATION OF THE CARDIAC GANGLION OF LIMULUS. W. Watson III*, G. Augustine, E. O'Connor*, R. Fetterer and G. Wyse* (SPON: R. Steinman). Marine Biological Laboratory, Woods Hole, Mass. 02543.

Cardiac ganglia of arthropods are favorable preparations for determining how neurotransmitters or neurohormones modulate neuronal activity. We have addressed this question by using the cardiac ganglion and heart of the horseshoe crab, Limulus polyphemus. Little is known about the regulation of cardiac ganglion activity in vivo; we therefore monitored the heartbeat and cardioregulatory nerve activity of intact Limulus using chronically implanted electrodes. The heartbeat provides a direct indication of cardiac ganglion activity, since it is generated by this ganglion. The Limulus heartbeat is altered in a variety of situations. Decreases in rate are observed in response to stimuli such as touch, changes in light intensity, or the presence of food objects. Acceleration of the heartbeat occurs during swimming. The heartbeat appears to be coordinated with respiratory activity, and thus also changes under conditions which affect respiration. All decreases in heart rate are associated with clear increases in the electrical activity of efferent units recorded extracellularly from the cardioregulatory nerves connecting the CNS and cardiac ganglion. There are other efferent units whose activity is correlated with increases in heart rate. This suggests that the CNS contains both excitatory and inhibitory cardioregulatory neurons. We have attempted to determine the neurotransmitters or neurohormones involved in cardioregulation. As amines are thought to serve a cardioregulatory role in other systems, we examined the catecholamine levels of the cardiac ganglion, cardioregulatory nerves, and CNS. Dopamine, norepinepherine, and epinepherine were found in all three of these structures using high pressure liquid chromatography with electrochemical detection. Octopamine has also been found in the cardiac ganglion by others. The presence of biogenic amines in these structures has been verified by localization with a glyoxylic acid histofluorescence technique. All four amines excite the isolated ganglion, increasing the rate of bursts of electrical activity recorded extracellularly. In summary, the activity of the cardiac ganglion of Limulus is modulated in vivo by neurons within the CNS. Biochemical, histochemical, and physiological data suggest that one or more amines may be involved in this cardioregulation.

1688 A 'QUANTAL' ELECTRIC CONNECTION BETWEEN NEURONS IN THE LEECH CNS. Birgit Zipser, Cold Spring Harbor Laboratory, Cold Spring Harbor, New York 11724, U.S.A.

A synaptic connection exists between leech neurons that is quantal in nature but is not blocked under conditions which interfere with chemical synaptic transmission. The connection is important for the neural control of mating since it occurs between two pairs of penile evertor motor neurons, the lateral and rostral cells. These neurons have previously been found to be directly coupled via an electrotonic synapse. In addition to this electrotonic transmission, I have found another excitatory lateral-to-rostral interaction with unusual properties. Transmission across this synaptic connection is unidirectional with a latency of about 4 msec. Intermittent failures in transmission are seen. These failures are not due to conduction block in the lateral cell since lateral cell spikes invariably give rise to small electrotonic coupling potentials in the rostral cell. The amplitude of the postsynaptic potentials (PSPs) fall into two discrete classes, with the larger PSPs being about twice the size of the smaller ones. In some preparations, spontaneous PSPs occur; these have amplitude distributions similar to evoked PSPs. These findings would ordinarily suggest that the interconnection is chemical; however, ion substitution experiments rule out a conventional chemical synapse. The PSPs persist in Ca-free solutions, including those to which the Ca-chelator EGTA (0.5 to 1mM) has been added. The single and double modes of the PSP amplitudes are not only maintained in Ca-free Ringer, but in fact, the number of failures decreases. Increasing the external Ca concentration inhibits transmission by increasing the number of failures. Ca channel blockers such as Ni (2.5mM) do not block transmission either. The mechanism by which this Ca-independent quantal transmission occurs is not clear. One way that the transmission could proceed is via the presence of 2 interposed interneurons with parallel electric connections to both rostral and lateral cells. The single and double PSPs could be generated by action potentials in one or both of these neurons. The facilitatory effects of Ca-deletion could then be attributed to removal of chemical inhibition from these hypothetical interneurons. Consistent with this hypothesis is the finding that the PSPs are blocked by tetrodotoxin at concentrations that do not eliminate action potentials in lateral and rostral neurons. Supported by NSF grant 78-13064.

NEURONAL SHAPE AND FUNCTION

1689 THE MORPHOLOGY OF MECHANOSENSORY NEURONS IN THE SKIN OF THE LEECH. Susanna Blackshaw* and John Nicholls. Dept. Neurobiol., Stanford Med. Sch., Stanford, CA 94305.

In the leech, the cell bodies of mechanosensory neurons lie within the central nervous system. They are easily identified and much is known about their electrical properties, their arborisation within the ganglia, their synaptic connections, and the way in which they regenerate to reform connections after injury. The receptive fields of individual neurons have been mapped physiologically and each cell innervates a clearly defined area of skin, its receptive field. By contrast, there is little information on their morphology in the skin. By injecting horseradish peroxidase into the cell body of a neuron in the ganglion we have now been able to follow the way in which the axon branches and terminates within its receptive field.

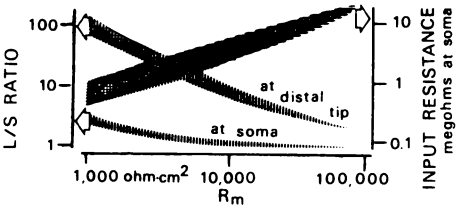
Neurons that respond to light touch branch repeatedly in deeper layers of the skin. The terminal branches of the axon then turn towards the surface between the skin epidermal cells. If the skin surface is viewed with Nomarski optics the touch cell endings can be seen as well-defined structures 2 - 3 μm in diameter lying between the epidermal cell profiles. An individual touch cell makes over a 1000 of these endings at the skin surface.

In contrast to the touch cells neurons that respond to pressure branch less profusely within their receptive fields, and branches of the axon end in deeper layers of the skin.

The use of peroxidase makes it possible to study the terminals of identified neurons by electronmicroscopy. Such information about fine structure provides a basis for further experiments on the specificity of skin innervation and reinnervation by identified mechanosensory neurons.

1690 SOMATIC *VS.* DENDRITIC SYNAPSES: MEMBRANE RESISTIVITY IS OFTEN UNIMPORTANT IN DETERMINING RELATIVE STRENGTHS. William H. Calvin and Katherine Graubard, Univ. of Washington, Seattle, WA 98195.

Not all synapses are equal; indeed, length constants have been interpreted to suggest that synapses on distal dendrites are "virtually ineffective" compared to somatic synapses. Dye injected cells have permitted estimates of membrane resistivity, R_m, using cell reconstructions and measured input resistance; unfortunately, R_m estimates vary many-fold, depending on how adequately the fine distal processes are visualized. Here we report that, for the same synaptic conductance change and driving potential, distal synapses deliver nearly as much charge (area beneath PSP, hereafter simply called the "PSP") to the soma as do somatic synapses. Furthermore, wide variations in R_m do not change this basic result. PSPs are calculated from the steady-state cable equation; our figure is based on the range of data (shading) from two cells of quite different appearance (a lobster stomatogastric cell and a model spinal motoneuron with d3/2 conserved) and is, we believe, representative of many dendritic trees. We plot the PSP size ratio (largest/smallest, i.e., local and most distant synapses). *For most R_m, the somatic PSP from a local synapse is less than twice as large as the PSP arriving from the most distant synapse* (L/S < 2, "at soma"). While this indicates relative synaptic strengths for impulse initiation, one must also consider presynaptic regions in the dendritic tree which could release transmitter in response to summed PSPs. The local PSPs near a distal tip are quite large due to the high input resistance, *often being 10-40X larger than PSPs spreading from somatic synapses or those on other dendrites* (L/S > 10, "at distal tip"). This potential for "regional computation," while always considerable (c.f., The Neurosciences Fourth Study Program 1979), is enhanced by lower R_m. Reasoning based upon analogies with axon length constants is often misleading when applied to dendritic trees, primarily because a dendrite is terminated centrally by a heavy load, that of the soma and other dendrites. *Voltage attenuation is also misleading: even if there is ten-fold attenuation between a distal tip and the soma, moving to a synapse from soma to tip will usually cause the local PSP to increase by a similar factor, so that the PSP seen in the soma changes less than two-fold.* (NIH grants NS04053, NS 09677, TW 00181.)



1691 ENDOGENOUS FLUOROCHROMES IN THE CAUDATE NUCLEUS. Joseph T. Cummins and Roger S. Rahn*. Dept. Psychiat. Sch. Med. UCLA, Los Angeles, CA, and VA Medical Center, Sepulveda, CA; Dept. Biol. Chapman College, Orange, CA.

Sections from the caudate nucleus were illuminated with a 325 nm He-Cd laser and studied with a triocular microscope modified with a dichroic mirror and quartz objective. Tissue fluorescence could either be photographed or measured by a monochrometer and photon counting system. 325 nm laser illumination of caudate sections revealed a number of endogenous fluorescent structures of potential neuroanatomical importance. These included: long fibers with bright blue fluorescence, triangular "nerve cell-like" structures and unresolved areas of fluorescence. The long fibers contain a fluorochrome with an emission maximum at 455 nm. Most caudate structures have a blue fluorescence; but green and red fluorescing structures are also seen. Counterstaining with thionin demonstrated that the blue fluorescing fibers contact nerve cells and that certain nerve cells have a blue fluorescence. Blue fluorescing structures were seen in fresh caudate slices perfused with Krebs-Ringer and following several methods of fixation of frozen caudate sections such as air drying, treatment with dimethylsulfoxide or dimethylsulfoxide plus dithiothreitol. The latter treatment suggests that the fluorescence does not arise from oxidation within the tissue section. Similar endogenous fluorescent structures were seen in caudate sections from mouse, rat or beef. These observations suggest that the fluorochromes have some importance in brain function and that the U.V. laser microscope may be a new approach to studying certain aspects of the microchemistry of the nervous system.

1692 CONDUCTANCE CHANGES DURING RECURRENT IPSPs IN HIPPOCAMPAL PYRAMIDS IN VITRO. Raymond Dingledine and Iver A. Langmoen*. The Institute of Neurophysiology, Univ. of Oslo, Norway.

Recurrent inhibitory synapses are located predominantly on the soma of CA1 pyramids, while excitatory synapses appear to be made exclusively on pyramidal cell dendrites (see review by Andersen in The Hippocampus, Isaacson & Pribram (ed), Plenum, 1975). The question is raised as to how these spatially separate inhibitory and excitatory synapses interact in this cortical neuron.

Intracellular recordings were obtained from antidromically identified CA1 pyramidal neurons in an in vitro slice preparation of the guinea pig hippocampus. Tungsten microcathodes were placed both in the alveus and among the afferent fibers in the apical dendritic layer of the pyramids. The time course of the impedance change underlying recurrent ipsp's was estimated by injecting current through the recording electrode in an a.c. bridge configuration (method of Hagiwara & Tasaki, J. Physiol., 143:114, 1958).

The dependence of the recurrent ipsp on the membrane potential was examined. A conductance increase was implicated, which at the resting potential was sufficient to drive the ipsp 30-60% of the distance to its reversal potential. By eliciting ipsp's in the presence of a 10 Hz sine wave current injected across the cell membrane, it was found that the timecourse of the membrane impedance change matched that of the ipsp itself, except that the maximum impedance decrease usually occurred slightly before the peak of the ipsp. Both the ipsp and its associated impedance change decayed nonmonotonically over a period of about 150 ms.

The inhibition afforded by the 2-10 mV peak hyperpolarization of the ipsp was considerable since the normal firing threshold, when measured in the same cells, was 5-12 mV above the resting potential. Furthermore, the probability of spontaneous discharge was depressed throughout the duration of the ipsp. The membrane potential at which spikes were initiated did not appear to be altered during the recurrent ipsp.

The ipsp conductance, if great enough, was able to shunt epsp's generated in the apical dendrites. This was demonstrated by adjusting the membrane potential to the ipsp reversal potential and showing non-linear summation of epsp's with recurrent ipsp's. However, such inhibitory conductance shunting was usually weak and could only be detected during the period of most intense impedance decrease (up to 15-25 ms).

Thus, the inhibitory actions of hippocampal recurrent ipsp's are mediated by a hyperpolarization and, if the ipsp is properly timed with excitatory potentials, by a conductance shunting effect. In these respects recurrent inhibitory mechanisms in the hippocampus appear similar to those for motoneuron ipsp's.

1693 "RECTIFICATION" UNDERLYING DIFFERENTIAL CHARACTERISTICS OF ANTI- AND ORTHODROMIC ACTIVATION OF A VERTEBRATE CENTRAL NEURON. Donald S. Faber and Paul G. Funch. Div. Neurobiology, Dept. Physiol., SUNY at Buffalo, Buffalo, NY 14214 and NYS Research Institute on Alcoholism, Buffalo, NY 14203.

The goldfish Mauthner cell (M-cell) is characterized by its large soma and a correspondingly large myelinated axon (M-axon), with the fiber diameter being 40-60 μm. These two regions are electrically coupled by a tapering axon hillock and a thin unmyelinated axon no more than 10-12 μm in diameter and 75 μm long. The functional role of such a constriction, which is typical of many vertebrate neurons, is not well established, although it is often assumed to electrotonically separate the soma and axon. We report here that the electrical properties of these different regions and their associated extracellular resistances provide for a "rectification". Specifically, there is minimal potential decrement from the soma or axon hillock to the M-axon, while there is significant attenuation in the opposite direction. This results in a low safety factor for antidromic invasion of the axon hillock but not for orthodromic activation of the M-axon.

Simultaneous intracellular recordings and current injections were used to measure input resistances of the M-cell soma and axon and the transfer resistance (R_T) between the two. R_T is approximately 140 kΩ, while the lumped resistance of the axon hillock and somatic membranes is about 200 kΩ. In contrast, the input resistance of the caudal M-axon is at least one order of magnitude higher. Furthermore, there is minimal decrement in the amplitude of eighth nerve-evoked EPSPs from the soma to the axon (typically < 20%), while the axon spike recorded somatically is reduced in amplitude by 80-90%. A simple electrical model based on our resistance measurements and the geometrical relations described above predicts such a "rectification". Furthermore, it provides a basis for analyzing previous observations: 1) There is a low safety factor and consequent delay for antidromic invasion of the axon hillock; 2) Antidromic invasion may spontaneously fail; and 3) Orthodromic propagation into and along the M-axon is nevertheless secured with no observable delay between activation of the axon hillock and the M-axon. Thus, antidromic stimulation of the M-cell may be used as a sensitive test for studying pharmacological and environmental alterations in membrane excitability, and may serve as a model for other regions of low safety factor, such as axonal branch points. (Supported in part by PHS Grant No. NS 12132.)

1694 ELECTROTONIC STRUCTURE OF HIPPOCAMPAL NEURONS. Russell A. Fricke, Thomas H. Brown and David A. Prince. Neurology Department, Stanford University Medical School, Stanford, CA 94305.

The hippocampus contains several spatially segregated classes of morphologically distinct neurons. Using the guinea pig in vitro slice preparation, we have examined the passive electrical membrane properties of neurons which we penetrated in the pyramidal layer of regions CA3 or CA1, or in the granular layer of the dentate gyrus. These layers principally contain the cell bodies and proximal dendrites of pyramidal and granule cells, respectively. Rallian "neuron parameters" were estimated in current clamp experiments. The method of analysis assumes, as a first approximation, that the cells can be represented by an isopotential "soma" compartment (consisting of a capacitance C_s in parallel with a conductance G_s) which is attached to a single "equivalent" dendritic cylinder having an input conductance G_d and electrotonic length L. Hyperpolarizing current steps were delivered to the cell and from the charging time constants and their weighting factors we estimated (See Norris et al, Neurosci. Abstr. 5, 1979) C_s, G_s and L, along with ρ, the "dendritic dominance." Average values for these electrical parameters are given below. The interpretation of these parameters, and their possible contribution to the characteristic firing patterns of granule and pyramidal cells will be discussed. (Supported by NS 06161 and NS 12151).

Electrical Constant	Presumed Neuronal Cell Type: Pyramidal Cell (N = 7)	Granule Cell (N = 7)
R_N (MΩ)[1]	42.4 ± 2.9	37.8 ± 3.8
τ_m (msec)[2]	17.1 ± 2.6	12.3 ± 1.9
G_s (nS)	6.9 ± 2.1	14.1 ± 2.3
C_s (pF)	139 ± 55	153 ± 9
L (X/λ)	1.0 ± 0.2	0.9 ± 0.1
ρ (G_d/G_s)	5.3 ± 2.5	1.4 ± 0.4

1695 "CONTINUOUS" IMPULSE PROPAGATION ALONG A MYELINATED VERTEBRATE AXON. Paul G. Funch and Donald S. Faber. Dept. Physiol., SUNY at Buffalo, Buffalo, NY 14214, and NYS Research Institute on Alcoholism, Buffalo, NY 14203.

The goldfish Mauthner axon (M-axon) is a large myelinated fiber, 40-60 μm in diameter, which lacks nodes of Ranvier. Its impulse conduction velocity is well below what would be predicted for saltatory conduction along a myelinated vertebrate fiber of similar diameter with a typical ratio (100-150) of internodal distance (L) to fiber diameter. The unusual character of impulse propagation suggested by these early observations has been studied by recording intracellularly in the soma while making successive penetrations of the M-axon with a second microelectrode. Hyperpolarizing current injections into the axon and soma during orthodromic and antidromic activation, respectively, separated the axon hillock and axon spikes from the composite action potentials observed in the M-axon. The magnitudes of these spike components as well as those of eighth nerve-evoked EPSPs and the maximum rate of rise of the axon spike have been plotted as a function of distance from the axon hillock (up to 7.6 mm). The resulting spatial profiles of the axon hillock spike and eighth nerve-evoked EPSPs indicate the space constant (λ) of the rostral M-axon is approximately 4.5 mm. In contrast, the caudal to rostral decrement in the axon spike amplitude is much less than predicted on the basis of these estimates of λ, and this profile is paralleled by that of the magnitude of its maximal rate of rise. Furthermore, the latency of the maximal rate of rise of the axon spike component is linearly related to distance and yields a conduction velocity of 47 m/sec. Morphological studies by Celio et al. (J. Neurocytol., 8:19-29, 1979) have shown that collaterals project about every 300 μm from the M-axon in the spinal cord of 20 cm long goldfish. These collaterals appear to be the only possible active membrane sites, suggesting that for the 13.5 cm fish used in this study there would be a very short electrotonic distance of about λ/20 for L. While saltatory conduction and very rapid conduction velocity normally accompany myelination, these findings lead us to suggest that impulse propagation in the M-axon is an essentially continuous process which, while slower, provides a high safety factor for conduction along the M-axon in the face of significant current loss through the many collaterals. (Supported in part by PHS Grant No. NS 12132.)

1696 PERIPHERAL NERVE MYELIN MORPHOLOGY IN ANIMALS OF DIFFERENT PLOIDY. S. A. George and M. J. Lemanski.* Biology Department and Neuroscience Program, Amherst College, Amherst, MA 01002.

As part of a continuing study of the morphology and function of neurons in animals of different chromosome number, we studied the relations between internodal length (L), axon diameter (d), and total fiber diameter (D) in individual sciatic nerve fibers from normal (diploid) and triploid Xenopus. Triploids (3 sets of chromosomes) were prepared by subjecting fertilized eggs to a hydrostatic pressure shock. Previous work in this laboratory and by others has shown that the nervous system and other organs of triploid amphibians contain larger, but fewer, cells than diploids of the same species. We confirmed this relation in Xenopus sciatic nerve, through fiber counts and measurements of fiber cross-sectional area.

Lengths of single fibers containing from 6 to 17 nodes were isolated after treating sciatic nerves with glycerol, and myelin dimensions were measured in 1351 internodal segments from these fibers. The relation between axon and fiber diameter was linear, but the relation was different for diploids and triploids: the average value of the ratio g=d/D was .625±.008 in diploids, compared to a value of .693±.006 in triploids, a highly significant difference. Thus the myelin sheath (D-d) was thinner around triploid fibers compared with diploid fibers of the same diameter. The internodal length L was also strongly correlated with axon diameter, and again the relation was a function of ploidy: L in triploid fibers was, on the average, longer than in diploid fibers of the same diameter. The volume of myelin in each internode was calculated from the values of L, d, and D, and in this case the triploid-diploid differences were more complex: triploids had a smaller myelin volume than diploids in fibers less than 10 μm in diameter, but triploids had more myelin per internode in fibers above 10 μm. Thus myelin morphology in animals of different ploidy is not simply scaled according to cell size differences in these classes of animals.

We also recorded sciatic nerve compound action potentials. The amplitude of these potentials in triploid nerve was significantly smaller than in diploid nerve, indicating a smaller total nodal area in triploid nerve. The average conduction velocity in triploid nerve was nearly identical to the diploid average, though the variability between animals was large. The conduction velocity might be expected to be greater in triploids because of their larger average fiber diameter, but we suggest that the altered myelin structure in triploids may reduce the conduction velocity in fibers of a given diameter below the value achieved in normal diploid fibers.

1697 AN INTERACTIVE CAMERA LUCIDA COMPUTER-MICROSCOPE. E.M. Glaser, M. Gissler* and H. Van der Loos*. Institute of Anatomy, University of Lausanne, CH1011 Lausanne, Switzerland.

Quantitative light microscopy has experienced a significant evolution in recent years due to its wedding with the laboratory minicomputer, a wedding facilitated by such ancillary devices as motor driven stages, video scanners, graphics displays, and graphics tablets. The resulting computer-microscopes have enabled the microscopist to acquire data rapidly and accurately and to analyze these data in a multiplicity of ways. Nonetheless, the microscopist has had to pay a substantial price for these assets: he has been divorced to a certain extent from intimate contact with the original image of the preparation. We have designed a computer-microscope system which reunites the investigator and preparation and which provides a highly flexible means for him to interact with the data acquisition and analysis procedures. The system is based upon image superimposition as provided by a camera lucida. The microscopist sees at one and the same time in a single visual field (a) the original image of the preparation, (b) a graphics display of the data acquired from this image, (c) a command 'menu' permitting him to control the system without taking his eyes from the oculars. The superimposition of the original image and the graphics display is maintained regardless of how the stepping motor driven stage is moved during the course of data acquisition. In practice, data are acquired either by stepping the stage, by 'drawing' with a graphics tablet stylus, or both. The combination of the two techniques greatly enhances the speed and accuracy of tissue examination. Because it is the original high resolution, fully chromatic image that the microscopist examines, the only optical limitations to the system are those inherent in light microscopy itself.

The computer-microscope is particularly well suited to the study of neurons stained in their entirety, as by Golgi methods. Since 3-dimensional stepping motor stage control is provided, sections of any thickness can be dealt with. The maintenance of image superimposition regardless of stage position permits viewing an unlimited expanse of the preparation with high magnification optics. This maximizes the amount of information that can be acquired. Chromatic aspects of the image can also be studied.

Other important tasks can be performed with the instrument. For example, serial sections can be aligned by letting the graphics display present the relevant contours from a neighboring section while the section on the stage is maneuvered to obtain the best registration. Another type of operation facilitates stereological analysis by having the graphics display present stereological grids selected from files stored in the computer.

1698 A COMPARISON OF RAPID GOLGI STAIN QUALITY IN FRESHLY PERFUSED HIPPOCAMPAL SLICES AND HIPPOCAMPAL SLICES MAINTAINED AND STIMULATED IN VITRO. Kristen M. Harris & Timothy J. Teyler, Program in Neurobiology, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

A rapid Golgi staining technique for brain tissue less than 0.5 mm thick (Harris, K. M. Soc. Neurosci. Abs. 1978, 4, A1053) was applied to hippocampal slices (0.3-0.4 mm thick). One Group of slices (Group A) was immediately perfused with 4% buffered paraformaldehyde and processed by this rapid Golgi technique. Other slices were placed in an incubation chamber (Alger & Teyler, Brain Res 1976, 110, 463-480) for up to 6 hours. Hippocampal slices from this second group were either stimulated (Group B) or allowed to remain undisturbed in the incubation chamber (Group C). All slices from Groups B and C were tested for spontaneous activity at the end of an incubation period. Those slices showing spontaneous activity were transferred to 4% buffered paraformaldehyde and rapid Golgi stained. Slices showing no spontaneous activity were discarded.

Qualitative light microscopic analysis of the rapid Golgi stained slices showed fully impregnated cell bodies, dendrites, dendritic spines, axons, and axonal varicosities in groups A, B, and C. Good stain quality was obtained whether the tissue was fixed in paraformaldehyde for 24 hours or for several days, from slices in all three groups.

It is suggested that this technique can be successfully applied to hippocampal slices that are experimentally manipulated in vitro. (NSF Grant BNS-78-23947)

1699 CABLE PROPERTIES, NEURONAL GEOMETRY, AND TRANSIENT POTENTIALS IN DENDRITIC SYSTEMS. Barry Horwitz, Physics Department, Texas Woman's University, Denton, Texas 76204.

A theoretical model has been developed which explores the way in which the geometrical structure of a neuron's dendritic tree affects the time course and amplitude of transient potentials generated at different locations on dendritic branches. The model, based on the work of Butz and Cowan[1], allows one to investigate dendritic systems which are not of the equivalent cylinder class of Rall[2]. We have examined a number of such systems and have developed an analytical way to evaluate the strength of the time-varying potentials that would be observed at the neuron's soma. Examples will be presented which will demonstrate how, for an input on a given branch, the potential observed at the soma depends upon such geometrical parameters as (1) the number of sister branches, (2) the branch lengths, (3) whether or not the dendrite bifurcates at a point distal to the input, and (4) given such a bifurcation, the lengths of the daughter branches.

1700 EARLY EXPERIENCE EFFECT ON DENDRITIC BUNDLES. Frances E. Jensen* and D. N. Spinelli. Departments of COINS and Psychology, University of Massachusetts, Amherst, MA 01003. SPON. A.Treehub

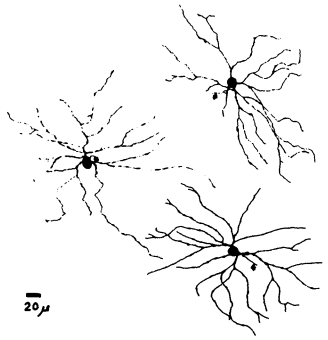
Dendritic bundles have been suggested as a possible anatomical substrate for movement sequencing (Scheibel and Scheibel, 1973). In a previous study, kittens received daily training sessions requiring the lifting of 1 forearm to avoid a small shock. Electrophysiological recordings from single cells in the Somato-Sensory cortex revealed a 200-300% enlargement of the somatotopic representation of the trained forearm relative to the untrained arm (Neurscience abstracts Vo 4. No. 2075, Science, 1979). We have now examined neuronal architecture of the brains of the same cats using Golgi-Cox staining. We compared the 2 hemispheres for cell count, dendritic density, dendritic length, dendritic bundling, shape of bundles, and the angle of branching of the dendrites incorporated in bundles. Dendritic trees in the cortex corresponding to the enlarged area associated with the trained forearm appeared more extensive (much larger) than those seen in the contralateral representation of the untrained forearm. The number of cell bodies stained in the 2 hemispheres was not significantly different, indicating that the staining had been uniform. In this study we specifically concentrated on an analysis of dendritic bundles to investigate the possibility that their formation may be altered, or guided, by early experience. Two notable findings relating to this were: 1) statistical analysis showed that the number of bundles in the trained area is significantly greater than that of the untrained one for all cats studied 2) in some cases the length of the bundles is also significantly greater in this cortical area. This data seems to indicate that early experience has a measurable impact on dendritic growth and bundling. As bundles are structurally bound and embedded into a matrix of nerve cells and axons, clearly once formed, they must be permanent. It seems unlikely that new bundles will form once dendrites have reached the end of their growth. If bundles are indeed implicated in motor sequences, a concept supported by these results, then it would become clear why behaviors involving precise motor sequences, such as in speech, if not learned during childhood - are never learned as well later. Further implications for the education of children will be discussed.

1701 DISPLACED GANGLION CELLS IN RAT RETINA. Peter Land and Neil Segil*. Dept. Biol. Str. Univ. Wash., Seattle, WA 98195.

The morphology of disolaced ganglion cells in rat retina was examined after diffusely filling these neurons with horseradish peroxidase by optic nerve injection. The somata of displaced ganglion cells measure between 10 and 18 μ in diameter (ave = 14 μ). One to four stout primary dendrites issue from the vitreal surface of the somata. The primary dendrites most often branch within 20 μ of the soma, and the axons generally arise from one of the primary dendrites. Most secondary and all higher order dendritic branches are extremely fine, and except for occasional bead-like swellings, their surface is smooth and spine free. The elliptical dendritic trees of these neurons as seen in flat mounted retinae averaged 240 μ in the long axis. Three examples of displaced ganglion cells drawn from three retinae are shown in the accompanying figure (arrows = axon).

In retinae embedded in celloidin and sectioned perpendicular to the optic fiber layer, the dendrites of disolaced ganglion cells are seen to ramify in the outer 1/3 to 1/2 of the inner plexiform layer. As described previously (Bunt et al., Brain Res. 73 [1974]), displaced ganglion cells were most common in the central portion of the retina.

Our results demonstrate a remarkable morphological homogeneity for displaced ganglion cells in rat retina. This result is perhaps less surprising in view of the information which currently is emerging with regard to the central connection of these neurons in other species. Determination of the central connections of displaced ganglion cells in rat and elucidation of their detailed morphology in other species should be useful in unraveling the significance of these neurons in the organization of the vertebrate visual system. (Supported by USPHS Grant EY 05185 from the National Institutes of Health.)



1702 FUNCTIONAL CHARACTERIZATION OF MORPHOLOGICALLY DISTINCT GIANT MOTOR SYNAPSES IN THE CRAYFISH CNS. Joseph F. Margiotta* and B. Walcott. Dept. Anat. Sci., HSC, SUNY at Stony Brook, Long Island, N. Y. 11794.

In a classic study, Furshpan and Potter (1959) showed that synaptic transmission at segmental giant motor synapses (GMS) in the crayfish CNS is electrical and that the impedance of these synapses between lateral giant axon (L.G.) and axons of giant flexor motoneurons (F_1) is much lower for applied orthdromic (L.G. to F_1) than antidromic currents. Our anatomical experiments involving cobalt backfilling and injection of fluorescent dyes reveal consistent differences in the gross morphology of F_1 at thoracic versus abdominal synapses. At the level of the last thoracic ganglion (T_8), the axon of F_1 is closely apposed to the L. G. for over 800 μm. At the second abdominal ganglion (A_2) this "contact length" extends for only 200 μm.The cell-to-cell contact in both cases is characterized by the presence of small dendrites which protrude from F_1 and presumably provide the basis for electrical coupling. We have exploited the difference in contact length to assess whether size in any way determines the functional characteristics of these morphologically distinct yet homologous rectifying synapses. This expectation assumes that F_1 acts as a distributed current source/sink along the entire contact length of the GMS. The individual length constants for L.G. and F_1 are 4.23 ± 0.70 mm and 1.90 ± 0.28 mm respectively. However, the trans-synaptic length constant of F_1 when measured by applying current to L.G. and recording the membrane potential in F_1 at different interelectrode distances is 3.37 ± 0.03 mm. This data strongly supports the assumption that F_1 acts as an effective current source or sink along the entire contact length of the GMS.

Differences in current-voltage (IV) properties are being used as an assay for functional comparison of these morphologically distinct synapses. Using a multiple microelectrode technique adapted from Watanabe and Grundfest (1961) we have obtained a family of IV curves for the GMS at T_8 and A_2. Although synapses at both locations display rectification, there are obvious quantitative differences. Consistent with its morphology, the T_8 GMS, having a larger contact length, typically has a lower impedance to antidromic currents (R_s = 1.43 ± 0.53 x 10^6 Ω) than does the A_2 GMS (R_s=6.72 ± 3.78 x 10^6 Ω). Synapses at both T_8 and A_2 show a nearly identical decreased impedance to orthodromic currents beyond a positive value of synaptic potential (V_s). The change to lower orthodromic impedance (R_s = 0.10 ± 0.01 x 10^6 Ω), however, always occurs at a lower value of V_s for thoracic (V_s = 19.9 ± 7.6 mV) than abdominal (V_s = 40.0 ± 8.3 mV) synapses. Both these features reflect an improved safety factor for transmission at thoracic giant motor synapses. Supported by NIH AM 18750.

1703 DIFFERENTIAL SOLUBILITIES OF CYTOSKELETAL PROTEINS IN SQUID AXOPLASM. James R. Morris* and Raymond J. Lasek. Dept. Anat. and Neurobiology Ctr., CWRU, Cleveland, OH, & Marine Biological Laboratory, Woods Hole, Mass.

Our goal is to study the forms which cytoskeletal proteins take under physiologic conditions. We have chosen to study squid giant axon axoplasm because it consists principally of cytoskeletal proteins (tubulin, neurofilament proteins (NFP), and actin) and can be rapidly separated from its axolemma by extrusion without detergents. Additionally, the solution conditions of squid axoplasm have been defined with respect to the dialyzable low molecular weight components. Thus, it has been possible for us to design a physiologic buffer (buffer P) which effectively replicates the solution conditions in the axon. A cylinder of fresh axoplasm was extruded from the giant axon directly into buffer P. Using SDS-PAGE, proteins diffusing into buffer P were compared to those remaining in axoplasm.

We found that axoplasmic cytoskeletal proteins have different solubilities. While essentially all of the NFP (>95%) remained in the axoplasm, most of the tubulin and actin diffused into buffer P (≈5/6 and ≈3/4 of the total respectively). The axoplasm swelled but maintained its cylindrical morphology in buffer P for 24 hrs. at 20°C. The mitochondria were also retained in the axoplasm. Electron microscopy showed the presence of intact neurofilaments (NF) and mitochondria and the absence of microtubules. The axoplasmic structure which retains the insoluble axoplasmic proteins is subsequently referred to as the axoplasmic ghost.

Because all the NFP remained in the ghost and electron microscopy showed the ghost to be principally NF, we conclude that essentially all axonal NFP are normally polymerized in NF and that little or no NFP are normally dissociated from the NF. A fraction of the tubulin and actin also remained attached to the ghost. This fraction must also exist as stable polymer. However, most of the tubulin and actin diffused into buffer P. This diffusible component must exist in the axon as monomers or as a polymer which is dissociable under physiologic conditions. It is possible to distinguish between monomeric and polymeric forms by analyzing the kinetics of their diffusion from the ghost into the buffer. Such an analysis demonstrates that the diffusion of tubulin and actin is slowed when compared to the kinetics predicted by the physical equations describing diffusion for monomeric proteins. Thus, three forms of cytoskeletal proteins exist in the axon: diffusible monomer, soluble polymer, and stable polymer. NFP differ from both tubulin and actin in that NFP exist solely as stable polymer while tubulin and actin may exist in all three forms in the axon.

1704 BRANCHING CHARACTERISTICS OF HUMAN CORTICAL NEURONS FROM TWO PRETERM INFANTS OF IDENTICAL CONCEPTUAL BUT DIFFERENT GESTATIONAL AGES. Albert M. Paldino and Dominick P. Purpura, Dept. Neuroscience, Rose F. Kennedy Center for Research in Mental Retardation and Human Development, Bronx, New York 10461.

The computer microscope was utilized to obtain quantitative information concerning the branching characteristics of human cortical neurons. Hippocampal pyramids from two normal human brains were analysed in regards to their angles of branching and spatial distribution of terminals. The infants who succumbed had similar conceptual ages (33 weeks c.a.) but differed in their gestational ages (g.a.). One pre-term infant was born at 33 weeks (g.a.) while the other was born at 29 weeks (g.a.) and survived for 4 weeks in the Neonatal Intensive Care Unit. Branch and fission angles were calculated for the neuronal processes and the results indicated that (1) the average dendritic branch and fission angles of neurons from the older g.a. specimen were significantly greater than those of neurons from the younger g.a. specimen; (2) the average axonal branch angle was slightly greater in the older g.a. specimen; and (3) the average axonal fission angle was slightly lower in the older g.a. specimen. Information regarding the bifurcation frequency vs soma distance will also be presented.

Spatial analyses of axonal and dendritic terminals reflect, in part, the maturational status of neurons. In regards to these pre-term infants, the data suggest that (1) the average dendritic radial separation of terminals was approximately 40% greater in the older g.a. specimen and (2) the average dendritic cylindrical radius was approximately 50% greater in the older g.a. specimen. These results suggest that dendritic development was more advanced in the older g.a. specimen. Data concerning axonal development will also be presented. Dendritic terminals were then classified as either apical or basilar. Spatial and angular distributions were obtained for each class which enabled quantitative assessments to be made regarding dendritic differentiation. For example, each class of terminals dominated, as expected, a different portion of the polar angle distribution; that is, most apical dendritic terminals were found to possess low (less than 60°) polar angle values, and most basilar dendritic terminals were found to possess high (greater than 100°) polar angle values. Information regarding the length of neuronal processes will also be presented.

The present study is intended, in part, to augment information concerning the developmental and structural patterns of neuronal processes. Attention to such patterns as they appear in normally and aberrantly developed human brain may elucidate the morphological substrate regarding certain forms of mental retardation.

1705 CABLE PROPERTIES OF MOUSE HIPPOCAMPAL NEURONS IN CELL CULTURE. John H. Peacock and Charles R. Walker*. Dept. of Neurology, Stanford University Medical School, Stanford, CA 94305.

Flow of electric current from a cell body into its branches is governed by a combination of geometric and electric factors. Estimates of distribution of current flow between soma and processes can be made from the cable equations derived by Rall (1) who has suggested that nerve cell cultures provide an opportunity to compare cable properties which have been separately determined from geometric and electrophysiologic measurements. We have studied hippocampal neurons during their first 21 days in culture. Young neurons have less extensive branching than in older cultures and are well visualized because the background nonneuronal cell layer is thin. These neurons have been studied in growth medium plus 5-10 mM added $CaCl_2$. The mean resting potential was -55 ± 1 mV, 98 cells; action potentials were recorded from each cell; and postsynaptic potentials occurred over the entire time span of study.

Detailed measurements of cell geometry were made from photographs (1250X) with a 10X ocular. Geometric measurements were used to calculate electrotonic lengths (L_D) of processes and summed conductances (ΣG_D) of processes in 8 neurons under sealed end conditions for a membrane resistivity (R_m) of 2000 Ωcm^2 and an internal resistivity of 70 Ωcm. Electrophysiologic data give input resistance (R_N), membrane time constants (τ_m and τ_1) and estimates of electrotonic length for the entire neuron (L_N).

L_D (from geometry) ranged from 0.4-1.8 whereas L_N (from electrophysiology) was 1.0-1.9 space constants. In these cells, the ratio of diameters of 55 daughter to parent branches raised to the 3/2 power was 0.61 ± 0.04 $(10^6)cm^{3/2}$. From branching analysis the weighting factor for current flow into primary trunks (Bo) was 0.29 ± 0.05. Thus mean current flow into the 18 primary trunks was about 29% of the current flow into an equivalent infinite cylinder. ΣG_D ranged from 0.6-26.6 nS. Corresponding soma conductances (G_S) were 2.3-4.4 nS. The sum of ΣG_D plus G_S equals G_N, the input conductance, which ranged from 2.9-29 nS. The reciprocal of G_N is R_N which varied from 35-345 MΩ.

In 3 cells, measured R_N was compared to predicted values from branching analysis. Here, R_m's of 1725, 1610, and 610 Ωcm^2 plus detailed geometry yield the recorded R_N's of 100, 100, and 106 MΩ's respectively. Furthermore, predictions of R_m from electrophysiology (see Rall, 1) are respectively 1330, 1620, and 640 Ωcm^2; hence geometric and electrophysiologic estimates of R_m and R_N fit reasonably well in these cases. The issue of whether cable properties change with development in culture will be addressed in subsequent work. (Supported by NIH grants NS 12151 and NS 07012).

1706 SYNAPTIC ULTRASTRUCTURE OF SINGLE PHYSIOLOGICALLY IDENTIFIED NEURONS USING COBALT. Christine E. Phillips, Department of Zoology, University of Cambridge, Cambridge CB2 3EJ,England.

Techniques for intracellular recording and iontophoresis of cobalt dye into identified neurons in the locust Schistocerca americana gregaria have been in routine use for a number of years. Many motorneurons to flight and leg muscles and some of the presynaptic interneurons have been physiologically characterised and their morphology examined at the level of the light microscope after silver intensified cobalt staining.

A technique has been developed to preserve the synaptic structures of dye marked motoneurons and local non-spiking interneurons. Electrodes containing a mixture of cobalt chloride and potassium chloride were used for recording, physiological identification and staining of the neurons. Ganglia were prefixed prior to sulfide precipitation of the cobalt, then fixed for electron microscopy and embedded in Epon 812.

Ganglia were serially sectioned at 2.5um. Sections were silver intensified on glass slides, photographed and re-embedded. Thin sections were stained with uranyl acetate and lead citrate and photographed in a Philips EM300.

The cobalt-silver complex appears as descrete dense particles ranging from 15nm to 40nm in diameter. The highest concentration was found in the cell body. The perineurium and glia lacunae exhibited non-specific silver reaction. Frozen sections of unfixed, control ganglia which were then silver intensified, showed that was due to an endogenous reaction. Silver precipitate in the cell body layer and in the neuropil was restricted to the injected neuron and could be found in terminal arborizations.

Using this technique, synaptic structures of identified motorneurons and presynaptic, non-spiking interneurons in the mesothoracic and metathoracic ganglia of the locust have been clearly seen.

This work was supported by N.I.H. postdoctoral fellowship No. 1 F 32 NS 06028 01.

1707 A NON-RANDOM PROCESS DETERMINES THE DIRECTION OF MYELIN WRAPPING. Whitman Richards, Ronald Kalil[1] and Claire L. Moore*.[2] Department of Psychology, M.I.T., Cambridge, Massachusetts 02139.

Over ten years ago, Peters (1964) observed that the internal and external mesaxons of developing myelin sheaths were often found in the same quadrant during the early stages of myelination. This observation, together with more recent work (Moore et al, 1976), suggests that the initial glial wrapping proceeds step-wise with complete 360° revolutions about a fiber. Little attention has been paid to the direction of wrapping, however. To explore this question, approximately 1100 fibers were examined at 10,000X in an EM montage covering 0.04 mm^2 of the optic tract of a 4-week-old kitten. The analysis shows that the direction of wrapping of neighboring fibers does not proceed independently of one another. For fibers in contact with the same glial cell, the probability of adjacent fibers being wrapped in the same direction is 75% rather than the 50% chance value. Furthermore, as one proceeds from one fiber to the next in a progression around a glial cell, then rarely do more than four reversals of the direction of myelin wrapping occur. A relaxation oscillator model for myelination is proposed, whereby glial "beats" of elongation and contraction about two axes cause its membrane to wrap fibers on opposite sides of the glial core in the same direction.

1708 MEMBRANE RESISTANCE AND ELECTROTONIC DECAY IN GUINEA PIG CA1 HIPPOCAMPAL PYRAMIDAL CELLS. Dennis A. Turner* and Philip A. Schwartzkroin. Dept. Neurol. Surg., Univ. Wash., Sch. Med., Seattle, WA 98105 U.S.A.

Input resistance (R_{in}) and other intracellular parameters were measured in CA1 cells in the in vitro hippocampal slice preparation. Subsequently, horseradish peroxidase was injected intracellularly and then reacted with diaminobenzidine and H_2O_2. Twelve pyramidal cells and 2 interneurons were successfully stained, with average R_{in} 27.8 ± 7.4 (mean ± S.D., megohm) for the pyramidal cells and 27.0 ± 1.0 for the interneurons. The specific quantitative anatomy of each cell was then reconstructed using computerized finite cable analysis (Rall, W. Exp. Neurol. 1:491, 1959). Specific membrane resistance (R_m, ohm-cm^2) averaged 2450 and 4860 for the pyramidal cells, comparing sealed-end and infinite cable terminations, respectively. R_m ranged between 915 (sealed-end) and 1050 (infinite cable termination) for the 2 interneurons, one of which appeared to be a basket cell histologically. Evaluation of the three-halves power of the diameters at branch points revealed an average of 1.001, for 2680 branch points.

Apical dendrites of pyramidal cells terminated at 1.2-2.5 length constants, while the basilar dendrites ended at 0.7-2.0. For voltage injected at the most distal apical and basilar dendritic terminations, only 0.4% would appear at the soma. For terminals within the stratum radiatum, 3.3% of the injected voltage would reach the soma. However, for current injected at the apical terminations, an average of 34% would arrive at the soma, as compared to 51% for the most distant basilar dendritic regions and 72% for the stratum radiatum terminations. Input resistances of these apical and basilar dendritic segments averaged 2.9×10^9 ohms. Thus, current in these cells achieves a higher transfer efficiency than voltage in electrotonic conduction from distal parts of the cell to the soma. The dendrite to soma conductance ratio in pyramidal cells averaged 3.5 ± 1.3 for the sealed end termination and 7.7 ± 3.1 for the infinite cable termination.

These measurements compare well with those on the motoneuron, and indicate that distal synaptic events may significantly influence ongoing activity at the soma, without active conduction.

NEUROPATHOLOGY AND NEUROIMMUNOLOGY

1709 MICROSCOPIC STUDY OF A TRAUMATIC/HYPOXIC BRAIN INJURY MODEL. E.L. Auen, K.D. Barron, L.R. Nelson and R.S. Bourke, Div. of Neurosurgery and Depts. of Anatomy and Neurology, Albany Medical College, Albany, NY 12208.

Light and electronmicroscopic techniques were used to examine various neuroanatomical sites in a brain trauma model presented elsewhere (see Nelson et al. this volume). The intent was to establish the neuropathological changes resulting from traumatic insult to brain in conjunction with and separate from hypoxic insult. The cats were divided into 4 groups. Group I cats received the traumatic insult and were sacrificed at various times beginning immediately after the insult. Group II cats received hypoxic insult (respired with 6% O_2 in N_2 for 30-60 min) and also were sacrificed at various times after the insult. Group III cats received the combination traumatic/hypoxic (60 min) insult and likewise were sacrificed at various times up to 24 hours post trauma. Group IV was the control receiving all surgical manipulations except trauma and hypoxia. Animals were killed under anesthesia with a paraformaldehyde-glutaraldehyde perfusion sequence and tissues from one hemisphere were embedded in epon while the other half of the brain was embedded in paraffin. The neuroanatomical sites studied included motor cortex, caudate,thalamus,cerebellum, brain stem, periaqueductal gray, ectosylvian gyrus, hippocampus, and spinal cord.

Group I animals showed a conspicuous degree of perivascular astroglial cell and process swelling. In 1µm epon sections stained with toluidine blue the perivascular astroglial cell swelling was easily observed. These expanded electron-lucent profiles in the perivascular position were scattered throughout the brain but particularly evident in motor cortex and cerebellum. The perivascular astroglial swelling was not observed immediately after trauma but was seen at 40 min post trauma. The Group II animals demonstrated a scattered and subtle perineuronal astroglial swelling mainly confined to motor cortex. Group III animals receiving the combined traumatic/hypoxic insult had a 50% mortality rate. Animals in Group III apparently destined to survive demonstrated variable degrees of astrocytic swelling depending on the neuroanatomical location and time of sacrifice. Group III animals destined to expire based on electroencephalogram criteria showed not only perivascular and perineuronal astroglial cell swelling but also chromatolytic changes in neurons and electron-dense nerve cells. Clumping of nuclear chromatin was observed with extrusion into the cytoplasm of both neuronal and astroglial cells. These pathological conditions occurred within 20 minutes from the traumatic insult. Group IV animals were normal in appearance. Supported by NIH Grant NS 13042.

1710 MULTIPLE FORMS OF THE COPPER(II)-CARNOSINE COMPLEX AND THEIR POSSIBLE INVOLVEMENT IN WILSON'S DISEASE. Charles Eric Brown and William E. Antholine*, Departments of Biochemistry and Radiology, The Medical College of Wisconsin, Milwaukee, Wisconsin 53226.

The copper(II)-carnosine complex has been well characterized in the crystal as a magnetically coupled cupric dimer that is chelated by two molecules of carnosine (β-alanyl-L-histidine). The complex in solution was assumed to consist only of a single copper(II) ion complexed to one molecule of carnosine with crystallization occurring when two of these complexes joined to form the dimer. Since the monomeric complex in solution was shown to be weak, no copper-carnosine was expected to form in vivo. We have found that the cupric monomer is formed in solution only when carnosine is in excess. There are four molecules of carnosine bound per copper(II) ion instead of only one as indicated by the nitrogen hyperfine splitting of the $g_{\parallel}$ low field $I=+\frac{1}{2}$ transition in the S-band ESR spectrum at 77°K (Fig. 1). In addition, the

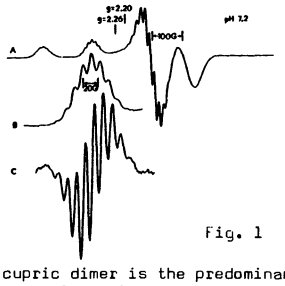

Fig. 1

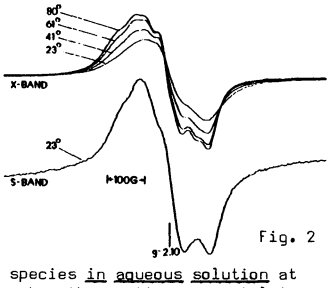

Fig. 2

cupric dimer is the predominant species in aqueous solution at physiological pH and temperature when the peptide and metal ion are at equimolar concentration. This stability in aqueous solution is demonstrated by the increase in ESR spectral intensity as the temperature is raised (Fig. 2). We have detected the dimeric species at concentrations as low as 10µM at which the sensitivity of the spectrometer is limiting. Similar results were obtained with anserine (β-alanyl-1-methylhistidine) but not with homocarnosine (γ-aminobutyryl-L-histidine). These observations may explain the finding that patients with carnosinemia, carnosinuria, anserinuria and deficient carnosinase activity in the serum (i.e. with elevated carnosine or anserine in the plasma and/or urine) exhibit neurological damage that mimics that of Wilson's disease (i.e. hepatolenticular degeneration, impaired copper metabolism by the liver resulting in deposition of copper in brain and kidney). 1711 IMPAIRED PROLIFERATIVE RESPONSE OF LYMPHOCYTES TO MEASLES ANTIGENS IN MULTIPLE SCLEROSIS. Vinh Cam*, Hon-Sum Ko*, Michael Lyons*, Charles Plank* and John Zabriskie* (SPON: N. E. Miller) Rockefeller Univ., New York, NY 10021.

The blastogenic index to measles antigens was studied in 23 patients with multiple sclerosis (MS) and compared to that in 23 normal controls and in patients with other neurological diseases. MS patients exhibited a consistently low response to measles antigens when compared to controls (mean response 45% lower than controls). However, responses to mumps, parainfluenza, bacterial antigens and PHA were normal.

Two factors appeared to be most important for successful cell proliferation to measles antigens: 1) the optimal cell concentration (1×10^6 cells/ml) and 2) the selection of a correct batch of human AB+ plasma. The HI titers to measles antigens in AB+ plasma and in the sera of all MS and control subjects, and their level of immune complexes were measured, and their HLA typed.

Further investigations demonstrated that approximately 70% of MS patients had increased levels of $Fc\gamma$ receptor bearing T cells ($T\gamma$) among their peripheral blood lymphocytes. The elevated $T\gamma$ level appeared to correlate with the depressed blastogenic response. Adherent, B, T, $T\gamma$, and $T\gamma$-depleted T cells were separated and their reactivity to measles antigen studied. The blastogenic response of MS patients was not restored by depletion of $T\gamma$ cells.

1712 UTILIZATION OF COMPUTERIZED TOMOGRAPHY IN THE DETECTION AND MANAGEMENT OF PEDIATRIC BRAIN TUMOR PATIENTS. D. DE MICHELE*, M. CERRONI*, L. SINKS*, D. MC CULLOUGH*, B. HAMILTON , W. NORMAN*, P. WEISS*, D. ROBERTSON*, D. SCHELLINGER*, H. MANZ*, AND J. MAZZIOTTA*. (SPON: R. ADAIR) GEORGETOWN UNIVERSITY MEDICAL CENTER WASHINGTON D.C. 20007, AND U.C.L.A. MEDICAL CENTER, LOS ANGELES, CA 90024.

Advances in therapy for pediatric cancer patients has been disproportionate among the different types of cancers. Clinical success rates with cerebral neoplasms has not been particularly consistent. This is due in part to a lack of precision methods whereby patient response to surgical, radio, and adjuvant chemotherapy can be assessed. In an attempt to resolve this situation we have developed a system for monitoring glioma development and response to treatment through employment of Computerized Tomography (CT). We believe the information gained from this system will enable us to treat our patients more effectively. Three parameters and how they interact are followed over time. These are, lesion volume, ventricular volume and total normal brain volume. This information is critically reviewed taking into account the drugs that are in use at the time. Therapuetic regimens are developed based on this volumetric data and continually updated. Secondly, neurological signs and symptoms can be correlated to neuroanatomical scan data. Ventricular, lesion and total brain volumes change unpredictably over time within the same patient and among different patients with the same histologically verified lesion. Changes in lesion volumes can be examined in conjunction with fluxes of ventricular and total brain mass determinations thus providing a detailed view of complete intra cranial dynamics in disease and during the entire course of multimodal therapy. This system will be described, advantages and disadvantages weighed, and its worth assessed by illustrative longitudinal case studies.

1713 TRANSPLANTATION OF RAT SCHWANN CELLS CULTURED IN VITRO INTO DEMYELINATED AREAS OF THE MOUSE SPINAL CORD. I.D. Duncan*, A.J. Aguayo, Dept. Neurol., McGill Univ., Montreal, Que. H3G 1A4, R.P. Bunge and P. Wood, Dept. Neurobiol. Washington Univ., St. Louis, Mo. 63110.

It has been shown in the rat by Blakemore (Nature 266:68,1977) that segments of the autologous sciatic nerve can be transplanted into regions of the spinal cord. The aim of the present study was to determine the feasibility of grafting cultured xenogenic Schwann cells to the mouse demyelinated spinal cord.

Laminectomies were performed on C57BL/6J mice and quaking (qk) mice in mid-lower thoracic area and the dura exposed and then incised. A hand held 20 µm tip glass micropipette connected to a microsyringe containing lysophosphatidyl choline (LPC) (10 µg/ml) was inserted into the dorsal columns and 1 µl injected at three sites. A small breach in the pia was made in the center of this area. Holtzman rat Schwann cells, cultured and separated from neurites (Brain Res. 115:36, 1976) were inserted into this breach and teased gently under the pia. The wound was closed and the animals allowed to survive from periods of between 2 and 15 weeks during which immune suppression was carried out by the twice weekly injection of host mice with antilymphocytic serum (ALS). From 2 weeks it was possible to detect spinal cord axons which were myelinated by Schwann cells. Myelination by Schwann cells was observed to extend along the dorsal columns of the spinal cord for a distance of approximately 200 µm, rostral and caudal to the site of the graft. These were especially obvious in the qk mice where axons well myelinated by Schwann cells were adjacent to and mixed with the host's hypomyelinated axons.

Early evidence that these Schwann cells were foreign was deduced by graft rejection techniques. These findings suggest that Schwann cells grown in vitro can ensheath and myelinate both demyelinated axons in the CNS as well as regenerating axons in the PNS (Aguayo et al, Neurology 29:589, 1979).

1714 DOPAMINE DEPLETION AND THE VISUAL EVOKED POTENTIAL. Robert S. Dyer, William E. Howell* and Robert C. MacPhail*. Neurotox. Div. Health Effects Res. Lab., U.S.E.P.A., Research Triangle Park, NC 27711.

It has recently been reported (Brain, 101:661, 1978) that patients with Parkinson's Disease have significantly longer visual evoked potential (VER) latencies than nonparkinsonian patients. This altered response to photic stimuli may result from the brain dopamine depletion known to correlate with Parkinson's disease, or from other nonspecific factors. We report here that brain dopamine depletion significantly increases the latency of the flash evoked potential from the visual cortex of rats. Chronically prepared rats were injected with the following drugs, presented in counterbalanced order once every three days: Alpha-methyl-para-tyrosine (AMT) (75 mg/kg 6 hrs + 75 mg/kg 2 hrs before testing), FLA-63 (25 mg/kg 4 hrs before testing), scopolamine (2 mg/kg 15 min before testing), naloxone (1 mg/kg 15 min before testing), and saline (2 ml/kg 6 hrs + 2 ml/kg 15 min before testing). In a separate experiment, ten animals were injected with (150 mg/kg) para-chlorophenylalanine (PCPA) and ten others were injected with saline. In this experiment all injections were given 3 days before testing. Peak-to-peak amplitudes and peak latencies of the potential evoked by 64 flashes were recorded. AMT significantly increased latency to the first negative peak (N1) (34.5±0.8 msec) compared to the saline control (30.1±0.3 msec), while FLA-63 did not alter latency (30.6±0.4 msec). AMT also increased latency of peaks P1 and P2. Dopamine depletion was apparently responsible for the altered latency, since depletion of norepinephrine by FLA-63, a dopamine-β-hydroxylase inhibitor, did not produce these alterations. AMT did not alter latencies of later peaks (N2, P3 or N3), thus demonstrating independence of these peaks from earlier ones (P1, N1, P2). Since the effect of AMT occurs in the first peak of the evoked potential, since the retina contains dopamine, and since thioridazine has been shown to increase the latency of the ERG A wave in humans (Int. Pharmacopsychiat. 13:151, 1978), it seems likely that the effect of AMT on the visual evoked potential occurs primarily at the retinal level. This interpretation is supported by the finding that AMT does not alter latencies of potentials recorded in the cortex following optic tract stimulation.

1715 LONG-TERM LEARNING DEFICIT IN THE RAT PRODUCED AFTER METHYL MERCURY EXPOSURE IN LATE GESTATION. C.U. Eccles and Z. Annau. The Johns Hopkins University, School of Hygiene and Public Health Baltimore, MD 21205.

Prenatal exposure to methyl mercury (MeHg) is known to cause central nervous system damage in a variety of species. The nature of the resulting deficits and the parameters involved in the manifestation of them is currently under investigation. A previous report from our laboratory demonstrated that the offspring of rats treated with 8 mg/kg MeHg on day 7 of gestation sustained long lasting learning deficits when tested in a two-way shuttlebox avoidance task as adults (Eccles and Annau, Neurosci. Abst., 4, p. 396, 1978). We have employed a similar design to examine the effects of the same dose of MeHg administered on day 14 of gestation.

Pregnant Long-Evans rats bred in our laboratory received 8 mg/kg of MeHg on day 14 of gestation. The control groups received sodium carbonate alone. On the day of birth, litters were culled to a standard size of 8, if possible. The pups were weighed on days 1, 7, 14 and 21.

Adult males were again weighed at 9 weeks of age. The spontaneous locomotor activity of each of these animals was measured for 1 hour in a Stoelting electronic activity meter. The rats were then tested in a two-way shuttlebox avoidance task. Training was carried out in daily 50-trial sessions until the criterion level of 10 consecutives avoidances was met. Avoidance behavior of animals that met the criterion was extinguished the following day. This was followed by a reacquisition period in which the animals were again required to make ten consecutive avoidances.

Neonatal weight data revealed a significantly reduced weight gain in the MeHg treated pups. The mean weight of the MeHg treated males at 9 weeks of age (235 g) was also reduced compared to that of controls (276 g).

There were no significant difference in spontaneous locomotor activity level between the two groups, although there was greater variability in the MeHg treated group for this measure. In the avoidance task, 80% of mercury treated rats did not reach criterion level of responding during the acquisition period. The rats that did meet the criterion required significantly more trials than controls. When treated rats that previously met criterion were tested during reacquisition, they again required a greater number of trials to reach criterion compared to controls.

The results indicate that MeHg administered on day 14 of gestation can result in a severe and long-lasting learning deficit in the absence of general motor debilitation. The effects seen after administration of MeHg on gestional day 14 were more severe than those observed after administration on day 7.

1716 FOCAL LACERATION AND CONTUSION OF RAT CEREBRAL CORTEX. D.M. Feeney, H.M. Murray, W.G. Dail Jr., M.G. Boyeson & R.T. Linn Depts. of Psych. & Anat., Univ. of New Mexico, Alb. NM 87131.

Changes in behavior, lesion histochemistry and morphology were studied at various times after unilateral laceration or contusion of rat cerebral cortex. As a model of laceration, four mm diameter undercuts were made in the area from which hindpaw movements can be evoked by electrical stimulation. In the first hours after injury, EEG was reduced to half prelesion amplitude at loci several mms distant from the undercut. At 24 hours, the lesion was not organized and only minor cell loss was seen in overlying cortex, however, an oxidative enzyme stain (alpha glycerophosphate dehydrogenase) showed extensive paling far beyond undercut cortex. By 4 days, cells adjacent to the undercut stained intensely for dehydrogenase. These apparently are macrophages and are filled with vacuoles containing hemosiderin-like material. Hypertrophied astrocytes now appear at the lesion as well as mitotic figures presumed to be hematogenous in origin. Between 9 and 15 days the undercut in the white matter enlarges to maximum size and alkaline phosphatase stain indicates a transition to a lined cavity. Hypertrophied astrocytes stain intensely for alpha glycerophosphate dehydrogenase by 15 days and superficial cortex above the cut is invaded by tissue from the meninges which appears vascular. The widespread cortical paling seen earlier with dehydrogenous stain is now restricted to cortex over the undercut. The EEG has returned to normal amplitude but high voltage spikes are seen in the vicinity of undercut cortex. Behavioral changes include: (1) At 4 days a 700% decrease in speed of locomotion on a narrow plank and a 10 fold increase in footslips. This recovers by 30 days. (2) Recovery is not dependent on practice since animals with identical injuries not tested during the 30 days post injury are also recovered by that time. (3) Spontaneous activity begins to increase at 24 hours, peaks at 6 days and returns to baseline by 40 days.

For cortical contusion, an apparatus delivered graded impacts to the "hindpaw" area of rat cortex. A tube guides a falling weight onto a footplate resting on exposed dura. Force is expressed as weight x distance dropped. Moderate and severe focal contusions, without subcortical involvement are obtained with a 4.5 mm footplate, penetration limited to 2.5 mm by use of a sleeve, and forces of 200 or 600g/cm. This model shows a contralateral hemiparesis with some recovery by 15 days. Hemorrhaging appears to begin in the white matter and is followed by the development over 15-30 days of a necrotic cavity lined with fibroblasts.

Supported by NIH Grant NS 13684-02.

1717 MORPHOLOGICAL AND BIOCHEMICAL ALTERATIONS IN A NEW RAT MODEL OF SPONTANEOUS ALCOHOL INTAKE. Barry Goldstein*, Ronald P. Hammer, Jr., Gaylord Ellison, and David S. Maxwell. Dept. Anat., Sch. Med., UCLA, Los Angeles, CA 90024.

This is a report on a method for producing rats which spontaneously and voluntarily ingest ethanol. The morphology of the brains and livers from a population of these animals has been examined. In addition, their liver alcohol dehydrogenase (AdH) activity has been studied and their brain AdH activity is currently under investigation.

Thirty-two rats were housed in a semi-naturalistic rat colony environment with ad lib access to 10% ethanol and water. After seven months of colony housing, all animals were captured, placed in individual cages and alcohol and water consumption were monitored. There was a wide range of alcohol appetites, five animals showed a marked alcohol preference (4.5-8.1 g/kg/day) while another eight animals consumed virtually no alcohol (0.3-0.7 g/kg/day.) The remaining nineteen animals consumed intermediate amounts of alcohol (0.9-4.3 g/kg/day.) These extremes of alcohol preference were apparently due to the colony housing since they did not occur in twenty-seven rats kept in isolation for the same length of time and also offered ad lib access to ethanol and water. Blood ethanol levels, spontaneous withdrawal signs, food consumption, and behavioral studies are currently being examined in a similar colony.

After the seven months in the colony, the animals were sacrificed and the brains and the livers were removed. The morphology of the nervous system was examined on an ultrastructural level and correlated with a Golgi study and a conventional light microscopic study. Fine structural alterations have been observed in the hippocampus, the mammillary bodies, the cerebral cortex, and the cerebellar cortex of the alcohol consuming rats. These alterations include numerous dendritic varicosities which contain smooth membranous vesicles. Some of these vesicles are continuous with the dendritic membrane while others are contiguous but not connected to the membrane. In the Golgi preparations, these dendritic varicosities often appear as vacuolated nodularities along the length of the dendrite.

The morphology of the livers from the alcohol consuming rats has also revealed structural alterations. Light microscopic examinations have indicated normal hepatic architecture in the animals that did not consume alcohol and a fatty metamorphosis in the alcohol consuming rats. The fine structure of these livers is currently being examined. In addition to the morphological studies of the liver, liver alcohol dehydrogenase activity was examined. The alcohol consuming rats had significantly higher liver AdH levels. (Supported by Grant #AA03513 from the National Institute on Alcohol Abuse and Alcoholism.)

1718 CONTENT AND FUNCTIONAL CAPACITY OF CEREBELLAR RNA FROM RATS WITH GRAFT VERSUS HOST DISEASE (GVHD). W. S. T. Griffin, M. Morrison*, and J. R. Head*. University of Texas Health Science Center at Dallas, Texas 75235.

The possibility of adverse effects on developing fetuses due to the passage of mature lymphocytes from the maternal to fetal circulation has long been recognized. Such passage can result in GVHD occurring during the period of brain development. However, our series of experiments, utilizing the rat cerebellum as a model, is the first to investigate the effects of such an immunological assault on the developing nervous system. We simulate maternal-fetal cell passage by intravenous injections of 40×10^6 parental strain lymph node cells (PSLNC) from Fischer rats (FI) into (FI x DA)F_1 hybrid rat pups on the day of birth. The F_1 hybrids do not recognize the PSLNC as nonself, but the PSLNC recognize the DA antigens present on the F_1 cells and attack host lymphoid tissue, the first of a cascade of events called GVHD. We have previously reported that GVHD decreased cerebellar DNA synthetic capacity, cell number and cellular components, perhaps due to a blood-borne factor released during lymphocyte interaction which inhibits proliferation. Here, we report the effects of GVHD on total RNA content (amount of rough endoplasmic reticulum, rER), RNA synthesis (^{3}H-uridine uptake into the RNA fraction), and RNA message capacity (separation of the various RNA species and the ability of mRNA to direct protein synthesis in a cell-free wheat germ culture). During acute GVHD (postnatal day 14) there was a decrease in 1) the amount of rER as shown by less staining by cresyl violet of cerebellar sections from animals with GVHD when compared to litter mate controls, 2) total RNA content (65% of control) as measured both by colorimetry and optical density, 3) ^{3}H-uridine uptake into the RNA fraction (65% of control), and 4) the overall translational capacity of mRNA (85% the biological activity of the control per unit of RNA). Two dimensional gel electrophoresis of the proteins synthesized by control and GVHD RNAs in in vitro cell-free protein synthesizing systems showed that about 200 to 250 separable proteins are synthesized by both fractions including α and β tubulins and β actin. The vast majority of these proteins appear qualitatively and quantitatively unchanged, but there were several spots in the experimental gels which were absent in the controls and vice versa. The overall conclusion is that there was a generalized reduction in the synthesis of the 200 to 250 proteins with isoelectric points between 4.5 and 7, suggesting a reduction in the amount or biological activity of the corresponding experimental mRNAs.

1719 MEASUREMENT OF ACETYLCHOLINE RECEPTOR AND ANTI-ACETYLCHOLINE RECEPTOR IMMUNOGLOBULINS USING THE ENZYME-LINKED IMMUNOSORBENT ASSAY. I. J. Griffith, J. A. Lettieri*, and N. L. Norcross*. Dept. of Microbiology, New York State College of Veterinary Medicine, Cornell University, Ithaca, NY 14853.

Recent evidence indicates that the pathogenesis of myasthenia gravis (MG) involves antibodies directed against nicotinic acetylcholine receptors (AChR). Antibodies to the AChR in both MG and an animal model of the disease, designated experimental autoimmune myasthenia gravis (EAMG), are routinely measured using a radioimmunoassay (RIA) utilizing 125-I-labelled α-bungarotoxin (α-BGT) as a specific label for the AChR. We have developed an alternative method for the quantitation of both AChR and anti-AChR immunoglobulins employing the enzyme-linked immunosorbent assay (ELISA).

In its simplest form, purified AChR is adsorbed to the walls of a polystyrene microtitre plate by incubation in carbonate buffer. This is followed by sequential incubation with excess anti-AChR serum, peroxidase-conjugated anti-immunoglobulins, and a suitable substrate. The degree of substrate catalysis is then determined by optical density measurements. This procedure can be adapted to measure AChR or anti-AChR immunoglobulins. With the use of an additional reagent, it is also possible to quantitate specific classes of anti-AChR immunoglobulins.

If α-BGT is adsorbed to the polystyrene, followed by AChR in phosphate buffer, and sequential incubations with reagents as described above, the assay becomes more broadly applicable. With this modification, it is possible to measure AChR in extracts of both electric organ and mammalian muscle tissue. Ligands which inhibit the binding of α-BGT and AChR demonstrate the specificity of the assay.

It has been demonstrated that there is a significant correlation between the presence of anti-AChR immunoglobulins and MG. Due to the relative simplicity of the ELISA in comparison to RIA methods, it is possible that this test may prove valuable as a clinical diagnostic tool for MG.

1720 EFFECTS OF LOCUS COERULEUS AND ANTERIOR HYPOTHALAMIC BRAIN LESIONS ON ANTIBODY FORMATION IN MICE. Nicholas R. Hall, John K. Lewis*, Richard T. Smith* and Steven F. Zornetzer. Dept. Pathol. University of Florida College of Medicine, Gainesville, Florida

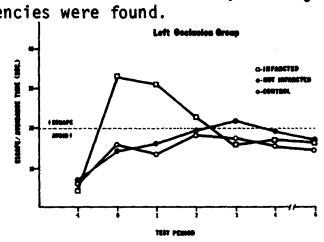
Previous data have shown that electrolytic lesions of the nucleus locus coeruleus are capable of inhibiting the subsequent formation of both granulocyte-macrophage colonies in tissue culture and hemopoietic colony forming units on the spleen induced by radiation exposure. Hemopoietic stem cells arising in the bone-marrow give rise to lymphocytes under the influence of the appropriate microenvironmental factors. The possibility that lesions of the nucleus locus coeruleus might exert an inhibitory influence over the immune system as measured by antibody formation was subsequently investigated.

Adult C57B/6J female mice received bilateral lesions induced electrolytically (300 uA for 10 seconds) in either the nucleus locus coeruleus or the anterior hypothalamus. Control animals were given nembutal anesthesia but were not manipulated surgically All subjects were ovariectomized to eliminate differences that might have been due to cyclic fluctuations of ovarian hormones. Animals were allowed 6 weeks recovery time before being injected with antigen. Sheep red blood cells were washed in hemaglutination buffer and injected ip in 0.25 cc of RPMI 1640 media. Five days later, the subjects were sacrificed by decapitation and trunk blood was collected as a source of serum for measuring hemaglutinating antibody titers. Brains were removed and sectioned for histologic verification of the lesion site.

Animals in both lesion groups were found to be good antibody responders. There was no statistical difference between those animals that had received lesions of the locus coeruleus and those with anterior hypothalamic lesions. Neither of the values obtained from the lesioned animals differed from the unlesioned control titer. These data suggest that the inhibitory influence of locus coeruleus lesions upon bone marrow stem cells is not manifested by a functional impairment of the immune system as assessed by using the above paradigm.

1721 THE RAPID AVOIDANCE TEST OF GERBILS AFTER UNILATERAL CEREBRAL ISCHEMIA. Charles J. Hannan, Jr., Andree J. Lloyd* and John J. McCloskey*. Clinical Investigation and Neurosurgery Service, and Pathology Department, Eisenhower Army Medical Center, Ft. Gordon, GA 30905.

Ninety male Mongolian gerbils completed 6 daily evaluations on the rapid avoidance test (RAT) in an attempt to quantitate the effects of cerebral ischemia produced by occluding a common carotid artery. Animals were trained in a shuttle box on a RAT schedule of 4 escape trials (tone and shock presented simultaneously for 40 sec) followed by 2 avoidance trials (20 sec of tone then 20 sec of tone and shock) with a 5 minute intertrial interval. Criterion for entry into the study was at least one successful response in the avoidance trials. One hundred and ninety six gerbils were trained with 26.5% rejected for not meeting the criterion. Animals were randomly assigned to groups for 1) right, or 2) left carotid artery occlusion, and 3) surgical controls. Animals were given the RAT just prior to surgery (animals failing to avoid were also rejected); at 3,5, or 7 hours after surgery; and then on 1,2,3,4 and 6 days post surgery. If animals died or were judged to be physically unable to perform the RAT they were eliminated from the study and additional animals were trained so that each group contained at least 30 animals at the end of the study. Of 104 animals entered into the occlusion groups, 40 died (right occlusion 17/49, left 23/55), therefore 64 occluded animals completed the study. Infarctions were histologically demonstrated in 14 of the 64 (21.9%) surviving animals (9 left, 5 right hemisphere). Mean values of performance on the RAT exhibited differences between groups, with animals which were found to be infarcted doing poorer than non infarcted or control animals, and left side infarcted animals doing worse than those with right side infarctions. No measure of escape/avoidance time or patterns of time was uniquely predictive of infarction, although significant population tendencies were found.



1722 IMMUNOCYTOCHEMICAL OBSERVATIONS ON DEMYELINATING LESIONS IN EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS (EAE). Yasuto Itoyama*, Nancy H. Sternberger*, Richard H. Quarles*, Steven R. Cohen* and Henry deF. Webster. NINCDS, NIH, Bethesda, MD 20205.

Focal changes in the distribution of myelin sheath constituents that occur during myelin breakdown are not well understood. To investigate these changes, we induced experimental allergic encephalomyelitis (EAE) by injecting an emulsion of spinal cord and complete Freund's adjuvant into strain 13 guinea pigs and Lewis rats. In guinea pigs, the first symptoms occurred 10-11 days after injection; all of them had a rapidly progressive illness and died on the 15-16th day. The rats became ill after 9-10 days; their illness was more severe 3-4 days later and all of them were recovering when sacrificed 17-19 days after injection. Animals were perfused with fixative before symptoms appeared, within 48 hrs of the first symptoms, and during severe illness. Rats also were perfused during recovery. Vibratome and paraffin sections were immunostained with antisera to myelin basic protein (BP), a major constituent of compact myelin, myelin-associated glycoprotein (MAG), located periaxonally in myelinated fibers, and immunoglobulin G (IgG) according to our modification of the peroxidase-antiperoxidase (PAP) method. The major findings were: 1) Early focal fragmentation of myelin sheaths was easier to identify with BP immunostaining than with LFB or other histological methods. 2) In more advanced lesions, fragmenting sheaths and demyelination were found beyond margins of perivascular infiltrations especially in the gray matter. 3) Demyelinating lesions in the gray matter also contained substantially fewer mononuclear cells than the white matter lesions of the same size. 4) In periventricular lesions, BP-stained myelin fragments were present extracellularly and in subependymal macrophages. Some macrophages were found between ependymal cells and a few were located intraventricularly. Their presence in the CSF may explain the elevated BP levels described by others in acute attacks of EAE and multiple sclerosis. 5) In zones of myelin fragmentation and breakdown, periaxonal staining by MAG antiserum was abnormal also. 6) In early EAE lesions, IgG was present perivascularly. Its penetration into the surrounding parenchyma increased as the lesions progressed. The IgG staining pattern was similar to that reported by others for EAE blood brain barrier experiments using tracers.

1723 TRIMETHADIONE INCREASES THE REDUCTION IN BRAIN MICROVASCULAR VOLUME AFTER PROLONGED CEREBRAL ISCHEMIA IN GERBILS. D.M. Jarrott*, and F.R. Domer. Depts. of Neurosurgery & Pharmacology, Tulane Univ. School of Medicine, New Orleans, La. 70112.

Qualitative methods of outlining the cerebral microcirculation with intravascular India ink have been used to describe a "no-reflow phenomenon" following ischemia. In this process reperfusion of the brain is hampered after ischemia by microvascular factors which obstruct blood flow to some capillary beds. The cause of the microvascular obstruction, its relevance to the various models of cerebral ischemia, and its quantitative determination have not as yet been accomplished. We have used a plasma label, ^{131}I-RISA, to investigate the microvascular volume of the gerbil and the changes that occur after one hour of bilateral carotid arterial occlusion. The normal, pentobarbital-anesthetized, gerbil has a cerebral blood volume of 14.4±0.7 µl/gm. After carotid occlusion this volume is decreased to 11.6±0.6 µl/kg ($P < .05$). When the gerbils are treated with trimethadione 300 µg/kg, the cerebral blood volume after ischemia is reduced even further to 10.0±0.5 µl/gm, which is significantly lower than that of the saline-treated gerbils ($P < .05$). Mongolian gerbils exhibit spontaneous seizures. The mortality rate after bilateral carotid occlusion is related to frequent and severe postischemic convulsions. Both spontaneous and stress-provoked convulsions are blocked by trimethadione and phenobarbital but not by phenytoin or pentobarbital. Administration of trimethadione 300 mg/kg to gerbils after one hour of bilateral carotid occlusion reduced the resulting mortality rate from 100% to 50% whereas phenytoin 10 mg/kg had no protective effect. Thus, the reduction of postischemic neuronal hyperexcitability produced by trimethadione might result in less postischemic hyperemia.This would explain the further reduction in microvascular volume observed in the postischemic period in trimethadione-treated gerbils.

1724 MORPHOLOGICAL CORRELATION OF THE NEURONAL AND GLIAL RESPONSE TO COMPLETE CEREBRAL ISCHEMIA. Larry W. Jenkins*, John T. Povlishock, and Donald P. Becker (SPON: D.P. Becker). Depts. of Anatomy and Neurological Surg., Med. Col. of Va., Virginia Commonwealth Univ., Richmond, VA. 23298.

Adult cats were subjected to 1.5 to 15 minutes of reversible complete cerebral ischemia both with and without subsequent post-ischemic reperfusion. In all animals rigorous physiological controls were employed both prior to and following the ischemic insult. Following the desired duration of complete ischemia and if permitted post-ischemic recirculation, all animals were perfused with aldehydes. Tissue samples from selected brain loci were then processed for light and electron microscopy. Through such a regimen the termporal development of both neuronal and glial morphological alterations were ascertained.

In those animals perfused immediately following 1.5 to 15 minutes of complete cerebral ischemia both the neurons and astrocytes manifested homogeneous cellular alterations. Such alterations consisted of progressive chromatin clumping, nucleolar condensation, and moderate dilation of the endoplasmic reticulum, Golgi complex and mitochondrial intracristal spaces. In contrast, in those animals subjected to comparable insults followed by post-insult recirculation, heterogenous neuronal and glial alterations were now observed. These were more pronounced with increased insult durations and reperfusion periods. Four characteristic types of neuronal responses were observed, while three characteristic types of glial responses were noted and as such were confined to the astroglia. At the ultrastructural level these characteristic neuronal responses ranged from subtle neuronal involvement as manifested by chromatin clumping and minimal cytoplasmic changes to markedly altered neurons displaying shrunken and electron dense perikarya. The astroglia demonstrated either discrete cellular changes reflected in minimal chromatin clumping or more pronounced perturbations as evidenced in dramatic cellular swelling. A reciprocal relationship between neuronal shrinkage and astroglial swelling was observed. At the ultrastructural level shrunken and electron dense neurons were always seen in relation to swollen astrocytic cell processes. Such an observation suggests that neuronal and astroglia cell volume shifts following complete cerebral ischemia may be related.

1725 CATALASE ACTIVITY IN NORMAL AND DENERVATED HEREDITARY DYSTROPHIC HAMSTER MUSCLE. Robert R. Jenkins and Diane Newsham*. Biology Dept., Ithaca College, Ithaca, NY 14850.

Catalase (H_2O_2 oxidoreductase, E.C. 1.2.1.6) has recently been shown to be present in skeletal muscle (Stauber and Schottelius, Exp. Neurol. 48: 524-33, 1975). The exact biological role of catalase has eluded investigators despite the voluminous amount of research which has been conducted on this enzyme. Work from the lab of Stauber et al. (Exp. Neurol. 55: 381-89, 1977) and our own lab has shown that catalase activity increases during various forms of muscle wasting such as tenotomy, casting and denervation. Our work has suggested that catalase may serve as a suitable marker for denervation since significant increases may be observed within two days of transection as compared to one week for other forms of atrophy. The present study was designed to determine whether a similar post denervation rise in catalase could be observed in genetically dystrophic hamsters. The study involved a comparison between Syrian normal control hamsters and dystropic (UM-X7.1) control and denervated animals. Catalase was analyzed on tissue homogenates of extensor digitorum longus, soleus, adductor magnus and myocardial muscles by the oxygen cathode method. Protein was determined by a modification of the biuret method. We have found that catalase activity is significantly greater in muscles which metabolize greater amounts of lipids. We also observed significantly greater catalase activity in the muscles most involved by the muscular dystrophy. Furthermore, denervated dystrophic muscles were found to have catalase activities which were significantly elevated above that of dystrophic controls. These results support the notion that catalase may serve as a possible marker in denervation.

1726 CAPRINE NEUROVISCERAL STORAGE DISORDER RESEMBLING MANNOSIDOSIS. Margaret Z. Jones, James G. Cunningham, Albert W. Dade and David M. Alessi*. Depts. Path. and Physiol., Michigan State Univ., East Lansing, MI 48824.

Of the genetically determined metabolic disorders which are expressed in animals by markedly abnormal neurological function at birth, the most common is bovine mannosidosis. Storage of mannose and N-acetyl glucosamine (glcNAC) in neurons and other cellular elements is evident in this disorder as cytoplasmic vacuoles bound by a unit membrane. Deficiency of alpha-D-mannosidase can be demonstrated in various tissues of affected animals. This report describes a similar disorder which has affected both male and female offspring of clinically normal Nubian goats. Affected neonates were unable to rise or bear weight on any limb. A coarse tremor in the head and all four limbs was exaggerated by movement. Miosis, ptosis, enophthalmos and intermittent tremor of the extraocular muscles were noted. Joints were hypermobile and proximal muscle atrophy was present. General physical examination was otherwise unremarkable. Radiographic studies revealed increased density of the distal femoral and proximal tibial metaphyses. Necropsy studies revealed no abnormalities of the joints. Marked diminution of myelination and ventricular dilatation were observed in the smaller brains of affected animals.

Light and electron microscopic studies of formalin and glutaraldehyde fixed tissues demonstrated numerous vacuoles bound by a unit membrane in the neurons of the cerebral and cerebellar cortex, in Schwann cells, endothelial cells, hepatocytes, Kupffer cells, renal tubular epithelium and reticuloendothelial cells of bone marrow, spleen, liver and lymph nodes. Vacuoles contained finely dispersed floccular material or sparse membranous fragments. Golgi type 2 neurons of the cerebellum were most affected of all neurons. Fewer oligodendroglial nuclei were seen in the myelin-poor white matter of affected animals. Axonal spheroids throughout the white matter contained aggregates of dense bodies and mitochondria. Biochemical studies (Dr. Glyn Dawson) revealed an eight-fold increase in urinary mannose and glcNAC. The activity of several hepatic lysosomal hydrolases, including alpha mannosidase, was elevated. Brain gangliosides, neutral glycolipids and phospholipids were not increased. Hepatic mucopolysaccharide levels were normal. The biochemical defect responsible for this caprine neurovisceral storage disorder remains to be determined.

This research was supported by the NIH Biomedical Research Support Grant of the College of Veterinary Med., Mich. State Univ.

1727 IN VIVO TRACER STUDIES OF SKELETAL MUSCLES IN GENETICALLY DYSTROPHIC HAMSTERS BEFORE AND AFTER CALCIUM IONOPHORE ADMINISTRATION. George Karpati and Stirling Carpenter*. Montreal Neurological Institute - McGill University, Montreal, Quebec, Canada H3A 2B4.

In genetically dystrophic hamsters (UM-X7.1), in the florid necrotic phase (60-120 days of age), 1% sodium fluorescein or horseradish peroxidase (HPO) was injected into the abdominal aorta. After 15 minutes the quadriceps, plantaris and soleus were removed. Cryostat sections were examined for peroxidase activity or fluorescence. Necrotic fibers with phagocytosis were usually brightly fluorescent and sometimes showed modest peroxidase activity. Occasional clusters of tracer-positive fibers were not obviously necrotic at the level of section. Only rare hypercontracted fibers were present. They were strongly fluorescent but did not react for HPO. In other dystrophic animals, one of two calcium ionophores (CaI), (A 23187-Lilly Res. Lab, or RO 2-2985/13) in dimethyl sulfoxide (DMSO) was injected into the abdominal aorta 15 minutes before the tracer. Numerous clustered and isolated hypercontracted fibers were then found in all muscles with or without in situ fixation. They were strongly fluorescent, but showed only faint peroxidase activity. Fluorescence was present diffusely in these fibers, but was especially prominent in a distribution corresponding to the surface membrane. In animals killed 24 hours after CaI administration, the prevalence of necrosis was not increased and hypercontracted fibers were rare. Controls (normal hamsters given CaI, and normal and dystrophic hamsters given DMSO) proved negative. Dystrophic hamster skeletal muscle cells respond to CaI with hypercontraction but, unlike their counterparts in Duchenne dystrophy, do not show tears of myofibrils and do not take up HPO. Their marked fluorescence suggests that only the smaller tracer was able to enter the muscle cell where it may bind to components of the surface membrane. The studies also suggest that this type of hypercontraction develops in vivo, but it does not necessarily lead to necrosis.

1728 RESOLUTION OF VASOGENIC BRAIN EDEMA. Igor Klatzo, Maria Spatz, Esther Chui* and Keigo Fujiwara*. Lab. Neuropathology & Neuroanatomical Sciences, NIH, Bethesda, MD 20205.

Development and resolution of the vasogenic brain edema (VBE) were studied in cats subjected to cryogenic cortical lesions. The basic parameters of VBE, i.e., an increment in water content of the tissue, an increased vascular permeability for various substances and especially for serum proteins, were assessed by specific gravity measurements, use of Evans Blue and application of immunohistochemical staining for cat serum proteins with peroxidase-antiperoxidase (PAP) reagents. Our observations indicate that resolution of the VBE proceeds from the periphery towards the original site of the lesion. This process coincided with a vigorous uptake of serum protein by the glia cells in the edematous area, as demonstrated by immunocytochemical staining according to the PAP procedure. Our studies suggest that the resolution of VBE is related to reduction of colloidal osmotic pressure in the extracellular spaces by the intracellular uptake of extravasated serum proteins in the edematous areas releasing the water to diffuse away and leading to resolution of edema.

1729 LYSOPHOSPHATIDYL CHOLINE INDUCED DEMYELINATION IN THE RABBIT CORPUS CALLOSUM. J.D. Kocsis*, S.G. Waxman*, R.E. Foster, and K.C. Nitta*. Dept. Neurol., Sch. Med., Stanford Univ., V.A. Hosp., Palo Alto, Ca. 94304.

Local injection of lysophosphatidyl choline (LPC) into the corpus callosum of the Dutch rabbit produces a focal demyelinating lesion. LPC (1% in normal saline) was injected in volumes of 1-4 µl through a glass micropipette (tip diam. 10 to 30µ) fixed to a microsyringe. The LPC was delivered over a period of 20 to 40 min. Survival times ranged from 1 hr. to 6 weeks. The lesions were assessed histologically using the Luxol fast blue stain for myelin and the Holmes silver nitrate method for axon cylinders. With these injection methods, the entire vertical extent (about 0.5 mm) of the corpus callosum could be demyelinated with minimal amounts of axonal degeneration. Ultrastructural analysis reveals pathological changes in the demyelinated zone ranging from sparse axonal degeneration to complete demyelination.

In some animals chronic stimulating electrodes were implanted in the corpus callosum near the midline and field potential recordings were obtained from the LPC pipette. The pipette was positioned at a point corresponding to the maximal negativity of the evoked callosal field potential, and LPC was injected at this level. After the injection the callosal field potentials were recorded with tungsten electrodes on consecutive days from the same animal. The fields evoked from single stimuli were reduced in amplitude minutes after LPC injection and this reduction persisted for several days. Another effect of the LPC injection was the reduction in the amplitude of the response evoked by the second of two paired stimuli at interstimulus intervals of up to several hundred msec. This is in contrast to the evoked response in control animals where the amplitude reduction occurs only with interstimulus intervals of up to about 3.0 msec. The present study indicates that it is possible to produce focal demyelinating lesions in fine caliber myelinated axons of the mammalian cerebrum. Therefore, it will be possible to study, over protracted periods of time, the physiological and morphological properties of focally demyelinated cerebral axons.

1730 BEHAVIORAL DEFICIT OF MICRENCEPHALIC RATS IN AVERSIVELY MOTIVATED LEARNING. Moon He Lee*, R. Haddad, Ausma Rabe and Ruth Dumas*. Neuroteratology Laboratory, New York State Institute for Basic Research in Mental Retardation, Staten Island, NY 10314.

Micrencephalic rats, the progeny of rats injected with 30mg/kg of methylazoxymethanol acetate (MAM Ac) on gestation day 15, are deficient in learning to reverse a previously learned position habit in a T maze. This deficit, originally observed in adult rats, has since been demonstrated in immature rats both before and after weaning. In all of these experiments, appetitive motivation was used. However, we have recently found that micrencephalic rats that had to learn to reverse a previously learned position habit to escape from a water filled T maze differ much more sharply from the normal rat. Similar results were obtained both before and after weaning. These findings, along with the previously reported differences in "behavioral arousal" of the micrencephalic rat (Rabe & Haddad, Federation Proceedings, 1972, 31: 1536-1539), suggest that, regardless of any deficit in cognitive function, micrencephalic rats (produced by prenatal treatment with MAM Ac) differ in motivational and/or emotional aspects. The behavioral differences are consistent with those that might be expected to result from the alterations in neurotransmitters in the cerebral cortex of the micrencephalic rat reported by Johnston et al. (Science, 1979, 203: 369-371). It would appear that estimates of the nature and extent of cognitive or other functional deficits in micrencephalic subjects may be grossly in error if the methods of appraisal do not take into account their altered emotional reactivity.

1731 UNILATERAL DFP NEUROPATHY: EVIDENCE FOR AXONAL SITE OF INITIATION. Herbert E. Lowndes, Richard D. Howland*, Thomas Baker and Rudy J. Richardson*. Dept. Pharmacol., CMDNJ, N.J. Med. Sch., Newark, N.J. 07103.

A method for producing a localized mono-neuropathy by intra-arterial injection of DFP has been described (Lowndes et al, Europ. J. Pharmacol. 29: 66, 1974) and morphologically characterized (Glazer et al, J. Neurocytol. 7: 741, 1978). The present studies were performed to confirm that the neurotoxin remained largely confined to the periphery of the injected limb, thus ruling out involvement of cell bodies in the etiology of the neuropathy. DFP (2 mg/kg body wt) labelled with ^{3}H-DFP (5 µCi/kg) was injected into the left femoral arteries of cats. One hr later, portions of the medial gastrocnemious (MG) and soleus (SOL) muscles, dorsal and ventral roots, triceps surae (TS) nerves, the sciatic nerve (SN) from roots to heel and spinal cord were removed bilaterally. DFP concentration was determined by liquid scintillation counting. The proximal-distal distribution of DFP in the sciatic was measured in 1 cm segments. Little DFP was found in the tissues of the non-injected leg. No significant differences were found in the content of left and right dorsal and ventral roots (range: 0.09-0.15 µg/g). Spinal cord segments were divided laterally and contained 0.38 and 0.37 µg/g of DFP on the right and left side, respectively. Left MG and SOL had 4.8 and 7.1 times as much DFP as the respective muscles on the right side. The SN from the injected side showed a proximal-distal gradient of concentrations of DFP: the most proximal segment had a mean conc. of 0.39±0.08 µg/g (SE) which increased over the next 12 cm to a peak of 2.49±0.33 µg/g. The most distal segment had a conc. of 1.11±0.13 µg/g. The left TS had a mean content of 2.56±0.48 µg/g. The contralateral SN showed no proximal-distal gradient and had a mean content for all segments of 0.24 µg/g. This neuropathy does not appear to involve perikarya but results from a direct action of DFP on axons and/or nerve terminals.

Supported by NS-11948.

1732 CELL PROLIFERATION AND REMYELINATION. Lidia M.N. Macedo* and Robert M. Herndon. Center for Brain Research, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642

The processes of cell proliferation and remyelination were studied in 1 month old rats using mitotic arrest with colchicine to identify proliferating cells. Demyelination was induced by the focal injection into the spinal cord of 2 µl of a 10 mg/ml solution of lysolecithin containing a small quantity of colloidal carbon to serve as a marker. 200 µg of colchicine was injected intraperitoneally 20 to 22 hrs before the animals were sacrificed. This procedure produced arrest in metaphase of any cells entering mitosis during this period. Animals were killed by perfusion at 1, 3, 5, 8, 12 and 28 days after lisolecithin. 24 hrs after lysolecithin injection there is a central area of necrosis, free of viable cells, surrounded by a large area in which there is virtually complete myelin breakdown and destruction of glial cells and invasion by a few macrophages with relatively good preservation of axons. By day 3, numerous lipid laden macrophages are present throughout the lesion. Many of the axons are denuded of myelin while others are surrounded by degenerating myelin remnants. There is already a suggestion of beginning remyelination at 5 days and easily recognizable remyelination is evident by day 28. Mitotic glial cells were scarce day 1. A few were seen at day 3, but they were more numerous at day 5 and day 8, apparently decreasing in numbers subsequently. The rapid appearance of dividing oligodendroglia which can be clearly identified by electron microscopy three days after lysolecithin injection, suggests that the cell proliferation may begin as a direct response to injury rather than requiring induction by denuded axons.

1733 MORPHOLOGICAL ALTERATIONS IN THE HIPPOCAMPUS OF CHRONIC ALCOHOLIC RATS. A Golgi study. Jesús P. Machado-Salas, Ernesto Espinosa* and José Trujillo*. Lab. de Neuromorfología Exp. y Apl. Depto. de Anatomía, Fac. de Med. UNAM. México, 20 D.F. MEXICO.

Review of the literature offers a good deal of physiological or biochemical studies regarding changes in the central nervous system, secondary to alcohol administration. On the other hand, recent anatomical studies are less common and, as far as we know, the tridimensional status shown by neurons, their prolongations and the neuropile as a whole, has not been described.

We have been studying, with Golgimethods and some other neurohistological techniques, the morphological changes that have developed in brains of alcoholic rats. For this purpose, we have raised three groups of rats under the following conditions: Control group: this group has been allowed to eat regular pellets and drink, ad libitum, common tap water. Experimental group A: this one also eats regular pellets and drink from a 10% alcohol solution. Experimental group B: these rats also receive the same type of pellets and drink from a 20% alcohol solution, as the only source of liquid. They have been kept, under constant conditions, for over a year. The liquid intake has been recorded every day, and the weight increment every other day.

We have been impressed by the qunatity and quality of changes occuring in the CNS of these rats. In this communication we describe the observations made in the hippocampal-dentate complex. 1. Increased glial population, including microglia. 2. Slender and spineless dendrites. 3. Swollen and fragmentated dendrites. 4. Enlarged mossy tufts (terminals), and 5. Evidence of dendritic proliferation with abnormal features. These changes are not age-related. The possible functional significance of these changes shall be discussed.

This study has been supported by "Centro Mexicano de Estudios en Salud Mental".

1734 DIENCEPHALIC INJECTIONS OF KAINIC ACID PRODUCE MYOCARDIAL NECROSIS. Patrick L. McGeer, C. Kek Galabru*, Edith G. McGeer and William J. Boyko*. Kinsmen Laboratory of Neurological Research, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5, and St. Paul's Hospital, Vancouver, B.C., Canada.

Bilateral injections of 3 nmoles of kainic acid (KA) into the thalamus produce the following triad of peripheral consequences: 1) periarteriolar myocardial necrosis, 2) elevated serum fibrinogen, 3) gross hematuria. Electrolytic lesions of the thalamus and intracerebral injections of KA at several other locations fail to produce this result. KA at much higher doses subcutaneously or intraperitoneally is also inactive. Some protection against myocardial damage is produced by reserpine or 6-hydroxydopamine, but atropine confers no protection. Urinary noradrenaline levels are markedly elevated following effective but not ineffective KA injections suggesting sympathetic "storm" may be one factor. Elevated serum fibrinogen is presumed to be related to tissue damage, while gross hematuria comes from bladder necrosis. The fact that myocardial damage may result from intracerebral lesions and/or pathological stimulation by KA may have clinical implications. Cardiac damage occasionally results in humans from strokes and intracerebral hemorrhage and no satisfactory explanation has ever been offered for the phenomenon of interstitial myocardial fibrosis. Such an end result might follow on repeated stress of cerebral origin. (Supported by the B. C. Health Sci. Res. Fund).

1735 VIRUS-INDUCED IMMUNORETINOPATHY IN NEWBORN RATS. Andrew A. Monjan and Manuel del Cerro, Department of Epidemiology, School of Public Health, Johns Hopkins University, Baltimore, MD and Center for Brain Research, University of Rochester School of Medicine, Rochester, NY 14642

A destructive developmental retinopathy can be induced by infecting rats, within the first 2 days of life, with lymphocytic choriomeningitis virus (LCMV). The lesion is immunologically mediated as attested to by the sparing effects of neonatal thymectomy or antilymphocyte serum. We now present a correlative optical and electron microscopic histopathological analysis of the changes occurring in the LCMV retinopathy. These data indicate that there are, within the cell population of the retina, various degrees of sensitivity to the immune reaction to LCMV. Thus, within the neural retina, there is a distinct gradient of degeneration from the outer to the inner layers. The rods are the least resistant with the ganglion cells being the most persistent of the neurons. Muller glial cells first react with a hypertrophic proliferation of the cytoplasmic lamellae which fill up some of the space vacated by the destroyed neurons and later they undergo pronounced atrophy. The least affected elements are the retinal pigment epithelial cells which, though infected, invariably survive, with comparative minor alterations, even after all the neuronal cells have degenerated. It is noteworthy that the progress of the lesion through the layers follows an exactly opposite direction than that of the spread of viral antigen as observed by immunofluorescence. Thus, while at 10 post-infection days, the antigen is still localized in the inner nuclear layer, morphological alterations are only seen in the outermost regions of the outer nuclear layer.

Finally, although the fluorescent antibody technique shows extensive distribution of the LCMV antigen, no unequivocal identification of viral particles has been made yet. This fact stands in sharp contrast with the profuse presence of viral particles observed in the LCMV infection of the immature cerebellum. Work is in progress to determine whether this difference originates from a sampling problem or represents a unique feature of the LCMV retinopathy.

1736 EARLY SEGMENTAL DEMYELINATION IN EXPERIMENTAL DIABETIC NEUROPATHY S.A. Moore*, R.G. Peterson, D.L. Felten, and B.L. O'Connor*, Anatomy Department, Indiana University School of Medicine, Indianapolis, Indiana 46223

Studies in this lab revealed a small but significant number of nerve fibers undergoing segmental demyelination (SD) in nerves showing a reduced nerve conduction velocity (CV) in 2 month diabetic rats made diabetic by alloxan and streptozotocin (STZ). Although SD is a consistent pathological finding that may account for reduced CV in diabetic humans, its presence in animal models is disputed even though decreased CV in these models is well documented.

As part of a comprehensive, long term, longitudinal study, the sural and tibial nerves from the mid-calf region of 2 month STZ and alloxan diabetic rats were studied using a teased fiber preparation and compared to age matched controls. Approximately 50 nerve fibers were teased from one sural and one tibial nerve of 9 STZ, 9 alloxan, and 11 control rats. A total of 13 nerve fibers from 8 of the diabetic rats showed evidence of SD. Only one nerve fiber in one control rat had similar evidence. Other pathology observed in diabetic nerves included myelin globules indicative of Wallerian degeneration, swollen axons, and apparent loop formation in internodal myelin.

Although the number of SD nerve fibers may seem small, it is significant in that only a small percentage (about 5%) of the total number of fibers was sampled and a relatively short length (<10% of total) of nerve was examined. Many more nerve fibers than those examined (as well as other areas of those fibers that were studied) may be involved in a demyelinating process.

That a significant number of nerve fibers are involved is supported by CV studies done in this lab on the same nerves showing evidence of SD. While as yet tentative, these studies revealed a slowing of CV in the sural nerve but not in the tibial, suggesting a preferential sensory involvement.

These data, suggesting preferential slowing of sensory CV that is accompanied by a possible morphologic correlate (SD), correspond well with descriptions of human diabetic neuropathy in the literature. In light of this, experimental diabetes in the rat induced by STZ and alloxan appear to be appropriate models for the investigation of human diabetic neuropathy.

1737 ENDONEURIAL FLUID PRESSURE DYNAMICS

Robert R. Myers, Henry C. Powell*, Michael L. Costello*
Veterans Administration Hospital and the University of California, San Diego, Departments of Anesthesiology Neurosciences and Neuropathology, La Jolla, CA 92093.

Recent technical advances have made it possible to record endoneurial fluid pressure (EFP) and have thus allowed investigation of nervous system transport phenomona in the peripheral nervous system, a system which is more amenable to control and experimental manipulation than the brain. We have employed the active, servo-null, micropressure system to record rat sciatic nerve pressures in four experimental groups of animals to explore the mechanisms of edema in peripheral neuropathy and to quantify the biophysical relationships between edema and EFP. Control EFP was 2.0 ± 1.0 cm H2O for adult, Sprague-Dawley rats. Significant differences were observed between controls and the following experimental groups:

Insult	Peak EFP
1. 6% $PbCO_3$ in water	9 cm H2O
2. 1000 ppm hexachlorophene in diet	17 cm H2O
3. 40% galactose diet	10 cm H2O
4. proximal crush injury	9 cm H2O

These studies reveal several mechanisms responsible for increased EFP. The blood-nerve-barrier (BNB) may be damaged by toxic injury to the endothelial cell as is seen in lead neuropathy. By contrast, hexachlorophene damages the myelin sheath without affecting the BNB. Edema is strictly confined to the myelin lamellae. In galactose neuropathy the synthesis of a poorly soluble macromolecule inside the BNB changes the local osmotic force causing fluid retention and elevated EFP. EFP changes following crush injury are the result of perturbations in all these mechanisms. Additional analysis of transverse sections in lead neuropathy suggest that the perineurial sheath has a compliance which is analagous to brain. As the edema fluid begins to accumulate, transfacicular area (TFA) increases but EFP does not change. Continued expansion of endoneurial volume is restricted by the perineurium which begins to stretch. This is associated with a rise in EFP. At approximately 10 cm H2O, EFP peaks but TFA continues to increase. This may be explained by proximo-distal transport of endoneurial fluid which is accentuated by high local EFP.

1738 A NEW HEAD INJURY MODEL FOR EVALUATION OF TREATMENT MODALITIES.

L.R. Nelson, E.L. Auen, R.S. Bourke and K.D. Barron, Div. of Neurosurgery and Dept. of Neurology, Albany Medical College, Albany, N.Y. 12208.

The evaluation of the effectiveness of various treatment modalities in head injury has been hampered by the lack of an appropriate animal model exhibiting extended coma and delayed death. We have developed an animal model that utilizes a repetitive translation plus rotation acceleration injury to the skull encased brain of the anesthetized cat (1400 positive and negative 80-85g impulses applied over 67 seconds) followed after 40 minutes by a one hour period of controlled respiration with 6% O_2 in N_2 which results in an arterial pO_2 of 24 ± 4 torr. This results in delayed death in approximately 50% of animals with an impaired rate of neurological recovery in many survivors. All surviving animals are given a numerically quantifiable neurologic examination at regular intervals up to 24 hours and all animals undergo autopsy examination. Approximately 10% of animals die early following the trauma alone and thus are not usable in evaluation of treatment modalities. Control studies evaluating anesthesia alone compared with anesthesia plus hypoxia show no mortality or morbidity from the hypoxia alone. Individual dose response characteristics for variation in duration of hypoxia, magnitude of repetitive acceleration and duration of repetitive acceleration have been worked out and demonstrate that an increase in any of the three parameters results in a corresponding increase in mortality. The data we have demonstrates that death can occur during or immediately following the repetitive acceleration injury if the magnitude or duration is great enough, however, extended coma or delayed death only occurs when the acceleration injury is followed by a period of hypoxia. This finding further underscores the importance of proper ventilatory support and oxygenation in the severely head injured patient. We have evaluated five treatment modalities to date on our model, three of which have resulted in a significant reduction in mortality rate and an improvement in the rate of neurologic recovery. The data from these studies will be presented. Supported by NIH grant NS13042.

1739 INCREASED AXONAL PROTEOLYSIS IN MYELIN-DEFICIENT MUTANT MICE.

R.A. Nixon. Ralph Lowell Laboratories, Harvard Medical School and McLean Hospital, Belmont, MA 02178.

Neurons appear to play a critical role in mediating the formation of myelin. In this study, we found specific alterations of axonal proteolysis in three mutant strains of mice which exhibit CNS hypomyelination. The degradation of axonal proteins was measured within a single neuron type, the retinal ganglion cell. Axonally transported proteins in the ganglion cell were labeled in vivo with ^{3}H-L-proline. After 5 days, intact optic nerves containing labeled axonal proteins were incubated in vitro in HEPES buffer, pH 7.4 (Dunlop & Lajtha, 1975, Brain Res. 34:333). Protein synthesis inhibitors were added to prevent reutilization of amino acids released by degradation. The rate of protein degradation was calculated as the ratio of TCA-soluble dpm to total dpm after 1h at 37° minus background which is the ratio from the contralateral nerve similarly incubated at 0°. An enzyme system with different properties, presumably Cathepsin D, was measured at pH 3.8.

In 3-4 wk. old myelin synthesis deficiency (msd) mice, the rate of axonal protein degradation was elevated 300% at pH 7.4 ($p<0.01$) and 170% at pH 3.8 ($p<0.001$) compared to the rates in littermate controls. In preliminary experiments comparable elevations of axonal protein degradation were measured in 3-4 wk. old jimpy (jp) mice (an allele of msd). In 4 wk. and older quaking (qk) mice, axonal protein degradation was normal at pH 7.4 (112%, n=16) but was increased 260% at pH 3.8 ($p<0.001$). The different abnormalities in qk and jp/msd suggest that the axonal proteolytic defects are not solely a consequence of hypomyelination. In isolated neural retina, protein degradation at pH 7.4 and at pH 3.8 was normal in each mutant. Finally proteins in glial elements of the optic nerve were labeled by incubating freshly sectioned nerves in vitro with ^{3}H-L-leucine and protein degradation was measured as above. In each mutant, glial proteins were degraded at the same rate as those in littermate controls at pH 7.4 and pH 3.8.

These results indicate that 1) axonal proteolysis is increased in mutant mice with defective myelination; 2) the proteolytic defects differ in mutants affected at different genetic loci but are similar in alleles; and 3) the defects are specific for axons (neurons) and are absent in the unmyelinated, histologically normal retina. The hypothesis is advanced that the primary molecular lesion in these mutants may be in neurons and that enhanced axonal proteolysis may be a major pathological mechanism (Supported in part by the William F. Milton Fund).

1740 STUDIES OF THE SODIUM AND CALCIUM COMPONENTS OF EVOKED ACTION POTENTIAL (EVAPS) FROM CULTURED RAT DORSAL GANGLIA NEURONS INFECTED WITH HERPES SIMPLEX VIRUS.

S. George Oakes*, Robert S. Pozos, Richard J. Ziegler*, and Roger W. Petry*. (SPON: E. K. Stauffer). Depts. of Physiology and Microbiology, University of Minn., Duluth, School of Medicine, Duluth, MN 55812.

Dissociated neuron cultures from rat dorsal root ganglia were maintained for 4-6 weeks. Normal electrophysiological parameters were first established. Morphologically similar cells showed a plateau in the falling phase and consistent EVAP properties.

Cultures were infected with 10^4 p.f.u. of herpes simplex virus type 1. Recordings were made at 2, 4, 6, 12, and 24 hours (hrs) (± 30 minutes) post-infection (PI) in Eagle's Minimum Essential Media (EMEM). The signals were recorded and analyzed using a PDP-12 computer. Changes in spike amplitude (SA) and duration (D) were most significant. EVAPS at 2 hrs PI were essentially normal. At 4 hrs PI there was a decrease in SA and a small increase in D. 6 hrs PI recordings showed a recovery in the SA to normal values and a slight increase in D compared to the normal. Recordings from the 12 hrs PI sessions showed a large decrease in SA and a very marked increase in D. Only local responses could be evoked at 24 hrs. Light microscopic studies showed fragmentation of the nucleolus and granulation in the cytoplasm at this time. Mock-infected cultures exhibited normal EVAPS for at least 48 hrs.

Recordings were also obtained in Na^+ free (NF), 10^{-8}g/ml tetrodotoxin (TTX), Ca^{++} free (CF) and 10 mM $CoCl_2$ recording solutions at the same time intervals after virus infection. 2 hrs PI, recordings in NF, TTX, CF and $CoCl_2$ were the same as those for uninfected cells in these recording solutions. EVAPS from the 4 hrs PI cultures in TTX were much like those from 4-hr PI in EMEM. Readings in $CoCl_2$ and CF recording solutions showed a decrease in SA compared to EVAPS from uninfected cells in these solutions. Recordings 6 hrs PI, in $CoCl_2$ and CF solutions were not significantly different from EVAPS of uninfected cells in the same solutions. 12 hrs PI there was a marked similarity in the characteristics of the EVAPS in NF and those in EMEM. Recordings in $CoCl_2$ and CF showed a decrease in SA.

Initial results indicate there is a transient block in the active Na^+ channels due to the virus infection at 4 hrs PI. Progressively the passive Na^+ component also appears to be altered at 12 hrs PI. A slight increase in D of the EVAP of infected cells recorded in TTX from 4 hrs PI indicates a possible change in the Ca^{++} component. Supported in part by USPHS Grant 1-R01-NS-13326-01A1.

1741 "CYTOPLASMIC BODIES" IN HUMAN SKELETAL MUSCLE CO-CULTURED WITH FETAL MOUSE SPINAL CORD COMPLEX. Edith R. Peterson*, Edmund B. Masurovsky, Alfred Spiro* and Stanley M. Crain. Depts. of Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Human skeletal muscle innervated by co-cultured explants of fetal mouse spinal cord complex leads to greatly enhanced differentiation of many regenerated muscle fibers (Pet. & Cr., Exper. Neurol. '72). "Cytoplasmic bodies" (W.K. Engel, Neurol. '62) developed abundantly (100-500 per culture) in muscle explanted from a biopsy of Duchenne dystrophy (9-month child). Many of these "bodies" were observed in mature muscle fibers that still showed characteristic contractions in response to spinal cord stimuli (3-4 months in vitro). Considerably fewer bodies (3-25 per culture) have been observed, at times, in cultures of normal or pathologic human muscle. These inclusion bodies are clearly discernible by high-power light microscopy in the living cultures as a central dense core, round or ovoid, surrounded by a clear halo -- not membrane-bounded. The bodies are most numerous in distended regions towards the ends of both undifferentiated or well-differentiated muscle fibers. They are less numerous in areas of cross striations. In the living cultures, birefringence of the halo can be demonstrated with polarized light microscopy, and Nomarski optics supports the view that this halo is not membrane-bounded. In fixed preparations, the central core is deeply stained with phosphotungstic hematoxylin. Occasional "cytoplasmic bodies" of a similar light microscopic appearance were reported in cultures of uninnervated chick (W.K. Engel,'62) and human muscle (Askanas et al. Acta Neuropath. '78). In our co-cultures, cytoplasmic bodies appear to be extruded near the ends of some muscle fibers, and to a lesser degree along intermediate zones of cross striated as well as less mature fibers.

Electron microscopy of these bodies in 7-16 week cultures reveal fine-structural features consonant with our light microscopy and with EM studies of certain myopathies in situ (McDonald and A. Engel, Acta Neuropath. '69). The central core consists essentially of a dense tangle of ~3-6 nm filaments, which merges with the surrounding halo composed primarily of radially arrayed ~5-7 nm filaments that may dovetail with nearby myofilament lattices. Thicker (~10-30 nm) filaments are seen at times in this zone which otherwise excludes such organelles as mitochondria, endoplasmic reticulum and triads.

McDonald and Engel ('69) considered these bodies to be anomalies of the Z-disc, but neither the complete organization of the structures nor the significance of their occurrence in myopathies is clear. This culture model may facilitate further analyses.

1742 THE OCCURRENCE OF ENDOTHELIAL LESIONS WITHIN THE CEREBRAL VASCULATURE AND THEIR RELATION TO THE PASSAGE OF HORSERADISH PEROXIDASE. John T. Povlishock, William I. Rosenblum, Hermes A. Kontos*, and Donald P. Becker. Dept. of Anat., Path. (Neuropath.), Med. and Surg. (Neurological), Med. Col. of Va., Virginia Commonwealth University, Richmond, Va. 23298.

The present investigation was undertaken to determine, if within the cerebral vasculature altered endothelial morphology always correlates with dysfunction of the blood-brain barrier. To this end 40 cats having received an IV injection of horseradish peroxidase (HRP) were subjected to either mechanical brain injury or an acute episode of systemic hypertension induced by angiotension. Following a brief survival the animals were perfused with aldehydes and their brains were sectioned on a vibratome. Serial sections were then collected in compartmentalized trays and the alternate serials were processed for either light microscopy or transmission (TEM) or scanning (SEM) electron microscopy. Light microscopy demonstrated that various loci throughout the neuraxis displayed peroxidase exudation. TEM examination of such sites revealed that the vasculature possessed endothelia displaying numerous HRP laden vesicles, vacuoles and tubules. Serial sections suggested that these HRP containing elements participate in the sequestration and transendothelial passage of the protein to the underlying perivascular basal lamina and brain parenchyma at the sites of HRP effusion. SEM study of such sites revealed that the vascular luminal surfaces possessed endothelia manifesting numerous vesicles. In contrast vasculature at sites with no peroxidase effusion lacked numerous endothelial vesicles; however, SEM revealed conspicuous endothelial balloon-like protrusions and crater-like concavities. These endothelial lesions ranged from 0.5 to 7.0 μm in diameter and were distributed randomly on the endothelial surface and along the marginal lines. TEM confirmed the SEM findings and demonstrated that the endothelial balloons were formed by large cytoplasmic vacuoles within the endothelia. Frequently, these large vacuoles were open to the luminal surface. These ruptured vacuoles were often collapsed and thereby reminiscent of the craters seen with SEM. It is apparent that conspicuous endothelial lesions may occur without any concomitant increase in the passage of proteins such as horseradish peroxidase and without the appearance of vesicles filled with HRP. A parallel study of pial vessels also showed severe endothelial damage without vesicle formation or HRP transport.

1743 ALTERED PERMISSIVENESS OF AUTONOMIC NEURONS FOR HERPES SIMPLEX VIRUS REPLICATION: AN EPIPHENOMENON OF THE AXON REACTION? Richard W. Price. Dept. Neurology, Cornell University Medical College, New York, NY 10021.

A model of herpes simplex virus (HSV) infection of the superior cervical ganglion (SCG) was used to investigate the variability in outcome of neural infection with this virus. BALB/c female mice were injected intraocularly with 8 x 10^4 plaque-forming units (PFU) of HSV Type 1, and the course of SCG infection monitored by assessing viral titers in ganglion homogenates. Delayed passive (antibody) immunization administered one day after viral challenge was employed to reduce intraganglionic viral replication and to preserve the integrity of the ganglion; such immunization does not prevent viral access to the SCG over axonal pathways.

Both surgical post-ganglionic neurectomy and systemic treatment with 6-hydroxydopamine (6-OHDA), 250 mg/kg, led to a marked increase in viral replication in the SCG with peak viral titers exceeding 10^4 PFU per ganglion compared to titers of 10 PFU or less in sham-operated or injected controls. In contrast to autonomic infection, virus replication in the trigeminal ganglion and inoculated eye was not significantly influenced by these procedures. Augmented viral replication in the 6-OHDA-treated animals was unaffected by prior preganglionic nerve section, but was blocked by pretreatment with desmethylimipramine. In addition, latent HSV infection (assessed by explantation-cocultivation of ganglia several weeks after viral inoculation) was reduced in inoculated mice subjected to surgical or chemical neurectomy.

These studies suggest that among the metabolic alterations accompanying the axon reaction is a change in the permissiveness of ganglion cells for viral replication. The hypothesis is offered that one or more of the metabolic changes induced by axotomy increases the probability that productive rather than latent HSV infection of the ganglion will occur. Exploitation of alterations in neuronal metabolism may represent a critical adaptive mechanism for HSV. Metabolic changes in neurons similar to those accompanying axotomy may be responsible for the switch from virus latency, a state which insures long-term persistence of virus in the human community, to reactivated productive infection which renders virus available for transmission to susceptible contacts.

1744 INTRACELLULAR MORPHOPHYSIOLOGICAL STUDIES OF CORTICAL NEURONS IN FELINE GM_1-and GM_2-GANGLIOSIDOSIS. D.P.Purpura, S. Highstein, A.B. Karabelas*, AND S.U. Walkley. Dept. of Neuroscience, Rose F. Kennedy Ctr., Albert Einstein College of Medicine, Bronx, N.Y. 10461

The gangliosidoses are inherited lysosomal hydrolase deficiency diseases characterized by progressive intraneuronal accumulation of uncatabolized glycolipids in various complex forms. Neurobehavioral deterioration in both human and feline GM_1 and GM_2-gangliosidoses occurs after an initial but variable period of normal postnatal development. Although the pathophysiological basis for the onset of neuronal dysfunction in the gangliosidoses is unknown it is widely held that such dysfunction is directly linked to the "cytotoxic" action of uncatabolized glycolipids and membranous cytoplasmic bodies (MCBs) whose accumulation presumably compromises normal intracellular organelles. We have attempted to test this "cytotoxicity" hypothesis by examining the functional status of cortical neurons in feline mutants with confirmed GM_1 or GM_2-gangliosidosis. Micropipettes for intracellular recording were filled with HRP for subsequent identification of impaled neurons. Cells encountered in motorsensory cortex were examined for antidromic (cerebral peduncle/pyramidal tract) or orthodromic (thalamic-VL) stimulation. Neurons impaled in feline mutants at various stages of clinical neurobehavioral deterioration exhibited membrane potentials and evoked PSP sequences qualitatively similar to those observed in normal animals of comparable ages. Although EPSP-spike discharge trains and spontaneous bursts were unremarkable the impression was gained that IPSPs evoked by thalamic stimulation were more prominent and were more frequently encountered in ganglioside-laden neurons than in neurons from normal cats. Several types of HRP-filled cells were recovered from preparations yielding satisfactory intracellular recordings. Neuron cell bodies were generally 2-3X the diameter of normal cells and were literally packed with MCBs. Thus accumulation of uncatabolized glycolipids and large numbers of MCBs in greatly enlarged cell somas does not influence electrogenic properties of cortical neurons in the feline gangliosidoses.

1745 ATROPHY OF CEREBELLAR DEEP NUCLEI IN THE STAGGERER MUTANT MOUSE. S. Roffler-Tarlov & K. Herrup, Dept. Neuroscience, Children's Hosp. Med. Ctr., Boston, MA 02115 and Dept. Human Genet., Yale Medical School, New Haven, CT 06510

Staggerer (sg) is an autosomal recessive mutation in mice affecting the development of the cerebellum. The most prominent pathological characteristic is an almost complete loss of granule cells. A majority of large neurons in cerebellar cortex are also missing. This finding, along with that of reduced wet weight and protein content in sg deep cerebellar nuclei (dcn) led us to ask if the sg gene affects all of the neuronal derivatives of the germinal zone of the roof of the fourth ventricle. These include deep nuclear cells, Golgi II cells and Purkinje cells.

We have made a histological examination of dcn from 20-day-old sg and control cerebella using serial sagittal 10 µm sections stained with cresyl violet. Starting with the first midline section in which deep nuclear cells appeared, we made sketches of the entire section and outlined the area containing the dcn as well as the area which included cells and white matter core. We weighed the paper areas occupied by the deep neurons with and without the white matter core in each of the sections and graphed these numbers with regard to distance from midline to approximate the total area occupied by white matter and the total area occupied by deep nuclei in sg and controls. We counted the deep nuclear cells in mutant and control animals using sections 50-100 µm apart. We tabulated the numbers of all neurons in which nuclear and cytoplasmic material was visible and graphed them with respect to distance from the midline.

We found that the number of neurons in sg dcn is not markedly different from that in normal dcn. However, the staggerer deep neurons are atrophied; cross-sectional area of representative sections revealed reduction in cell body size of all populations of deep neurons. The diminished size of the sg dcn is also caused by a reduction in the areas occupied by both the nuclei themselves and the white matter surrounding them.

We conclude that 1) the sg gene acts uniquely on those derivatives of cells from the ventricular germinal layers which become Purkinje and Golgi II cells and, 2) transneuronal degeneration does not take place in staggerer deep nuclei. The atrophic changes are likely to be a secondary effect and preliminary observation of two sg/sg ↔ +/+ chimeras support this hypothesis. Shrinkage of staggerer deep nuclear cells may be the result of early denervation by Purkinje cell axons or the consequence of their never having been innervated.

NIH Grants 12200 and HD 12213-01.

1746 MODIFICATION OF AMPHETAMINE TOXICITY BY HERPES SIMPLEX VIRUS INFECTION OF THE CENTRAL NERVOUS SYSTEM. Richard F. Seegal and John E. Hotchin. Div. Labs. and Research, NYS Dept. of Health, Albany, NY 12201.

Acute central nervous system (CNS) infection with herpes simplex virus type 1 (HSV) increases locomotor activity and aggressive behavior in mice and metabolism of catecholamines (Lycke, Norrby & Roos, J. Neurol. Sci. 22, 277, 1974). Using a model in which mice are immunized by peripheral inoculation two weeks prior to central infection, we (Seegal & Hotchin, Birth Defects, 13, 179, 1978, NeuroScience Abstracts 4, 407, 1978) noted decreased spontaneous & d-amp. induced locomotor activity. To further analyze this model, we have examined the effects of peripheral injections of d-amp. and other sympathomimetic agents on mortality in pre-immunized centrally infected HSV mice.

Percent Mortality in HSV Infected Mice (24h. after Inoculation)

DRUG	DOSE (mg/kg)	N	HSV	CON
d-amphetamine sulfate				
5 day post IC	50	24	50	79*
	100	24	88	83
14 day post IC	50	25	72	60
	100	25	92	84
Isoproterenol HCl	200	15	0	0
	400	15	20	33
Clonidine HCl	75	15	27	67*
	100	15	87	100
Apomorphine HCl	150	15	69	46
	200	15	92	82
Carbachol	4	12	75	83

*Significantly different from control values

Based on the above results, we conclude that: (1) the protective effect of HSV on d-amp. induced death is a temporary phenomenon; (2) the effect is restricted to adrenergic neurons (no differential mortality between HSV and control groups was noted for carbachol or apomorphine); and (3) the phenomenon involves a partial saturation of α adrenergic receptor sites (differential deaths were seen with clonidine but not isoproterenol, blockade was overcome by high d-amp. and clonidine).

The immunized centrally infected HSV mouse provides not only a means of examining long-term interactions between infection and pharmacological agents, but may also represent a model for neurological disorders of brain catecholamines.

1747 FORMATION OF EPHAPTIC CONNECTIONS AFTER PERIPHERAL NERVE INJURIES. Zeev J. Seltzer* and Marshall Devor (SPON: Donald Price). Neurobiol. Unit, Life Sci. Inst., Hebrew Univ., Jerusalem, Israel.

Injury to peripheral nerves breaks the isolation between adjacent axons, thus producing acute artificial synapses at the injury site. These, however, decay within minutes after the lesion. In contrast to this acute phenomenon, we found that starting 30 days after the lesion, persistent electrical cross-talk between pairs of axons can be detected. In adult rats we cut the sciatic nerve and prevented its regeneration, promoting the formation of a neuroma. At intervals thereafter, in acute preparations, we severed the L_{4-6} dorsal or ventral roots and delivered electrical stimuli (0.1 msec, 1.5 Hz, up to 4 mA) to their distal portion. In all animals that survived at least 30 days after the lesion, we recorded from ventral or dorsal root strands that were cut centrally. Each action potential responded at fixed threshold and latency (3.5-28.0 msec) to each stimulus pulse. The possibility that we were stimulating and recording from one continuous axon possessing a long recurrent sprout, can be ruled out for at least 75% of the fibers recorded at 30-35 days after the lesion, on the basis of response latency. There is, therefore, cross-talk between independent axons. The interaction must occur in the vicinity of the injury since local anesthetic block or section of the nerve just proximal to the neuroma eliminates it. Such interactions were found to exist between pairs of motor fibers, sensory fibers and sensory and motor fibers. In a few rats we estimated only the fraction of the sensory to motor ephapses. By stimulating the neuroma we counted the number of motor fibers in each recorded strand. The mean fraction of these being ephaptically connected to sensory fibers was 6.8%. This interaction is probably electrical and not chemical, as it is bidirectional and has a very high safety factor (absolute refractoriness as determined by the double pulse method at as little as 0.55 msec; some follow tetanus to 1000 Hz). Based on collisions of action potentials initiated either at the dorsal root or at the sciatic nerve juxtaproximal to the neuroma, we could calculate the conduction velocities of the sensory and motor axons involved in each ephapse. Their conduction velocity histograms is the same as the distribution of dorsal and ventral root fibers in a neuroma. We repeated some of these experiments in rats that underwent sciatic section and immediate end to end resuture or after sciatic crush. In each of these we observed ephapses essentially identical to the neuroma ephapses. The occurrence of ephapses after peripheral injury lends support to longstanding hypothesis concerning their existance and possible contribution to various peripheral neuropathies.

1748 MULTIPLE SCLEROSIS: SENSITIZATION TO PERIPHERAL NERVE AND CNS MYELIN BASIC PROTEIN-A SERIAL STUDY. William Sheremata, AND Alan Sazant.* Dept. of Neurology, School of Medicine, U. of Miami, Miami, Fla 33101.

Numerous studies have documented immune responses to myelin, myelin constituents, and to oligodendrocytes in multiple sclerosis. However, prospective studies of sensitization to peripheral nerve have not been reported. We have therefore performed serial studies in 6 normals and in 20 patients with multiple sclerosis. Young patients, early in their clinical course were selected for this study. The Thor-Rocklin Indirect Macrophage Migration Inhibition Factor (MIF) assay was employed using human peripheral nerve and human central nervous system (CNS) myelin basic protein as antigens. A 10 mcgm./ml. concentration of basic protein and a 1/3000 dilution of a partially clarified homogenate of nerve was used for the lymphocyte cultures.

A group of normal controls gave a mean migration index of 96+ 6.5 (S.D.) with basic protein, and 101+11 with dilutions of 1/3000 peripheral nerve. All Multiple Sclerosis patients within 3 weeks of a exacerbation responded to myelin basic protein with signifigant results. Four, at the height of their exacerbations also responded to peripheral nerve. Occasional responses to peripheral nerve (2) and to basic protein (7) were seen apart from obvious clinical activity in these patients. Two controls had laboratory exposure to myelin basic protein and peripheral nerve. Lymphoblastic transformation with myelin basic protein gave positive results after, but not before such exposure, while MIF assays remained negative.

Sensitization to peripheral nerve may be a factor in producing some peripheral nervous system pathology as has been reported. Such results, however may only reflect the presence, in the in vitro preparation of peripheral nerve, of a second basic protein which is identical to CNS basic protein. Processing of the nerve may reveal antigenic sites not normally exposed. Limited studies using a purified basic (P2) protein preparation supplied by Dr. E.H. Eylar nevertheless closely parallel the results obtained using crude peripheral nerve. The positive MIF assays with CNS myelin basic protein in acute attacks ofmultiple sclerosis (in contrast to other assay systems) may reflect B cell depletion, or other alterations in lymphocyte subpopulations induced during cell separation procedures peculiar to the assay. (Sazant et al, in press).

1749 ALTERATIONS IN MAZE PERFORMANCE ASSOCIATED WITH CHRONIC IMMUNE COMPLEX DISEASE. David W. Shucard, Steven A. Hoffman, Ronald J. Harbeck*, Andree A. Hoffman* and Hilary A. Brodie*. Dept. of Behavioral Sciences and Dept. of Medicine, National Jewish Hospital and Research Center, Denver, CO 80206.

Evidence is accumulating to suggest that immune complexes may be responsible for altering central nervous system (CNS) functioning in individuals with systemic lupus erythematosus (SLE). Studies from our laboratories and others, using animal models, have shown an array of CNS-associated effects of laboratory induced immune complex disease. These include immune complex deposition in the choroid plexus, changes in cerebrospinal fluid composition, and effects on behavior. In this investigation a rat model was used to study the effects of chronic immune complex disease on CNS functioning and on subsequent maze learning performance. Chronic immune complex disease was induced in rats by 3 initial subcutaneous injections of bovine serum albumin in Freund's incomplete adjuvant followed by biweekly or triweekly intravenous injections of bovine serum albumin. Behavioral measures of speed, errors and trials to criterion in a Lashley Maze were obtained. Proteinuria used as an index of the disease process was assessed over the course of the experiment. At the end of the study, the presence of immune complex deposits in the kidney and choroid plexus was determined by immunofluorescence microscopy. The results indicated that there were differences in maze performance associated with proteinuria levels. Experimental animals with elevated proteinuria produced significantly less errors and had fewer trials to criterion than either the experimental animals with low proteinuria or the controls. These same findings were obtained when animals were retested in the maze after a two week interval. Immunofluorescence data showed that none of the control animals but a majority of experimental animals showed evidence of immune complex deposits in both kidney and choroid plexus. In general, choroid plexus immunofluorescence was of lower intensity and more variable than that seen in the renal glomeruli. Furthermore, the data indicated that immune complex deposits in the choroid plexus may be related to performance in the maze. These results confirm and extend previous data from our laboratories reporting behavioral changes associated with the induction of chronic immune complex disease in rats. The types of behavioral alterations observed may be related to changes in attention-related mechanisms in the CNS. (Supported in part by USPHS Grant NS-12394.)

1750 MEMBRANE ELECTRICAL EVENTS ASSOCIATED WITH LYMPHOCYTE KILLING OF CULTURED NERVE CELLS. Cathy L. Stephens, Sandra Fitzgerald*, and Pierre A. Henkart*. NCI & NICHHD, NIH, Bethesda, MD 20205.

Intracellular microelectrode recordings were made of neuroblastoma-glioma hybrid cells (NG 108-15) while they were attacked by thymus derived (T) killer lymphocytes. Spleen cells from C57 Bl/6 strain ($H\text{-}2^b$) mice were sensitized in vitro in a standard 5-day culture against irradiated B10.A or A/J ($H\text{-}2^a$) mice in order to generate killer T cells which would recognize $H\text{-}2^a$, (the haplotype from which the neuroblastoma-glioma target cells were derived). Using the standard ^{51}Cr release assay with the neuroblastoma-glioma target cells, lysis was observed with such b anti-a lymphocytes but not with similarly sensitized a anti-b lymphocytes or with b lymphocytes co-cultured with irradiated b haplotype cells. Several lines of evidence indicate that killer T-lymphocytes induce channels in the target cell's membrane which allow ions to equilibrate across the membrane leading to colloid osmotic lysis. To investigate the membrane electrical events associated with this killing, intracellular microelectrode recordings were made in a neuroblastoma-glioma cell while adding activated T-lymphocytes and until the cell either completely lost its membrane potential or until the electrode was withdrawn after a long term recording (up to 4 hrs.). Prior to any treatment the resting potential of these cells was $\sim$ -60 mV; and the cells were typically electrically silent, but produced action potentials following intracellular stimulation. After lymphocytes were layered over the target cells, large reversible depolarizations (20-40 mV) lasting from 3-30 secs. were seen in the target cells. Between intermittent depolarizations the resting membrane potential remained constant.

Although all recorded cells maintained a normal resting membrane potential for over an hr after lymphocyte treatment, later (78-140 mins) 27% of these cells irreversibly lost their membrane potential following an abrupt depolarization from $\sim$ -60 to OmV.

All of the electrical changes described were seen using $H\text{-}2^b$ anti-$H\text{-}2^a$ lymphocytes; the control lymphocytes which did not show ^{51}Cr release from these target cells did not cause significant electrical changes in the target cell membrane. Our results suggest that while T-lymphocytes initially may transiently increase membrane permeability, progressive conic equilibration following the interaction of target cells and T-lymphocytes does not seem to occur.

1751 ETHANOL-INDUCED ALTERATIONS IN HIPPOCAMPAL AFTERDISCHARGES AND AFTERDISCHARGE THRESHOLDS. H.S. Swartzwelder, C.T. Johnson*, B.C. Cooley*, and R.S. Dyer. Psych. Dept. Towson State Univ., Baltimore, MD. and U.S. E.P.A., Research Triangle Park, NC.

Electrically induced hippocampal (HPC) afterdischarges (ADs) and their sequelae have been recommended as an index of neural function against which to measure toxicant-induced change. The properties of HPC ADs have been characterized both under normal conditions and following exposure to a number of toxicants. The present experiment was designed to assess the effects of acute systemic ethanol exposure upon some of these endpoints. Thirty male hooded rats were bilaterally implanted with bipolar stimulating and recording electrodes in the dorsal HPC. On test days animals were injected with either 0, 0.125, 0.25, 0.50, 2.0, or 3.0 g/kg of ethanol (IP) in a 20% (w/v) solution. Thirty minutes later AD thresholds were determined by a method similar to that described by Pinel et al., (1976). Each animal received each dose once in a counterbalanced order. Tail vein blood samples were taken immediately after the AD and assayed to determine blood-ethanol concentration. The most clear and profound effects were observed with the 3.0 g/kg dosage. Blood-ethanol concentrations at this dosage typically fell between 212 and 305 mg/dl. At this dosage the threshold for AD production was elevated, AD duration was decreased, and the frequency of spikes within ADs was decreased. These results parallel those obtained in previous investigations concerning sodium pentobarbital-induced alterations in HPC ADs and their sequelae, and suggest alterations in HPC ADs as an index of alcohol-induced neurophysiological depression. The results will be discussed in light of a dose response study on ethanol-induced changes in single unit activity in the hippocampus (Neuropharmac. 18: 63, 1979).

1752 ALUMINUM ENCEPHALOPATHY-INHIBITION OF HEXOKINASE BY ALUMINUM. George A. Trapp* (SPON: P.C. Jobe). Research Service, Veterans Administration Hospital and Dept. Psychiatry, LSU School of Medicine, Shreveport, La. 71130.

The aluminum encephalopathy model of aluminum neurotoxicity and neurofibrillary degeneration (NFD) has been studied in experimental animals and may have some relationship to human renal dialysis encephalopathy and also to a variety of conditions which lead to NFD, including Alzheimer's Disease. In the absence of specific information about aluminum function, we considered the possibility that aluminum exerts toxic effects by interference with well-known metal-activated reactions. We selected magnesium-dependent phosphoryl transfer catalyzed by yeast hexokinase as a convenient example for study.

Aluminum-ATP complex gives kinetics of linear competetive inhibition against magnesium-ATP as the varied substrate (K_m= 8×10^{-4} M, $K_i = 4 \times 10^{-4}$ M), and is non-competetive against glucose ($K_m = 3 \times 10^{-4}$ M). Aluminum-ATP was not a phosphoryl donor in this reaction and velocity is zero in absence of magnesium. The stability constant (K_s) for aluminum-ATP was 7.4×10^5 M and K_s for magnesium-ATP was 1.9×10^4M. Chromium-ATP, a known inhibitor of HK had K_s 2.5×10^5 M and gallium-ATP had K_s of 2.3×10^6 M.

We conclude that aluminum ion is a dead-end inhibitor of hexokinase. K_i is in the range of aluminum concentrations seen in experimental animal models of aluminum toxicity in brains. Inhibition of this or some other magnesium-ATP enzyme may be an important step in the genesis of NFD in animals or dialysis encephalopathy in man.

1753 DEVELOPMENT OF ABNORMAL NEURON MORPHOLOGY IN FELINE GANGLIOSIDOSIS. Steven U. Walkley, Dominick P. Purpura and Henry J. Baker*. Dept. Neuroscience, Albert Einstein College of Medicine, Rose F. Kennedy Center for Research in Mental Retardation and Human Development, Bronx, N.Y. 10461.

Recent studies strongly suggest that the pathophysiology of ganglioside storage disease is intimately linked to progressive changes in neuron shape and synapse distribution rather than to simple cytotoxic effects of ganglioside accumulation (Brain Res. 116: 1-21, 1976). Of primary interest is the formation of abnormalities termed meganeurites, which are enlargements at the juncture of neuron soma and axon possessing synaptic contacts of unknown origin. Preliminary studies of feline GM_1 gangliosidosis have revealed similar morphological changes present in various types of neurons in the CNS (Brain Res. 143: 13-26, 1977).

The availability of colony-reared cats with GM_1 and more recently GM_2 gangliosidosis, which bear remarkable similarity to the disorders seen in children (Science 174: 838-839, 1971; Science 196: 1014-1017, 1977), has made possible a systematic study of the development of these morphological changes in the face of progressive neurological deterioration. Although clinical signs are similar in these two types of feline gangliosidosis, the neurobehavioral deterioration progresses at different rates. The earliest clinical signs, hind-limb weakness and head tremor, are seen at 6-8 weeks of age in GM_2 mutants and 12-15 weeks in those with GM_1 gangliosidosis. Similarly, onset of recumbency is more rapid in GM_2 cats, occurring at 4 months as opposed to 6-7 months in GM_1 mutants. Terminal states are reached by 6 months in GM_2 cats and 12 months in GM_1 cats.

Progressive morphological alterations can be demonstrated in Golgi preparations of neurons during the course of clinically evident neurological deterioration. Changes in individual neurons are type-specific and some types (e.g. Purkinje cells of cerebellum) demonstrate no abnormalities. Examples of affected neurons include pyramidal cells of cerebral cortex, medium spiny cells of caudate and putamen, apparent intrinsic neurons of thalamus, and stellate cells of cerebellum. Examples of alterations occurring in particular neurons include simple enlargement of the soma (nonprogressive), pre-meganeurite structures progressing to meganeurites, variable focal enlargements in dendritic trees, and secondary neurite formation, primarily from abberant sites such as meganeurites. Changes seen in any one neuron type are both specific and consistent, however, especially in pre-terminal stages, apparent normal neurons of a particular kind can be demonstrated in proximity to those showing morphological abnormalities. (Supported by NS-07512 and NS-10967.)

1754 CHARACTERISATION OF BRAIN TISSUE IN PEDIATRIC BRAIN TUMOR PATIENTS USING COMPUTERIZED TOMOGRAPHY. P. WEISS*, M. CERRONI*, D. DE MICHELE*, L. SINKS*, D. MC CULLOUGH*, D. ROBERTSON*, B. HAMILTON, W. NORMAN* D. SCHELINGER*, H. MANZ*, P. CRISP, AND J. MAZZIOTTA*. (SPON: P. CRISP) GEORGETOWN UNIVERSITY MEDICAL CENTER WASHINGTON D.C. 20007, AND U.C.L.A. MEDICAL CENTER, LOS ANGELES, CA 90024.

A system for monitoring glioma development and response to multimodal therapy utilizing Computerized Tomography (CT) has been developed at Georgetown University Medical Center. In implementing this program, we have found that in addition to compilation of ventricular, lesion, and total brain volumes in our patients, it has become within our reach to examine various intra cranial tissues through CT generated data. This is accomplished by on line data processing of scans based on a software package that produces frequency distribution histograms of CT density coefficient numbers and computes ventricular, lesion, and total brain volume and mass. CT histogram analysis permits us to separate ventricular system and contents from surrounding brain tissue, and normal from pathological tissues. This has value in that it allows us to check the accuracy of lesion, ventricular, and total brain volume determinations by summation of points represented under histogram tissue curves. Secondly, and equally important, we can distinguish between frank edema and tumor seeding in the absence of visible gross lesion in a scan series. We believe this program has great promise in that it enables us for the first time to follow the course of intra cranial disease in an exacting fashion that has been previously unavailable. This has optimal utility because we can now tailor therapy for each patient rather than make clinical judgements based on hindsight. Finally, we are hopeful that once a sufficient data base has been assembled on different types of tumors, it may be possible to employ this data diagnostically prior to craniotomy and biopsy.

1755 PATHOLOGY OF TAPETUM AND RETINA OF TAURINE-DEPLETED CATS. G. Y. Wen, H. M. Wisniewski*, J. A. Sturman, A. A. Lidsky, A. C. Cornwell* and K. C. Hayes*. NYS Institute for Basic Res. in Mental Retardation, Staten Island, NY 10314. Montefiore Hospital and Med. Center, Bronx, NY 19467. Harvard School of Public Health, Boston, MA 92115.

Taurine is widely distributed in animal tissues and is present in especially large amounts in the retina. Within the retina, taurine is present in greatest concentration in the photoreceptors. A series of studies demonstrated that cats fed a synthetic diet with casein as the sole source of protein become taurine-depleted and suffer central retinal degeneration in which the photoreceptors become damaged and eventually are lost completely. In this paper we report disorganization and degeneration of tapetal cells from taurine-depleted cats in addition to photoreceptor damage. Adult cats were fed a synthetic (taurine-free) diet or the same diet supplemented with 0.4% taurine for 18 months. Animals were sacrificed by perfusion. The eyes were removed and hemisected. The posterior half of eye was mapped and divided into 18 areas. There was an approximately 50% reduction in size of the tapetum in the taurine-depleted cats. In the center region of tapetum, the number of layers of tapetal cells was reduced from 12-16 to 2-3. Electron microscopic examination revealed varying degrees of disorganization and disruption of the tapetal rods in the taurine-depleted cats. In some cells, the tapetal rods, when present, were shorter, thicker and more electron-dense than in tapetal cells of taurine-supplemented cats. Some of the tapetal rods appeared broken. These changes apparently lead to the formation of electron-dense droplets reminiscent of pigment granules. In other tapetal cells from taurine-depleted cats the normal lattice arrangement of tapetal rods was apparently retained. Dietary deficiency of taurine resulted in the degeneration of photoreceptors and depigmentation in the retinal epithelium and choroid. The disk membranes of photoreceptors were disoriented, vesiculated and disrupted. The cell bodies of photoreceptors also underwent pyknotic degeneration. Both electroretinogram responses and visual evoked potentials of the taurine-depleted cats were greatly reduced. Amino acid analysis showed a severe depletion of taurine in the retinae and other tissues of these cats when not supplemented with taurine. This study demonstrated that the dietary deficiency of taurine in cats induces the pathological, biochemical and electrophysiological changes in the retinae. (This study was supported by the Office of Mental Retardation and Developmental Disabilities of the State of New York and by Public Health Service grants HD-11129 and EY-00631 from NIH).

1756 ACTIVATION OF "AUTOMATIC" SWALLOWING BY SEROTONIN AGONISTS IN RATS WITH EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS. Susan R. White and Detlef Bieger. Fac. Med. Memorial Univ. Nfld., St. John's, Nfld., A1B 3V6.

Depressed neuronal sensitivity to serotonin has been found in both the peripheral nervous system (Weinstock, et al., Brain Res. 125, 1977, 192) and in the lumbar spinal cord (White, Brain Res., in press) of animals with paraplegia resulting from experimental allergic encephalomyelitis (EAE). The purpose of the present study was to determine whether EAE also impaired serotonergic responsivity at the brainstem level. A convenient index of this activity is the periodic swallowing displayed by rats under urethane anesthesia (Bieger, et al., Neuropharm. 16, 1977, 245) which has been shown to be mediated, in part, by a serotonergic mechanism in the lower brainstem (Bieger, et al., Eur. J. Pharmacol. 18, 1972, 128). In the present experiment we examined "automatic" swallowing activity in EAE rats exhibiting complete hindlimb paralysis. The EAE rats displayed periodic swallowing under urethane anesthesia at rates and forces comparable to control rats. Intravenous administration of the serotonin precursor, 5-hydroxytryptophan, or the serotonin agonist, Quipazine, enhanced the rate of swallowing in both EAE and control rats. Neither of these drugs, however, increased the amplitude of lumbar monosynaptic reflexes in EAE rats, while both had marked facilitatory effects in control rats. These results suggest that serotonin sensitivity is depressed at levels of the neuraxis manifesting motor disability during the disease but is preserved at levels where motor impairment is not evident.

NEUROPEPTIDES

1757 NALOXONE ALTERS LOCOMOTION AND INTERACTION WITH ENVIRONMENTAL STIMULI. Amy T. Arnsten* and David S. Segal. Dept. Psychiatry, Sch. Med., UCSD, La Jolla, CA 92093.

Effects of the opiate antagonist naloxone were examined on the behavioral response pattern of rats in a novel environment. After injection with saline or naloxone (0.5, 5.0 or 25 mg/kg, s.c.), the rats were monitored for locomotion and both frequency and duration of contact with stimuli in a multicompartment exploratory chamber. Naloxone produced a dose-related reduction in locomotion and in frequency of contact with stimuli. At the lowest dose tested this reduction was accompanied by an increase in total duration of contact and in time spent per contact with the stimuli. In contrast, the highest dose of naloxone decreased the duration of contact with stimuli and induced prolonged periods of inactivity. An intermediate response was observed with 5.0 mg/kg naloxone. These findings indicate that lower doses of naloxone may enhance interaction with environmental stimuli while the predominant effect of higher doses is a general suppression in behavioral activity.

1758 EFFECT OF ADH ON CALCIUM-DEPENDENT RELEASE OF SEROTONIN AND ENDOGENOUS LEVELS OF SEROTONIN FROM HIPPOCAMPAL SLICES. Sid Auerbach* and Peter Lipton (Spon. Peter Lalley) Dept. Physiol, U of Wis., Madison Wis. 53706

DeWied has reported that intracerebroventricular injection of ADH corrected learning deficits in rats lacking the ability to synthesize ADH (Brain Res. (1975)85,152). Rigter has shown that administration of ADH can reverse CO_2-induced amnesia of a learning task and that an increase in endogenous hippocampal 5HT was associated with this reversal (Brain Res. (1977)120,485). The data is consistent with the hypothesis that ADH may affect behavior by a direct or indirect effect on 5HT turnover in the hippocampus. We have used hippocampal slices as an *in vitro* model to study the effect of ADH on 5HT.

Thin slices of rat hippocampus were incubated in oxygenated buffer at 37°C. Endogenous levels of 5HT were measured by a radioenzymatic method (Fed. Proc. (1977)36,2134). 5HT levels were 2.59±.11 ng/mg prot. after a 30 minute incubation in normal buffer followed by a 10 minute period of incubation in high K^+ (63mm) buffer as compared to 4.42±.31 when Ca^{++} was omitted from the high K^+ buffer. This Ca^{++}-dependent decrease in 5HT is interpretable as equal to 5HT release as a result of depolarization-induced exocytosis. If 10^{-7}M ADH was included in the incubation medium during the exposure to high K^+, the levels of 5HT after 10 minutes was 3.31±.28. The difference in 5HT levels in the presence of ADH compared to control was significant ($P<.05$) and amounts to a 31% inhibition of 5HT depletion by the ADH.

In a second series of experiments, slices were preincubated with ^{3}H-5HT, and Ca^{++}-dependent, high K^+ induced release of radioactivity was measured during a 10 minute period. Release of radioactivity into the medium was decreased from 52.6%±1.6 of total radioactivity in slices to 49.6%±1.7 by ADH (10^{-8}-10^{-6}M).

The data is consistent with the hypothesis that ADH is acting in the hippocampus to inhibit Ca^{++}-dependent release of 5HT. The results could also be explained by postulating that ADH increases 5HT synthesis. Increased synthesis would decrease the specific activity of ^{3}H-5HT and result in an apparent decrease in release and in the increased endogenous levels of 5HT that we observed. The observed effect of ADH must be on serotonergic nerve terminals as 5HT containing cell bodies are not found in the hippocampus. The hippocampus, as a part of the limbic system may be involved in learning behavior. An effect of ADH on 5HT metabolism in hippocampus may be a partial basis for reported effects of ADH on behavior. 1759 INTRACELLULAR PROCESSING OF α-MSH AND ACTH IN HYPOTHALAMIC NEURONS: A PRELIMINARY STUDY. A. Barnea, G. Cho*, and J. C. Porter, Depts Ob/Gyn & Physiol, Green Ctr for Reprod Biol Sci, Southwestern Med Schl, Dallas, TX 75235.

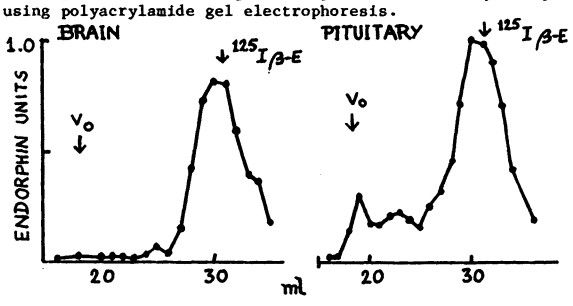
Immunoreactive α-MSH (α-MSH$_i$) (Oliver and Porter, Endocrinology 102: 697, 1978) and ACTH (ACTH$_i$) (Krieger et al., Proc Natl Acad Sci 74: 648, 1977) are present in hypothalamic tissue. The current view is that in the pars intermedia of the hypophysis of the rat, α-MSH is derived from ACTH, and ACTH in turn is derived from a large (31K) precursor by a process involving a series of cleavage reactions. In addition to α-MSH$_i$ and ACTH$_i$, hypophysial cells contain significant amounts of the 31K precursor as well as intermediate forms between the 31K precursor and ACTH. We have addressed the question whether the processing of ACTH$_i$ and α-MSH$_i$ in the hypothalamic cells proceeds by a mechanism similar to that operating in the cells of the pars intermedia. We have analyzed the molecular forms of ACTH$_i$ in extracts of the hypothalamus and pars intermedia and calculated the amounts of the various forms of ACTH$_i$ and α-MSH$_i$. ACTH$_i$ and α-MSH$_i$ were extracted from hypothalami and neurointermediate lobes of adult male rats with 5M acetic acid (Eipper and Mains, Biochemistry 14: 3836, 1975). The various forms of ACTH$_i$ were separated by means of gel filtration using columns of Sephadex G-50 (superfine) under denaturing conditions (8M urea containing 0.5% 2-mercaptoethanol). ACTH and α-MSH were quantified by RIA. The recognition site of the ACTH antibody was contained within the amino acid sequence 11-16 of ACTH, and the antibody had no apparent cross-reactivity with α-MSH. The antibody to α-MSH had no apparent cross-reactivity with ACTH. The elution profiles of hypothalamic ACTH$_i$ and pars intermedia ACTH$_i$ were identical, and were indicative of the presence of three species of molecules crossreacting with the antibodies to ACTH: a large ACTH$_i$ which was eluted with the void volume, an intermediate ACTH$_i$, and a small ACTH$_i$ which co-eluted with hACTH$_{1-39}$. The K_d for large ACTH$_i$ was 0; for intermediate ACTH$_i$, 0.21 ± 0.007 (mean ± SD, N=8); for small ACTH$_i$, 0.32 ± 0.007; and for α-MSH$_i$, 0.72 ± 0.026. Of the total ACTH$_i$ in the hypothalamus, 60% was associated with large ACTH$_i$, 10% with intermediate ACTH$_i$, and 30% with small ACTH$_i$. Of the total ACTH$_i$ in the pars intermedia, 70% was associated with large ACTH$_i$, 10% with intermediate ACTH$_i$, and 20% with small ACTH$_i$. Based on weight, the ratio of α-MSH$_i$ to total ACTH$_i$ in extracts of the pars intermedia was significantly ($P<0.001$) higher than that in extracts of the hypothalamus: 13.2 ± 1.85 (mean ± SE, N=10) and 2.1 ± 2 (N=10), respectively. On the basis of these findings, it would appear that ACTH and its possible precursors are present in the rat hypothalamus and that the processing of ACTH in hypothalamic tissue may proceed in a manner similar to that in the pars intermedia. However, on the basis of the marked difference between the ratio of α-MSH$_i$ to ACTH$_i$ in the hypothalamus and in the pars intermedia, we suggest that the mechanisms of processing and/or storage of α-MSH in the hypothalamic cells may differ from those operating in the cells of the pars intermedia.

1760 ENDORPHIN IMMUNOREACTIVE MATERIAL IN THE BRAIN AND PITUITARY OF THE RAT EMBRYO. Alejandro Bayon, Wm. J. Shoemaker, Robert J. Milner*, Raana Azad*, and Floyd E. Bloom.. A.V. Davis Ctr. for Behav. Neurobiology, The Salk Inst., La Jolla, CA 92037.

We have previously shown that endorphin immunoreactive material appears in the rat brain early in ontogenetic development. This work is an initial attempt to characterize this material. Embryonic day 16 rat brains and pituitaries were extracted in boiling 0.2 N HCl. Extracts from several animals were pooled, centrifuged, neutralized, and lyophilized. The reconstituted samples were analyzed by permeation chromatography and fractions assayed for endorphin immunoreactivity as indicated below.

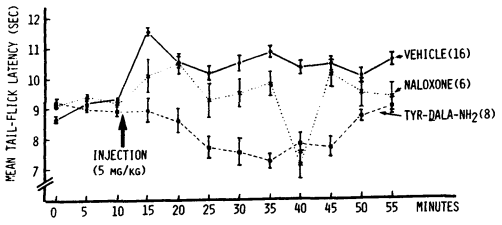
A single peak, co-eluting with ^{125}I-β-endorphin, was observed in extracts of embryonic brain, indicating that in the embryonic brain, as in the adult, very small amounts - if any - of the higher molecular weight endorphin are present. In contrast, embryonic pituitary extracts showed a substantial amount of larger endorphin-like material (possibly β-LPH and 31K protein). However, the relative contribution of these peaks to the total pituitary endorphin is much lower than in the adult where β-LPH is the predominant species. This difference might indicate different physiological roles for β-endorphin and β-LPH in prenatal and postnatal life. Currently, we are characterizing the higher molecular weight endorphins in the embryonic pituitary using polyacrylamide gel electrophoresis.



The endorphin RIA is equally sensitive, on a molar basis, to β-endorphin and β-LPH (1 unit = 1 ng β-endorphin immunoequivalents). Extracts obtained from 10 embryos were run through controlled pore glass-glycophase 200 columns (1 x 50 cm) in 0.1 M ammonium acetate, 0.1% triton-X 100. Recovery from the column was >90%.

1761 HYPERALGESIA AND REVERSAL OF ENKEPHALIN- AND STIMULATION-INDUCED ANALGESIA BY THE DIPEPTIDE TYR-DALA-NH_2. James D. Belluzzi, William H. McGregor and Larry Stein. Wyeth Laboratories, Philadelphia, Pennsylvania 19101.

Tyr-DAla-NH_2 has weak, naloxone-reversable, analgesic activity at an intraventricular dose of 100µg (McGregor, Stein & Belluzzi, 1978). We report here that, at 6µg centrally, or after systemic administration (5 mg/kg, s.c.), the dipeptide has the opposite effect, producing hyperalgesia and reversal of opiate- and stimulation-induced analgesia. The pain sensitivity of rats was assayed in the D'Amour-Smith tail-flick test. In a first experiment, analagesia was induced by morphine sulfate (2.5 mg/kg, s.c.) or the enkephalin analog DAla^2, DLeu^5-NH_2 (1µg, intraventricularly). Administration of the dipeptide 15 minutes after the onset of analgesia significantly shortened the duration of analgesic action of both compounds. In a second experiment using a weak heat stimulus, the effects of the dipeptide alone on normal pain sensitivity were examined. Tyr-DAla-NH_2 produced a significant hyperalgesia compared to controls (see Figure). Naloxone had smaller insignificant effects at doses of 1.25-20 mg/kg, s.c. If the pain threshold is normally elevated by circulating endorphins, these results suggest that Tyr-DAla-NH_2 is more effective than naloxone in reversing the action of endogenous endorphins. In a third experiment, profound analgesia was induced by electrical stimulation of the midbrain central gray. The dipeptide reversed this analgesia intermittently for approximately 30 minutes. Tyr-DAla-NH_2 thus lowers normal pain thresholds and antagonizes the analgesic action of opiate peptides and central gray stimulation. The mechanism of action of the dipeptide is presently unclear. Some presynaptic effect (such as inhibition of endorphin release or synthesis) seems more likely than a postsynaptic action, however, since the dipeptide has only weak affinity for the opiate receptor.



Hyperalgesia produced by Tyr-DAla-NH_2

1762 EFFECTS OF β-ENDORPHIN ON BODY TEMPERATURE IN THE MOUSE. Alan S. Bloom and Liang-Fu Tseng*, Department of Pharmacology and Toxicology, Medical College of Wisconsin, Milwaukee, Wisconsin 53226.

The effects of intracerebroventricular (ICV) injection of β-endorphin (β-END) on temperature in mice was studied at ambient temperatures of 10°, 20° and 31° C. Male Swiss mice were injected ICV with β-END in 5 µl of sterile saline. The observed results were dependent on both the dose used and the ambient temperature. Doses of β-END between 0.03 and 1.0 µg produce a dose related hyperthermia at an ambient temperature of 20° C. At this same ambient temperature, a 10 µg dose produced significant hyperthermia (-6.11° C). In mice studied at 31° C hyperthermia was produced by all doses (0.03-10.0 µg) tested. At an ambient of 10° C hyperthermia was produced by the lower doses of β-END and hypothermia by the higher doses (3 and 10 µg). These data demonstrate that the ICV administration of low doses of β-END produce an increase in body temperature whereas higher doses may cause the animal to become poikilothermic.

EFFECTS OF β-END ON BODY TEMPERATURE

Dose (µg)	31°	20°	10°
0.03	0.78 ± .23	0.96 ± .15	0.01 ± .16
0.1	0.90 ± .07	1.16 ± .16	0.41 ± .16
0.3	0.96 ± .13	1.30 ± .14	0.61 ± .17
1.0	1.48 ± .16	1.35 ± .23	0.48 ± .32
3.0	1.04 ± .16	0.32 ± .46	-5.22 ± .97
10.0	1.40 ± .14	-5.30 ± .75	-14.01 ± .54

Values shown are the difference in effect between drug treatment and saline control groups at 60 minutes after injection (N=8 to 10).

The effect of naloxone (1 mg/kg, sc) on both the low dose (0.3 µg) and high dose (10 µg) effects of β-END was also examined. Pretreatment with naloxone significantly blocked the hypothermia produced by 10 µg of β-END at 20° and 10° C. Naloxone did not block the hyperthermia produced at 31° C by the 10 µg dose. Similarly, the hyperthermia produced by the 0.3 µg dose of β-END was not blocked by naloxone at any ambient temperature. These data suggest that β-END may produce its hyperthermia and poikilothermic effects at different sites. (Supported in part by USPHS Grant # DA 00124).

1763 IMMUNO- AND ENZYME CYTOCHEMISTRY OF NEUROSECRETORY NEURONS IN NORMAL AND SALT-TREATED MICE. R. D. Broadwell, C. Oliver* and M. W. Brightman*. NINCDS and NIDR, NIH, Bethesda, MD 20205.

Supraoptic neurons of the hypothalamo-neurohypophysial system produce and secrete the octapeptides oxytocin and vasopressin. These neurons respond to alterations in osmolarity of the extracellular fluid and, therefore, can serve as a model for correlating morphological and physiological events associated with hyperosmotic stress. Supraoptic perikarya from control mice and mice given 2% salt water to drink for 5-8 days have been studied using immuno- and enzyme cytochemical techniques. Antibody directed against neurophysin, the carrier protein for the octapeptides, was used in conjunction with the peroxidase-anti-peroxidase (PAP) technique to stain, immunologically, organelles associated with production and packaging of the octapeptides. Thiamine pyrophosphatase (TPPase) activity was used as a marker for Golgi saccules. Acid phosphatase (ACPase) activity in Golgi associated Endoplasmic Reticulum from which Lysosomes arise (GERL) was demonstrated using ß-glycerophosphate and cytidine-5'-monophosphate as substrates.

With light microscopic immunocytochemical methods, supraoptic cell bodies stain positively for anti-neurophysin, indicating that these cells synthesize the associated octapeptides. PAP reaction product for neurophysin immunoreactivity was localized ultrastructually in the nuclear envelope, rough endoplasmic reticulum, Golgi saccules, secretory granules, and secondary lysosomes. Under normal conditions, TPPase activity was restricted to the innermost 1 or 2 Golgi saccules, whereas ACPase activity was confined to GERL and secondary lysosomes. Neurosecretory granules arose predominantly from GERL. When the animals were hyperosmotically stressed by salt loading, nearly all Golgi saccules and GERL were TPPase reactive. Secretory granules were now formed from all Golgi saccules as well as GERL. Little or no ACPase activity could be demonstrated in GERL. When the animals were allowed to recover for a period of 10 days after salt treatment, the ACPase activity in GERL returned to normal; however, the elevated TPPase activity and secretory granule formation seen in Golgi and GERL saccules with osmotic stress persisted.

These results reveal a morphological basis for metabolic responses and interrelationships among the Golgi apparatus, GERL, and secretory granules within peptidergic neurons of the hypothalamo-neuro hypophysial system and, thus, may be of value for considering similar morphological correlates in other peptidergic neurons.

1764 α-MELANOTROPIN-LIKE (α-MSH) IMMUNOREACTIVITY IN RAT AND HUMAN CEREBROSPINAL FLUID. Clivel G. Charlton*, Thomas L. O'Donohue*, Cinda J. Helke, Russel L. Miller* and David M. Jacobowitz (SPON) A. M. Laties). Lab. Clin. Sci., NIMH, Beth., Md. 20205 and Dept. of Pharm. Howard Univ., Washington, D.C. 20059.

An extensive α-MSH containing neuronal system has recently been described in the rat brain (PNAS 75, 1968). The perikarya of this system are located primarily in the arcuate nucleus lesion of which markedly depletes α-MSH concentrations throughout the brain.

In an attempt to measure the in vivo release of α-MSH, the lateral ventricle of chloralose-urethane anesthetized rats were cannulated and perfused with artificial cerebrospinal fluid (CSF). The perfusate was collected from an indwelling cannula in the cisterna magna at 20 min intervals. α-MSH concentrations in the CSF were determined by radioimmunoassay. Initially, approximately 180 pg of α-MSH/20 min interval was detected in the CSF. These concentrations gradually decreased and then stabilized. Rats hypophysectomized for 2-3 weeks had CSF α-MSH concentrations similar to controls.

In human CSF, an α-MSH-like immunoreactive compound has also been detected. Concentrations ranged from 4.0 to 73.3 pg/ml with mean of 22.9 pg/ml.

These data suggest that α-MSH present in CSF is not derived primarily from the pituitary gland but may represent neuronally released α-MSH.

1765 CHARACTERIZATION OF HIGH MOLECULAR WEIGHT ENKEPHALIN-LIKE IMMUNOREACTIVITY IN RAT BRAIN. Steven R. Childers and Solomon H. Snyder. Dept. Pharmacol., Sch. Med., Johns Hopkins Univ., Baltimore, MD 21205

In pituitary, as well as in hypothalamus, β-endorphin is formed from proteolytic breakdown of high molecular weight (MW) protein precursors. The relationship of these precursors to enkephalin is not clear, especially since β-endorphin and enkephalin possess different regional distributions in brain. In order to determine whether other high MW proteins may be enkephalin precursors, various preparations of rat brain were assayed for reactivity with enkephalin antisera. The antibodies were specific for met- or leu-enkephalin, and did not cross react with β-endorphin. The post-mitochondrial supernatant of rat brain was extensively filtered through Dia-Flo PM-10 membranes and eluted on a Sephacryl S-200 column. Two peaks, MW >100,000 and MW 40,000, of enkephalin immunoreactivity were observed. Neither peak non-specifically bound the ^{3}H-met-enkephalin ligand, nor appeared to bind endogenous enkephalin. The 100,000 MW peak, however, bound non-specifically to normal rabbit IgG, indicating the presence of an immunoreactive artifact. The 40,000 MW peak did not bind to normal rabbit IgG and, when prepared from microwave-irradiated brains to inactivate proteases and incubated with trypsin, formed lower MW enkephalin immunoreactivity as determined on P-10 columns. Further analysis revealed that the tryptic product was slightly larger than enkephalin, suggesting that trypsin-like enzymes are not the actual enkephalin-forming enzymes in the brain. However, unlike the high MW activity, the tryptic product did display reactivity in the opiate radioreceptor assay in addition to the enkephalin radioimmunoassay. These results suggest that enkephalin in brain may be formed from high MW protein precursors. (Supported by USPHS Grants DA-00266 and DA-01645.)

1766 IMMUNOCYTOCHEMICAL VISUALIZATION OF LUTEINIZING HORMONE RELEASING HORMONE (LHRH) IN VIBRATOME SECTIONED MURINE BRAIN. Claudia J. Clayton*and Gloria E. Hoffman (SPON: Bernard Weiss). Depts. Neurol. and Anat., Univ. of Rochester Sch. Med. and Dent., Rochester, NY 14642.

The unlabelled antibody-enzyme method of immunocytochemistry was used to visualize LHRH perikarya and fibers in vibratome sectioned rat and mouse brains. Adult male Sprague-Dawley rats and Swiss-Webster mice were fixed by cardiac perfusion of 10% neutral formalin or Zamboni's solution, and brains were removed and sectioned at 75 or 100um thickness. Immunocytochemical staining was performed using a modification of the method of Grzanna et al. (Proc. Nat. Acad. Sci. USA, 75: 2502-2506, 1978). Similar results were obtained with several anti-LHRH sera, including 743, 744 and 940 (Arimura), B4305 and B18 (Sternberger) and 4 (Silverman). No staining of perikarya or fibers was observed using primary antisera which had been preabsorbed with synthetic LHRH.

LHRH perikarya were not confined within traditional nuclear boundaries. Perikarya and fibers were found within and dorsal to the lateral olfactory tract, adjacent to the optic tract, within and lateral to the medial preoptic nucleus, within and dorsal to the OVLT, and in the septal and basal portions of the vertical limb of the diagonal band. Neurons extended rostrally from the medial septal nucleus and the nucleus triangularis to the medial olfactory peduncle, and a few scattered perikarya were seen in the main and accessory olfactory bulbs. LHRH perikarya and fibers also were found along the ventro-lateral border of the hypothalamus, with an occasional neuron in arcuate nucleus. Fibers were present in anterior hypothalamus, in subependymal and lateral hypothalamic areas, and within and ventral to the medial mammillary nuclei. The median eminence received fibers from both rostral and lateral directions. Positively stained perikarya and fibers were present in fornix and hippocampus, and in cortex adjacent to the rostrum of the corpus callosum. Longitudinally oriented LHRH fibers were present dorsal to the corpus callosum, with a few fibers branching dorsally. LHRH fibers also were observed in the subfornical organ, periventricular nucleus of the thalamus, medial habenular nucleus, fasciculus retroflexus, interpeduncular nucleus and mesencephalic central gray.

At the light microscopic level certain LHRH perikarya appeared to be contacted by LHRH fibers, indicating the possible existence of interconnections within the LHRH neuron system.

1767 ELECTRON MICROSCOPIC LOCALIZATION OF NEUROPHYSIN-LIKE IMMUNOREACTIVITY IN TERMINALS OF THE RAT POSTERIOR PITUITARY: AN ALTERNATIVE METHOD USING FROZEN-DRIED, OsO_4 FIXED TISSUE. David Coulter and Robert Elde. Department of Anatomy, Medical School, University of Minnesota, Minneapolis, Minnesota 55455.

Radioimmunoassay studies of somatostatin remaining in dehydrated hypothalami indicate that approximately 90% of this neuropeptide is lost as a result of dehydration in an alcohol series, but that little or none is lost in tissue frozen-substituted in solvents such as 100% ethanol or acetone. Frozen-dried and resin infiltrated tissue was used in this study, and it likewise is expected to retain the neuropeptide.

The use of frozen-dried tissue for EM localization of neuropeptides permits two variables in fixation protocols: whether or not the tissue is prefixed by perfusion with paraformaldehyde before freeze-drying, and whether or not the frozen-dried tissue is post-fixed with OsO_4 vapor before infiltration. Prefixation with paraformaldehyde is advantageous for handling the tissue prior to freezing but results in some loss of immunoreactivity and compromises the morphological quality of the tissue. Postfixation of frozen-dried tissue with OsO_4 vapor does not seem to diminish immunoreactivity at all, at least for neurophysin and somatostatin, and has the advantage of yielding excellent and familiar images in the electron microscope.

Blocks of fresh or paraformaldehyde-fixed rat posterior pituitary were frozen on a metal surface at -196° C, dried in a temperature controlled environment for 2-3 days, fixed with OsO_4 vapor, and infiltrated with resin. Following polymerization of the plastic, serial ultrathin sections were cut and placed alternately on grids and glass slides. Slides were stained with anti-bovine neurophysin II (1:50) for 12 hours at 45° C, followed by fluorescein labeled protein A (100 ug/ml) for 2 hours. These were photographed using a 40 X oil immersion lens and yielded detail approaching the limits of resolution of the light microscope. Useful images were obtained even with sections 300 A in thickness. Some of the grids were stained with uranyl magnesium acetate and used only for electron micrography. Other grids were used first for electron micrography, then immunostained for neurophysin and photographed again in the fluorescent microscope, yielding images of terminals that could be enlarged and superimposed unambiguously on the electron micrographs.

This technique may prove to be of considerable value in the localization of neuropeptides in the nervous system. Maximum immunoreactivity is retained in the sections, the sensitivity of the immunofluorescence method is sufficient for the detection of small terminals in ultrathin sections, and these images can be correlated with electron micrographs having excellent morphology. Supported by NSF.

1768 PARTIAL ANTAGONISM OF STRESS INDUCED ANALGESIA BY ACTH PRETREATMENT. Hugh E. Criswell and Miriam David*. Dept. Psychol., Williams Coll., Williamstown, MA 01267.

If stress induced analgesia results from β-endorphin released concomitantly with ACTH, pretreatment with ACTH should block analgesia through feedback inhibition. To test this hypothesis we trained 56 rats for 10 consecutive days using the flinch-jump procedure to obtain stable jump thresholds. On day 11, the animals were divided into 3 groups. One group received no drug treatment and served as a control, one received 20 mg/kg of naloxone 1 hour prior to testing, and a third received 3 IU/Kg of ACTH 12 hours prior to testing. All drugs were administered SQ. Each of these groups was further divided into one group which received a cold water swim (2°C for 3 min) and another which received a warm water swim (29°C for 3 min) ½ hour prior to testing. An harmonic mean analysis of variance showed statistically reliable ($p < 0.01$) effects of drugs, swimming and water temperature as well as interactions between the drugs and swimming and drugs and water temperature. Individual t tests showed statistically reliable increases in jump thresholds for both hot and cold water animals in all drug groups. The increases were reliably smaller for the animals pretreated with naloxone and ACTH when compared to noninjected controls but the two groups were not different from each other ($p > 0.10$).

These results support previous work showing that cold water swimming produces analgesia which is partially reversed by naloxone. They further show that an equivalent blockade of stress induced analgesia can be produced by pretreating animals with large doses of ACTH. This suggests that feedback inhibition of ACTH release also blocks release of β-endorphin and opens the question of whether experimental effects previously attributed to changes in ACTH and glucocorticoid levels may be due to changes in β-endorphin levels.

1769 SOMATOSTATIN IN RAT CORTICAL NEURONS IN CELL CULTURE: SYNTHESIS AND PHYSIOLOGIC EFFECTS. John Delfs*, Marc Dichter, Richard Robbins*, James Connolly* and Seymour Reichlin* (SPON: Howard Blume). Dept. Neurology, Children's Hospital Medical Center, Boston, MA 02115.

Rat cortical neurons maintained in a dissociated cell culture system have been assayed for various neuropeptides. The cultures contained somatostatin (SS) and substance P; ACTH, LHRH, TRH, and ADH were not detected by standard radioimmunoassay techniques. SS concentration of both cells and media went from undectable at 0 to 5 days to nanogram levels after 3 weeks in culture.

Immunofluorescent staining showed SS positivity only in neurons and in no other cellular elements. Approximately 5% of the neurons contained somatostatin. Staining was prevented by prior adsorption of the anti-SS antibody with synthetic cyclic SS. SS-containing neurons had no definite morphologic appearance.

Direct application of SS by microperfusion (0.1 to 10 μM) to cortical neurons in these cultures during intracellular recording produced no significant change in resting membrane potential, membrane resistance, or action potential characteristics. SS did change the frequency of spontaneous background synaptic activity, usually increasing the rate of the postsynaptic potentials observed in the control state, whether these were inhibitory or excitatory.

These data support the hypothesis that SS acts as a neuromodulator in cortical synaptic transmission.

1770 CHARACTERIZATION OF PEPTIDERGIC NEURONS IN MONOLAYER CULTURES OF SPINAL CORD BY IMMUNOHISTOCHEMISTRY AND SCANNING ELECTRON MICROSCOPY. R. Elde, S.L. Erlandsen*, J.L. Barker and J.H. Neale. Dept. Anat., Univ. Minn. Med. Sch., Minneapolis, MN 55455; Lab. Neurophysiol., NINCDS, Bethesda, MD 20014; Dept. Biol. Georgetown Univ., Washington, D.C.

Mechanically dissociated fetal mouse spinal cord cells were grown in monolayer on collagen-coated glass coverslips. After varying periods of time, dissociated dorsal root ganglion (DRG) cells were added to some cultures. After 2-6 weeks, cultures were fixed with 4% paraformaldehyde at 4°C for 2 hrs. Fluorescence immunohistochemistry was accomplished using antisera to met-enkephalin (ME), somatostatin (SOM) and substance P (SP). Specificity of staining was established using antisera pretreated with an excess of the appropriate antigen prior to application on cultures. After observation and photography using fluorescence and phase contrast microscopy, the coverslips of cultured neurons were prepared for scanning electron microscopy (SEM) according to standard procedures.

Spinal cord cultures exhibited striking networks of varicose fibers, terminals and neuronal perikarya after incubation with ME antiserum. The fibers and terminals were frequently in close apposition to dendritic profiles and perikarya of unstained neurons. Immunofluorescence within neuronal perikarya often was restricted to a narrow zone of perinuclear cytoplasm. The perikarya containing ME immunoreactivity were predominantly multipolar and of small to medium diameter. A large increase in the number of immunoreactive SP and SOM fibers, terminals and perikarya was observed in cultures to which DRG had been added. These fibers and terminals, like those seen with ME antiserum, made frequent contact with unstained dendrites and perikarya. However, many SP and SOM immunofluorscent perikarya were small, smooth and bipolar and were identical to DRG neurons as identified by phase contrast microscopy. Examination of cultures with SEM revealed additional morphological details of the interaction of the varicose fibers and terminals with dendrites and perikarya. The morphological characteristics of the immunohistochemically identified peptidergic neurons in vitro resemble the morphology of the same population of peptidergic neurons in situ. Such findings suggest the utility of using cultured neurons as a model of neuronal architecture, connectivity and physiology. (Supported in part by a McKnight Scholars Award to R. E.).

1771 **DISTRIBUTION OF SOMATOSTATIN-CONTAINING NEURONS IN THE GUINEA PIG FOREBRAIN.** **S.C. Feldman*, A.-J. Silverman and E. Lichtenstein* (SPON. J.R. Currie) Dept. of Anatomy Columbia University, P&S, and Hospital for Joint Diseases and Medical Center, New York, NY 10032.**

Recent studies have suggested that somatostatin (SRIF) is contained in both neurosecretory and non-neurosecretory neurons and may function as a neurotransmitter as well as a neurohormone. We have undertaken a study of the distribution and morphology of SRIF-containing neurons in the guinea pig forebrain. SRIF was localized in 6 um paraffin sections by the unlabeled antibody enzyme technique of Sternberger using an antiserum to SRIF. Following immunocytochemical identification of SRIF, sections were counterstained in cresyl violet. Perikaryal diameter was determined by measuring the long and short axes using a 40x objective and 12.5 x ocular equipped with a measuring reticule. Neurons were included only if the nucleolus was visible. The diameters of SRIF-containing neurons were determined in the following areas (range and (mean)): Neocortex: 6.5-15 μm (10.2 μm); Caudate and Putamen: 9-13 μm (11.7 μm); Amygdala: 10-15μm (12.3 μm); Nucleus of the diagonal band: 8.5-15.5 μm (12.3 μm); Hippocampus: oriens layer, 11-18.5 μm (13.6 μm); molecular layer, 10-13.5 μm (11.4 μm); pyramidal layers (CA_1-CA_4), 11-12.5 μm (11.8 μm); Hypothalamus: anterior hypothalamus, 10-19 μm (14.2 μm); lateral hypothalamus, 10-12 μm (11.2 um), ventromedial nucleus, 10-12 μm (11.2 μm). In many cells of the forebrain SRIF was present in thick, unbranched processes, presumably dendrites, and in thin, beaded fibers which could be axons. SRIF-containing neurons in the neocortex appeard round or oval. Whereas most of these cells had only one immunoreactive process, generally beaded, some neurons had 3-4 thick SRIF-containing dendrites. In the caudate and putamen most SRIF neurons had dendrites and axons which extended for considerable distances (60-320 μm to 160-300 μm, respectively). Neurons in the oriens layer of the hippocampus were oval with 1-2 dendrites whereas in the molecular layer no immunoreactive processes could be traced to cells of origin. In the pyramidal layers, SRIF neurons showed only one, thin, process which branched at its distal end. In the lateral hypothalamus SRIF neurons had no visible processes whereas those in the anterior hypothalamus-periventricular zone had one to several immunoreactive processes. SRIF neurons in the ventromedial nucleus tended to be small with none or one immunoreactive process. Our results suggest that SRIF is synthesized in several different types of neurons; the functional implications of this remain to be determined. Supported by HD10665 to A.J. Silverman and Postdoctoral Training Grant 1-TK-32 GM07061 to S.C. Feldman.

1772 EXCITATORY ACTION OF OPIOID PEPTIDES ON CULTURED HIPPOCAMPAL PYRAMIDAL CELLS. B.H. Gähwiler. Pharmaceutical Division, Preclinical Research, SANDOZ Ltd., CH-4002 Basle, Switzerland.

Spontaneous activity was recorded intracellularly from rat hippocampal pyramidal cells maintained in explant cultures for several weeks. Pyramidal cells were recognized morphologically by their size and by their characteristic pattern of dendritic arborization following injection of horseradish peroxidase into single neurons.

Bath application of opioids or opioid peptides rapidly increased the amplitude of epsp's until large depolarization shifts and spike bursts occurred. Using the stable methionine enkephalin analogue, FK 33-824, excitatory effects were observed at concentrations as low as 10^{-8}M. The effects were dose-dependent, high concentrations of FK caused sustained depolarization of the membrane. Identical results were obtained with morphine (10^{-6} to 10^{-4}M), met-enkephalin (10^{-5}M) and leu-enkephalin (10^{-4}M). The effects of all these substances were shown to be reversible and naloxone-sensitive.

Our findings that these peptide effects were mimicked by blockade of GABA receptors with bicuculline methochloride and abolished by synaptic isolation with 8 mM Mg^{2+} suggest that the excitatory action of opioid peptides on hippocampal pyramidal cells comes about by removal of tonic gabaergic inhibition by basket cell interneurons (also Siggins et al., Soc. of Neuroscience, 8th Annual Meeting, St. Louis, 1978). Since iontophoretic application of enkephalins directly onto pyramidal cells in control solution unexpectedly produced similar excitatory effects, the possibility is raised that enkephalin receptors are located presynaptically on pyramidal cell afferent terminals.

1773 EFFECTS OF OPIATE AGONISTS AND AN ANTAGONIST ON AMINO ACID RESPONSES OF CULTURED SPINAL NEURONS. D.L. Gruol, J.L. Barker, and T.G. Smith*, LNP, NINCDS, NIH, Bethesda, Md. 20014.

The effects of several opiate agonists and an antagonist on the amino acid responses of spinal neurons was studied using cultured, dissociated, fetal mouse spinal neurons and conventional electrophysiological techniques. Intracellular recordings were made from large (25 to 50 μM) neurons which had been maintained in culture for 1 month or longer. The recording media consisted of Hank's BSS plus Hepes buffer (25 mM) and 10 mM $MgCl_2$. The putative amino acid neurotransmitters glycine (GLY), γ-aminobutyric acid (GABA), β-alanine (β-ALA) and glutamate (GLU) were applied extracellularly by iontophoresis. The opiate agonists and antagonist were applied by superfusion. All effects were dose-dependent and reversible.

When applied at 10 to 100 μM concentrations, the opiate agonist levorphanol (LP) depressed the inhibitory responses evoked by GLY and β-ALA but did not effect the inhibitory GABA response or the excitatory glutamate response. Dextrorphan (DP), the stereoisomer of LP, was ineffective or only slightly depressed the GLY response at these concentrations (effect on β-ALA not tested). Morphine (50 μM), another opiate agonist, also depressed the inhibitory GLY and β-ALA responses without altering the GABA response (effect on GLU not tested). The ability of naloxone (NAL), an opiate antagonist, to reverse the LP and morphine depressions is presently being tested to determine if these effects are mediated by opiate receptors. Leucine-enkephalin, an endogenous opioid peptide believed to act at opiate receptors, did not effect the amino acid responses of these neurons although such modulatory effects of leucine-enkephalin have been observed in other cultured spinal neurons.

(-)-NAL, the form of NAL which is active at opiate receptors, depressed the inhibitory GABA response when applied at 0.1 to 1 mM concentrations but did not depress the GLU response. The GLY response was slightly depressed at the higher (-)-NAL concentrations. This effect of (-)-NAL was not stereospecific since (+)-NAL, the stereoisomer of (-)-NAL, also blocked the GABA response. (+)-NAL did not alter the GABA or GLU response when applied at 10 to 100 μM concentrations but completely blocked the GLY response. The effect of (-)-NAL on GABA dose-response curves suggests that (-)-NAL acts as a competitive antagonist at the GABA receptor but the mechanism underlying the (+)-NAL depression of the GLY response has yet to be determined.

1774 MOUSE BRAIN ENKEPHALIN LEVELS: LACK OF EITHER DIURNAL RHYTHMICITY OR ALTERATION BY ACUTE OPIATE TREATMENT IN C57B1/6J AND DBA/2J MICE. G. Gwynn*, R.C. Frederickson and E.F. Domino. Dept. of Pharmacology, Univ. of Michigan, Ann Arbor, MI 48109 and Lilly Research Laboratories, Indianapolis, IN 46206.

The purpose of these studies was to examine the involvement of the enkephalin putative neurotransmitters (Met-ENK and Leu-ENK) in the genotype-dependent differences in behavioral responsiveness observed in C57B1/6J (C) and DBA/2J (D) inbred mouse strains.

A diurnal rhythm in hotplate (52°C) jump latency was observed in both C and D mice ($P < .01$). At both a.m. and p.m. timepoints D mice exhibited significantly longer latencies than C mice ($P < .001$). Acute p.m. administration of naloxone (NLX; 3.2 and 10 mg/kg s.c.) but not of 0.9% NaCl induced a significant lowering of jump latencies in both strains. The magnitude of this hyperalgesic effect was greater in D than C mice at both doses of NLX, resulting in similar post-NLX jump latencies in the two strains. After acute a.m. treatment with morphine (MRP; 1-100 mg/kg s.c.), D mice showed a biphasic depressant-stimulant pattern of locomotor activity (LMA) and potent antinociception while C mice exhibited solely a stimulant LMA pattern and relatively poor antinociception (Gwynn and Domino, Pharmacologist 19: 170, 1977).

Unrestrained mice were sacrificed by focused microwave irradiation (<0.4 sec.) and whole brain (minus cerebellum) ENK levels were determined by RIA. In both the Met-ENK and Leu-ENK RIA, curves generated by serial dilutions of mouse brain extracts and of standard ENK solutions were parallel. Interassay ENK cross-reactivity was less than 7%.

No evidence in either strain for a diurnal rhythm in Met-ENK or Leu-ENK was found. Both a.m. and p.m. Met-ENK, but not Leu-ENK, levels were significantly greater in D than C mice. Neither a.m. MRP (10 and 32 mg/kg s.c.) nor p.m. NLX (10 mg/kg s.c.) significantly altered levels of either ENK in C or D mice.

	Met-ENK (N=10) (pm/g)		Leu-ENK (N=8) (pm/g)	
	C57	DBA	C57	DBA
A.M.	725 ± 20	820 ± 25*	205 ± 14	200 ± 12
P.M.	715 ± 28	806 ± 22*	192 ± 14	186 ± 14

These data do not support a correlation between whole brain ENK levels and any of the strain differences in behavior noted above. The strain difference in brain Met-ENK may, however, speculatively, be involved in other established behavioral differences between C and D mice (Oliverio et al., Adv. Biochem. Psychopharmacol. 11, 411, 1974).

1775 IMMUNOHISTOCHEMICAL LOCALIZATION OF SUBSTANCE P AND OTHER PUTATIVE NEUROTRANSMITTERS IN OLD WORLD PRIMATES. Suzanne Haber* and Robert Elde (SPON: V. Seybold). Dept. Anat., Sch. Med., University of Minnesota, Minn. Minn. 55455.

The hypothesis that Substance P may serve as a neruotransmitter was greatly strengthened by immunohistochemical studies which revealed its immunoreactivity in discrete, but widespread neuronal circuites. Furthermore, these studies have shown sites where Substance P is morphologically related to other neuronal circuits containing identifiable putative transmitters. Since possible species differences may have important implications for interpreting results as models for the human brain, these studies were undertaken to study the distribution of Substance P and morphologically related neuromodulators in nonhuman primate brain.

Six monkeys were perfused normally or pretreated with colchicine 48 hours before perfusion for better localization of cell bodies. Groups of twenty-five consecutive 10u cryostat sections were cut every 750u: three were stained with cresyl violet; two sections were processed for immunofluorescence for each of five antibodies; one additional section for each antibody served as an absorption control; and the remaining sections were stored for future use.

Preliminary observations of Substance P immunoreactivity suggest a high density of fibers in the area of the globus pallidus, substantia nigra, and the substania gelatinosa of the spinal cord. Moderate fiber density was in many areas including the stria terminalis and the nucleus accumbens. Sparse to moderate innervation was seen in various parts of the hypothalamus.

The findings of this study should give a more representive indication of the distribution and morphological relationship between Substance P and other neuromodulators in the human brain.

1776 TRITIUM LABELING OF β_p-ENDORPHIN BY REDUCTIVE METHYLATION FOR *in vitro* BINDING TO RAT BRAIN MEMBRANES. R. Glenn Hammonds, Jr.*, Nicholas Ling*, and David Puett* (Spon: R. Kuczenski). Department of Biochemistry, Vanderbilt University, Nashville, TN 37232 and Laboratory for Neuroendocrinology, The Salk Institute, La Jolla, CA 92037.

A labeled endorphin derivative of sufficiently high specific radioactivity to be useful for *in vitro* binding assays has been prepared by reductive methylation of synthetic β_p-endorphin. The tritium labeled ε-N-dimethyl β_p-endorphin ($[^3H]$-Me β_p-EP), with a specific activity of 9.8 Ci/mmol, was homogeneous by gel exclusion chromatography and polyacrylamide gel electrophoresis; over 90% of the label was present as dimethyllysine. In equilibrium binding studies using a washed particulate fraction from rat brain, $[^3H]$-Me β_p-EP bound in a non-cooperative fashion and exhibited a dissociation constant of 0.3-0.6 nM; the receptor concentration was between 100 and 300 pmol/mg protein. Displacement of $[^3H]$-Me β_p-EP from brain membranes was the same using native and labeled peptide indicating that the tritium labeling did not alter the peptide-receptor affinity. The binding of $[^3H]$-Me β_p-EP was also decreased by several opiate alkaloids, enkephalins, and α and γ endorphin, but not by several other peptides including ACTH and the C-terminal fragments of β_p-endorphin corresponding to the sequences β_p-lipotropin 63-91 and 80-91. (Supported by NIH grants: AM 15838, AM 18811, HD 09690, and by the William Randolph Hearst Foundation.)

1777 β-ENDORPHIN INDUCED EPILEPTIFORM ACTIVITY INCREASES LOCAL CEREBRAL METABOLISM IN HIPPOCAMPUS, AMYGDALA AND SEPTUM. Steven J. Henriksen, Frederic Morrision, and Floyd E. Bloom. A.V. Davis Ctr., The Salk Inst., La Jolla, CA 92037.

The non-convulsive limbic EEG epileptiform activity elicited by intraventricularly administered β-endorphin (Henriksen et al.PNAS 75 (10) 5221-5225, 1978) was metabolically mapped using the ^{14}C-2-deoxyglucose technique (Sokoloff et al 1977,J. Neurochem. 28, 897-916). Rats were implanted with chronic jugular catheters, lateral ventricular cannulae, and electrodes for monitoring EEG activity in dorsal hippocampus and frontal cortex. Following a baseline EEG recording β-endorphin (15-17 μg in 15 μl of Ringer's solution), or an equal volume of Ringer's solution alone, was administered intraventricularly to rats and immediately followed by a intracardial bolus of ^{14}C-2-deoxyglucose. EEG was monitored continuously for 30 min after which animals were sacrificed and brains prepared for autoradiography. Rats exhibiting electrographic epileptiform activity (N=6) demonstrated significantly increased metabolic activity throughout the hippocampus compared to controls. Larger increases were observed in ventral compared to either dorsal hippocampus or the dentate gyrus as assessed by quantitative densitometry. The lateral septum showed increases consistent with the known anatomical projections to this nucleus from the hippocampal gyrus. Significantly increased metabolism was also observed in the medial nucleus of the amygdala while decreased metabolism occurred in the medial geniculate body. Animals administered β-endorphin but who exhibited only high voltage synchronous cortical slow waves with no epileptiform activity demonstrated metabolic activity similar to controls but with slight increases only in ventral hippocampus. These metabolic studies support our earlier electrographic observations that the epileptiform activity induced by intraventricularly administered β-endorphin is primarily limited to limbic brain areas. Furthermore since these limbic epileptiform events are induced with doses of β-endorphin that do not induce analgesia nor postural rigidity, this suggests a specific role for opioid mechanisms in the regulation of limbic excitability. Recent microiontophoretic studies (Siggins et al. Soc. N.S. Ab. 131, 1978) have demonstrated opioid induced excitations of hippocampal pyramidal neurons are primarily the result of opioid inhibitions of inhibitory interneurons. The role of other limbic areas in the induction of epileptiform events following intraventricular β-endorphin is presently being investigated. (Supported by DA-01785-03 and the Klingenstein Foundation.)

1778 **EVIDENCE FOR MULTIPLE OPIATE RECEPTORS IN BRAIN.** **William A. Hewlett,* Huda Akil[1] and J.D. Barchàs.** Dept. Psychiatry, Sch. Med., Stanford Univ., Stanford, CA 94305; [1]Ment. Health Res. Ctr., Univ. Mich., Ann Arbor, MI 48109.

Three populations of opiate receptors μ, κ and σ have been described by Martin et al. (J. Phamacol. Exp. Ther. 197:517-533, 1976). A number of morphines, morphinones, benzomorphans and oripavines have been pharmacologically characterized in terms of their interaction with each of these receptors. The abilities of opioid peptides and certain representatives of the above classes to displace the binding of ^{3}H-naloxone, ^{3}H-morphine, ^{3}H-cyclazocine, ^{3}H-UM1071,* ^{3}H-Leucine-enkephalin and ^{3}H-β-endorphin were examined in a washed membrane preparation of rat brain. Unlabled opiate compounds show marked differences in their ability to displace the binding of these tritiated opiates. This differential displacement is currently being investigated in brain regions. The significance of these studies will be discussed in relation to current models of multiple opiate receptors in brain.**

1779 LHRH PERIKARYA SEND AXONS TO THE OLFACTORY BULB IN THE HAMSTER. Gloria E. Hoffman, Barry J. Davis and Foteos Macrides. Dept. of Anatomy, Univ. of Rochester Med. Sch., Rochester, NY 14642 and Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

The relationship between luteinizing hormone-releasing hormone (LHRH) perikarya and axons in the forebrain and the olfactory bulb were studied in the hamster using the unlabelled antibody peroxidase method. The animals were anesthetized with pentobarbital, perfused with either neutral formalin or Zamboni's fixative and sectioned on a vibrating microtome. Two projections from LHRH perikarya in the forebrain to the olfactory bulb were observed. One projection could be traced from fusiform-shaped perikarya in the medial septal area and from perikarya within the septal and basal portions of the vertical limb of the diagonal band of Broca (DB). The axons coursed through the medial aspect of the olfactory peduncle directly into the granule cell layer of the caudal main olfactory bulb (MOB). A second population of immunoreactive axons could be traced into the olfactory bulb from a distinctive LHRH neuron population which was located in the superficial plexiform layer of the ventromedial surface of the brain. These LHRH perikarya extended rostrally from the level of the anterior hippocampus into the olfactory peduncle to the medial border between the anterior olfactory nucleus and the MOB. These neurons were frequently seen to be intermingled with axons arising from other LHRH perikarya of this group. In the bulb, the fibers coursed along the perimeter of the MOB and accessory olfactory bulb (AOB) within the superficial aspect of the glomerular layers. These axons entered the periglomerular region and external plexiform layers of both the MOB and AOB. HRP injections into the MOB and injections of tritiated amino acids into the medial aspect of the olfactory peduncle and in the medial septum/DB region have confirmed these direct projections to the olfactory bulb. These data will be compared to results in rat and mouse.

The presence of LHRH projections to the olfactory bulb suggests that LHRH may have functions different from its role in direct regulation of pituitary output of gonadotropins.

1780 NALOXONE IN THE THERAPY OF SHOCK: STUDIES ON THE SITE AND MECHANISM OF ENDORPHIN INVOLVEMENT. John W. Holaday, Thomas P. Jacobs, and Alan I. Faden. Dept. of Medical Neurosciences, Walter Reed Army Inst. of Research, Washington, DC 20012.

The effects of parenterally administered naloxone in improving the cardiovascular pathophysiology of endotoxic, hypovolemic, and spinal shock in rats have been demonstrated in our laboratory (Nature, 275; Science, in press; submitted). In the present studies, we used these shock models to determine if the therapeutic effects of naloxone were centrally mediated and involved an antagonism of pituitary endorphins. Moreover, the effects of naloxone on the altered body temperature and respiratory rates in shock states were also examined.

Hypovolemic shock was studied in conscious, freely-moving male Sprague Dawley rats (250-300 g) previously prepared with indwelling cannulae in the external jugular vein and tail artery. Spinal shock was induced by acute transection of the cervical spinal cord at C6-C7 in anesthetized male rats weighing 500-800 g. In spinal shock studies, naloxone was injected parenterally through the external jugular vein cannula or intracerebroventricularly (ivt) into the lateral ventricle through an implanted guide tube. Injection of a dye solution ivt at the end of experiments was used to confirm accuracy of ventricular guide placement. Colonic temperature was obtained by means of a rectally inserted thermistor; respiratory rates were counted by observation. Hypophysectomized rats and sham-operated controls were purchased from Zivic-Miller Laboratory.

In spinal shock, cervical cord transection produced a transient bradycardia and hypertension followed by a loss of mean arterial pressure (MAP) to a value approximately 20 mmHg below control values minutes later. Intravenous naloxone HCl (10 mg/Kg) or ivt naloxone HCl (48 μg in 20 μl saline) restored MAP and pulse pressure (PP) to control values within 5 min; no significant effect on heart rate was observed. Respiratory rates and colonic temperature which were depressed by spinal transection, were significantly reversed by subsequent intravenous or ivt naloxone injections.

In pilot studies, hypovolemic shock was induced in conscious hypophysectomized and sham-operated rats by bleeding to 40 mmHg for 20 min. The effects of saline injections were compared to subsequent naloxone HCl injections (1 mg/Kg). Preliminary results indicate that hypophysectomized rats do not respond as well as sham-controls to the improvement in MAP and PP produced by naloxone.

Our results provide evidence that the decline in respiratory rates, colonic temperature, and blood pressure in spinal shock is mediated through a central mechanism that is naloxone sensitive and independent of sympathetic control. Preliminary evidence for the possible involvement of pituitary endorphins in hypovolemic shock was also obtained.

1781 RELEASE OF α-MELANOTROPIN (α-MSH) FROM RAT HYPOTHALAMIC SLICES IN VITRO. Gunnar E. Holmquist*, Thomas L. O'Donohue*, N. B. Thoa*, Terry W. Moody and David M. Jacobowitz (SPON: A. I. Leshner). Lab. Clin. Sci. and Biol. Psych. Branch, NIMH, Beth., Md. 20205 and Dept. of Pharm., Howard Univ., Washington, D.C. 20059.

An extensive system of α-MSH-containing nerves which originates primarily from the arcuate nucleus of the hypothalamus and projects to many forebrain, midbrain and some hindbrain sites has recently been described. A common feature of neurotransmitters is a depolarization-induced release mechanism. In this study, such a mechanism was investigated using an in vitro approach. Fresh rat hypothalami were sliced (approximately 225 μm) using a tissue chopper. Sections were suspended in 0.6 ml of a modified Krebs-bicarbonate buffer which was maintained at pH 7.4-7.6. α-MSH released into the medium was analyzed by radioimmunoassay.

High concentrations of α-MSH diffused from the slices into the medium immediately upon incubation. Rinsing the slices with buffer reduced the baseline release to 31 pg/2 minutes. Stimulation with K^+ (50 mM) resulted in a marked increase (250%) in α-MSH release. K^+ stimulation in the absence of calcium (1 mM EGTA) also resulted in α-MSH release but was signficantly attenuated compared to K^+ stimulated release in the presence of Ca^{++} (5 mM). Veratridine (100 μM) also markedly stimulated α-MSH release (380%). Once again this release was significantly depressed in the absence of Ca^{++}. These results suggest an α-MSH release process and support a neuroregulatory role for this peptide.

1782 REGULATION OF HIPPOCAMPAL [MET^5]ENKEPHALIN CONTENT FOLLOWING RECURRENT MOTOR SEIZURES. J.S. Hong, P.L. Wood, J.C. Gillin*, H.-Y. T. Yang* and E. Costa. Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032

Unilateral intrahippocampal injection of kainic acid (K.A.) (1 μg in 1 μl of 0.9% NaCl) produced recurrent motor seizures lasting about 5 hr and a selective change in the [met^5]enkephalin (ME) content of hippocampus. Six to 12 hr after injection, there was a small decrease in ME content in both injected and contralateral hippocampus, however within 24 hr after the injection the ME content was increased. The elevation in the injected hippocampus reached a maximal level (200%) after 2 or 3 days, this plateau lasted longer than 14 days. In contrast the ME content of the contralateral side increased by a greater extent reaching a peak at day 2 (300%) but returned to control level by day 14. The increase in ME content was greatly reduced when cycloheximide was administered intraventricularly 6 hr after intrahippocampal injection of K.A. This result suggests that the increase in ME content elicited by K.A. injection is probably due to an increase in the synthesis of ME rather than to a decrease in the efflux of ME from the hippocampus. The selective increase in hippocampal ME content was also elicited by intraseptal, intrastriatal or intraventricular injections of K.A. Since all the procedures caused recurrent motor seizures it is suggested that the change in hippocampal ME content after K.A. may be related to the recurrent seizures elicited by K.A. In fact the increase in ME content after intraseptal injection of K.A. was blocked when muscimol, an anticonvulsant, was injected together with K.A. Moreover, the increase in hippocampal ME 2 days after recurrent seizures was also induced by isoniazid or by repeated electroconvulsive shock (4 shocks given at 30 min intervals). Thus, it appears that prolonged recurrent seizures may cause a selective increase in the production of hippocampal ME.

1783 RAT BRAIN MEMBRANE BINDING AND SYNAPTOSOMAL UPTAKE OF ^{3}H-IMIPRAMINE AND ^{3}H-COCAINE. Robert B. Innis, Fernando M. A. Corrêa and Solomon H. Snyder. Dept. of Pharmacol., Sch. Med., Johns Hopkins Univ., Baltimore, MD 21205

The tricyclic antidepressants and cocaine are potent inhibitors of the synaptosomal reuptake of norepinephrine. In addition, the tricyclic antidepressants are potent antagonists of muscarinic cholinergic, α-noradrenergic and histamine receptors. These interactions may explain the therapeutic actions and side effects of these drugs. We have studied the binding of ^{3}H-imipramine (^{3}H-IMI), ^{3}H-desipramine (^{3}H-DMI) and ^{3}H-cocaine to rat brain membranes. The binding of ^{3}H-IMI to crude brain membrane fractions is saturable, and subcellular fractionation suggests a synaptosomal localization of the ^{3}H-IMI binding site(s). Imipramine (10^{-5}M) displaces 60-70% of total bound counts with an IC_{50} of approximately 80 nM. Scatchard analysis indicates binding to at least two separate sites with affinities of 4 and 20 nM. The detailed pharmacologic profile of ^{3}H-IMI binding will be described, and the possible interaction with the binding with ^{3}H-phencyclidine (^{3}H-PCP) will be discussed.

In order to investigate the mechanism of inhibition of norepinephrine uptake by the tricyclic antidepressants and cocaine, we have studied the synaptosomal uptake of ^{3}H-IMI and ^{3}H-cocaine. The uptake of both of these ligands appears dependent on time, temperature, and the integrity of the synaptosomal preparation. The data suggest that imipramine and cocaine inhibit the uptake of norepinephrine by being taken up themselves into synaptosomes. The detailed pharmacologic and kinetic parameters of synaptosomal uptake of ^{3}H-IMI and ^{3}H-cocaine will be described.

1784 A PEPTIDE RESEMBLING LUTEINIZING HORMONE RELEASING HORMONE AS A LIKELY TRANSMITTER IN SYMPATHETIC GANGLIA OF THE FROG. Yuh Nung Jan*, Lily Yeh Jan* and Stephen W. Kuffler. Dept. Neurobiology, Harvard Medical School, Boston, MA 02115

A peptide that resembles luteinizing hormone releasing hormone (LHRH) was found to be a likely transmitter for the late slow excitatory postsynaptic potential (epsp) that lasts for many minutes in the bullfrog sympathetic ganglia, because (1) Radioimmunoassays established that 100-800 pg of a LHRH-like substance is contained in the lumbar chain of sympathetic ganblia. The peptide is confined to those spinal nerves that contain a distinct group of preganglionic axons which initiate the late slow epsp, (2) Five days after ipsilateral preganglionic axons are cut, 95% of the LHRH-like material disappears from ganglia, while the LHRH immunoreactivity triples in the spinal nerves proximal to the cut region, (3) The LHRH-like substance is released by raising the external potassium concentration; this release is calcium dependent. (Proc. Natl. Acad. Sci. USA 76 1501-1505, 1979).

Recent electrophysiological experiments have shown that LHRH or two of its analogs, when applied by pressure from a micropipette to the cell surface, produce a depolarization of long latency and slow time course similar to that of the late slow epsp. The conductance changes during the peptide-induced depolarization are also comparable to those during the late slow epsp. Further, a potent antagonist of LHRH in mammalian systems completely blocks the nerve evoked late slow epsp as well as the LHRH-induced depolarization, suggesting that the late slow epsp is mediated by a LHRH-like peptide.

1785 SITE OF ENKEPHALIN ACTION IN THE HIPPOCAMPUS. Robert A. Jensen, Joe L. Martinez, Jr., Robert Craeger*, John Veliquette*, James L. McGaugh, and Gary Lynch. Department of Psychobiology, School of Biological Sciences, University of California, Irvine, CA 92717.

Evidence indicates that enkephalins exert a powerful modulating influence in the operation of the hippocampus. We now report data that points to the site and mode of action of enkephalin in the hippocampus. In these studies, the enkephalin analog D-Ala-D-Leu-enkephalin (H_2N-Tyr-D-Ala-Gly-Phe-D-Leu-OH) or naloxone was superfused over the in vitro hippocampal slice preparation and the electrical response to stimulation was recorded.

Hippocampal slices (600 μm) were placed in a recording chamber and were continuously perfused with fresh, warm (33°-35°C), oxygenated (95% O_2; 5% CO_2) medium. Bipolar stimulating electrodes were placed in the Schaffer-commissural projections extending to the pyramidal cell apical dendrites. Stimulation electrodes were also placed in the alveus, the fiber bundle that carries the axons of the pyramidal cells. These two electrode placements allowed for both orthodromic and antidromic activation of the pyramidal cells. One recording micropipette was placed in the regio superior dendritic zone to record extracellular activity resulting from Schaffer-commissural stimulation. A second micropipette was placed in the pyramidal cell body layer to record the "population spike" response of these cells to stimulation.

The "population spike" response of pyramidal cells to Schaffer-commissural stimulation was highly sensitive to the enkephalin and demonstrated dramatic increases in amplitude even with concentrations as low as 10 nanomolar. The onset of this effect was rapid and was reversed by perfusion with peptide-free medium. Naloxone, by itself, had no detectable effect on this response, but it blocked the effect of enkephalin. Additionally, even at concentrations in the micromolar range, enkephalin had no observable effect on synaptic potentials generated by Schaffer-commissural stimulation nor did it affect the antidromic potential recorded in the cell body layer to stimulation of the alveus.

Taken together, these findings suggest that enkephalin acts to attenuate the phasic inhibitory effects of a class of inhibitory interneurons (basket cells) that are brought into play by Schaffer-commissural stimulation. Experiments pairing antidromic with orthodromic stimulation have provided indirect evidence that these interneurons are not activated by the recurrent collateral interneurons and, instead, may be a category of interneurons involved in feed-forward inhibition. Supported by a grant from the McKnight foundation (J.L.McG.) and research grants MH 12526 (J.L.McG.), MH 19793 (G.L.), AG 00538 and BNS 76-17370 (J.L.McG. and G.L.).

1786 PHARMACOLOGICAL DISSOCIATION OF THYROTROPIN-RELEASING HORMONE (TRH) ANTAGONISM OF PENTOBARBITAL (PB) INDUCED NARCOSIS AND HYPOTHERMIA. Peter W. Kalivas* and Akira Horita* (SPON: Lawrence Halpern). Depts. Phcol. and Psychiatry, Sch. Med., Univ. of Wash., Seattle, WA 98195.

Microinjection of TRH into the lateral ventricle will significantly antagonize narcosis duration and hypothermia in male S.D. rats pretreated with PB. In addition, TRH will also induce shaking behavior resembling that seen during opiate withdrawal. To examine if these three effects of TRH are mediated by the same neurochemical substrate, we injected rats i.p. with a number of pharmacological agents either 10 min. prior to or 10 min. following i.p. administration of 40 mg/kg PB. Twenty min. following PB induced loss of righting reflex, animals received bilateral intracerebroventricular injections of either 1 μm TRH dissolved in 1 μl saline or saline alone. Colonic temperature was monitored at 10 min. intervals, shaking counted following TRH or saline, and narcosis duration determined by return of righting reflex. Pretreatment agents were dissolved in saline or distilled H_2O and included; 5 mg/kg atropine sulfate, 0.5 mg/kg muscimol, 300 mg/kg sodium salicylate, 1.0 mg/kg cyproheptadine or 0.5 mg/kg 6-chloro-2 (1-piperazinyl)-pyrazine (MK-212, 5-HT agonist). Sodium salycylate had no effect on any of the three TRH responses. Muscimol partially inhibited shaking and reversal of hypothermia, and while prolonging the duration of narcosis in animals receiving TRH, it also potentiated narcosis in animals receiving saline such that TRH was still determined to significantly antagonize narcosis duration. Atropine antagonized TRH reversal of narcosis, but was without effect on shaking and hypothermia. A similar response to atropine was observed with cyproheptadine indicating it may be acting in its capacity as an anticholinergic rather than as an antiserotonergic. MK-212 completely abolished all aspects of the TRH response. These data indicate that the capacity of TRH to antagonize PB narcosis can be pharmacologically distinguished from the shaking and temperature responses. Reversal of PB narcosis involves cholinergic systems, while activation of GABA systems will selectively antagonize the temperature and shaking responses. The sensitivity of all three responses to MK-212 is interesting, esp. in view of other data demonstrating that serotonergic agents will inhibit TSH release by TRH as well as inhibit electrically induced release of immunoreactive TRH from hypothalamic synaptosomes. (Supported by NIH Grant MH-29503)

1787 SUBSTANCE P-LIKE IMMUNOREACTIVITY (SPLI) AND TARGET ORGAN REPRESENTATION WITHIN THE NUCLEUS SOLITARIUS (nS) AND VAGAL MOTOR NUCLEUS (DMN X). David M. Katz and Harvey J. Karten, Depts. Biology (DMK) and Psychiatry and Anatomy (HJK), SUNY at Stony Brook, Stony Brook, New York 11794.

The distribution of SPLI within the nucleus solitarius and dorsal motor nucleus of the vagus nerve was compared with the representation of peripheral target organs within these two cell groups in pigeons. The distribution of SP was mapped by immunocytochemical techniques, using monoclonal antibodies to SP. Several cytoarchitecturally distinct regions within DMN X and nS contained extremely dense plexuses of immunoreactive fibers which were not seen in tissue stained with antibodies absorbed against synthetic SP. Two approaches were used to identify the peripheral organs represented in these regions.

First, horseradish peroxidase (HRP) labelling of specific vagal branches was used to identify the central projections of vagal sensory neurons to nS as well as the cells of origin of vagal motor fibers within DMN X (cf. Katz,D.M., and Karten,H.J., 1977,1978, Neurosci.Abs.). In a second set of experiments, target organ representation within DMN X and nS was mapped by studying the distribution of acetylcholinesterase (AChE) within these regions following selective axotomy of individual vagal branches. Both DMN X and nS contain abundant stainable AChE which is severly depleted following peripheral vagal axotomy. One week after transection of specific vagal branches, animals were perfused with 4% paraformaldehyde,and the brains were processed for AChE histochemistry. A very precise correlation was found between the results of the AChE depletion and HRP studies.

Those regions of DMN X which are richest in SPLI project to organs of the gastrointestinal tract: the esophagus, crop, and proventriculus. The crop is a food storage organ, and is responsible for the prolactin-stimulated production of "crop milk". The proventriculus, or glandular stomach, secretes pepsinogen and hydrochloric acid. Vagal sensory neurons which innervate these same organs project centrally to those regions of nS which stain most intensely for SP. Other regions of nS, such as those receiving aortic afferents (Katz,D.M. & Karten,H.J., 1979,Br.Res., in press), and of DMN X, exhibited some SPLI.

Our findings provide anatomical evidence for the involvement of SPL immunoreactive fibers within the central nervous system in autonomic pathways which mediate specific visceral functions. Some of these pathways may be involved in the neural regulation of gastrointestinal secretory functions, such as the vagally mediated release of pepsinogen and hydrochloric acid.

1788 DOES NALOXONE SUPPRESS SELF-STIMULATION BY DECREASING REWARD OR INCREASING AVERSION? John E. Kelsey, James D. Belluzzi and Larry Stein. Wyeth Laboratories, Philadelphia, PA 19101.

The opiate-antagonist naloxone suppresses self-stimulation (SS) of enkephalin-rich brain regions, but interpretation of this effect is unclear. According to Belluzzi & Stein (1977), who assume that positive reinforcement is mediated in part at opiate receptors, naloxone acts to block endorphin-mediated reward. However, it is possible that naloxone decreases SS, not by blocking reward, but by increasing aversion. This alternative is plausible because naloxone blocks the aversion-reducing or analgesic effects of opiates and endorphins. The second alternative implies that naloxone's suppressive action should be greatest at SS sites where the stimulation also produces analgesia, and it should be least at SS sites where analgesia is not a factor. 53 rats had electrodes implanted in a region of midbrain central gray reported to yield both SS and stimulation-induced analgesia (SPA) (Mayer et al., 1971). Electrodes were assayed first for SPA (D'Amour-Smith tail-flick test) and then SS, and fell into 4 groups on the basis of positive (+) or negative (-) response in each test. 34 cases were positive for SS; these were evaluated for sensitivity to naloxone (2.5 mg/kg, s.c.) after stabilization of 1-hour SS rates. Surprisingly, self-stimulators that failed to exhibit analgesia (group + -) were suppressed by naloxone to at least the same extent as those that did display analgesia (group + +). Since naloxone failed to act preferentially at analgesic sites, the notion that naloxone suppresses SS merely by increasing aversion was not supported. Rather, the data are consistent with the hypothesis that naloxone blocks endorphin-mediated reward.

Group (SS:SPA)	N	Self-Stimulation (Mean ± S.E.M.)		Thresholds (Mean ± S.E.M.)	
		Control Rate (Responses)	Naloxone Rate (% Control)	SS (μA)	SPA (μA)
+ +	20	2983 ± 317	66.8 ± 6.5	89.0 ± 12.0	250.0 ± 21.5
+ -	14	2612 ± 281	56.2 ± 9.1	115.3 ± 13.3	-
- +	14	-	-	-	212.5 ± 24.3
- -	5	-	-	-	-

1789 METHIONINE-ENKEPHALIN-LIKE IMMUNOREACTIVITY IN FETAL RAT BRAIN CELLS IN AGGREGATING CULTURE AND IN MOUSE NEUROBLASTOMA CELLS. Elinor L. Knodel* and Elliott Richelson. Depts. of Psychiatry and of Pharmacology, Mayo Fdn., Rochester, MN 55901

Brains from fetal rats of 14-16 days gestation were mechanically dissociated and grown as aggregates in rotation culture. The aggregates were fixed in buffered 4% paraformaldehyde and 8 μm frozen sections were prepared. Sections were stained by the indirect immunofluorescence method using antibody to methionine-enkephalin (a gift from R. Elde). The specificity of the reaction was determined by staining with antiserum pre-incubated with 1 mg/ml methionine-enkephalin.

In aggregates cultured for 2 or 3 days, only background fluorescence was observed; however, by 6 days many aggregates contained specifically-labeled cells, which were generally scattered throughout the aggregate. Occasionally, fluorescent cells were clustered in groups in the central portion of an aggregate, known to be comprised mainly of neuronal cells in older aggregates.[1] After 4-5 weeks in culture very few aggregates had brightly fluorescing cells in their central areas. Both cell bodies, excluding nuclei, and cell processes were labeled. Incubation of the aggregates overnight with 10^{-4}M morphine had no effect on the fluorescence.

About 5% of mouse neuroblastoma cells (clone NIE-115) in stationary phase also contained methionine-enkephalin-like immunoreactivity, but the staining pattern differed from that seen in the fetal brain cells. Occasionally whole cells were labeled, including their nuclei. Most of the positively-staining neuroblastoma cells contained one or two brightly labeled inclusions, much larger in size than the storage vesicles for neurotransmitters. Thus, although these cultures of neuroblastoma and fetal rat brain cells contain few specific binding sites for opiates, the present results suggest that they may synthesize and store endogenous opiates.

1790 HYPOTHALAMIC BRAIN SLICES: ANGIOTENSIN II SENSITIVE CELLS IN OVLT. W. Douglas Knowles and M. Ian Phillips. Dept. of Physiology, University of Iowa, Iowa City, IA 52242.

Angiotensin II (AII), when injected into the brain, has powerful biological effects including drinking, a pressor response, and vasopressin release. Low dose injection, lesion, and binding studies point to the organum vasculosum of the lamina terminalis (OVLT) as a receptor area mediating these effects. In a previous study, AII was applied microiontophoretically to this region and sensitive cells were found, but this was done in anesthetized animals. To study the effects of AII on the OVLT in the absence of anesthetics, possible modulatory effects of other brain regions, and uncontrolled physiological variables, the brain slice technique for the hypothalamus was developed in our laboratory.

Adult male albino rats were decapitated and blocks of their brains containing the hypothalamus and preoptic area were sectioned in the frontal plane at 300μ with a Vibratome while immersed in cold Yamamato's solution. The slices were mounted between two nylon nets in a chamber through which oxygenated (95% O_2, 5% CO_2) solution at 35±1°C flowed. Three-barrelled micropipettes (5 to 20 Megohms) were used for recording and iontophoresis. The barrels contained: recording- 3M NaCl and Fast Green dye, test- 1 mg/ml AII pH 4.5, control- 0.9% NaCl or 1 mg/ml Saralasin pH 4.5.

35 cells in 9 rats were tested. Of 32 cells in the OVLT, 91% responded to AII by increased firing rates, 3% had no response, and 6% were inhibited. Control applications of saline on 14 of the OVLT cells caused increased firing in 64%, but had no effect on 29%, and inhibited 7%. Saralasin (an AII antagonist with similar structure) ejections on 15 of the OVLT cells excited 60%, had no effect on 13%, and inhibited 27%. Statistical comparison ($p<.01$) of the frequency of firing during test and control applications to each of 22 OVLT cells showed that 64% of the cells fired at a higher frequency to AII than to control applications, 4% showed no response to AII or control ejections, and 32% showed the same response to AII and control applications. A dose response relationship of increased excitation with increased ejection of AII was seen in all of 9 cells tested.

These experiments demonstrate the recording from neurons in the hypothalamus in rat brain slices. The results show that the majority of cells tested in the OVLT are sensitive to AII. AII application increases the firing rate of cells in this region significantly more than control applications. These data support the hypothesis that the OVLT is a brain receptor area for AII. 1791 ACTH ACCELERATION OF REGENERATION OF CRUSHED PERIPHERAL NERVE AND DENERVATED SKELETAL MUSCLE. Ted T. Kung* and Fleur L. Strand. Schering Corp., N.J. and Biology Dept., N.Y.U., N.Y. 10003.

Recent studies have shown that ACTH has direct neurotrophic activity. This study was undertaken to determine whether ACTH treatment can accelerate the rate of regeneration of crushed peripheral nerve and denervated muscle in intact and adrenalectomized (adx.) rats. Animals were treated with 0.25 U of ACTH 1-39 daily following nerve crushing for periods of up to 40 days. The regeneration rate was measured by foot-flick response to pain, distance between 1st and 5th digit (d1-5), average length of regenerated axons, and incorporation rate of amino acids by the denervated muscles.

ACTH-treated adx animals recovered sensation and functional movements more rapidly than did untreated groups. D_{1-5} and foot-flick response to pain showed similar results. The average length of regenerated axons nine days after crushing for the adx-ACTH group was significantly longer (3.99 ± 0.47 mm) than that of adx-saline group (2.68 ± 0.36 mm). The incorporation rate of amino acids in adx-ACTH group, as measured 9-14 days after denervation, was increased significantly over that of untreated adx controls. Histological and histochemical examination of the muscles showed that ACTH has no effect on muscle weight, fiber diameter and fiber types as compared to their control groups. However, increase in number of enlarged endplates and more endplates with branched pre-terminal fibers were observed.

1792 NEUROTOXIC AGENTS REDUCE SOMATOSTATIN CONTENT OF THE RAT NEURAL RETINA. Norma Lake and Yogesh C. Patel*, Dept. of Research in Anaesthesia, and Fraser Labs, Dept. of Medicine, McGill University, Montreal, Quebec, Canada, H3G 1Y6.

Recent reports by ourselves and others have described the presence of somatostatin-like immunoreactive material (SLI) in the rat neural retina. In an attempt to localize this SLI we have utilized neurotoxic agents and have examined their effects on retinal SLI and morphology. Kainic acid is a glutamate analog which exerts neurotoxic effects on CNS neurones and, when given intraocularly to young chicks, causes marked degeneration of cells in the inner nuclear layer of the retina, particularly amacrine interneurones (Schwarcz and Coyle, 1977, Invest. Ophth. Vis. Sci. 16, 141). We have found similar degeneration in the retina of adult rats injected intraocularly 48 hours previously with 120 nmol of neutralized kainic acid. This was associated with a marked reduction of retinal SLI as measured by radioimmunoassay, from 1.24 ± 0.14 pg SLI/ μg protein in saline controls ($n = 7$) to 0.43 ± 0.05 pg SLI/ μg protein in kainic acid treated rats ($n = 8$). The second retinotoxic compound which we examined was monosodium glutamate (MSG) which we administered subcutaneously (2 mg/ g body weight) on a daily basis to rats for the first ten days of postnatal life. Histological examination of the retinas from 23-25 day old MSG-treated rats showed considerable degeneration in the inner plexiform layer and cell losses in the inner nuclear and ganglion cell layers. Concurrently there was a severe reduction of retinal SLI to 10% or less of control levels. These studies suggest the localization of retinal SLI within a population of neurones of the inner retina, perhaps within some amacrine and ganglion cells. SLI is present in sufficient quantities to suggest that it may have a neurotransmitter or neuromodulator role at these sites in the neural retina.

1793 IS THERE A ROLE FOR THE ENDOGENOUS OPIOID PEPTIDES IN THE REGULATION OF BLOOD GLUCOSE? Claudia Landau‡ Roberta Palmour*, and J.-K. Chang*. (SPON: E. Wm. Yund). Dept. Physiol. & Genet. U. California, Berkeley, CA 94720, Peninsula Labs, San Carlos, CA.

The presence, distribution and pharmacological properties of highly specific opiate receptors within the central nervous system and in anterior pituitary, gut and vas deferens have been the focus of intensive research. Several lines of evidence suggest that opioids and opiate receptors exist in other peripheral tissues. Preliminary evidence from this laboratory describes specific opioid binding sites in rat kidney and adrenal glands. While many of the reported effects of opioid peptides may be mediated through central or pituitary receptors, peripheral sites may also play some role in physiological regulation. Holaday et al. (PNAS 74:4628, 1977) found that adrenalectomized (Adx) mice responded to iv β-endorphin with severe respiratory depression, cyanosis and seizures, while intact mice did not. The suppression of these effects by pretreatment with dexamethasone, the similarity between these toxic effects and insulin shock, and the recent report of Ipp et al. (Nature 276:190, 1978) that β-endorphin stimulates insulin release in an in vitro pancreatic perfusion system all suggest a relationship between glucose regulation and opioid peptides.

We have tested the possibility that opioid peptides participate in blood glucose regulation using intact and adx rats. Saline, insulin, morphine, β-endorphin and the enkephalin analog tyr-D-ala-gly-N-me-phe-met(O)-ol (P8625) were administered iv to adx and intact rats. Blood was drawn at 0, 15, 30 and 60 min.; glucose, insulin, glucagon and endorphin levels were measured. Core body temperature, respiratory rate, blood pressure and other visible autonomic signs were monitored. Gross behavior and catalepsy were evaluated.

Adx rats given insulin iv exhibited signs of severe respiratory depression, peripheral cyanosis, hypothermia and flaccid immobility. Adx rats given morphine showed typical opioid effects--muscular rigidity, cataleptic immobility and peculiar postures. Adx rats treated with 2.5 mg/kg P8625 showed autonomic effects similar to, but more severe than those seen in insulin-treated animals. Following ip injection of 10 mg glucose, respiratory depression, cyanosis and hypothermia were reversed, unmasking typical opioid effects.

Comparison of the opioid and glucoregulatory effects of β-endorphin and P8625 will be discussed as will general physiological effects of these peptides.

1794 EFFECTS OF SOMATOSTATIN ON THE ATPase ACTIVITIES OF SYNAPTOSOMES OF RAT CEREBRAL CORTEX. Sheu L. Lee* and Viktor Havlicek, Dept. of Physiology, Faculty of Medicine, Univ. of Man., Winnipeg, Canada, R3E OW3.

Somatostatin has been found to be present in many structures of the rat brain including cerebral cortex. Synaptosomal pellet of the cerebral cortex has 40 times higher concentration of somatostatin than the whole cortex. Upon cell depolarization with high extracellular potassium ions tissue slices of the cerebral cortex show calcium dependent release of somatostatin. All these findings allow us to speculate that somatostatin is a putative neurotransmitter or neurohormone in the cerebral cortex (Havlicek and Friesen in Central Nervous System Effects of Hypothalamic Hormones and other Peptides, Ed. R. Collu, A. Barbeau et al., Raven Press, N.Y., 1979, 361-402). In the present study we show that somatostatin inhibits the activity of Na-K-ATPase (EC 3.6.1.3) in rat cerebral cortical synaptosomal fraction. The activity of Mg-ATPase was not significantly affected (Fig. 1) and there was no detectable effect on Ca-Mg-ATPase (for methods see Lee and Phillis, Can. J. Physiol. Pharmacol. 55, 961-969, 1977). Decrease of the ouabain-sensitive Na-K-ATPase of the synaptosomal membranes by somatostatin will result in depolarization of the membrane potential, which is in accord with out in vivo experiments in which somatostatin applied iontophoretically stimulated activity of cortical neurons in unanesthetised rabbits (Ioffe, Havlicek et al, Brain Research 153, 414-418, 1978) and caused membrane depolarization (see Havlicek and Friesen, 1979).

1795 REGULATION OF PITUITARY β-ENDORPHIN BY PINEAL MELATONIN Robert M. Levy*, Huda Akil**, Stanley Watson** and Jack Barchas (SPON: L. Mathers). Nancy Pritzker Laboratory of Behavioral Neurochemistry, Department of Psychiatry and Behavioral Sciences, Stanford Medical School, Stanford, CA 94305 and **Mental Health Research Institute, University of Michigan School of Medicine, Ann Arbor, MI 48109.

Melatonin, N-acetyl-5-methoxy-tryptamine, a major product of the mammalian pineal gland, has long been implicated in the regulation of pituitary function. Changes in the levels, synthesis and release of several pituitary peptide hormones, including GH, prolactin, ACTH and MSH have been observed following a variety of manipulations involving the pineal gland. As both of these neuroendocrine organs lie outside the blood-brain barrier, the neurohumoral regulation of the pituitary gland by pineal melatonin exists as an interesting possibility. In light of the recent discovery that β-endorphin (β-END) shares with ACTH and β-MSH a common 31 K amino acid precursor (Mains, Eipper and Ling, PNAS, 74:3014-3018, 1977), we have attempted to determine whether this pituitary opiate peptide hormone is subject to physiological regulation by pineal melatonin.

To approach this problem, we have performed a number of manipulations known to alter the function of the pineal gland and measured the subsequent effects on the level of pituitary β-END by radioimmunoassay. These manipulations include exposure of animals to several altered lighting regimens known to alter melatonin synthesis and release, pinealectomy, intracerebroventricular and intravenous injection of varying doses of melatonin and the intravenous administration of highly specific antibodies raised against melatonin-BSA conjugates. Following the experimental manipulations, animals were sacrificed, pituitary glands were removed over Dry Ice, and β-END was extracted from the tissue. Radioimmunoassay of β-END from these extracts was performed as has been previously reported.

Preliminary results from these studies indicate that in those conditions where plasma and cerebrospinal fluid melatonin levels would be expected to be decreased, pituitary levels of β-END were significantly elevated. Melatonin administration, on the other hand, produced a significant decrease in pituitary β-END. These studies suggest a complex interaction between pineal melatonin and pituitary β-END and further implicate the pineal gland in the physiological regulation of pituitary peptide hormones.

1796 PEPTIDE ACTION ON INDIVIDUAL GIANT DOPAMINE NEURONS: ELECTROPHYSIOLOGICAL AND MICROFLUORIMETRIC ANALYSIS. W. Lichtensteiger and D. Felix*. Inst. Pharmacol. and Brain Res. Inst., Univ. Zürich, Zürich, Switzerland.

The giant dopamine neuron (GDN) in the left pedal ganglion of the snail Planorbis corneus provides a model system for studies of biophysical and histo- or biochemical parameters at the cellular level. Intracellular recordings were performed on GDN in vitro. The preparation was frozen to -195°C during electrical recording and processed for histochemical microfluorimetry of catecholamine fluorescence. Fluorescence intensity of GDN is correlated with their firing rate (Lichtensteiger, Felix and Hefti, Brain Research, in press), in analogy to the situation encountered in rat dopamine (DA) neurons.

We used this preparation in order to study cellular actions of representatives of two groups of centrally active peptides which affect the functional state of mammalian DA neurons. When administered to the bath (1 μM), lysine vasopressin (LVP) caused an acute rise in membrane resistance of GDN as checked by injection of depolarizing or hyperpolarizing current, with enhanced firing in response to depolarizing current. An analog with behavioral activity in mammals, desglycinamide-lysine vasopressin showed a similar but stronger action. In contrast membrane resistance was reduced after ACTH 4-10 (1-5 μM) in the majority of GDN. LVP exerted variable effects on spontaneous activity while ACTH 4-10 lowered activity and often induced a rhythmic pattern. The relation between cellular fluorescence intensity and spontaneous activity remained largely unchanged after LVP which suggests that transmitter changes were mainly related to the level of neuronal activity also after peptide administration. Injection of current and manipulation of cation transport by themselves affected fluorescence intensity. These effects are being further analyzed.

Our results illustrate the potential usefulness of this giant molluscan neuron for correlative studies of different aspects of peptide action at the level of individual neurons.

1797 α-L-ASPARTYL-L-ALANINE INCREASES MEPP AMPLITUDE. Ramon Lim, Shu Tim Cheung* and John W. Crayton, Brain Research Institute and Depts. of Surgery (Neurosurgery) and Psychiatry, University of Chicago, Chicago, Ill. 60637

α-L-Aspartyl-L-alanine (asp-ala) is a dipeptide we isolated from the pig brain (Cheung & Lim, Biochim. Biophys. Acta, in press). The biological activity of asp-ala is tested on a rat phrenic nerve-diaphragm preparation. At 10^{-5} M asp-ala enhances neuromuscular transmission by increasing the amplitude of MEPP by 35%. The increase is noticeable during the first 30 min. of intracellular recording and is sustained up to at least 120 min. in the presence of the drug (see table and tracings below). However, the effect is maintained even after washing out the drug following the first 30 min. The free amino acids L-aspartic acid and L-alanine do not show noticeable effects under similar conditions. Another dipeptide, α-L-aspartyl-glycine, which has been isolated from urine but not from the brain, also does not have any effect. The results suggest asp-ala as one of the neural peptides capable of modulating synaptic transmission. (Supported by USPHS grant No. NS-09228)

Time course of asp-ala effect on rat diaphragm

	No. of Diaphragms(n)	No. of Fibers	Amplitude of MEPP (mV)	Frequency of MEPP (No. per min.)
pre-drug (A)	9	90	.59 ± .042 (S.D.)	122 ± 39 (S.D.)
0-30' (B)	9	26	.80 ± .142 (p < .002)	108 ± 45 (N.S.)
30'-60'	9	38	.76 ± .132 (p < .003)	125 ± 39 (N.S.)
60'-90'	9	38	.78 ± .132 (p < .002)	123 ± 31 (N.S.)
90'-120'	9	38	.77 ± .122 (p < .002)	125 ± 44 (N.S.)

1798 CHARACTERIZATION OF MET- AND LEU-ENKEPHALIN RELEASE FROM RAT STRIATUM: INHIBITION BY ACETYLCHOLINE. Iris Lindberg* and June L. Dahl. Dept. Pharmacology, Univ. of Wisconsin Medical School, Madison, WI 53706.

The release of met- and leu-enkephalin from superfused striatal slices was studied. Pooled caudal striatal sections from five rats were chopped into 0.3 mm slices and divided among four superfusion filters. The slices were superfused for 15 min. with warm oxygenated Krebs-bicarbonate (containing 60 µg/ml bacitracin) at a rate of 0.35 ml/min. Fractions were collected at 2-min. intervals. After the collection of three baseline fractions, stimulated release was elicited by a 4-min. exposure to Krebs containing 50 mM potassium, followed by superfusion with normal Krebs. Enkephalins in slices and perfusates were measured by radioimmunoassay (leu-enkephalin antibody was a gift of Dr. Richard Miller; met-enkephalin antibody was purchased from Immunonuclear Corp.). Results are expressed as the percentage of the initial tissue enkephalin released per min.

The mean basal release rates ± SEM of met- and leu-enkephalin were 0.21 ± 0.02%/min. and 0.50 ± 0.07%/min., respectively. After subtraction of basal release rates, the net increase in leu-enkephalin release induced by exposure to 50 mM potassium was 1.36 ± 0.16%/min., whereas that of met-enkephalin was 1.22 ± 0.15%/min. No potassium-stimulated increase could be observed in the absence of calcium. When the calcium concentration was increased from 2 mM to 5 mM, potassium-stimulated rate of release of the enkephalins approximately doubled. The addition of 50 µM acetylcholine to the superfusion medium inhibited the basal release of leu- and met-enkephalin by 66 and 59%, respectively; net potassium-stimulated release was inhibited 79% (leu-enk) and 18% (met-enk). 100 µM acetylcholine virtually abolished potassium-stimulated leu-enkephalin release, while inhibiting basal release by 55%. At the higher concentration of acetylcholine, basal release of met-enkephalin was inhibited by 44%, while stimulated release was inhibited by 63%.

While a greater proportion of tissue leu- than met-enkephalin was released, the absolute amount of met-enkephalin released exceeded that of leu-enkephalin. The ratio of met- to leu-enkephalin released averaged 1.25 ± 0.10 in baseline fractions but rose to 2.23 ± 0.12 during potassium stimulation. The latter value more closely approximates the tissue ratio of the enkephalins found after perfusion (3.35 ± 0.10). It is likely that the lower ratio found in the superfusates is related to the differential degradation of the two peptides (Bayon *et al.* (1978) PNAS 75, 3503); this possibility is currently under investigation. (Supported by DA 00697; Iris Lindberg is an NIH Predoctoral Trainee supported by GM 07107.)

1799 DISTRIBUTION OF α-MELANOTROPIN (α-MSH) IN DISCRETE NUCLEI OF THE CAT BRAIN. V. John Massari*, Thomas L. O'Donohue*, Y. Tizabi*, and David M. Jacobowitz (SPON: G. M. Moolenaar). Dept. of Pharm., Howard Univ., College of Med., Washington, D.C. 20059 and Lab. Clin. Sci., NIMH, Bethesda, Maryland 20205.

Recently α-MSH has been localized within neurons in the arcuate nucleus, and in neuronal processes in the rat brain. In this study, α-MSH (or α-MSH-like immunoreactivity) has also been detected in cat brain. Five mongrel cats of mixed gender were sacrificed under Ketamine anesthesia and their brains were rapidly removed and frozen on dry ice. The brains were alternately sliced into 600 µm thick slabs and 60 µm sections in a cryostat at -8°C. Individual brain nuclei were microdissected from the tissue slices using needles having an internal diameter of 1000, 750, 500 or 300 µm essentially according to the method of Palkovits. The micropunches were placed in 100 µl of 2N acetic acid, boiled for 10 min. and homogenized by sonication. α-MSH was assayed by radioimmunoassay. The sensitivity of the assay is approximately 1.5 pg.

The highest concentrations of α-MSH were found in the arcuate nucleus, median eminence, and suprachiasmatic nucleus (≥ 25pg/µg). High levels of α-MSH were found in the medial preoptic nucleus, periventricular nucleus of the hypothalamus, and paraventricular nucleus of the thalamus (≥ 10 pg/µg). Very low levels of α-MSH were found in all cerebral cortical areas, neo- and paleostriatum, the geniculate nuclei, and the superior and inferior colliculi (≤ 1.0 pg/µg). Within the periaqueductal gray, successively greater concentrations of α-MSH were found in a rostral to caudal progression. Moderate amounts of α-MSH were also detected in the dorsal and median raphe nuclei.

These data indicate that α-MSH is differentially distributed within different nuclei of the cat brain and lend support to the hypothesis that α-MSH may be a CNS neurotransmitter or neuromodulator.

1800 IMMUNOCYTOCHEMICAL STUDIES ON NEURONAL PEPTIDES IN DISSOCIATED SPINAL CORD-DORSAL ROOT GANGLION CELL CULTURES. E. Matthew*, E.A. Neale, P.G. Nelson and E.A. Zimmerman. Dept. of Neurol., Columbia University, New York, NY 10032 and Lab. Devel. Neurobiol., NICHD, NIH, Bethesda, MD 20014.

Fetal mouse spinal cord (SC) and dorsal root ganglion (DRG) neurons grown in dissociated cell culture were examined by immunocytochemistry for endogenous neuronal peptides. Neurons of the intact mammalian spinal cord have been shown by others to contain immunoreactive substance P, enkephalin and neurotensin, while DRG neurons are reactive for substance P and somatostatin. Neurons grown in culture for 4-6 weeks were assayed for these peptides by an indirect immunoperoxidase technique using peroxidase-anti-peroxidase (PAP) complexes. Paraformaldehyde-fixed monolayers were reacted with primary antiserum directed against substance P, neurotensin (both from S. Leeman), leu-enkephalin (from S. Snyder) or somatostatin (from E. Lichtenstein). Specific immunoreactivity was tested by preincubation of each antiserum with synthetic homologous antigen. Reaction products to PAP were formed using 3,3'-diaminobenzidine tetrahydrochloride or 4-chloro-1-naphthol.

Complex networks of varicose fibers were observed in SC-DRG cultures after incubation with antiserum against substance P or enkephalin; reactivity was more extensive for enkephalin. Stained neuronal somata were small diameter cells, rounded or stellate in form, with a number of reactive neurites. The most intense staining was associated with 'beaded' neuronal processes, many of which contacted the processes and encrusted the somata of non-reactive cells. In DRG cultures (without SC cells) grown in NGF-containing medium, a large majority of cells displayed immunoreactivity for substance P, although no DRG cells were reactive for enkephalin. In SC cultures, each of these peptides was localized within a small number of neuronal somata. It appears, therefore, that some DRG and small SC neurons in dissociated cell culture contain substance P, while enkephalin can be demonstrated only in SC cells.

Immunoreactivity to somatostatin was seen in most neurons in NGF-treated cultures prepared from ganglia, and in occasional small neurons in combined SC-DRG cultures. Neurotensin immunoreactivity was detected in some fibers and in small stellate cell bodies in combined SC-DRG cultures.

The demonstration of endogenous neuronal peptides within neurons in dissociated SC-DRG cell cultures speaks for the development of specific chemical properties by these cells. The two-dimensional anatomy and ready accessibility of individual cells further advocate this system for studies of the morphologic and electrophysiologic interactions among peptidergic neurons.

1801 PEPTIDE MODULATION OF ADRENAL PARANEURONS. Fumio Mizobe*, Deanne M. Dean* and Bruce G. Livett, Division of Neurology, The Montreal General Hospital and McGill University, Montreal, Canada

Adrenal paraneurons provide a model tissue culture system of non-neoplastic cells of neural crest origin. We have previously shown that adrenal medullary chromaffin cells can be isolated in a highly purified form by retrograde perfusion with collagenase and density gradient centrifugation on Percoll™ gradients[1,2]. When plated on collagen coated plastic tissue culture dishes under conditions known to favor sympathetic neurite outgrowth in culture, these adrenal chromaffin cells produce long catecholamine-containing varicose processes and exhibit a Ca^{2+}-dependent release of ^{3}H-NE characteristic of noradrenergic neurons in culture[2]. Pharmacological studies have shown that the cells have nicotinic not muscarinic receptors[3]. The availability of this homogeneous adrenergic cell system has enabled a study to be made of the role of peptides as neuromodulators.

Substance P (10^{-8}-$5x10^{-5}$M; ID_{50} = $1.3x10^{-6}$M) and somatostatin (ID_{50} = $1.8x10^{-5}$M) produced a dose-dependent inhibition of the ACh ($5x10^{-5}$M) and nicotine ($5x10^{-6}$M) stimulated ^{3}H-NE release from these adrenal paraneurons. In contrast, the K^+ evoked release (56mM K^+) was not inhibited, and neither SP or somatostatin (10^{-8}-$5x10^{-5}$M) had any effect on the release of ^{3}H-NE in the absence of the nicotinic agonists. Other peptides known to be present in the adrenal medulla, beta-endorphin, leu-enkephalin and met-enkephalin inhibited the ACh ($5x10^{-5}$M) but not the K^+ (56mM) induced release only at peptide concentrations greater than 10^{-5}M (ID_{50} approximately $3x10^{-4}$M). Whether this pharmacological inhibition of the nicotinic response by these opioid peptides is physiologically significant is presently under investigation using peptidase inhibitors.

The results support a role for these peptides as putative neuromodulators in the nervous system.

1802 BOMBESIN-LIKE PEPTIDES: NEUROTRANSMITTERS IN MAMMALIAN BRAIN? Terry W. Moody, Nguyen B. Thoa*, Thomas L. O'Donohue*, David M. Jacobowitz, Agu Pert and Candace B. Pert. Biological Psychiatry Br. and Lab. of Clinical Science, NIMH, Bethesda, MD 20205

Bombesin, a tetradecapeptide isolated from frog skin, is active in the gastrointestinal tract and brain. In the central nervous system bombesin induces hyperglycemia and hypothermia with a well-defined structure activity relationship which corresponds to that required for receptor binding. Specific bombesin receptors, which show a markedly heterogeneous distribution in rat brain, are highly enriched in the periaqueductal gray and nucleus accumbens. Microinjections of bombesin (<1 µg) into these areas cause profound analgesia and enhanced locomotor activity, respectively.

Endogenous bombesin-like peptides have been detected using immunocytochemical techniques as well as by radioimmunoassay combined with microdissection techniques using an antibody which recognizes the C-terminal of bombesin. Bombesin-like immunoreactivity was observed in discrete varicose nerve fibers. The concentration of bombesin-like immunoreactivity was 30-fold greater in high regions (nucleus tractus solitarius, interpeduncular nucleus, median eminence, arcuate nucleus and substantia gelatinosa) than low regions (caudate, hippocampus and cingulate cortex). After intraventricular injection of vinblastin, neuronal cell bodies were observed in the preoptic, hypothalamic and mammallary nuclei as well as the mesencephalon. The distribution of bombesin-like peptides and substance P is strikingly coincidental, however, radioimmunoassay analysis of high-pressure liquid chromatographic fractions of brain extracts indicates that the two peptides are distinct.

Also, the subcellular distribution of bombesin receptors and bombesin-like peptides was investigated using our radioreceptor assay and radioimmunoassay. The greatest number of bombesin receptors and bombesin-like peptides is present in the synaptosomal fraction, suggesting an association with nerve terminals.

In addition, the release of bombesin-like peptides from rat hypothalamic slices was investigated. The amount released increased 2-3 fold when the brain slices were treated with depolarizing stimuli such as K^+ or veratridine in the presence of Ca^{++}. These results suggest that endogenous bombesin-like peptides may have a physiologic role in the synaptic function, either as neurotransmitters or neuromodulators.

1803 SOMATOSTATIN AND SUBSTANCE P LEVELS IN CULTURED SENSORY NEURONS ARE INFLUENCED BY ENVIRONMENTAL FACTORS. Anne W. Mudge* (SPON: E. Floor). Dept. of Physiol., Harvard Med. Sch., Boston, MA 02115

The peptides somatostatin (SOM) and substance P (SP) are present in separate populations of small diameter sensory fibers which project to the spinal cord dorsal horn. SP is thought to be involved in excitatory transmission in the nociceptive pathway. SOM on the other hand has generally inhibitory effects in the nervous system and its role in the nociceptive pathway is not clear. This abstract reports that cultured sensory neurons contain predominantly either SP or SOM depending on the conditions in which the neurons are grown.

Dorsal root ganglia from 9-10 day-old chicken embryos were dissociated and cells plated to yield three types of cultures--(1) neurons grown in the virtual absence of nonneuronal cells; (2) neurons together with ganglionic nonneuronal cells; or (3) ganglionic nonneuronal cells grown without neurons. The growth media contained nerve growth factor (NGF). Cultures were extracted in 2 M acetic acid and peptide content was measured by RIA. After four weeks, neuron-alone cultures contained 2049±227 fmol SP and 266±69 fmol of SOM; neurons plus ganglionic nonneuronal cell cultures contain 909±53 fmol SP and 5759±379 fmol of SOM; that is, the ratio of SOM/SP was increased from 0.13 to 6.25. The number of neurons was the same in both conditions. Cultures of nonneuronal cells alone do not contain detectable amounts of either peptide. Moreover, a similar result was obtained if neurons grown in the absence of nonneuronal cells were fed with medium which had been "conditioned" by incubation on ganglionic nonneuronal cells.

It is unlikely that an NGF-like material produced by the nonneuronal cells is the agent responsible for this change in SOM/SP ratio. First, the cultures were grown in saturating concentrations of NGF. Second, the addition of NGF to neuron-alone cultures at a dose sufficient to cause a 2-fold increase in the number of neurons surviving caused a 4-fold increase in the level of both SP and SOM with no change in the ratio of SOM/SP.

Extracts of CNS tissue added to the media produce the opposite effect: SOM/SP is decreased. Previous results in this laboratory have demonstrated that somatostatin (as well as enkephalin, 5-HT and NE) can inhibit Ca-action potentials in the cell soma as well as inhibit SP release from the neurons. The effects of these inhibitory compounds on the SOM/SP ratio is being investigated. (These experiments were carried out in the laboratories of G.D. Fischbach and S.E. Leeman, and were supported by NIH grants GM 00919 and AM 16510.)

1804 NEUROTOXIC ACTION OF CAPSAICIN ON SPINAL SUBSTANCE P NEURONS. J.I. Nagy*, S.R. Vincent, Wm.A. Staines*, H.C. Fibiger, T.D. Reisine, and H.I. Yamamura. Division of Neurological Sciences, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5, and Department of Pharmacology, University of Arizona, Tucson, Arizona, USA, 85724.

Studies were made of the effects of neonatal injections of capsaicin on the ultrastructure of the neonatal spinal cord and some biochemical and behavioral parameters in the adult. Electron microscopic observations revealed degeneration and glial engulfment of boutons and unmyelinated axons in the dorsal horn 2 and 6 hours after subcutaneous neonatal injections. Capsaicin treatment had no effect of the activities of glutamic acid decarboxylase and choline acetyltransferase in the dorsal horn. Results of substance P measurements in the CNS showed no effect of capsaicin administration on striatal, hypothalamic or nigral substance P content, whereas spinal cord dorsal horn substance P levels were reduced by 46%. ^{3}H-Naloxone binding in dorsal horn tissue revealed a 37% decrease in opiate receptor levels in capsaicin-treated animals which kinetic analysis showed to be due to a change in receptor density rather than affinity. Capsaicin-treated animals showed significantly increased latencies to respond to a noxious thermal stimulus. Latencies to respond in the tail-flick and hot-plate tests were 166% and 144% respectively of control values.

The present values are consistent with the proposal that at least some primary sensory afferent neurons may utilize substance P as a neurotransmitter of nociception. Also supported by our findings is the emerging view of an intimate association between substance P and enkephalin neurons in pain mechanisms in the dorsal horn. If continued investigation shows the neurotoxicity of capsaicin in the neonate to be highly selective for the substance P neurons of the spinal ganglia, then it should prove to be a useful and important tool for the determination of the precise mechanisms by which substance P neurons participate in the transmission of specific sensory modalities.

1805 FURTHER STUDIES ON CENTRAL NERVOUS SYSTEM EFFECTS OF NEUROTENSIN, AN ENDOGENOUS PEPTIDE. C.B. Nemeroff, G.N.Ervin,* P.J. Manberg,* A.J. Osbahr, III,* S. Felts,* L.S. Birkemo* and A.J. Prange, Jr.* Biol. Sci. Res. Ctr., Depts. Psychiat., Pharmacol. and Psychol. and the Neurobiology Program, Univ. North Carolina, Sch. Med., Chapel Hill, NC 27514.

Neurotensin (NT), an endogenous tridecapeptide distributed heterogenously in the central nervous system of a variety of mammalian species, has previously been demonstrated to produce diminished locomotor activity, hypothermia, potentiation of barbiturate-induced sedation and antinociception after intracisternal (IC) administration in mice and rats. Because of similarities between certain of the properties of acknowledged neuroleptic aspects and NT, evaluation of the effects of the peptide in a variety of pharmacological screening procedures was performed. NT (3-100 µg IC in adult male mice), like neuroleptics, exhibited significant activity in the Julou-Courvoisier traction test, a measure of muscle relaxation. The simultaneous IC administration of the endogenous tripeptide thyrotropin-releasing hormone (TRH) abolished this effect of both neuroleptic agents and NT. The administration of either NT or haloperidol via bilateral nucleus accumbens cannulae in adult male rats blocks certain of the behavioral effects (↑locomotor activity and rearing) induced by d-amphetamine (2 mg/Kg IP). Further studies sought whether IC NT in mice blocks the behavioral effects of peripherally administered apomorphine in a paradigm designed to test striatal (and not mesolimbic) DA receptors (Psychopharmacol 50:1-6, 1976). NT showed no activity in this test. In the final series of experiments NT-induced antinociception was assessed and compared with the activity of ten other endogenous peptides. Adult male mice received IC injections of 1 µg NT (or another peptide in an equimolar dose) or vehicle and tested for antinociceptive activity by the Janssen method (measurement of latency to withdraw tail from 48°C water bath; Arzneitmittel-Forsch 13:502-507, 1963). β-endorphin was the most potent antinociceptive agent tested but NT was quite potent,possessing significantly greater activity than met-enkephalin, leu-enkephalin and morphine. Conclusions: (1) NT possesses activity in certain neuroleptic screening tests (e.g. Julou-Courvoisier test); (2) Direct n.accumbens injection of NT, like haloperidol, blocks certain effects of d-amphetamine, suggesting an interaction of NT at mesolimbic DA synapses; (3) in a test devised to measure blockade of striatal DA receptors, NT exhibited no activity; (4) TRH blocks certain behavioral effects of both neuroleptics and NT, (5) NT, unlike neuroleptics, possesses significant antinociceptive activity after IC administration. (Supported by NIMH MH22536, MH32316, and NICHHD HD-03110).

1806 SEPARATION, IDENTIFICATION AND QUANTITATION OF BIOLOGICALLY ACTIVE PEPTIDES BY HIGH PRESSURE LIQUID CHROMATOGRAPHY (HPLC): A PREREQUISITE FOR RADIOIMMUNOASSAY CHARACTERIZATION. Thomas L. O'Donohue*, Gunnar E. Holmquist* and David M. Jacobowitz. Lab. Clin. Sci., NIMH, Beth., Md. 20205 and Dept. of Pharm., Howard Univ., Washington, D.C. 20059.

HPLC provides a rapid means for resolving and quantitating mixtures of closely related peptides. For example, peptides differing by one amino acid, (e.g., Angiotensin II and Angiotensin III), or by only one molecular component (e.g., α-MSH, deacetylated α-MSH and deamidated α-MSH),were easily resolved by reverse phase (µBondapak/C_{18}, Waters Associates) gradient chromatography.

Using a solvent system composed of acetonitrile and trialkylammonium phosphate buffer at low pH, peptides from biological samples can be quantitated with precision and great reproducibility with minimal sample prepurification. Acid extracts from pituitary or brain are injected onto Sep-Pak C_{18} Cartridges (Waters Associates). Using buffers of high polarity,ions, impurities, and low molecular weight polar compounds can be rapidly removed. Peptides of interest are then eluted with an appropriate solvent of less polarity. These eluates are lyophylized, resuspended and chromatographed on the HPLC. Comparison of sample peak heights with known standard peak heights of identical retention times, yields a direct determination of peptide concentration in the tissue. For example, concentrations of α-MSH and vasopressin in the pituitary can be determined by absorbance at 280 nm.

HPLC also provides a rapid and accurate means for characterizing the specificity of antibodies. Antibodies which are determined to be specific by their recognition of the antigen but, lack of cross-reactivity with commercially available peptides, may recognize unidentified compounds in biological samples. We have recently seen that this is the case with antibodies to α-MSH, bombesin and substance P. These antibodies were deemed specific by both cross reactivity tests and by traditional column chromatographic techniques. HPLC, however, identified other tissue components which cross react with the antibodies. It is concluded that HPLC should be used as a minimum prerequisite for determining specificity of an antibody.

1807 SELF-ADMINISTRATION OF MORPHINE, LEVORPHANOL, AND DALA AT HYPOTHALAMIC AND NUCLEUS ACCUMBENS SELF-STIMULATION SITES. M.E. Olds* (SPON: A. Yuwiler). Division of Biology, California Institute of Technology, Pasadena, CA 91125

Adult male rats implanted chronically with a cannula guide and two electrodes glued to its shaft were tested for self-stimulation before and after self-administration tests for morphine, levorphanol, dextrophan and DALA.

For direct injection into the hypothalamus at sites yielding low to moderate rates self-stimulation, rats learned to discriminate between two pedals placed at opposite ends of a plexiglass test chamber, one that delivered 20 nl of morphine, 5 µg/µl for each depression of the lever, and the other that yielded nothing. The rates on the active lever were higher for morphine 5 µg/µl concentration than for the vehicle, which was artificial cerebrospinal fluid, and were higher for morphine 10 µg/µl than 5 µg/µl.

High-rate hypothalamic self-stimulators learned to reverse repeatedly when the active lever was changed from side to side in successive sessions and delivered 20 nl of morphine/press of 10 µg/µl. Responding was reduced on both levers and discrimination between active and inactive levers was reduced when naloxone (1-2 µg/µl) was mixed with morphine, or when it was given systemically (1 mg/kg). Extinction after morphine was slow and often produced higher rates of responding than during the acquisition session.

High-rate hypothalamic self-stimulators self-administered DALA (0.1 and 1 µg/µl concentration) but rates were generally lower than for morphine and reversal was more difficult to achieve. Responding was attenuated for a mixture of DALA and naloxone injected into the hypothalamus. Levorphanol was approximately as effective as morphine but dextrophan yielded lower self-administration response rates.

Moderate-rate nucleus accumbens self-stimulators self-administered morphine and levorphanol. Non-self-stimulators with probe and cannula in the caudate nucleus did not self-administer morphine or did so at very low rates.

Post-drug self-stimulation tests yielded rates of responding for the electrical reward comparable to those seen in pre-drug tests, a result indicating minimal functional damage to the elements responsible for self-stimulation behavior even after repeated self-administration tests.

The data are interpreted to indicate the need of both opiate receptors and high rates of self-stimulation behavior to obtain self-administration for intracerebral injection of opiates. This finding is viewed as supporting the notion that structures known to support self-stimulation behavior may mediate the reinforcing properties of morphine, levorphanol and DALA. (PHS DAO 1541).

1808 SOMATOSTATIN EFFECTS ON GLUTAMATE AND GABA TRANSPORT IN FROG SPINAL CORD. A.L. Padjen[1] & R.A. Davidoff, Depts. of Pharmacol. & Ther., McGill Univ., Montreal, Quebec H3G 1Y6 & Neurology Service V.A. Hospital & Dept. of Neurology, Univ. of Miami, School of Medicine, Miami, FL 33152.

Somatostatin is present in frog spinal cord, presumably in primary afferents (unpublished observations), as in mammals. However, effects of somatostatin on synaptic transmission do not favor its role as a primary afferent excitatory transmitter but suggest a possible "neuromodulatory" role (cf. Padjen, Neurosci. Abs. 3, 411, 1977). In concentrations of 10^{-6}-10^{-5}M somatostatin caused selective dose dependent depression of glutamate but not of GABA evoked responses on both motoneurons and primary afferents recorded by sucrose gap technique in isolated superfused frog spinal cord (synaptic transmission blocked by TTX or high Mg). These experiments were extended to an analysis of the effects of somatostatin on the uptake and release of (^{3}H) glutamate and (^{3}H) GABA in frog spinal cord slices (for methods see Davidoff & Adair, J. Neurochem. 24, 454, 1975; Brain Res. 118, 403, 1976). Somatostatin (10^{-5}M) caused a small but significant increase in (^{3}H) glutamate (10^{-7}M) high affinity uptake (+20%; control: 0.277 ± 0.031 SEM nmoles/g/min; with somatostatin: 0.333 ±0.045, n= 6) but no change in (^{3}H) GABA (10^{-7}M) high affinity uptake (+5%; control: 0.386 ± 0.061; with somatostatin: 0.404 ± 0.061; n = 6). On the other hand the increase in (^{3}H) glutamate release evoked by 40 mM K^+ was significantly depressed by the same concentration of somatostatin (no somatostatin: +156% ± 7.0 of resting efflux; with somatostatin: +114.3% ± 6.1; n = 6) without affecting K^+ evoked release of (^{3}H) GABA (no somatostatin: +157.3 ± 12.6; with somatostatin: +158.3 ± 7.8; n = 6).

These results suggest that somatostatin specifically interferes with glutamate transport in frog spinal cord. They contrast with somatostatin produced facilitation of ventral root potentials evoked by dorsal root stimulation, a pathway which is presumed to be mediated in part by glutamate.

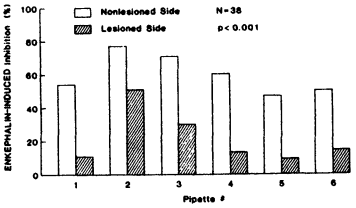
1809 CATECHOLAMINERGIC MODULATION OF ENKEPHALIN ACTION. M.R. Palmer, J. Stewart, M. Perlow†, W. Freed†, R. Wyatt†, B.J. Hoffer*. Depts. of Pharmacology and Biochemistry, University of Colorado Medical Center, Denver, Colorado, 80262, and †NIMH, St. Elizabeth's Hospital, Washington, D.C., 20032.

The interaction between iontophoretically applied D-Ala^2 methionine enkephalinamide (2dA) and catecholamine afferents to frontal cortex was investigated in rats. The depression caused by iontophoretically applied 2dA were similar to those observed after micropressure ejection from the same pipette, thus showing that the depressions are not artifacts of the iontophoretic technique. Antipsychotic agents known to block catecholamine receptors such as spiroperidol, α-fluphenthixol and (+) butaclamol, reversibly antagonized the enkephalin depressions when administered i.v. The biochemically inactive isomers of these antipsychotics, β-fluphenthixol and (-) butaclamol, had no such effects. Unilateral lesions of the catecholaminergic projections to frontal cortex produced by interstial injection of 6OHDA resulted in an ipsilateral decrease in 2dA efficacy, and in an elimination of the antagonism of 2dA depressions by antipsychotic agents.



The effects of dopamine and 2dA were similar only in deeper layers of the cortex; above 800 µm, any one neuron often showed differing responses to the two agents. The depression caused by 2dA were not antagonized by Mg^{++}, iontophoretically applied at levels high enough to reduce spontaneous activity. It is concluded that intact catecholaminergic transmission is required for the full expression of enkephalin depressions in frontal cortex, and that this mechanism probably does not involve a presynaptic release of catecholamines by enkephalin. Perhaps catecholamines act as postsynaptic modulators to augment neuronal responsiveness to enkephalins. (Supported by AA03527. M.P. has a fellowship from Pharmaceutical Manufacturers' Association, and a scholarship from the Reiger Educational Trust.)

1810 INVESTIGATION OF DES-TYROSINE^1-γ-ENDORPHIN ACTIVITY AT NEUROLEPTIC BINDING SITES IN RAT BRAIN AND OF OPIATE AND NEUROLEPTIC BINDING IN HUMAN SCHIZOPHRENIC BRAINS. N.W.Pedigo, T.D.Reisine, N.C.Ling[a], E.D.Bird[b], L.L.Iversen[b] and H.I.Yamamura, Dept. of Pharmacology, Univ. of Arizona, Tucson, AZ 85724, [a]Neuroendocrinology Lab, The Salk Institute, La Jolla, CA 92112, and [b]MRC Neurochemicalpharmacology Unit, Dept. of Pharmacology, Cambridge, England CB2-2QD.

Since the discovery of endorphins, endogenous morphine-like peptides, there has been considerable research directed towards understanding their possible role in psychiatric disorders. We have sought to contribute to this dynamic field of research by examining the possible activity of des-tyrosine^1-γ-endorphin (DTγE, βLPH_{62-77}), a proposed endogenous neuroleptic peptide, at ^{3}H-spiroperidol [^{3}H-S] binding sites in rat frontal cortex, corpus striatum and nucleus accumbens-olfactory tubercle. DTγE, in concentrations from 1 nM to 100 µM, did not inhibit ^{3}H-S binding in any of these brain regions, while control dose-response curves for haloperidol and (+)-butaclamol indicated 80-90% specific ^{3}H-S binding. The DTγE was not degraded during the binding assay as its final concentration was verified by high pressure liquid chromatography. The inability of DTγE to inhibit speicfic ^{3}H-S binding suggests that this peptide does not act at the neuroleptic receptor labeled by ^{3}H-S in these brain areas. It is possible that DTγE may be acting through mechanisms which require in vivo activation or, alternatively, DTγE may represent a new class of antipsychotic drugs with properties unlike other known neuroleptic agents.

We have also measured ^{3}H-S and ^{3}H-naloxone binding in the frontal cortex, caudate and putamen of brains obtained at autopsy from eleven schizophrenic patients. Eight of these patients had previously been treated with neuroleptic drugs. Binding of ^{3}H-S was significantly increase in the caudate (39%) and putamen (51%), but was not altered in the frontal cortex. These changes were due to an increased number of ^{3}H-S binding sites without any change in receptor affinity. In contrast, ^{3}H-naloxone binding was not significantly changed in the frontal cortex or putamen, but was reduced 43% ($p<.05$) in the caudate. Again this was due to a decrease in the number of opiate receptors rather than a change in their affinity. These receptor alterations could reflect neurochemical changes in schizophrenia or may in part represent drug-induced changes following long-term neuroleptic therapy.

1811 ELECTROPHYSIOLOGICAL RESPONSES TO ANGIOTENSIN II AND LUTEINIZING RELEASING HORMONE. M. Ian Phillips and Dominik Felix*. Dept. Physiol. & Biophys., Univ. of Iowa, Iowa City, IA 52242 and Brain Res. Inst., Univ. of Zurich, Zurich, Switzerland.

Angiotensin II (AII) and luteinizing releasing hormone (LHRH) are neuropeptides which both produce behavioral effects when injected into the brain. Interest in the brain circumventricular organs as possible receptor sites for central effects of AII have focused on the subfornical organ (SFO) and the organum vasculosum of the lamina terminalis (OVLT). Previously, we have shown that the SFO in cat contains cells which are responsive to AII when it is applied directly by microiontophoresis. In the present study we have used a ventral approach to the OVLT of the rat for direct application by microiontophoresis of AII. Rats were anesthetized with urethane and the optic chiasm surgically revealed by microdissection. Extracellular action potentials were recorded through the central barrel of a 5-barrel glass micropipette. This contained 4 M NaCl and fast green dye. The tip diameter was approximately 4µm with a resistence of 4-12MΩ. LHRH (Beckman) 10mM, pH 5.5 angiotensin II (Calbiochem.), prepared as a 10^{-3} M solution in distilled water with a final pH of 4.5. Saralasin (Beckman) was prepared the same as AII. The criterion for a response to the peptides was a change of 20% or more in the firing rate. Only stable units were tested. The peptides were ejected with cationic currents. Cells were tested by application of LHRH or AII for 1-2 minutes with intervals between doses being several minutes to allow full recovery from testing. At the end of testing a rat, a fast green dye marker was made at the site of the last recorded unit. 87 units were tested in the OVLT or lamina terminalis. 55 were excited by AII, 25 not influenced and 7 were inhibited. Responses to AII lasted for the length of application and the latency of onset varied. Those cells which responded to AII were inhibited by Saralasin. When Saralasin was applied at the same time as AII, the response to AII was diminished or abolished. Saralasin alone diminished cell firing. Dose response curves to AII were established in several of the excited cells. Thus, cells in OVLT responded to AII with high sensitivity and specificity. LHRH produced inhibition in this region. 22 cells which responded to LHRH were all inhibited.

The results confirm other evidence that the OVLT may be an AII receptor site. They support the hypothesis that this region of the rat brain may be important in such basic functions as thirst and blood pressure control since these functions have been ascribed to AII. The inhibitory responses to LHRH suggest a negative feedback system and that this region may be involved in the control of sex behavior.

Supported by grants from NSF and Swiss NSF.

1812 USE OF SUBSTANCE P PARTIAL FRAGMENTS TO CHARACTERIZE SUBSTANCE P RECEPTORS OF SPINAL CORD AND INTESTINE. M.F.Piercey, F.J. Einspahr* and L.A.Schroeder*. The Upjohn Company, CNS Research, Kalamazoo, MI 49001.

Several substance P (SP) partial fragments were tested for their effects on cat dorsal horn neurons and guinea pig ileum. Ileal segments were mounted in 5 ml baths of aerated Tyrode's solution (37°C). Potencies were measured as the doses required to cause half maximal contractions. C-terminal fragments as small as the hexapeptide (SP6) retained full SP potency. Potencies of the C-terminal penta- and tetrapeptides (SP5 and SP4) were much lower, while the C-terminal tripeptide (SP3) and the N-terminal decapeptide (SPN10) were inactive. SP tachyphylaxis completely eliminated the effects of SP and its analogs, but not those of non-SP receptor stimulants (acetylcholine, bradykinin, serotonin). Thus all SP fragments elicited their contractions via SP receptor stimulation.

Microiontophoresis was used to test the effects of the SP analogs on spinal cord dorsal horn neurons. Unanesthetized decerebrate cats with L1 spinal sections were used. Analogs (1 mM in 165 mM NaCl) were ejected electroosmotically from seven-barrelled microelectrodes onto dorsal horn neurons whose firing rates were monitored by a central recording barrel. Nearly all SP-excitable cells were excited by C-terminal fragments as small as SP6; smaller C-terminal fragments only occasionally excited these cells. Surprisingly, the N-terminal analog, SPN10, weakly excited about half the SP-excitable cells on which it was tested. The excitatory effects of SP fragments were slow, resembling that for SP. Thus, it is unlikely that SP's slow time course is due to its being broken down into a smaller, more rapidly acting fragment. None of the SP fragments excited SP-insensitive cells. Thus, it is concluded that the excitatory effects of all SP partial fragments were mediated through a common SP receptor located on specific dorsal horn neurons.

Because SP6 was the smallest SP fragment possessing full biological activity on both the ileum and the spinal cord, the SP receptors for both tissues must be quite similar. However, since SPN10 was weakly active in the dorsal horn, but not the ileum, these receptors cannot be totally identical.

1813 THE ACTIONS OF THE MOLLUSCAN NEUROPEPTIDE FMRFamide ON A MOLLUSCAN NEUROMUSCULAR JUNCTION. David A. Price. Dept. of Biological Sciences, Florida State University, Tallahassee, FL 32306.

The molluscan neuropeptide FMRFamide (phenylalanyl-methionyl-arginyl-phenylalanine amide) has excitatory actions on the isolated radula protractor muscle of Busycon contrarium. To determine what role, if any, the peptide might have in the normal function of this muscle, I examined the pharmacological interaction of FMRFamide with the presumed neurotransmitters, acetylcholine (ACh) and 5-hydroxytryptamine (5HT), and compared them to its effects on contractions elicited by nerve stimulation.

ACh causes contractures of the radula protractor which can be relaxed with 5HT, often with the simultaneous induction of spontaneous rhythmical activity. The main action of FMRFamide is ACh-like, though the FMRFamide induced contractures develop and decay more slowly than those induced by ACh. Since this action of FMRFamide is unaffected by ACh antagonists, it, presumably, represents a direct action of the peptide on the muscle and not an action on ACh-containing nerves. However, low concentrations of FMRFamide (less than 10nM) often cause a response resembling that seen with mixtures of ACh and 5HT. Since this oscillatory response is somewhat sensitive to ACh antagonists and is easily desensitized, it might be mediated through the nerves.

If the nerve trunk innervating the radula protractor is stimulated at low frequency (0.2/sec) with short (0.2 msec) pulses, a uniform train of distinct twitches is obtained. Low concentrations (less than 10nM) of FMRFamide in the bathing medium increase the twitch amplitude with no increase in the resting tone. ACh antagonists sharply decrease the twitch height. FMRFamide contractures developed in the absence of nerve stimulation relax when nerve stimulation is resumed.

These results support the supposition that ACh and 5HT are neurotransmitters at the radula protractor neuromuscular junction. Though FMRFamide has direct actions on the radula protractor, it is apparently not released by nerve stimulation, at least not in sufficient quantity to cause a twitch and so is likely not a neurotransmitter. It might be acting as a neuromodulator.

1814 INSULIN STIMULATES MACROMOLECULAR SYNTHESIS AND BINDS TO SPECIFIC RECEPTORS IN CELLS CULTURED FROM RAT BRAIN. Mohan K. Raizada* and Robert E. Fellows. Dept. of Physiology and Biophysics, The University of Iowa College of Medicine, Iowa City, Iowa 52242.

Although the effects of insulin on protein synthesis and cell growth have been characterized in non-neuronal tissues, they have not been studied extensively in brain. Insulin has been found in brain at levels which are higher than, and possibly independent of plasma insulin levels. Insulin immunoreactivity has also been detected in specific areas of brain, including olfactory bulb and brain stem. In order to extend our studies of the role of insulin in brain development, we have utilized primary cultures of fetal rat brain to investigate the effects of insulin on macromolecular synthesis, and to determine if specific insulin receptors are present in these cultures. Trypsin dissociated cells from rat brain, obtained at 20 days gestation, were grown in Dulbecco's modified Eagle's medium with 10% fetal bovine serum. On day 8, cultures consist of a background monolayer of glial and other cells, on top of which lie individual and clusters of "phase dark" cells, identified as neurons on the basis of morphological, electrophysiological and biochemical criteria. Incubation of cultures with insulin caused a time- and dose-dependent increase in ^{3}H-thymidine (TdR) and ^{3}H-uridine incorporation into TCA precipitable material. Maximum (2.2-fold) stimulation of TdR incorporation occurred 10 hr after incubation with 0.16 μM insulin. The same concentration of insulin caused a 2.0-fold increase in ^{3}H-uridine incorporation in 1 hr. Binding of ^{125}I-insulin to cultures was time- and pH-dependent and 85-90% specific. Porcine insulin competed for ^{125}I-insulin binding, with 35% inhibition at a concentration of 8 nM and 55-60% inhibition at 16 nM. Insulin analogs including desoctapeptide insulin, competed for ^{125}I-insulin binding in the order of their biological potency. Unrelated peptides, including glucagon and angiotensin II, did not compete for ^{125}I-insulin binding. The half-life of ^{125}I-insulin dissociation from receptors was 15 min. Scatchard analysis of binding data gave a curvilinear plot which could be resolved into two components representing high affinity ($Ka=2x10^{11}M^{-1}$) and low affinity ($Ka=4x10^{10}M^{-1}$) sites. Of the estimated $7.5x10^{4}$ total binding sites per cell, 28-30% represented high affinity sites. These studies demonstrate that cultured cells from rat brain contain specific insulin receptors which may mediate the action of insulin on macromolecular synthesis. Additional data suggest the effects of insulin on brain may be due at least in part to insulin synthesis within the central nervous system. Supported by NIH grant 1 RO1 HD11184-1.

1815 ENTRY OF OPIOID PEPTIDES INTO THE CENTRAL NERVOUS SYSTEM. S.I. Rapoport, W.A. Klee*, K.D. Pettigrew* and K. Ohno.* Nat'l Inst on Aging, Balto., MD 21224 and Nat'l Inst of Mental Health, Bethesda, MD 20014.

Cerebrovascular permeability of 4 modified opioid peptides -- [D-Ala^{2}]-methionine enkephalin amide, [D-Ala^{62},^{14}C-Homoarg^{69}]-β-lipotropin 61-69, [D-Ala^{2},^{14}C-Homoarg^{9}]-α-endorphin and [D-Ala^{2},^{14}C-Homoarg]-β-endorphin -- was measured in the conscious rat by the compartmental analysis method of Ohno et al., (Amer. J. Physiol., 253, H299, 1978). 5-10 μC$_i$ of radioactive peptide was injected i.v. as a bolus. Femoral artery plasma concentration, C_{plasma} dpm/ml, was followed until decapitation and fit by the following equation to give values of A_i and $\alpha_i(sec^{-1})$, where n = 2-4: $C_{plasma} = \sum_{i}^{n} A_i e^{-\alpha_i t}$. Parenchymal brain concentration C_{brain} dpm/g, calculated as net minus intravascular radioactivity, was represented as $dC_{brain}/dt = PA(rC_{plasma} - C_{brain}/V)$, where r = unbound tracer fraction in plasma, V = cerebral distribution volume of tracer, P = cerebrovascular permeability(cm sec^{-1}) and A = 240 cm^{-1}(capillary surface area/cm^{3} brain). Substitution of the first into the second equation and integrating gives brain concentration at time T of decapitation:

$$C_{brain}(T) = \sum_{i}^{n} \frac{rA_i\, PA}{PA/V - \alpha_i} \left(e^{-\alpha_i T} - e^{-PAT/V}\right).$$

The latter equation was fit to experiments with each tracer to give P and V. V = 0.32 for [D-Ala^{2},^{14}C-Homarg^{9}]-α-endorphin, demonstrating distribution in the brain extracellular space. P ranged from 1.2 x 10^{-6}cm $sec^{-1}$for [D-Ala^{2} ^{14}C-Homoarg^{9}]-α-endorphin to 3.9 x 10^{-6}cm sec for [D-Ala^{2}, ^{14}C-Homoarg]-β-endorphin, whereas the Brain Uptake Index technique indicates that peptides are impermeable at the cerebrovasculature (Cornford et al., Endocrinol. 103, 1297, 1978). Peptide permeability approximates the permeability of glycerol or thiourea, is 1/100 the permeability of caffeine or antipyrine, and 100 times the permeability of sucrose or erythritol. Permeability is sufficiently high to allow peptides into the brain extracellular space with a half-time of 4-12 min following a step rise in plasma concentration. The findings are consistent with observed central effects to some systemically administered opioid peptides, and suggest that feedback may operate, via the blood-brain barrier, between circulating peptides and brain sites that regulate their release into the systemic circulation.

1816 ENKEPHALIN NEURONS IN GOLDFISH HYPOTHALAMUS:PHYSIOLOGY & MORPHOLOGY STUDIED BY INTRACELLULAR RECORDING & LUCIFER YELLOW MARKING. T.A. Reaves, Jr. and J.N. Hayward. Dept. Neurology & Neurobiology Program, University of North Carolina, Chapel Hill, NC 27514.

Having described the presence of enkephalin (ENK)-containing neurons, with axons projecting to the pituitary gland, interspersed among the vasotocin (VT)- and isotocin (IT)-containing neurons of the goldfish preoptic nucleus (NPO; Reaves & Hayward, 1979), we now report the physiological and morphological characteristics of immunocytochemically-defined ENK neurons. We made intracellular recordings from antidromically identified NPO cells (Hayward, 1974) with glass micropipettes filled with the fluorescent dye, 3% Lucifer Yellow-CH (LY; Stewart, 1978). Having measured the cell's electrophysiological properties, we injected LY into the cell with 10-20 nA of anionic current for 1-5 min, perfused the brain, fixed it with Bouin's, prepared it for paraffin histology and examined the sections cut at 6-10 uM for LY fluorescence. We injected and located only one LY-marked cell for each side of the brain and traced them and all their processes with camera lucida. We stained, immunocytochemically, serial sections through the LY-marked soma to determine the peptidergic cell type. We identified chemically 30% of LY-filled cells as ENK neurons, the remaining 70% of the cells studied we identified chemically as VT or IT neurons. NPO ENK cells showed resting membrane potentials and action potentials similar to other neurons. Pituitary gland stimulation at threshold levels yielded long antidromic latencies while stepwise increases in the stimulus strength caused the invasion latency to shorten in an all-or-none fashion. Dye-marked ENK cells measured 14-42 uM with their processes projecting into the hypothalamic neuropil and to the pituitary gland. Where we saw extensive axonal branching, long sections of axons, axonal and dendritic processes and varicosities clearly, we also visualized three distinct ENK cell somata (unipolar, bipolar, multipolar) lying throughout the NPO, 50-250 uM deep to the ependymal lining of the preoptic recess of the third ventricle. In many cases, the physiological and morphological characteristics of LY-filled, chemically-defined VT and IT neurons resembled ENK cells closely. In summary, our data 1) support the one-neuron, one-peptide hypothesis; 2) illustrate the interspersed nature of complexly mixed groups of NPO peptidergic neurons; and 3) suggest that cell morphology, cell location within the NPO & cell electrophysiology are inadequate criteria for distinguishing ENK cell types. The three morphological ENK cell types (unipolar, bipolar, multipolar) may represent distinct functional subsets of this peptidergic opioid neuron.

1817 EFFECT OF CYCLO(LEU-GLY) ON MORPHINE DEPENDENCE AND MORPHINE-INDUCED DOPAMINE RECEPTOR SENSITIVITY

R.F. Ritzmann, Roderich Walter*, and Hemendra N. Bhargava*, Department of Pharmacognosy and Pharmacology, University of Illinois at the Medical Center, Chicago, IL 60612

The effect of cyclo(Leu-Gly) on the development of morphine tolerance and physical dependence as well as morphine-induced alterations in dopamine (DA) receptor sensitivity were assessed. Mice were rendered physically dependent on and tolerant to morphine by subcutaneous (S.C.) implantation of morphine (75 mg/kg free base) pellets for 3 days. A dose of 0.18 μmoles of cyclo (Leu-Gly) injected S.C. 2 hours prior to the pellet implant prevented the development of physical dependence as measured by changes in body temperature observed during either abrupt or naloxone-induced withdrawal. Cyclo(Leu-Gly) also inhibited the development of tolerance to morphine analgesia; however, the acute treatment did not modify morphine analgesia in tolerant mice.

The dose of the DA agonist apomorphine (APO) necessary to produce an increase in locomotor activity determined 24 hours after the removal of the pellets was lower in morphine-dependent mice relative to placebo controls. The pretreatment with cyclo(Leu-Gly) in the same manner which blocked the development of physical dependence and tolerance also prevented the increase in DA receptor sensitivity. Similar results were obtained using the hypothermic response to the DA agonist piribedil (20 mg/kg ip). Piribedil produced a greated hypothermic response (15 & 30min) in morphine dependent mice given cyclo(Leu-Gly) than in dependent mice given saline injection. Mice pretreated with cyclo(Leu-Gly) and chronic morphine treatment did not differ from morphine-naive mice in their response to piribedil. The injection of cyclo(Leu-Gly) on the third day of morphine treatment, at a time when physical dependence and tolerance could be demonstrated, did not alter either the signs of physical dependence and tolerance, or DA receptor sensitivity. These data indicate that cyclo(Leu-Gly) administered prior to morphine administration in mice prevents the increase in "DA receptor sensitivity" which accompanies the development of physical dependence and tolerance to morphine.

This work was supported by U.S. HS Grant AM-18399, by NSF Grant GB-42753 and BNS-76-1129, and by the Ill. Dept. Ment. Hlth. and Develop. Disabil. Grant 904-02.

1818 INTERACTION OF SUBSTANCE P WITH VARIOUS TREATMENTS MODIFYING CATECHOLAMINERGIC SYSTEMS.

Daniel B. Rondeau*, François B. Jolicoeur*, George Fouriezos* and A. Barbeau. Dept. Neurobiol., Clin. Res. Inst. of Mtl., Montreal, Quebec, Canada.

There is growing evidence that the undecapeptide substance P (SP), among other peptides having CNS effects, may functionally interact with the neurochemical mechanisms of the basal ganglia. In the present study, intraventricular injection of SP in a dose of .30 μg/rat increased motor activity in rats rendered hypokinetic by bilateral microinjections of 6-hydroxydopamine into the anterolateral hypothalamus. Behavioral observations indicated that grooming and not locomotion was mainly responsible for the greater activity scores. The reversal of the hypokinesia produced by administration of apomorphine, 1 mg/kg sc, to these 6-OHDA treated rats was not potentiated by SP.

Locomotion, grooming and rearing in a 16 squares open field (88 X 88 X 60 cm) was recorded in rats following intraventricular injection of SP in doses of .60 and 2.5 μg/rat. The lower dose of the peptide significantly increased locomotion and grooming. The effects of the same doses of the peptide on the hypokinesia induced by α-methyl-para-tyrosine, phenoxybenzamine and haloperidol were then examined. SP did not affect the behavioral depression produced by α-methyl-para-tyrosine (250mg/kg) and phenoxybenzamine (20 mg/kg). However, SP systematically reversed the decrease in locomotor activity induced by a relatively small dose of haloperidol (.1 mg/kg). On the other hand, SP did not counteract the hypokinesia and catalepsy resulting from the administration of a higher dose of this dopamine antagonist (3 mg/kg).

These results will be examined in light of the hypothesis that peptidergic pathways may exert a trophic modulation on catecholaminergic functions and may contribute to the pathogenesis of the extrapyramidal disorders.

1819 BOVINE ADRENALS CONTAIN HIGH LEVELS OF ENKEPHALINS AND EVEN HIGHER LEVELS OF SEVERAL PUTATIVE ENKEPHALIN PRECURSORS.

J. Rossier, R.V. Lewis*, A.S. Stern*, S. Stein* and S.Udenfriend*. Roche Institute of Molecular Biology, Nutley, NJ, 07110.

Adrenal medullas from several species have been shown to contain enkephalin-like materials by radioimmunoassays and by immunohistology. Using HPLC and a fluorescamine detection system, we have now shown that bovine adrenals contain Met^5-enkephalin and Leu^5-enkephalin. One hour after sacrifice bovine adrenal medullas were homogenized in 1 N acetic acid, 20 mM HCl supplemented with 0.1% mercaptoethanol, 1 μg/ml PMSF and 1 μg/ml pepstatin. After gel filtration on a G-75 column, fractions with M_r below 1000 were analyzed by HPLC on Lichrosorb RP-18 eluted with gradients of 1-propanol in 0.5 M formic acid, 0.4 M pyridine, pH 4. Two peaks corresponding to Met^5-enkephalin and Leu^5-enkephalin were obtained. These peaks were characterized by radioreceptor assay, two different enkephalin radioimmunoassays and amino acid composition. A typical preparation from 3 adrenals (6.5 gm) contained 1.57 nmol/gm Met^5-enkephalin and 0.28 nmol/gm of Leu^5-enkephalin. Similar values are found in the rat striatum. We have also prepared chromaffin granules which were found to account for all the enkephalin content of the adrenals.

The existence of putative precursors for enkephalins in the adrenal was also investigated. Adrenal extracts were submitted to gel filtration on G-75 and each fraction was incubated with TPCK trypsin in order to generate active opiate peptides. In the absence of trypsin none of the fractions over M_r 5000 were found to contain opiate activity. Trypsin treatment produced no opiate activity in the void volume fractions but did so in all the fractions with M_r between 20,000 and 1,000. Treatment of these fractions with trypsin yielded a total of 3.14 nmol Leu^5-enkephalin equivalent/gm of adrenals in the radioreceptor assay, When a radioimmunoassay with a N-terminal Met^5-enkephalin serum (JR235) was used, a total value of 7.0 nmol/gm Met^5-equivalent was found. When a C-terminal Leu^5-enkephalin serum (RB92) was used, a total value of 0.13 nmol Leu^5-equivalent was found after trypsin. Trypsin digests of several fractions with M_r between 20,000 and 1,000 were analyzed on HPLC and found to yield two peaks of opiate activity neither of which corresponded to Met^5-or Leu^5-enkephalin, or β-LPH 61-69. Gel filtration of acid extracts of chromaffin granules displayed nearly the same pattern with one major difference: trypsin digest of the 20,000 M_r fractions yielded 3 times less opiate activity than similar fractions of the whole adrenal medulla. Adrenal medulla extracts contained no β-endorphin or its precursors, β-LPH and pro-opiocortin. All these findings are consistent with our previous reports that β-endorphin and the enkephalins arise via different pathways. J.R. is Charge de Recherche INSERM (France)

1820 INTERANIMAL TRANSFERABILITY OF LEARNED AVERSION TO .1% SACCHARIN.

Lawrence Scrima*, David T. Corey* and Alfred Choo* (SPON: Peter L. Carlen). Dept. Psych. & Biol., York Univ., Downsview, ON, Canada

Interanimal transfer of brain extracts has been used in studies aimed at elucidating the role of neuromolecules in learning and memory. Problems associated with this approach have centered around the validity of the selected conditioned behaviors as representative of learning and the prevalence of confounding stressful variables. The selection of a well defined behavior and paradigm that keeps stress variables to a minimum is crucial. Taste aversion is a paradigm of this nature. The purpose of our investigation was to test the interanimal transferability of taste aversion learning in Wistar rats.

Experimental donors (ED) were injected intraperitoneally (IP) with lithium chloride (aversive) after 30 min access to .1% saccharin on 2 consecutive days. Two hrs after the second conditioning, ED were sacrificed by decapitation, brains homogenized, centrifuged and the supernatant lyophilized, all under cold conditions. Control donors (CD) underwent the same procedures except that they had access to tap water (Experiment 1) or were injected 90 min before access to .1% saccharin (sham conditioning)(Experiment 2 & 3). In each experiment (Experiment 3 within parentheses), recipients (ER & CR) were given 30 min access to .1% saccharin 12(24) hrs after the subdural (IP) injection. Recipients were given a lithium chloride injection IP 3 hrs after access to saccharin started. Twenty-eight hrs later and each subsequent day at the same time, recipients had simultaneous 6(1) hr access to .1% saccharin and tap water after taking licks from each solution.

Analysis of variance for the group X trial interaction indicated that ER had significantly lower saccharin consumption than CR (trials 1-22) in Experiment 1 ($p<.05$); no difference in Experiment 2; tended to drink less saccharin (trials 1-35) in Experiment 3 ($p<.1$); and had highly significant lower saccharin consumption (trials 1-22) in Experiments 1 and 3 combined ($p<.01$) with no differences due to procedure disparities.

The independent and pooled data from Experiments 1 and 3 suggest that the brain extracts from ED fostered an enhanced aversion to .1% saccharin in ER. Since saccharin consumption of ER and CR converge during later trials in these two experiments, the results appear to be related to learning rather than some permanent change. In Experiment 2, a convulsive and lethargic reaction was observed after subdural injection; this did not occur in either Experiment 1 or 3. Results from Experiment 2 may have been confounded by this reaction.

This paradigm has potential as a model for behavioral-neuromolecular investigations of the interanimal transfer of taste aversion (.1%, .5%, etc saccharin, maple, etc) and also those to purify and study mechanisms of action of such putative neurochemicals.

1821 PEPTIDE HORMONE EFFECTS IN THE ABDOMINAL GANGLION OF APLYSIA CALIFORNICA. Ronald L. Seaman†, Robert L. Moss and Martin J. Lynch*, Dept. of Physiology, University of Texas Health Science Center at Dallas 75235. †Present Address: Biomedical Research Group EME/STL, Engineering Experiment Station, Georgia Institute of Technology, Atlanta, Georgia 30332.

The abdominal ganglion of Aplysia californica was used to investigate the effects of peptides on the firing rates of invertebrate neurons. Abdominal ganglia from summer animals were studied in artificial seawater at 22 to 24°C. The peptides were applied at 1 μM in artificial seawater.

About one-half of the tested white-cell neurons (R3-R13) responded to luteinizing hormone-releasing hormone (LHRH, Ayerst). Responses to the bath applications of this peptide were increases in firing rate which lasted 25 to 80 minutes. The increased rate persisted if the bath was returned to normal seawater. In one instance, a second application of LHRH applied at 80 minutes after an initial application produced a second increase in firing rate. The absence of a change in firing rate by the remaining white-cell neurons suggests that, in terms of LHRH sensitivity, there may be two types of white cells.

The activity of other neurons in the abdominal ganglion changed in the presence of peptides. Application of LHRH altered the firing pattern of burster L2 but did not affect activity in bursters L10 and R15. The firing of a darkly pigmented neuron near R15 slowed and stopped in the presence of Substance P (Bachem). Activity did not resume for this cell when the bath was returned to normal seawater.

Some neurons in the abdominal ganglion of Aplysia californica are thus sensitive to the two peptide compounds tested. Interneurons may be involved in some of the responses, but since the white cells have no synaptic inputs, the effects on them are probably direct. The effects, when observed, lasted for several minutes and continued after the peptide in solution had been removed. Both LHRH and Substance P are present in mammalian nervous systems. Their actions on Aplysian neurons suggest these neurons as potential models for the membrane effects of these peptides. The sensitivity of invertebrate neurons to mammalian hormones may be more common than originally thought. (Supported by a Biomed. Res. Support Grant through UTHSCD to RLS, Program Project HD09988 to RLM, and NIH 4-S07-RR-05426-17.)

1822 PATHWAYS IN MOUSE AND RAT BRAIN CONTAINING VASOACTIVE INTESTINAL POLYPEPTIDE (VIP): AN IMMUNOCYTOCHEMICAL STUDY. Katherine B. Sims*, Donald L. Hoffman*, Earl A. Zimmerman, and Sami I. Said* (SPON: Virginia M. Tennyson), Dept. Neurol., College of P&S, Columbia Univ., NY 10032, and Dept. Med., Univ. Texas Health Science Center at Dallas, TX 75235.

Vasoactive intestinal polypeptide (VIP), a 28 amino acid residue peptide originally isolated from gut, is known to be present in brain by bioassay, radioimmunoassay and immunocytochemistry. By immunofluorescence it was previously demonstrated in cell bodies in cerebral cortex and amygdala and in nerve fibers innervating cerebral blood vessels and a number of nuclear regions including amygdala, accumbens, and suprachiasmatic hypothalamus and parabrachial brainstem. Although reactive perikarya were reported in arcuate region of mouse hypothalamus, they were not found in rat. We have studied both mouse and rat brains by immunoperoxidase technique using peroxidase-anti-peroxidase complexes (PAP) on 6 μm deparaffinized Bouins immersioned-fixed sections on glass slides and unmounted at 50 μm cryostat sections from animals perfused with paraformaldehyde-lysine-periodic acid and penetrated with Triton X-100. Preabsorption of anti-VIP with synthetic VIP abolished all reactivity while equimolar secretin, which shares structural homologies, had no effect. All previous immunocytochemical findings were confirmed except for the arcuate nucleus which was devoid of reactive cells. Instead, in both species, cell bodies containing VIP were found in the basal portions of the suprachiasmatic nucleus and their projections could be traced dorsally to the paraventricular, periventricular, and dorsomedial nuclei of the hypothalamus and on to the periventricular thalamus. In all other respects both species were identical as well. A much more extensive distribution of VIP was found than previously appreciated. Cell bodies were found to be scattered throughout the caudate, in central grey of the midbrain particularly ventral to the aqueduct and extending ventrally in the midline, in ventrolateral medulla in the nucleus of the tract of the trigeminal and extending dorsally and laterally into its substantia gelatinosa. A few cell bodies were also found in preoptic hypothalamus and bed nucleus of the stria terminalis. Many fibers were found in these and other regions including the entire length of the spinal cord. The most dense projections were found in bed nucleus, central nucleus of the amygdala, and nucleus of the solitary tract in the medulla. It is apparent that VIP, like substance P and enkephalin, is widely distributed in brain and spinal cord in multiple pathways, and like other peptides thus far studied does not appear to innervate cerebellum.

1823 IMMUNOREACTIVE THYROTROPIN RELEASING HORMONE (TRH) OUTISDE THE HYPOTHALAMUS REALLY IS TRH. Eliot Spindel* and Richard Wurtman (SPON: M. J. Fernstrom)

Massachusetts Institute of Technology, Cambridge, MA 02139

Controversy exists concerning the identity of immunoreactive TRH in brain areas outside the hypothalamus. To establish its identity we analyzed regions of rat brain by thin layer chromatography (TLC), ion exchange chromatography, high pressure liquid chromatography (HPLC) and bioassay. By all methods of analysis, all TRH immunoreactivity corresponded exactly to that of synthetic TRH.

Tissue was extracted with either 2N acetic acid or 90% methanol; then subjected to one of three different HPLC separations or two different TLC separations. Ion exchange chromatography on SP sephadex was used to further purify acetic acid extracts prior to TLC or HPLC. For HPLC analysis, tissue extracts were lyophilized, resuspended in the HPLC solvent and injected into the HPLC. Timed fractions were collected, lyophilized, and reconstituted for TRH radioimmunoassay (RIA). Tritiated TRH or 3-methyl TRH was used for an interanl standard. The following three reverse phase HPLC systems were used at 30°C, 2 ml/min with a Waters microbondapak C18 column: 1)20% acetonitrile in 0.01 N NH4Ac, pH 4.0; 2) 0.5% acetonitrile in 0.01 N NH4Ac, pH 4.0; 3) 2.75% acetonitrile + 0.1% hexane sulfonic acid in 0.02 N acetic acid. The high acetonitrile content of system one would have eluted any large peptides which cross reacted with the TRH antibody. System three uses hexane sulfonic acid to form ion pairs with the imidazole proton of TRH and is extremely selective for small, positively charged peptides.

For TLC analysis, methanol extracts of brain tissue were spotted directly on the plates; acetic acid extracts were lyophilized (with or without preliminary ion exchange purification), resuspended in methanol and spotted. Two solvent systems were used: 1) methanol:methylene chloride (200:300) on Whatman K1 plates or 2) chloroform:methanol:NH4OH (60:25:5) on Whatman LK5D plates. After development, 0.5 cm sections of the plates were eluted directly into phosphosaline for TRH RIA. Tritiated TRH was used for an internal standard.

Analysis of extracts of hypothalamus, preoptic area, septum, brain stem, striatum, and pancreatic islets by the methods described above showed that all TRH immunoreactivity corresponded exactly and only to synthetic TRH. Thus despite the low molecular weight of TRH, the TRH RIA is highly specific.

1824 CORTICAL AND HIPPOCAMPAL SPREADING DEPRESSION INDUCED BY INJECTIONS OF MET- AND LEUENKEPHALIN AND BY D-ALA^2-METENKEPHALINAMIDE. U. Sprick*, K. Ornstein*, M.-S. Oitzl* and J.P. Huston (SPON: A. Borbély). Institute of Psychology, University of Düsseldorf, 4000 Düsseldorf, FRG.

Leuenkephalin, metenkephalin and d-ala^2-metenkephalinamide were microinjected into the hippocampus and neocortex of 250 rats to examine the effects on EEG and slow wave potentials. All substances were found to elicit spreading depression (SD) in both the neocortex and hippocampus. A dosage required to elicit spreading depression in at least 50% of the trials was determined by testing doses of 100μg/μl, 50μg/μl, 12.5μg/μl, 6.25μg/μl and 3.125μg/μl, always injected in 1μl of distilled water.

The following minimal doses were required for the induction of SD in at least 50% of the trials:

	Hippocampus	Neocortex
Leuenkephalin	12.5 μg	6.25 μg
Metenkephalin	100.0 μg	100.0 μg
D-Ala^2-Metenkephalinamide	12.5 μg	6.25 μg

Lower doses were required to induce hippocampal seizure activity in at least 50% of trials: leuenkephalin - 12.5 μg, metenkephalin - 50 μg, and d-ala^2-metenkephalinamide - 6.25 μg. Injection of naloxone prevented the elicitation of spreading depression.

The differences between the various enkephalins in terms of the effective dosages to induce spreading depression could be related to different receptor or acceptor densities.

It should be noted that some of the various reported behavioral effects of intracranial injections of the enkephalins could be artefacts of hippocampal and/or cortical spreading depression.

1825 DEMONSTRATION OF OPIATE BINDING IN AN INVERTEBRATE ORGANISM, M. EDULIS. George B. Stefano, Richard M. Kream*, R. Suzanne Zukin and Edward J. Catapane. Dept. Biochem. Albert Einstein Coll. of Med., Bronx, N.Y. 10461.

Opiate action has been investigated in the marine mollusc Mytilus edulis as a model invertebrate system. The opioid ligands, I-125-labelled-levallorphan (Lev) and FK 33-824 (a sulfoxide-carbinol derivative of methionine enkephalin with enhanced stability) bind stereospecifically and with high affinity (K_D's = 3.5 nM and 4.0 nM, respectively) to M. edulis pedal ganglia homogenates. Specific binding constitutes approximately 75% of total binding for both ligands at 4C for 1 nM Lev and FK 33 824. In addition, the ability of a series of enkephalin derivatives, including D-ala-met-enkephalin and FK 33 824, to alter dopamine levels in M. edulis was examined. All peptides examined produced an increase in dopamine levels of as much as 50%. D-ala and FK 33-824 increased dopamine levels at a much lower dose due to their resistance to proteolytic attack. Naloxone blocked the effects of the peptides on dopamine metabolism.

1826 EVIDENCE FOR ENDORPHIN MODULATION OF LOCUS COERULEUS

Howard K. Strahlendorf, Jean C. Strahlendorf, and Charles D. Barnes. Department of Physiology, Texas Tech University School of Medicine, Lubbock, Texas 79430.

The locus coeruleus (LC) has been shown to contain a high density of opiate receptors. Systemically administered and ionotophoretically applied opiates exert a potent depressant action on coerulear cell firing rate. Anatomical and immunohistochemical studies have revealed the existence of β-endorphin containing axons emanating from cell bodies localized in or near the arcuate nucleus (Arc.N.) of the hypothalamus which project to various brain sites including LC. We have therefore investigated the effect of arcuate nucleus stimulation on LC activity.

Extracellular LC unit activity was recorded with metal microelectrodes in α-chloralose anesthetized cats. Brief conditioning trains (25-300 μA, 3 shocks, 100 Hz) delivered to the Arc.N. produced profound inhibition (average 1000 msec, N= 30) of spontaneous coerulear cell discharges. Intravenously administered naloxone (Nal) (2.5 - 5.0 mg/kg) reduced by 50% the period of arcuate-induced inhibition. In three instances Nal totally eliminated arcuate-elicited inhibition. Additionally, naloxone always increased spontaneous cell activity. In contrast to Nal systemically administered morphine (Mor) inhibited spontaneous LC unit activity in a dose related fashion and augmented the hypothalamic derived inhibition. Nal 5mg/kg reversed Mor activity to beyond pre-drug levels. To characterize the stereospecificity of the response, dextrorphan was administered. This inactive enantiomer failed to mimic morphine actions on LC cells. The results suggest that LC may be tonically influenced by the β-endorphin system originating from the arcuate nucleus.

Supported in part by the Tarbox Parkinson Disease Institute of Texas Tech University School of Medicine and NIH Grant HL7289.

1827 INHIBITION OF EVOKED UNIT DISCHARGES IN THE PERIAQUEDUCTAL GRAY BY HYPOTHALAMIC STIMULATION

Jean C. Strahlendorf, Howard K. Strahlendorf, and Charles D. Barnes. Department of Physiology, Texas Tech University School of Medicine, Lubbock, Texas 79430.

Available anatomical and immunohistochemical evidence supports the concept of an endorphin containing neuronal system which has its origin in the hypothalamic arcuate nucleus (Arc.N.), and projects via long axons to various brain structures including the periaqueductal gray (PAG). That the PAG is an important structure with regard to opiate analgesia derives from studies demonstrating a high density of opiate receptors within this area and numerous investigations showing the PAG to be analgesically active when tested with microinjected opiates. Beta-endorphin is particularly active in this sense, inducing intense prolonged analgesia when applied to the PAG. We have therefore investigated the effect Arc.N. activation on PAG activity.

Single cell activity was recorded with stainless steel microelectrodes stereotaxically directed at the ventral-lateral aspects of the mesencephalic PAG in chloralose anesthetized, paralyzed, and artifically ventilated cats. Evoked discharges were incurred by strong electrical shocks (> 2.0 mA) applied to the sural nerve exposed in the popliteal fossa. Brief trains (100 Hz, 3 pulses, < 500 μA) of conditioning stimuli were applied to the Arc.N. ipsilateral to the recording side. Four units encountered displayed spontaneous activity. Arc.N. stimulation produced a period of total cessation of cell firing lasting 250 msec in one instance but failed to affect the 3 remaining units. Eighteen cells which discharged in response to sural shocks were tested with Arc.N. stimulation (C-T paradigm). Arc.N. suppressed sural evoked discharges by an average of 54% (range 3-100%). Intravenously administered naloxone (Nal) 2 to 5 mg/kg failed to markedly attenuate Arc.N. elicited inhibition and did not affect sural evoked activity. These results indicate that the Arc.N. is capable of inhibiting evoked PAG single unit activity, but unlike effects observed in locus coeruleus (this meeting) this inhibition is not changed by the narcotic antagonist Nal.

Supported in part by NIH Grant HL7289 and the Tarbox Parkinson's Disease Institute of Texas Tech University School of Medicine.

1828 RADIOIMMUNOASSAY OF ENKEPHALIN: IMMUNOREACTIVE ENKEPHALIN LEVELS IN CAT SPINAL CORD. Tsung-ping Su*, Charles W. Gorodetzky and James A. Bell*. NIDA Addiction Research Center, Lexington, Ky. 40583

Antibody against methionine-enkephalin (Met-Enk) was produced in rabbits and used in radioimmunoassay (RIA). The antibody obtained gave a sensitive assay with 50% displacement of ^{3}H-Met-Enk at a concentration of 7 nM of unlabeled Met-Enk. The antibody was 1/35 as reactive to Leu-Enk and less than 1/1500 as reactive to β-endorphin as to Met-Enk.

In order to explore the involvement of opioid peptide in spinal neuronal function, the enkephalin RIA was used to determine the immunoreactive enkephalin content in cat spinal cord. The L_7-S_1 segments of the cat spinal cord were chosen for analysis of enkephalin levels, because intraspinal microinjection of Met-Enk into this area has been shown to depress the nociceptive C-fiber reflex recorded from the L_7 and S_1 ventral roots in the acute decerebrate spinal cat (Bell et al., Fed. Proc. 37, 763, 1978). The distribution of enkephalin in the dorsal and ventral sections of spinal cord was studied. The L_7-S_1 segments were dissected out as a unit, divided into dorsal and ventral sections at the level of the central canal, and processed for RIA. In agreement with an immunohistochemical report (Simantov et al., PNAS 74, 2167, 1977), our data indicate that the enkephalin content in the dorsal section of spinal cord is higher than that in the ventral section. The table below summarizes the levels of enkephalin found in dorsal and ventral sections of the spinal cord in three cats. Levels of enkephalin were expressed in terms of arbitrary enkephalin units (U-Enk; Rossier et al., PNAS, 74, 5162, 1977). One U-Enk = 1 f·mole Met-Enk, if sample contains no Leu-Enk.

Enkephalin Levels (U-Enk/mg wet tissue)

Cat #	1	2	3
Dorsal Section	412	515	442
Ventral Section	188	104.5	205.5

This study demonstrates a sensitive method for measuring spinal cord enkephalin levels and presents data which support a hypothesis that enkephalinergic neurons are present in the dorsal horn of the spinal cord of the cat.

1829 **Enkephalinase: Preliminary Characterization and Effect of Phosphorylation.** Sue Sullivan,* Joachim D. Raese,* Huda Akil,[1] Deborah Blacker* and Jack D. Barchas. Dept. Psychiatry, Sch. Med., Stanford Univ., Stanford, CA 94305; [1]Ment. Health Res. Ctr., Univ. Mich., Ann Arbor, MI 48109.

Metabolism of the enkephalins in brain tissue can occur via at least two different enzymatic routes. A soluble aminopeptidase can liberate the N-terminal tyrosine and a membrane-bound endopeptidase can cleave the gly-phe bond, thus liberating the tripeptide tyr-gly-gly (TGG) and phe-leu or phe-met. This endopeptidase (enkephalinase) has subcellular and regional brain distributions which correlate with the opiate receptor, whereas the amino peptidase does not. Enkephalinase is thought to be specific for the endogenous enkephalinergic system. It is a metalloenzyme which is completely inhibited by 1,10 phenanthroline (1mM) and partially inhibited by EDTA (1mM). EGTA has little effect on enzymatic activity indicating a lack of calcium dependence. The metal cofactor is apparently very strongly bound as extensive dialysis does not affect enzymatic activity. Enkephalinase is inhibited by various enzyme resistant analogues of the enkephalins and by the peptides tyr-gly, phe-leu and gly-gly-dlphe. Preliminary evidence suggests that enkephalinase is inhibited by phosphorylating conditions. Further experiments are in progress to elucidate the mechanism of this inhibition.

1830 EFFECTS OF NALOXONE ON COPULATION IN RATS AND THE ROLE OF ENDOGENOUS OPIATES IN A SPONTANEOUS REWARDING BEHAVIOR. Henry Szechtman*, Rabi Simantov* and Moshe Hershkowitz. Depts. Isotope Research and Genetics, The Weizmann Institute of Science, Rehovot, ISRAEL

Morphine has two well known behavioral effects: it induces analgesia and it induces euphoria. Endogenous opioid peptides, endorphins and enkephalins, compete with morphine at specific receptor sites in the brain and therefore should also possess these two behavioral effects. Indeed, it has been shown that injections of endorphins or enkephalins induce analgesia, and that rats self administer enkephalins indicating that the peptides have also rewarding effects. Yet in most behavioral paradigms designed to determine the physiological function of the endogenous opiates, there is no possibility for "analgesia" and "euphoria" (reward) to occur simultaneously. Both phenomena are part of copulation: there is profound analgesia before orgasm and hypersensitivity immediately afterwards; there are also many indications that coitus can be highly rewarding. Therefore we investigated whether mating behavior of male rats is altered by the specific opiate receptor antagonist, naloxone, and whether mating alters the content of opioid peptides in different brain regions and the pituitary. In 3 independent replications, naloxone (4 mg/kg, i.p., 5 minutes before test), altered significantly, only one parameter of copulatory performance: it extended the refractory period after an ejucalation (10-17% increase in the postejaculatory interval). This suggests that the blockade of opiate receptors may had extended the period of hypersensitivity following ejaculation. Measurement of opioid peptides (radioreceptor assay) indicated that there was a significant decrease in the content of opioid peptides in the midbrain but not in the hypothalamus, caudate or pituitary (compared to unmated controls). Thus opioid peptides may be released during sexual behavior producing simultaneously: a) a decrease in aversiveness of intense sexual stimulation, and b) an enhancement of its reward value.

1831 BOMBESIN DISRUPTS THERMOREGULATION IN RATS AT HIGH AND LOW ENVIRONMENTAL TEMPERATURES. Yvette Taché*, Quentin J. Pittman and Marvin Brown (SPON: W. Vale). Peptide Biology Laboratory, The Salk Institute, La Jolla, CA 92037.

Bombesin, a tetradecapeptide originally isolated from frog skin causes hypothermia when given intracisternally to rats at low ambient temperatures (T_A). The demonstration of bombesin-like immunoreactivity and bombesin-specific binding sites in rat brain raises the possibility that an endogenous bombesin-like peptide might play a role in thermoregulation in the rat. We have, therefore, undertaken the following studies to assess the action of bombesin on thermoregulation in unrestrained, unanesthetized rats.

Male Sprague-Dawley rats (250-300g) were implanted with 22 ga lateral ventricular cannulas. Following a minimum of 5 days recovery from surgery, rats were placed in individual cages in an environmental room where T_A could be precisely regulated. Rectal temperatures (T_R) were recorded at 30 min intervals from 60 min to a minimum of 90 min after injection. Bombesin, or an inactive analog were injected in a volume of 10µl of sterile, pyrogen-free artificial CSF made up fresh prior to injection.

The effects of intraventricular (ivt) bombesin (1ng-10µg) on T_R were tested at T_A's of 4°, 24°, 31°, 33° and 35°C. At all T_A's tested, control injections of the bombesin analogs [D-Trp^8]-bombesin or [D-Leu^{13}]-bombesin were without effect on T_R. At 4°C, bombesin caused a reduction in T_R with a return to normal T_R within 3.5 hr following the threshold dose of 50ng. Higher doses caused a more profound and longer lasting hypothermia with T_R decreasing by a maximum of 7°C at doses of 500ng-1µg. At T_A = 24°C, 1µg bombesin reduced T_R by 2°C, whereas administration of this amount at T_A's of 31 and 33°C was without effect on T_R. However, at T_A = 35.5°C, 1µg bombesin caused T_R to increase by 1.6°C (0.5-2.1°C, n = 11) with no further increase apparent at a dose of 10µg bombesin. The hyperthermia observed at high T_A could be reversed to a hypothermia by transferring the rats to a T_A of 4°C within 1 hr of drug administration.

These results confirm and extend previous findings by demonstrating a reversible hypothermic effect of bombesin administered ivt to the unanesthetized rat. Administration of bombesin to rats exposed to high T_A's revealed a hyperthermic action for this peptide. These findings demonstrate a disruptive effect of bombesin on thermoregulation at temperatures above and below thermoneutrality and suggest an inhibitory action on both heat production and heat loss pathways.

1832 EFFECT OF STRESS ON THE CONCENTRATION OF SOMATOSTATIN (SRIF) IN DISCRETE HYPOTHALAMIC AND EXTRAHYPOTHALAMIC REGIONS OF THE RAT. L. Cass Terry and William R. Crowley. Dept. Neurology & Pharmacology, Univ. Tenn. Center Health Sciences, Memphis, TN 38163.

Plasma growth hormone levels fall and remain low for several hours after stress in the rat. This effect is partially reversed by iv administration of antiserum to somatostatin. The present study was undertaken to determine the role of CNS SRIF in stress-induced suppression of growth hormone (rGH) secretion.

Adult male Sprague-Dawley rats kept on 14:10h light:dark cycle with food and water ad libitum were forced to swim for 30 minutes beginning at 1000h in a tank filled with water at 37.5°C. They were sacrificed immediately afterwards by decapitation. Their brains were snap-frozen and serum collected from trunk blood. Serum rGH was assayed using NIAMDD RIA kits. Somatostatin was determined in 10 microdissected, individual brain nuclei by a highly specific and sensitive radioimmunoassay.

Serum rGH was significantly ($p<.001$) lower in stressed animals compared to "nonstressed" controls (6.4± 1.0 vs 49.5± 12.5 ng/ml respectively). Swimming stress resulted in a significant reduction of SRIF in the median eminence*(ME)($p<.001$) and the medial portion of the caudate nucleus*(MCN)($p<.05$)(see table). There were no significant changes of SRIF in the periventricular n.(PVN), arcuate (ARC), ventromedial (VMN), medial preoptic (MPO), suprachiasmatic (SCN), accumbens (ACC), central amygdaloid (CAN) or interstitial stria terminalis (NIST) nuclear regions.

SRIF (pg/ug protein) + SEM

	ME	PVN	ARC	VMN	MPO
Stress	*362± 32.6	53.5± 5.5	56.9± 4.8	14.4± 1.6	10.1± 1.6
Control	679± 96.2	56.8± 2.8	67.5± 7.3	17.2± 1.5	11.9± 1.7

	SCN	NIST	MCN	ACC	CAN
Stress	20.5± 2.2	31.9± 3.1	*9.6± 0.5	22.4± 2.9	14.6± 1.6
Control	24.2± 2.6	31.8± 2.4	11.6± 0.9	24.8± 1.9	20.1± 3.2

Swimming stress resulted in a significant reduction of SRIF in two discrete brain regions, the median eminence and medial aspect of the caudate nucleus. These results suggest: (1) stress-induced suppression of growth hormone secretion in the rat is mediated by the release of somatostatin from nerve endings in the median eminence into the adenohypophyseal portal system to inhibit pituitary release and, (2) somatostatin-containing nerve fibers which innervate the caudate nucleus may influence extrapyramidal mechanisms associated with prolonged physical stress. (Supported by a New Investigator Grant from the Univ. Tenn.)

1833 IMMUNOHISTOCHEMICAL VISUALIZATION OF ENKEPHALIN AND CHOLECYSTOKININ FIBERS IN HIPPOCAMPUS FOLLOWING SELECTIVE DENERVATION. Donald R. Thorne*, Stephen W. Scheff, Dwight Hand*, Robert Elde and Carl W. Cotman. Dept. of Psychobiol., U.C., Irvine, CA 92717

Several immunohistochemical studies have reported the immunoreactivity of various peptides in hippocampal formation of the rat. Met-enkephalin (M-Enk) and cholecystokinin (CCK) are particularly prominent in the CA2 area of the hippocampus. It was of interest to determine whether these immunoreactive fibers were a) intrinsic to the hippocampus and b) would display a sprouting response similar to other neuronal afferents.

Young adult rats were subjected to a variety of surgical procedures which removed all or only part of the afferent pathways to the hippocampus. Unilateral lesions of the entorhinal cortex eliminated the major cortical inputs while an aspiration of the fimbria-fornix removed those inputs arising from the contralateral hippocampus and the septal nuclei. Additionally, some animals were given a transection of the dorsal psalterium, thus removing the crossed temporo-ammonic tract and an aspiration of the ventral, ipsilateral hippocampus was included. Still other animals were injected with 0.8 µg kainic acid unilaterally which totally destroyed regions CA3, CA4 and portions of CA1 pyramidal cell region. Antisera directed against either M-Enk or CCK were used for immunohistochemical peptide localization utilizing an immunoperoxidase staining technique on 10 µm thick frozen sections fixed with 4% paraformaldehyde in phosphate buffer.

Normal adult animals demonstrated positive staining for both M-Enk and CCK at all levels of the hippocampus with the staining restricted primarily to the CA2 pyramidal cell zone and with minimal staining observed in the subiculum. Adult, lesioned animals demonstrated staining patterns which were indistinguishable from sham-operated controls at the light microscopic level. In addition, no other area of the hippocampus was observed to contain positive staining for M-Enk or CCK following the surgical or chemical lesions. However, animals injected with kainic acid at 5 days of age and sacrificed as adults, demonstrated a marked deficit in positive staining for both CCK and M-Enk. Studies have also shown that immature rats (less than 30 days of age) demonstrate a striking difference in staining intensity from adult animals.

The present findings suggest that the immunoreactive fibers containing M-Enk and CCK are intrinsic to the hippocampus and are probably associated with small interneurons in the CA2 region. In addition, these peptide-containing fibers do not appear to sprout outside their normal terminal zones. (Grants MH19691)

1834 D-ALA^2-METHIONINE ENKEPHALINAMIDE AND MORPHINE ARE ANTICONVULSANT AFTER CENTRAL ADMINISTRATION IN RATS. F.C. Tortella, A. Cowan, and M.W. Adler, Dept. of Pharmacology, Temple University School of Medicine, Philadelphia, PA 19140.

Large subcutaneous doses of morphine and several other postulated µ receptor agonists raise the seizure threshold of rats to flurothyl, a volatile convulsant (Adler *et al*, JPET *198*:655, 1976; Cowan *et al*, Develop. in Neurosci. *4*:469, 1978). Yet, the central administration of enkephalins, β-endorphin, or morphine has been shown to produce an epileptiform EEG pattern that is not, however, associated with overt behavioral convulsions (Urca *et al*, Science *197*:83, 1977; Henriksen *et al*, Proc. Natl. Acad. Sci. *75*:5221, 1978; Tortella *et al*, JPET, in press). In our view, these findings may be simply another instance of a dissociation between EEG changes and behavioral events. In the present study, we administered morphine or D-ala^2-met enkephalinamide (D-ala) intracerebroventricularly (icv) to rats and now report that both compounds raise the seizure threshold in the flurothyl test.

Male, albino Sprague Dawley rats (initially 180-200 g) were implanted with the icv cannulae aimed at the right lateral ventricle 7 days prior to testing. Morphine (5 and 20 µg), D-ala (10, 40, and 80 µg), or sterile water was injected manually in a 5- or 10-µl volume over a 60-sec time period. Using dose-effect and time-course EEG data previously reported by Tortella *et al* (JPET, *206*:636, 1978), we monitored seizure threshold at the time of peak effect for both compounds: 20 min postinjection for D-ala (all doses) and 75 or 130 min postinjection for 5 and 20 µg morphine, respectively. With groups of 6-9 rats, both doses of morphine increased seizure threshold by 14% above the control range of 370-420 sec. A dose of 10 µg of D-ala produced a similar 14% rise in seizure threshold; 40 µg and 80 µg of D-ala raised seizure threshold above control by 49% and 67%, respectively. Time-effect studies may reveal even greater anticonvulsant effects. At the time of flurothyl challenge, both D-ala (40 and 80 µg) and morphine (20 µg) induced a *profound* state of behavioral stupor characterized by exophthalmos, immobility and generalized muscle rigidity. Wet-dog shakes occurred only after the administration of D-ala. Pretreatment with naloxone (0.1 and 1.0 mg/kg, s.c.), 15 min before testing, antagonized both the behavioral and anticonvulsant effects.

From these results, we conclude that both morphine and D-ala are anticonvulsant in the rat (when tested at the time of their peak drug effects on EEG and behavior) even though they produce an epileptiform EEG. D-ala is more effective than morphine in this respect.

1835 PEPTIDE HORMONE RELEASE OF STEREOTYPED MOTOR PROGRAMS IN AN INSECT: ROLE OF CYCLIC GMP. James W. Truman, Susanne M. Mumby*, and Susan K. Welch*. Dept. Zool., Univ. Washington, Seattle, WA 98195.

A peptide hormone, the eclosion hormone, triggers a 1.5 hour program of stereotyped behavior when injected into silkmoths. When the peptide is added to the isolated CNS of these animals, it evokes the corresponding program of motor activity (Truman, J.W., 1978, J. Exp. Biol. 74, 151-173).

A series of 3 methylxanthines were tested for their ability to evoke the behaviors in vivo. The relative potencies were isobutylmethylxanthine≫theophylline>caffeine; potencies which were similar to their ability to inhibit the breakdown of cyclic nucleotides in other systems. Also, protection of endogenous cyclic nucleotides by pretreatment of moths with low doses of phosphodiesterase inhibitors markedly enhanced the sensitivity of moths to injected peptide. Injection of cyclic nucleotides into moths caused the typical behavioral responses with cyclic GMP being more than 100 times more potent than cyclic AMP. Exogenous cyclic GMP also acted directly on the isolated CNS to evoke the characteristic motor programs.

Injection of the partially purified peptide into animals was followed by an increase in nervous system cyclic GMP but not cyclic AMP. The increase preceded the first behavioral response to the hormone. The use of various doses of hormone showed that the behavioral effectiveness of each dose was correlated with its ability to cause a cyclic GMP increase. It was concluded that the long term behavioral changes caused by the eclosion hormone are mediated through an increase in cyclic GMP in the nervous system of the moth.

1836 EFFECT OF MORPHINE ON SUBSTANCE P NEURONS IN RAT SPINAL CORD AND BRAIN. Linda L. Vacca, Susan J. Abrahams* and N. Eric Naftchi*. Depts. of Path. & Anat., Med. Coll. GA, Augusta, GA 30912, Lab. Biochem. Pharmacol., IRM, NYU Med. Ctr., New York, NY 10016.

Adult male Sprague-Dawley rats were treated with morphine (3, 10, 40 mg/kg, s.c.) for 3 or 7 days. The effects on substance P-containing neurons were assessed by the Sternberger peroxidase anti-peroxidase (PAP) method and the double bridge PAP method of Vacca et al (J. Histochem. Cytochem. 26: 226, 1978) in the spinal cord and midbrain. Compared with saline and naloxone-treated controls, spinal cord from morphine-treated rats demonstrated increased amounts of immunoreactive substance P (SP) in three regions: substantia gelatinosa (including Rexed's lamina I), Rexed's lamina V, and the ventral horn. Certain midbrain regions, which included the interpeduncular nucleus and A10 area, also exhibited different amounts of immunoreactive SP. The immunoreactivity was found within presumed varicose processes cut in longitudinal and transverse section. The data suggest that morphine can affect the release of intraneuronal substance P. However, not all regions in the brain and spinal cord were affected in the same manner. SP-containing processes which surround the central canal and occur in the substantia nigra were not substantially influenced, and remained similar to those of controls. Such differential effects may reflect regional differences in the numbers and types of opiate receptors or in their pre- and post-synaptic locations. More detailed dose response and opiate binding studies are in progress. In addition, we are examining the effect of morphine on immunoreactive enkephalin-containing neurons. (Acknowledgements: We wish to thank Dr. Susan Leeman for providing us with rabbit anti-SP serum, and Dr. Margaret Kirby for her role in initiating the work at Med. Coll. GA. The work was supported by Med. Coll. GA Biomedical Research Grant 10-16-04-3611-23 and Edmond A. Guggenheim Research Endowment and DHEW-RSA Grant Nos. 16-P-56801/2 and 13-P-57975/2-01).

1837 IMMUNOCYTOCHEMICAL LOCALIZATION OF GASTRIN-CHOLECYSTOKININ-LIKE PEPTIDES IN THE BRAIN AND HYPOPHYSIS OF THE RAT. Jean-Jacques Vanderhaeghen * and Françoise Lotstra * (SPON: E. H. Cantor) Neuropathology Department, Brugmann University Hospital, Free University of Brussels, B-1020 Brussels, Belgium.

Peptidic material reacting with antigastrin 2-17 serum, but of lower weight than gastrin hexadecapeptide has been detected by radioimmunoassay in the central nervous system of various vertebrates (Nature 257 : 604-605, 1975). This material is also present in crude extracts of substance P (Naunyn-Schmiedeberg's Arch. Pharmacol. 305 : 189-190, 1978) and most of it consists in the sulphated COOH-terminal octapeptide of cholecystokinin (Proc. Natl. Acad. Sci. USA 75 : 524-528, 1978).

Using serum raised against sulphated COOH-terminal octapeptide of cholecystokinin, recognizing equally well gastrin heptadecapeptide or sulphated COOH-terminal octapeptide of cholecystokinin, the immunoenzyme histochemical localization of gastrin cholecystokinin-like peptides will be presented in the CNS and hypophysis of the rat, treated and untreated with colchicine.

Neuronal cell bodies and fibers are present in neocortex, hippocampus, amygdala, substantia nigra, nucleus supra opticus and nucleus paraventricularis, nucleus linearis, nucleus raphe dorsalis, nucleus parabrachialis and in A10 region. Fibers are present in thalamus, hypothalamus, in caudate putamen, in brain stem, in posterior horns of spinal cord and in neurohypophysis.

Controls with sera absorbed (solid phase absorption) with oxytocin, vasopressin, neurophysin I, neurophysin II, enkephalin and substance P are positive. Controls with sulphated COOH-terminal octapeptide of cholecystokinin or with gastrin heptadecapeptide are negative.

Studies will be presented using sera raised against enkephalin, substance P, somatostatine, oxytocin, vasopressin neurophysin I and neurophysin II in combination with sera against sulphated COOH-terminal octapeptide of cholecystokinin (double staining technique).

1838 **MET- AND LEU-ENKEPHALINS AND MET-ENKEPHALIN-LIKE PEPTIDES IN THE ADRENAL MEDULLA: STUDIES ON STORAGE, SECRETION, AND SYNTHESIS.** **O.H. Viveros, E.J. Diliberto, Jr.*, E. Hazum*, and K.-J. Chang*. Dept. of Medicinal Biochemistry and Dept. of Molecular Biology, Wellcome Research Lab., Research Triangle Park, N.C. 27709**

Secretion of catecholamines from the adrenal medulla occurs by exocytosis. In this process, fusion of the chromaffin vesicle and plasma membranes is followed by extracellular release of the intravesicular contents. Vesicular proteins and peptides of unknown circulating extramedullary function are secreted along with catecholamines [Kirshner, et al., Mol. Pharmacol. 3: 254 (1967); Viveros, et al., Life Sci. 7: 609 (1968)]. Recently, in a continuing effort to explore the biological significance of these proteins and peptides, we have found enkephalin-like materials (ELM) in adrenomedullary chromaffin vesicles which are secreted by physiological stimuli. ELM, measured as met-enkephalin equivalents, were examined in acetic acid extracts of adrenals from nine mammalian species. The ELM content ranged from a low of 0.29 ± 0.03 nmol/g wet weight in the rat medulla to a high of 21.2 ± 1.2 nmol/g in the dog. These peptides were confined to the medulla of the adrenal gland. Storage in the chromaffin vesicles was indicated by a pattern identical to the catecholamines (CA) and dopamine-β-hydroxylase on differential and on continuous sucrose density gradient centrifugation. Separation of ELM on Sephadex G-50 and by HPLC indicated four peptide peaks of M_r below 2,000; two of these peaks correspond to met- and leu-enkephalin. The ELM are secreted from the perfused dog adrenal by the same stimuli that secrete CA and in the same proportion as contained within the gland. Furthermore, secretion is blocked by Ca^{2+} deprivation and by blockers of CA secretion. Increased splanchnic nerve discharge induced by insulin hypoglycemia depletes ELM and CA in parallel from the cat adrenal medulla. In guinea pigs and cats, low doses of reserpine deplete CA markedly with no immediate change in ELM levels. ELM are elevated three-fold by the second and third day after reserpine when CA are 20% below control. At 10 days, ELM remain elevated by two-fold when CA are still 40% below control. These results suggest that the CA content may be one of the factors regulating synthesis of ELM and that ELM storage in the vesicle precedes CA synthesis and storage. These findings strongly support a role for adrenomedullary enkephalins as neurohormones and suggest that enkephalins may exert important neuroendocrine functions outside the CNS.

1839 ENKEPHALIN IMMUNOREACTIVE SITES IN RAT FOREBRAIN: AN IMMUNOHISTOCHEMICAL STUDY. James K. Wamsley, W. Scott Young III and Michael J. Kuhar. Dept. Pharmacol. Expt. Ther., Johns Hopkins Univ., Sch. Med., Baltimore, Md. 21205.

Our laboratory has recently completed a detailed analysis of enkephalin immunoreactive areas in the rat forebrain. We employed untreated animals as well as animals pretreated (48 hrs) with colchicine (to interrupt axonal transport and thus cause immunoreactive cell bodies to become more apparent) administered by either cerebrointraventricular (50 µg) or peripheral subcutaneous (120-180 µg/gm body weight in two 24 hr periods) injections. The primary rabbit antisera used was directed against methionine-enkephalin, but is thought to also react with leucine-enkephalin containing neurons. The antigen-antibody complexes were visualized by using fluorescent and unlabeled (PAP) antibody techniques.

Our data agree well with the description of enkephalin containing areas reported by other laboratories. We have, however, identified many areas of enkephalin-like immunoreactivity which have not been previously reported. These areas include enkephalinergic cell perikarya located in the pars lateralis and medialis of the nucleus mamillaris medialis, nucleus ventralis corporis geniculati lateralis, nucleus parafascicularis, nucleus anterior and nucleus posterior hypothalami, nucleus periventricularis rotundocellularis and stellatocellularis, nucleus mamillaris prelateralis, nucleus tractus diagonalis (Broca), nucleus septalis fimbrialis, organum vasculosum lamina terminalis, subfornical organ, and the nucleus paratenialis, among others. Areas of immunoreactive fiber localization, not immediately associated with immunoreactive cell somata, were found in the subiculum of the hippocampal formation, cortex piriformis, cortex entorhinalis, ansa lenticularis, fasciculus mamillothalamicus, fasciculus mamillotegmentalis, dorsal and ventral commissura supraoptica dorsalis, the fibrae periventriculares thalami and hypothalami, and others.

None of these areas demonstrated the reaction product when either antisera preadsorbed with met-enkephalin or when normal rabbit sera was used. Many immunoreactive cell perikarya were found near non-reactive fiber pathways and many of the nuclei showing enkephalin immunoreactivity are known to be associated with various neuroendocrine functions. [Supported by USPHS grants DA00266, MH00053 (M.J.K.), MH07624 (W.S.Y.), and HD05739 (J.K.W.)].

1840 β-ENDORPHIN AND α-MSH: COMMON CELLS OF ORIGIN AND BINDING PROPERTIES. Stanley J. Watson and Huda Akil. Mental Health Res. Institute, Dept. Psych., Univ. Mich., Ann Arbor, MI 48109.

After the discovery of β-Lipotropin (β-LPH) and β-Endorphin (β-END) in mammalian pituitary, several studies indicated its common distribution with ACTH-like immunoreactivity (ACTH-LI) in corticotrophs and intermediate lobe cells. We and others reported the presence of β-LPH and β-END in rat brain. Since ACTH-LI was found along with these peptides in pituitary, brain was immunohistochemically studied for ACTH as well. We have shown that β-END, β-LPH and ACTH-LI were located in the same hypothalamic neurons. These data are seen as strongly supporting the notion of a common 31K precursor for ACTH-β-END proposed by Mains et al., and extending that hypothesis to include brain cells.

Although ACTH-LI was clearly demonstrated in brain, it was not clear whether ACTH-LI was actually ACTH or α-MSH, as both would react with the ACTH antisera used. We therefore have studied α-MSH-LI (antiserum a kind gift of Drs. Weber and Voigt, Ulm, Germany) and β-END-LI (antiserum a kind gift of Drs. R. Mains and B. Eipper, Univ. of Colorado) in serial 4µm sections of rat brain. Both antisera are blockable with 1µM authentic peptide. The β-END antibody is not blocked by α-MSH nor is the α-MSH antibody blocked by β-END. The β-END antibody is 100% cross-reactive with β-LPH, whereas the α-MSH antibody is not blocked by ACTH $_{1-24}$, $_{1-39}$ or $_{17-39}$. In all animals studied α-MSH was found in β-Endorphin cells. It is therefore concluded that the brain systems contain β-END/α-MSH immunoreactivity. Because this suggests that both peptides may be stored and released from the same neurons, we have investigated the possible existence of specific "receptors" for them. The binding properties of ACTH and its fragments and the interactions with β-Endorphin at the binding sites will be described. Parallels and differences between binding of ACTH/α-MSH and β-Endorphin will be discussed.

1841 IMMUNOCYTOCHEMICAL LOCALIZATION OF ANGIOTENSIN II IN THE CNS OF WISTAR KYOTO AND SPONTANEOUSLY HYPERTENSIVE RATS. James A. Weyhenmeyer* and M. Ian Phillips. Dept. of Physiology & Biophysics, University of Iowa College of Medicine, Iowa City, IA 52242.

Studies from several laboratories have suggested a physiological role for angiotensin II in drinking behavior and blood pressure response. In this communication we report localization of angiotensin II-like immunoreactivity, by the unlabelled antibody enzyme method, in specific structures or regions of brain. Since it has been shown that blood pressure in spontaneously hypertensive rats (SHR) can be lowered by central injections of angiotensin II antagonist, we have compared the presence of angiotensin II-like material in SHR and their normotensive controls from Wistar Kyoto (WKY) rats. Twelve young adult WKY and SH rats were anesthetized with diethyl ether and perfused via the left ventricle with saline followed by phosphate buffered picric acid-paraformaldehyde, pH 7.4. Vibratome sections, at 50μ and 100μ, were pretreated with triton X-100. The sections were incubated with a 1:1000 dilution of rabbit anti-angiotensin II, titered at 1:95,000 by RIA at 50% binding, for 24 hr at 24°C. The tissue was subsequently incubated with a 1:100 dilution of goat anti-rabbit IgG and a 1:200 dilution of rabbit peroxidase antiperoxidase. Staining was completely eliminated by the substitution of primary antiserum preabsorbed with angiotensin II. No staining was observed when pre-immune serum was substituted for the primary antiserum.

Angiotensin II-like immunoreactivity was demonstrated in both WKY and SH rats. Cell bodies were observed in supraoptic nucleus, hippocampus and cerebral cortex of both strains. Fiber tracts with darkly staining varicosities were found in the cortex, corpus callosum, septum, striae terminalis, amygdala, hippocampus, fimbria, medial preoptic area, hypothalamus, thalamus, striae medullaris, caudate, putamen, periaqueductal gray and reticular formation of both WKY and SH rats. These fibers, containing angiotensin II-like material, were found in isolation and not in bundles or tracts.

A significant increase in positively staining fibers in the SH rats compared with the WKY rats was demonstrated in the lamina terminalis surrounding the organum vasculosum. This finding, supported by receptor binding studies on angiotensin II previously reported from our laboratory, suggest that the organum vasculosum is an important site for the central regulation of blood pressure in the SH rats.

We are grateful to Detlev Ganten, University of Heidelberg, for supplying the angiotensin II antiserum. JAW is supported by a PMA Foundation Fellowship Award. Supported by NSF grant #BNS77-24415 and RSDA to MIP.

1842 INTRASEPTAL INJECTIONS OF PROLACTIN MODULATE DOPAMINERGIC REGULATION OF HIPPOCAMPAL ACh METABOLISM. Paul L. Wood, D.L. Cheney and E. Costa. Dept. of Pharmacol., Merck Frosst Labs., Dorval, Canada and Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C.

Prolactin has recently been reported to regulate the release of striatal dopamine (Perkins and Westfall, Neuroscience 3: 59, 1978). As a result of these observations, we have examined the actions of prolactin on the turnover rate of acetylcholine (TR_{ACh}) in several brain regions. The striatum and the hippocampus were chosen as areas in which dopaminergic terminals are known to regulate TR_{ACh} trans-synaptically while the frontal cortex and parietal cortex were examined as areas in which trans-synaptic dopaminergic regulation of TR_{ACh} does not appear to be operative. Prolactin administered intraventricularly (i.v.t.) reduced the TR_{ACh} in the striatum and hippocampus while the cortical areas were unaffected. Intraseptal injection of prolactin reproduced the action of the peptide injected i.v.t. on the TR_{ACh} in hippocampus but not in striatum. These data suggest that prolactin acts in the septum via changes in the activity of A_{10} neurons impinging on the cholinergic septal hippocampal cell bodies. In addition, the reduction in striatal and hippocampal TR_{ACh} induced by i.v.t. prolactin were nullified by 6-hydroxydopamine lesions of the A_9 and A_{10} dopaminergic cell bodies. In summary, our data suggest that prolactin decreases the TR_{ACh} in the hippocampus and striatum by augmenting the release of dopamine from dopaminergic terminals innervating these brain areas.

NEURO-PHARMACOLOGY

1843 EFFECT OF ACUTE ADMINISTRATION OF ACRYLAMIDE UPON DOPAMINE RECEPTORS IN THE RAT STRIATUM. A. K. Agrawal*, S. C. Bondy*, R. E. Squibb* (SPON: C. L. Mitchell). Lab. of Behav. and Neurol. Toxicol., Natl. Inst. of Environ. Hlth. Sci., Research Triangle Park NC 27709.

The binding of tritiated spiroperidol to membranes prepared from the striatal region of 6 week old male Sprague Dawley rats was studied. This region had considerably more specific binding activity than other region studied (cerebral cortex, hippocampus, cerebellum, hypothalamus, midbrain, pons-medulla). This interaction had high affinity characteristics. Binding equilibrium was reached within 10 min at 37° and the association was rapidly reversible. Stereospecificity of binding was demonstrated by use of d- and l-butaclamol. Scatchard plot analysis was performed using ^{3}H-spiroperidol. The dissociation constant (K_D) for this interaction in control rats was 0.56 x 10^{-9}M and the striatal binding density was 42 pmoles/100 mg protein. Twenty-four hours after treatment with acrylamide, administered orally by gavage, dopamine receptor binding was measured. Any binding of 10^{-9}M ^{3}H-spiroperidol in the presence of 10^{-6}M haloperidol was taken to be non-specific. There was a significant increase ($p<0.05$, analysis of variance followed by the Least Significant Difference test (two-tailed) in ^{3}H-spiroperidol binding at all acrylamide doses tested (50, 100, 200, and 250 mg/kg). There was clear dose dependent response up to 100 mg/kg. Since the highest dose of the neurotoxic agent caused pronounced mortality (62%), further kinetic analysis was carried out using an intermediate dose level (100 mg/kg). The dissociation constant for spiroperidol binding to striatal membranes of these animals was 0.40 x 10^{-9}M and the binding site density was 48 pmoles/100 mg protein. These data indicated that the effect of the acrylamide was largely to increase (40%) the affinity of binding of these receptors toward the labeled ligand while the number of receptors available for binding was not altered in such a pronounced manner (14%). Dopamine levels in striata of untreated and dosed animals were determined fluorimetrically. There was no significant change in dopamine concentration in animals dosed at 50, 100, and 200 mg/kg relative to control values.

1844 EFFECT OF PENTYLENETETRAZOL ON MAMMALIAN NEUROMUSCULAR JUNCTION: POSTSYNAPTICALLY MEDIATED DEPRESSION. B. J. Albala, C. G. Carlson* and C. G. Muniak*. Div. Biopsychology, Syracuse University and Dept. Physiology, Upstate Medical Center, Syracuse, N.Y. 13210

The synthetic analeptic drug pentylenetetrazol (PTZ) is a convulsant agent when administered peripherally in sufficient doses. The mechanism of action by which PTZ induces epileptic-like neural and motor activity has not been adequately elucidated. Research conducted by Eccles and his colleagues (*J. Physiol. 168:* 500, 1963) demonstrated that PTZ did not significantly affect either presynaptic or postsynaptic inhibition in spinal neurons. The present experiments will attempt to determine whether PTZ exerts any effect at the mammalian neuromuscular junction.

In vitro intracellular recordings from the diaphragm of young mice (17-23 days of age) were conducted utilizing 3 M KCl glass microelectrodes. PTZ was added to normal mouse Ringer's solution to achieve a final concentration of 25-100 mM. The addition of PTZ significantly lowered the amplitude (25-75 %) of the spontaneous miniature endplate potential (MEPP) and produced a slight increase in the frequency of MEPP discharge. Following the application of PTZ in higher concentrations, muscular contractions induced by low frequency phrenic nerve stimulation were abolished. During subsequent recording, small endplate potentials (EPP) were observed at a constant latency following each stimulating pulse to the phrenic nerve (i.e. no failures of transmission were observed). In similiar experiments in which cobalt was used to partially block the release of neurotransmitter, PTZ significantly lowered the amplitude of the average EPP, with a concurrent reduction of the unitary evoked potential. These results suggest that PTZ may be exerting a depressant neuromuscular action via some postsynaptic mechanism. Consistent with this interpretation, initial experiments indicate that PTZ reduces the endplate response to a constant pulse of iontophoretically applied acetylcholine. Throughout the course of these experiments the administration of PTZ did not significantly alter the resting potential. Furthermore, the PTZ-induced amplitude depression was reversed following the substitution of fresh Ringer's solution.

In summary, the results of these experiments indicate that PTZ has a postsynaptic depressive effect at the mammalian neuromuscular junction. The specific cellular mechanism by which PTZ exerts its depression at this nicotinic synapse is not presently clear.

1845 GUANINE NUCLEOTIDES AND MAGNESIUM ION DO NOT ALTER AGONIST OR ANTAGONIST COMPETITION FOR RAT STRIATAL ^{3}H-SPIROPERIDOL BINDING SITES. A.C. Andorn*, S.Y. Cech*, S. Johnson* and M.E. Maguire (SPON: S.G. Younkin), Depts. of Pharmacology and Psychiatry, Case Western Reserve Univ., Sch. of Med., Cleveland, OH 44106.

Guanine nucleotides regulate β-adrenergic receptors (β-ARs) and other receptor types. In β-AR systems, this type of regulation appears to reflect the degree of receptor-adenylate cyclase coupling. We have recently shown (Bird and Maguire, J. Biol. Chem., 253: 8826, 1978) that Mg^{++} alters agonist affinity for β-AR in a manner opposite that of guanine nucleotides. We can now show that the guanine nucleotide effect on agonist affinity for β-ARs is dependent upon a pre-existing magnesium effect. In the absence of Mg^{++}, guanine nucleotides have no effect on ligand binding to β-ARs. We therefore examined the ability of Mg^{++} and guanine nucleotides to alter ligand binding to ^{3}H-spiroperidol (^{3}HSP) binding sites in rat striatum as such sites are proposed to be dopaminergic receptors. We report here that Mg^{++} and other ions have no effect on agonist or antagonist competition for either of the two ^{3}HSP binding sites routinely observed in rat striatum (Andorn and Maguire, Soc. for Neurosci. 1978, IV, 509). GTP, $GppCH_2p$ and ATP at concentrations from 1 μM to 10 mM have no effect on agonist or antagonist competition for the specific ^{3}HSP binding sites or on specific ^{3}HSP binding itself. This lack of effect is observed in the presence or absence of Mg^{++} (or sodium). There is a small effect of guanine nucleotide on nonspecific (and therefore total) binding of ^{3}HSP at relatively high nucleotide concentrations (0.1 - 1.0 mM). However, this does not result in any change of specific binding whether defined by the use of either agonist or antagonist ligands. There are two possible conclusions from these binding data: (1) neither ^{3}HSP binding site in rat striatum is coupled to adenylate cyclase, or (2) one or both of these sites may be poorly coupled to adenylate cyclase. This situation would be analogous to that observed in certain β-AR-cyclase systems (Maguire et al., Adv. Cyc. Nucl. Res. 8: 1, 1977. We obviously favor the latter conclusion in view of abundant biochemical evidence for the existence of a dopamine-sensitive adenylate cyclase. Since substantial data indicate that the general structure of the receptor-adenylate cyclase complex is invariant from system to system, we further suggest that detailed examination of the coupling mechanism per se will help elucidate the role of dopamine-sensitive adenylate cyclase in the striatum. 1846 EFFECT OF CHRONIC ADMINISTRATION OF MONOACYLCADAVERINES ON SLEEP-WAKING BEHAVIOR IN MICE. Helen A. Baghdoyan* and Matej Stepita-Klauco. Dept. Biobehavioral Sciences, U. Conn., Storrs, Ct. 06268.

Monoacylcadaverines have been suggested recently as possible biological markers for schizophrenia (1). They were demonstrated to be formed from cadaverine in the rat brain (2). Endogenous cadaverine has been shown to be present in mammalian brain and blood (3), and is elevated in both tissues during behavioral sleep (4). The following study is being conducted in an attempt to assess the effects of chronic administration of these compounds on sleep-waking behavior.

Adult, C57BL/6 male mice were implanted with gold wire electrodes for recording the EEG and a modified EMG. Animals were recorded continuously for 6 days under each of the following conditions: baseline, control (administration of saline) and drug administration. A recovery period lasting 6-12 days was also obtained. Drugs in saline were administered via chronically implanted osmotic minipumps. Three behavioral states, waking, slow wave sleep (SWS) and desynchronized sleep were recognized.

The average duration of SWS was significantly decreased below both baseline and control durations ($p<.01$) in animals receiving monoacetylcadaverine at a dose of 100 ng/hr. This decrease in the mean duration of a SWS episode was observed during the lights-on period only, whereas night durations remained unchanged. The total amount of SWS was slightly but not significantly decreased. There was no change in the number of SWS episodes. Similar results were seen in animals receiving monoacetylcadaverine at a dose of 100 ug/hr, the major difference being that with the higher dose the effect was seen sooner after the onset of drug administration. Studies of the effects of cadaverine and monopropionylcadaverine on sleep-waking behavior are now in progress.

1847 ACTIONS OF IONTOPHORETICALLY APPLIED MORPHINE ON RAT HYPOTHALAMIC TEMPERATURE-SENSITIVE NEURONS. Frank Baldino, Jr.*, Alexander L. Beckman, and Martin W. Adler. Dept. Pharmacology, Temple Univ. Sch. Med., Philadelphia, PA 19140, and A.I. duPont Institute, Wilmington, DE 19899.

The acute administration of morphine in the rat produces a biphasic effect on body temperature (Tb). Morphine appears to exert this influence by acting in the preoptic/anterial hypothalamus (POA). The purpose of this study was to analyze the response of temperature-sensitive neurons in the POA to iontophoretic application of morphine (M) and naloxone (NX).

These experiments were conducted in male Sprague-Dawley rats (350g) that were anesthetized with Urethan^{R} (1g/kg i.p.) and placed in a stereotaxic instrument. Two bilateral water perfused thermodes, implanted rostral to the POA, were used during the experiments to vary hypothalamic temperature (Th) over a range of 10° C. Th was sensed by a bead thermistor inserted into an implanted stainless-steel re-entrant tube positioned to the left of midline, symmetrical with the POA recording site. Recording of single cell discharges and iontophoretic application of test compounds were made with 5-barrel glass micropipettes (tip diameter, 5 μ).

Sixty one cells were analyzed for their response to M and NX. Of the 60 cells, 34 were unresponsive to changes in Th within the range of 32-42°C and were classified as temperature-insensitive cells. Twenty cells responded with an increased firing rate (FR) to an elevation in Th and were therefore classified as warm-sensitive cells. Seven cells responded with a decrease in FR to increases in Th and were therefore classified as cold-sensitive cells.

M (50-100 nA) increased the FR of 12 warm-sensitive cells, the other 8 were unaffected. None were inhibited. The FR of 6 cold-sensitive cells was decreased after M application. One cell was unaffected and none were excited. The temperature-insensitive cells responded variably to M application. Four cells were excited, 19 inhibited, and 11 remained unaffected.

NX (≤15 nA) antagonized morphine's excitatory effect in 4 of 8 warm-sensitive cells. Low currents of NX (≤15 nA) had no direct effect, while higher currents produced inhibition. NX antagonized the inhibitory response of M on 1 of 2 cold-sensitive cells while having a direct inhibitory action on the other.

Our results demonstrate that M excited warm-sensitive cells which are assumed to mediate heat-dissipation responses, and inhibited cold-sensitivie cells, which are assumed to mediate heat-gain responses. These actions parallel morphine's hypothermic action in the intact animal, and therefore suggest that M lowers Tb by exerting a coherent action on POA warm- and cold-sensitive neurons. Since these effects were antagonized by naloxone, the action of morphine on warm- and cold-sensitivie cells seems to be mediated by an opiate receptor.

1848 SIMILAR MOTOR EFFECTS OF 5HT AND TRH IN CHRONIC SPINAL RATS AND MONKEYS. Hugues Barbeau* and Paul Bédard*, (SPON: Louis Larochelle), Dept. Anatomie, Laboratoires de neurobiologie, Université Laval, Pav. Notre-Dame, 2075 ave de Vitré, Québec, Qué. G1J 5B3.

We have previously established (Bédard, P., Barbeau, H. et al., Brain Research, Vol. 169-2, June 1979) that 5 days after transsection of the spinal cord in rats, DL-5hydroxytryptophan, 100 mg/kg i.p. induces a powerful muscle contraction in extensor muscles of the tigh. This effect of 5-HTP progressively increases until the twentieth day after transsection. It is possible to quantify the response to 5-HTP and various agonists of serotonin by measuring the integrated EMG of extensor muscles of the tigh. This effect is not mimicked by drugs acting on other systems (Noradrenaline, Dopamine, Acetylcholine and GABA).

Thyrotropin-releasing hormone (TRH) is a tripeptide which has, besides it's hypophysiotropic action, been shown to be an active substance in the central nervous system of several species. The mechanisms of this action however remains unclear.TRH given at a dose of 5 to 10 mg/kg i.p. to rats spinalised at least 15 days previously elicits a strong motor response in both extensor and flexor muscles which is identical to that produced by 5-HTP and 5HT agonists. The effect of TRH last between 10 to 60 minutes and can be markedly inhibited by cyproheptadine 10 mg/kg. Glutamic acid 10 mg/kg i.p., one of three amino-acids which constitute TRH, did not reproduce the effect of TRH. A similar effect was seen in a monkey rendered paraplegic one month previously.

This finding suggest that TRH directly stimulates 5HT receptors located on neurons situated in the lumbar spinal cord in both rodents and primates.

1849 BEHAVIORAL SUPERSENSITIVITY TO APOMORPHINE WITHOUT REGIONAL CHANGES IN cAMP IN RAT BRAIN. Vernice E. Bates, Robert H. Lenox, G. Jean Kant, and James L. Meyerhoff. Dept. of Medical Neurosciences, Walter Reed Army Inst. of Research, Washington, DC, and Dept. of Psychiatry, University of Vermont, Burlington, VT.

Stereotypy has been related to stimulation of striatal dopamine (DA) receptors. Supersensitivity of the striatal DA receptor has been inferred from an increased stereotypic response to DA agonists, in: 1) a hyperthyroid model in guinea pigs; 2) guinea pigs and rats chronically given amphetamine; and 3) rats chronically given DA antagonists such as haloperidol.

Addition of DA or DA agonists to striatal homogenates results in an increase in cAMP. In models of DA receptor supersensitivity, an increased cAMP response to DA in striatal homogenates has been reported. However, in other studies, no increase in cAMP response was found. We were interested in determining whether the above models of supersensitivity would produce an increased in vivo response of striatal cAMP to apomorphine (APO).

Three models of supersensitivity were studied in the rat. In the first model, animals were administered haloperidol daily for 28 consecutive days; 2.5 mg/Kg initially for 7 days with the dosage increased by 2.5 mg/Kg every 7 days to a final dose of 10 mg/Kg. Seventy-two hours after the last dose, the rats were challenged with APO (0.3 and 10 mg/Kg) and scored for stereotypy by blind raters at 1.5, 3 and 5 min after injection. The rats were sacrificed 7 min after APO challenge by a high power microwave inactivation system developed in our laboratory (Lenox, et. al., J. Cyclic Nuc. Res. 3:367-379, 1977). cAMP and cGMP were measured in corpus striatum, nucleus accumbens, olfactory tubercle, substantia nigra and cerebellum by radioimmunoassay.

In the second model amphetamine 5 mg/Kg was given daily for 14 consecutive days followed by 10 mg/Kg for 7 days. Seventy-two hours after the last dose, APO challenge, stereotypy recording, sacrifice and assay were performed as above. In the third model, thyroxine 250 μg/Kg daily was administered for 28 days. Seventy-two hours after the last dose, the animals were challenged with APO 0.3 mg/Kg. Stereotypy scores, sacrifice and assay were performed as above.

An increased stereotypic response to APO challenge was seen only in the chronic haloperidol model ($p < .05$). Neither cAMP response nor cGMP response to APO was increased following any of the chronic treatments. Significant increases in cGMP were observed in several regions following apomorphine 10 mg/Kg possibly due to increases in motor activity (Meyerhoff et al., Life Sci. 24: 1125-1130, 1979). We conclude that behavioral supersensitivity to APO can occur without demonstrable changes in the in vivo response of cAMP.

1850 EFFECT OF GUANINE NUCLEOTIDES ON AGONIST BINDING TO ANTERIOR PITUITARY DOPAMINE RECEPTORS. Judith E. Beach,*Michael J. Cronin and Richard I. Weiner. Dept. Ob-Gyn. and Reprod. Sci., Univ. of Calif. Med. Sch., San Francisco, Ca. 94143.

Postsynaptic dopamine (DA) receptors in the caudate nucleus appear to be coupled to adenylate cyclase. The binding affinities of agonists, but not antagonists, for these receptors is decreased by the presence of GTP and other guanine nucleotides, as is generally observed for cyclase-linked receptors. We have extended these studies to DA receptors in the anterior pituitary where there is little evidence for a DA-sensitive cyclase. Membrane fractions of the steer anterior pituitary were prepared as previously described (Endocrinology 104:307, 1979). Membranes were incubated with approximately 1 nM of ^{3}H-spiperone (^{3}H-SPIP), a DA antagonist, in a Tris buffer (pH 7.4) at 37 C for 15 min. Bound ^{3}H-SPIP was separated from free at equilibrium by rapid filtration and the trapped radioactivity counted. The ability of various conc. of DA agonists and antagonists to compete for the ^{3}H-SPIP binding was tested in the presence and absence of 0.3 mM GTP, GDP, GMP, Gpp(NH)p, or ATP.

	Ki (nM)		Magnitude
AGENT	CONTROL	+0.3mM GTP	Shift
Agonists:			
DA	703	2162	3
ADTN	32	102	3
apomorphine (APO)	25	70	3
bromergocryptine (CB-154)	16.5	20	1.2
Antagonists:			
spiperone	2.7	2.6	1
d-butaclamol (d-BUTAC)	2.7	3.1	1

GTP caused a significant($p<0.01$)3-fold increase in the inhibition constants (K_i's) for DA agonists with the exception of CB-154. GDP and Gpp(NH)p caused similar effects on agonist binding; however, GMP and ATP had no effect. No change was observed with any of the guanine nucleotides on the affinity of antagonist binding. Hill coefficients of unity were calculated for SPIP,d-BUTAC and CB-154. However, Hill coefficients of approximately 0.5, which were not altered by GTP, were measured for DA, APO and ADTN competitions, indicating either negative cooperativity or multiple binding sites. All of the agonists used in this study including CB-154 are potent inhibitors of prolactin secretion from the anterior pituitary. An interpretation is that ^{3}H-SPIP binds to multiple sites in the anterior pituitary. One of these sites is sensitive to regulation by guanine nucleotides.

1851 COMPARISON OF MORPHINE ABSTINENCE SYNDROME IN AWAKE AND HIBERNATING GROUND SQUIRRELS. Alexander L. Beckman, Toni L. Stanton, Carmen Eckman*, Martin W. Adler, and Sheryl Glassman*
Alfred I. duPont Institute, Wilmington, DE 19899 and Dept. Pharm., Sch. Med., Temple Univ., Philadelphia, PA 19140.

The hibernating mammal offers a unique opportunity to expand our understanding of narcotic actions in the CNS because the natural range of brain activity from deep hibernation to the awake state is exceedingly wide. The purpose of these experiments was to describe the morphine abstinence syndrome in the euthermic (i.e., not hibernating) ground squirrel, in which the level of brain activity is comparable to that of other mammals, and during hibernation, when the brain is in a profound state of natural depression.

Euthermic, drug-naive male and female California golden-mantled ground squirrels (Citellus lateralis) were subcutaneously implanted under light ether anesthesia in the interscapular region with two 75 mg morphine pellets during the spring, summer, fall, and winter seasons. Hibernating, drug-naive animals received the same administration of morphine. In all animals, morphine abstinence was either precipitated 72 hours after pellet implantation with naloxone (1 mg/kg, s.c.) or by abrupt withdrawal. The morphine abstinence syndrome was characterized by quantifying the occurrence of signs displayed in the 30-min. period following naloxone injection or 24-hr following removal of the morphine pellets.

Euthermic ground squirrels displayed a pronounced and characteristic morphine abstinence syndrome consisting of exploratory behavior, nesting, grooming, vocalization, shakes, yawning, chewing, chromodacryorrhea, digging, dyspnea, eyetwitch, flattened posture, ptosis, and a forward-extended tail. In addition, there were seasonal and ambient temperature dependent changes in the occurrence of some signs of the naloxone-precipitated abstinence syndrome. Abrupt withdrawal produced only a very mild abstinence syndrome, with few or no signs. Control animals received only naloxone and displayed no abstinence signs.

Experiments on hibernating animals produced strikingly different results. Animals exposed to morphine and tested with naloxone during hibernation displayed no abstinence signs. Similar results were obtained from animals exposed to morphine during hibernation which were deliberately aroused to the euthermic state and immediately tested with naloxone. These results suggest that the state of hibernation alters the development of physical dependence on morphine in some, as yet unknown, manner. (Supported by NIDA Grant DA 02254 and the A.I. duPont Institute).

1852 REPEATED ELECTROCONVULSIVE SHOCK (ECS) AND MORPHINE TOLERANCE: DEMONSTRATION OF CROSS-SENSITIVITY IN THE RAT. Gregory Lucas Belenky and John W. Holaday. Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, DC.

In a complementary set of studies, we have found repeated ECS sensitizes opiate-naive rats to the acute effects of a single morphine injection, and induction of morphine tolerance sensitizes ECS-naive rats to the acute effects of a single ECS.

In the first experiment, opiate-naive rats were given transauricular ECS (160V, 60Hz, 2 sec) daily for nine days. Twenty-four hours after their last ECS they were tested for sensitivity to morphine using single subcutaneous doses of 4 or 15 mg/kg of morphine sulfate. Following morphine, the repeated-ECS groups were more cataleptic ($F = 5.26$; df 1,21; $p = .032$), more analgetic [F(tail flick latency) = 4.73; df 1,21; $p = .041$] and hypothermic ($F = 8.19$; df 1,21; $p = .009$) when compared to sham-ECS control groups.

In the second experiment, ECS-naive rats were made tolerant to morphine by the implantation of morphine sulfate pellets (75 mg) 72 hours and again 24 hours prior to testing. On the day of testing the morphine-pellet rats were tolerant to morphine as indicated by the lack of significant differences in tail flick latencies, respiratory rates, and body temperatures when compared to a placebo-pellet implanted control group. Following these pre-measures, both groups of rats were given a single trans-auricular ECS (160V, 60Hz, 2 sec). Post-ECS the morphine tolerant rats were more cataleptic ($t = 2.55$, df = 7, $p = .038$), more analgetic [t(tail flick latency) = 3.50, df = 7, $p = .011$], respiring less ($t = 6.41$, df = 7, $p = .0004$) and hyperthermic ($t = 2.86$, df = 7, $p = .024$) when compared to the placebo-pellet implanted control group.

These experiments demonstrate, on the one hand, repeated ECS sensitizes to the effects of morphine, and, on the other hand, morphine tolerance potentiates the effects of ECS. This cross sensitivity suggests the physiological changes following repeated ECS and the induction of morphine tolerance share common neurobiological mechanisms.

1853 THE DIFFERENTIAL EFFECTS OF DORSAL HORN OR VENTRAL HORN INTRASPINAL MICROINJECTIONS OF NOREPINEPHRINE (NE) AND 5-HYDROXYTRYPTAMINE (5HT) ON NOCICEPTIVE C-FIBER REFLEXES (CFR) IN THE ACUTE DECEREBRATE SPINAL CAT. J. A. Bell* and T. Matsumiya* (Spon: W. R. Martin), NIDA Addiction Research Center, Lexington, KY. 40583

CFR's recorded from an L_7 ventral root were evoked by stimulation of the ipsilateral superficial peroneal nerve with a stimulus intensity (15 v 2 msec duration) sufficient to activate C-Fibers. All microinjections (vol 0.5 µl) were performed via glass micropipettes (tip diameter 50 µm) placed either 1 mm (dorsal horn) or 3 mm (ventral horn) below the surface of the spinal cord in the L_7 segment. Control dorsal horn or ventral horn microinjections of NaCl (2 M, pH 3) had no effect on the CFR. Dorsal horn microinjections of 5HT rapidly depressed the CFR to 59% of control at 15 min. Ventral horn microinjections of 5HT facilitated the CFR to 280% of control at 15 min. Dorsal horn microinjections of NE depressed the CFR to 50% of the control at 15 min, whereas ventral horn microinjections of NE facilitated the CFR to 374% of control at 15 min. Pretreatment of the preparation with intravenous administration of naltrexone (0.5 mg/kg) antagonized the depressant effects of the dorsal horn microinjections of NE (101% of control at 15 min), whereas the depressant effects of the dorsal horn microinjections of 5HT were not antagonized by naltrexone (62% of control at 15 min). These data support a hypothesis that NE acts in the dorsal horn of the spinal cord to depress the segmental nociceptive CFR by activating an intermediary system which is sensitive to an opiate antagonist (naltrexone) blockade, whereas 5HT may act directly in the dorsal horn to depress the CFR.

1854 LITHIUM(LI)AND TRYPTOPHAN(TP)SYNERGISM IN CENTRAL SEROTONERGIC PATHWAYS IN THE MURICIDAL RAT, Sr. P. Broderick, I. Sanghvi*, V. deP. Lynch* and P. Cervoni*+. St John's Univ., Coll. of Pharm., Jamaica, NY, 11439 and USV Pharm. Corp., Tuckahoe, NY 10707 (+Lederle Lab, Pearl River, NY 10965).

Therapeutically, the use of Li or TP as thymoleptic remains controversial. The effects of Li on TP on central serotonergic pathways were studied in rat muricidal(mouse killing)behavior(MB), a model pragmatically employed to screen antidepressant drugs.

We have previously shown(Pharmacol., 1978)Muricidal Behaviour Antagonism(MBA)by Li and TP, both acutely and chronically, in isolated, male Long Evans rats, with no significant neurotoxic impairment on rotarod performance. Li and TP acted synergistically on MBA; the synergism was also reflected in Li and TP plasma levels.

In present study, forebrain and hindbrain steady state 5-HT and 5-HIAA levels were determined in these muricidal aberrant rats. The steady state levels of 5-HT and 5-HIAA were 0.12 ug/gm and 0.28 ug/gm respectively. Both acute and 7 day treatment with Li, 0.5 meq/kg, i.p. and TP, 100 mg/kg, i.p. alone and in combination, significantly increased($p<0.001$)steady state 5-HT and 5-HIAA levels. 5-HT turnover studies revealed a 5-HT turnover rate of 0.26-0.29 ug/gm/hr, and a turn over time of 204-208 min. for muricidal controls. Li and TP combination significantly($p<0.001$)restored neuronal activity to a more usual range,(0.64-0.72 ug/gm/hr and 84-96 min. respectively). In order of activity, the effects were Li+TP>TP>Li. Hindbrain 5-HT turnover was significantly higher($p<0.001$)over forebrain 5-HT turnover in the chronic Li+TP combination group. However, within the forebrain a significant difference ($p<0.01$)in 5-HT steady state values was found between right and left hemispheres in 83% of the animals following treatment with Li, 0.5 meq/kg/day, i.p. for 7 days.

Our data show that Li acts, at least, in part, through serotonergic pathway and the MB can be modified by serotonergic influences. Results also show a decreased plasma TP level, consistent with decreased 5-HT 5-HIAA and 5-HT turnover in muricidal rats, and suggest that Li and TP act synergistically on 5-HT pathways, possibly via increased TP uptake into brain. This synergism has important therapeutic implications.

1855 EFFECTS OF CHRONIC OPIATE RECEPTOR ANTAGONISM BY NALTREXONE ON ASPECTS OF MATERNAL BEHAVIOR IN MICE. David Brown* and George R. Peterson. Pharmacol. Dept., Wright St. U. Sch. Med., Dayton, OH 45435.

Panksepp and collaborators (Pharmacol. Biochem. Behav. 9: 213, 1978; Neurosci. Abs. 3:303, 1977) reported that the narcotic antagonist naloxone disrupted certain mother-infant interactions in various species, thus suggesting that endogenous opiate-like substances may play a role in the mediation of intraspecies social bonding. By use of a long-term delivery system consisting of 1.5 mm beads containing 2 mg of naltrexone base in a 90/10 polylactic/glycolylic acid copolymer (Dynatech R/D Comp., Cambridge, MA; beads supplied by NIDA), the consequences of chronic blockade of opiate receptors on maternal behavior could be explored.

As soon as feasible after delivery, mothers were implanted subcutaneously with either two naltrexone beads, two sham beads or were left untreated. The naltrexone was 100% effective as judged by its ability to block a > ED_{99} dose of morphine sulfate (i.p., 20 mg/kg) for approximately 30 days. The behavior of sham-implanted and untreated mice were never significantly different from one another. However, pup-retrieval time of naltrexone-treated mothers was disrupted and significantly prolonged for at least the first 10 days. The pups of untreated mothers gained weight at a significantly slower rate than controls for the first 5 days, after which time treated and controls did not differ. The fact that treated animals eventually showed weights that were not different from controls may have been attributable to a significantly higher mortality rate (30% vs. 7%) among treated animals, thus removing the most slowly growing pups from the population pool. The naltrexone-effect on retrieval times was reversible: removal of the beads restored normal behavior. In addition, animals manifesting normal behavior first would show the disturbed behavior upon naltrexone implantation. Placing treated mothers with litters from untreated parents indicated that the behavior of the mothers rather than the pups had been altered. Attempts to reverse this naltrexone-mediated behavior with clonidine (10-250 μg/kg, i.p.), a specific α-agonist that reverses opiate-withdrawal signs, were unsuccessful. These observations support the hypothesis of a role for endorphins in mediating social bonding and do not support one for a noradrenergic component in these behaviors. (Supported by Biomed. Res. Support Grant Program, N.I.H. 1-507-RR07155-01 and 1-R01 DA02004-01 [N.I.D.A.]).

1856 EFFECT OF ALCOHOL INGESTION ON PHYSIOLOGICAL ACTION TREMOR. Scott A. Burgstahler*, Robert S. Pozos, Roger W. Petry*, Paul Iaizzo*. Department of Physiology, University of Minnesota, Duluth, School of Medicine.

During voluntary motion of the hand there is a concomitant high frequency involuntary oscillation called Physiological Action Tremor (PAT). Since it has been reported that alcohol can decrease the amplitude of Pathological Action Tremors, the present study was undertaken to see if alcohol would also have a similar influence on PAT. If this occurs, insight into the relationship between Physiological and Pathological action tremors would be obtained.

PAT was recorded using an AVR-250 accelerometer taped on the dorsal side of a styrofoam sandwich which enclosed the hand. EMGs of the extensors and flexors of the wrist were recorded using Beckman biopotential surface electrodes. Accelerometer and EMG signals were recorded onto a Hewlett Packard tape recorder and later analyzed on a PDP-12 computer. Subjects were allowed to drink the alcoholic beverage of their choice until they felt intoxicated. An intoximeter (CMI) was used to quantitate the blood alcohol content of the subjects.

In non-intoxicated subjects, data analysis showed that the maximum displacement values (2500 μ) from acceleration records of PAT of the hand occurred at 8-12 hz. However, there was another significant frequency band of 2-4 hz in most subjects. After intoxication (0.1 mg % blood alcohol content), the amplitude of PAT was significantly reduced, but the frequency range remained constant.

Ingested alcohol has been reported to decrease sympathetic neuronal activity and reduce the amplitude of tremor in Pathological situations. Arterial injections of alcohol in the periphery appear to have no effect on the amplitude or frequency of the tremor and therefore the effects of alcohol are though to occur at the spinal cord or higher levels. Based on our observations, PAT might have a significant neural component. Also since alcohol decreases the amplitude of PAT and is reported to do the same with Clinical Essential Tremors, the same mechanism controlling PAT might also be the substrate for these clinically observable tremors.

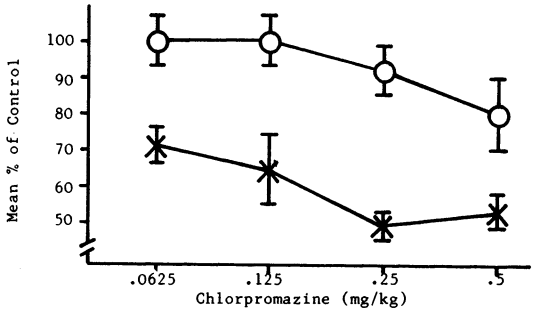
Research was supported in part by funds from Sea Grant(DOC-NA-519A-B-00025. Authors gratefully acknowledge the use of the intoximeter lent by Dr. J. Schaefer, Director of A.O.D.A.P., University of Minnesota.

1857 CORRELATION BETWEEN THE EFFECTS OF CHLORPROMAZINE ON SPINAL CORD ACTIVITY AND ALPHA-ADRENERGIC BLOCKADE. J.S. Carp*, P. Brigham* and R.J. Anderson (SPON: A. Raines). Dept. of Pharmacol., Geo. Washington Univ., Washington, D.C. 20037.

The effects of chlorpromazine (CPZ) on monosynaptic spinal cord transmission and on adrenergic, cholinergic, and histaminergic receptors were compared in alpha-chloralose anesthetized cats. Monosynaptic transmission between dorsal and ventral roots (L6, L7, or S1) in intact cats was significantly depressed ($P < .05$) by doses of .0313 to .5 mg/kg of CPZ i.v. This response plateaued at approxmately 50% of the control response.

In spinal, vagotomized cats, the cardiovascular responses to a series of agonists (norepinephrine, acetylcholine, epinephrine, histamine and isoproterenol) were recorded before and after cumulative doses of CPZ ranging from .0156 to .5 mg/kg. Only the response to epinephrine was depressed by CPZ in this dose range. Larger doses (from 2 to 10 mg/kg) depressed the response to norepinephrine. Since the isoproterenol response was unaffected, the effect of CPZ on norepinephrine and epinephrine was probably due only to alpha-adrenergic blockade.

The slopes of the dose-response curves obtained from the adrenergic blockade and the spinal cord depression were parallel (see below), suggesting that CPZ is affecting spinal cord responsiveness through an alpha-adrenergic mechanism. The descending noradrenergic bulbospinal pathway (Anden et al., Eur. J. Pharm. 2:59, 1967) is the most likely site of action, since previous work has shown that CPZ has no depressant effect on spinal cord activity in spinal animals (Preston, JPET, 118: 110, 1956).



1858 COMPARING THE EFFECTS OF NALOXONE AND PICROTOXIN ON SCHEDULE-CONTROLLED RESPONDING IN THE PIGEON: POSSIBLE GABA-ANTAGONISTIC EFFECTS OF NALOXONE. Richard B. Carter and J. David Leander*, Depts. of Psychology and Pharmacology, Univ. of North Carolina, Chapel Hill, N.C. 27514.

The narcotic antagonist naloxone has recently been demonstrated to possess GABA-antagonistic properties (Dingledine, et al., Eur. J. Pharmacol. 47:19-28, 1978). For this reason we decided to compare its effects to a known indirect antagonist of GABA, picrotoxin. The effects of naloxone (10.0-80.0 mg/kg, i.m.) and picrotoxin (0.1-0.56 mg/kg, i.m.) were studied alone and in combination with doses of pentobarbital (3.0 and 10.0 mg/kg, i.m.), diazepam (1.0-10.0 mg/kg, p.o.), clonazepam (0.3-3.0 mg/kg, p.o.) and muscimol (0.25 and 0.50 mg/kg, i.v.) on the responding of pigeons maintained under a multiple FR 30, FI 5-min schedule of food presentation. Naloxone and picrotoxin alone both produced dose-related decreases in responding without appreciably affecting the FI patterning. Pentobarbital alone produced dose-related increases in responding. Diazepam alone produced an inverted U-shaped dose-effect function, increasing rates at intermediate doses and decreasing them at the highest dose. Clonazepam and muscimol alone both produced dose-related decreases in responding. When administered in combination with either naloxone or picrotoxin, pentobarbital shifted each curve to the right by a factor of 2 or more. The 3.0 mg/kg dose of pentobarbital did not affect FI patterning either alone or in combination with naloxone or picrotoxin whereas the 10.0 mg/kg dose did. In contrast, 3.0 mg/kg of diazepam attenuated the effects of a 0.56 mg/kg dose of picrotoxin, but not of an 80.0 mg/kg dose of naloxone. Diazepam alone or in combination always influenced FI patterning. Similarly, 1.0 mg/kg of clonazepam also attenuated the effects of 0.56 mg/kg of picrotoxin, but not of 80.0 mg/kg of naloxone. Clonazepam alone or in combination always influenced FI patterning. Muscimol, a direct GABA receptor agonist, did not attenuate the effects of either 0.56 mg/kg of picrotoxin or of 80.0 mg/kg of naloxone at any dose. Thus, naloxone would appear to share some similarities with picrotoxin when their effects are compared on schedule-controlled responding in the pigeon. Supported by USPHS grants DA-01711 and ES-01104 and a research grant-in-aide from Sigma Xi.

1859 ETHANOL ORAL SELF-ADMINISTRATION IN NAIVE AND TOLERANT DROSOPHILA MELANOGASTER. S. S. Chawla*[1], J. M. Perron*[2] and C. Radouco-Thomas[1]. Unité de Recherche sur l'Abus des Drogues et de l'Alcool, Hôp. St-François d'Assise, Dépt. Pharmacol., Faculté de Médecine[1] and Dépt. Biol., Faculté des Sciences[2], Université Laval, Québec, Canada.

A method to measure the microvolumes of ethanol solutions self-administered orally by Drosophila melanogaster Meigen is described. The apparatus consists in a battery of eight experimental units, each one composed of a plastic chamber and an injection circuit. The net amount of ethanol taken has been examined in various experimental conditions: ethanol alone, ethanol-sucrose solutions at various concentrations and ethanol-sucrose cube. The net values for each day were obtained by computing the difference between gross values and evaporation per day figures. The data obtained in naïve drosophila show that the amount of self-administered ethanol is directly related to the concentration of ethanol; the consumption of sucrose solutions is inversely proportional to the concentration of sucrose. Observations on 14 days showed that the lethality increased with the raise in the concentration of ethanol and decreased with the raise in the concentration of sucrose (sucrose-water solutions 0,5%-3%).

Experiments have been carried out also on adult drosophila which have been exposed to ethanol during their entire life cycle. The preliminary results suggest that this new self-administration method could be envisaged for the study of the experimental dependence on ethanol and other addictive psychotropic drugs.

1860 DIFFERENTIAL EFFECTS OF CAFFEINE ON REGIONAL BRAIN BIOGENIC AMINES IN RATS. Dorothy T. Chou, Holly Cuzzone*, Jean Springstead*, Rida Ali* and Kenneth Hirsh. General Foods Corporation, Technical Center, Tarrytown, New York 10591.

Caffeine is well known to increase alertness and decrease drowsiness and fatigue. However, the site and mechanism of its effects on the central nervous system (CNS) are not completely understood. We report here the results of a study of the possible involvement in caffeine's CNS effects of three biogenic amines, serotonin (5-HT), norepinephrine (NE) and dopamine (DA). In order to identify the site of action, the endogenous levels of the biogenic amines in regional brain structures were studied before and after caffeine administration. Ninety male Sprague Dawley rats weighing 175-200 gm were used. The caffeine doses studied were 0, 2.5, 12.5, 25 and 50 mg/kg given by mouth. The animals were decapitated 1 hour after intubation with caffeine solution and the cerebral cortex, corpus striatum, hypothalamus, hippocampal formation, pons-medulla, cerebellum and midbrain raphe areas were dissected out over ice. 5-HT, NE and DA were extracted simultaneously from each of the brain areas using the butanol extraction method and assayed fluorometrically. A nonparametric statistical method was used to analyze the data. Our results show that the low dose of caffeine, 2.5 mg/kg P.O., selectively increased the 5-HT level in midbrain raphe ($p < 0.025$). Doses of 12.5, 25 and 50 mg/kg P.O. produced a dose-related increase in 5-HT level in midbrain raphe, and also in cerebral cortex and cerebellum with the response to 50 mg/kg being significantly greater than water control. The 5-HT concentrations in the remaining 4 brain areas were unchanged by caffeine at the doses studied. Caffeine, 50mg/kg P.O., selectively increased DA level in corpus striatum. NE levels were unchanged in all brain areas at the caffeine doses studied. Our conclusion that caffeine modified the disposition of 5-HT in cerebral cortex, cerebellum and particularly in midbrain raphe suggests that caffeine's action on CNS may be, at least in part, mediated through a serotonergic pathway. It has been postulated that brain serotonergic systems, especially the midbrain raphe serotonergic pathway, participate in sedation and sleep mechanisms. In addition, caffeine induced DA increases in corpus striatum may indicate the possible involvement of the dopaminergic system in caffeine's action on mood elevation and motor activity stimulation since the dopaminergic pathway has been suggested to participate in control of both motor function and mood. Furthermore, our results show that caffeine changes the endogenous levels of these 3 biogenic amines in a non-uniform manner in the 7 brain areas studied. These observations imply that caffeine exerts differential effects at different brain structures and on the different neurotransmitter systems.

1861 THIOHEXITAL ENANTIOMERS: PHARMACOLOGICAL ACTIVITY. H. DIX Christensen, W.C. Goad*, Philip Abraham* and F.I. Carroll*. Dept. Pharm., OUHSC, Okla. City, OK 73190 and RTI, Research Triangle Park, N.C. 27709.

Quantitative pharmacological differences exist between the optical antipodes of barbiturates. Racemic thiohexital in humans has a fast metabolism rate, 25% per hour, but possesses undesirable side effects of hiccoughs and twitching of extremities (Mark et al., Anes. 29:1159 (1968)). The relative anesthetic potency, toxicity, and incidence of side effects as a function of the configuration of thiohexital were investigated in Charles River, CF-1 male mice. The AD_{50} (loss of righting reflex), and LD_{50} values with 95% confidence limits after intraperitoneal administration are as follows:

Stereoisomer	(mg/kg)	Slope	Potency Ratio
AD50			
Racemic	25.8 (24.5-27.2)	1.14 (1.06-1.22)	-
(+)	18.8 (17.4-20.3)	1.25 (1.06-1.48)	1.37
(-)	27.3 (25.9-28.8)	1.16 (1.09-1.24)	1.06
LD50			
Racemic	63.5 (58.0-69.5)	1.23 (1.02-1.49)	-
(+)	59.8 (56.0-63.9)	1.14 (1.05-1.23)	1.06
(-)	66.1 (59.9-72.9)	1.21 (1.06-1.40)	1.04

There were no significant differences in onset, 3.68 ± 0.40 min., and duration of anesthesia, 12.11 ± 1.92 min., when the compounds were administered at the respective AD_{50} value to sets of 40 mice. Although the incidence of tremor on recovery was less for the (+) stereoisomer than (-) or racemic mixture, it is still significant compared to other alkyl-substituted barbiturates. When administered intravenously, the onset and potency are dependent upon the rate of injection, because of the high lipid solubility.

This study in addition to others with barbiturate enantiomers suggests that binding to receptor(s) is determined by the absolute configuration.

1862 p-CHLOROPHENYLETHYLAMINE - A UNIQUE SEROTONIN AGONIST. Eunyong Chung Hwang and Melvin H. Van Woert*. Depts. of Neurol. and Pharmacol., Mount Sinai Sch. of Med., New York, N.Y. 10029.

p-chlorophenylethylamine (p-CPEA) is structurally similar to p-chloroamphetamine (p-CA) and both compounds are potent releasers of synaptosomal serotonin (5HT). Like p-CA, we found that the release of synaptosomal 5HT by p-CPEA *in vitro* can be completely counteracted with 10^{-6}M fluoxetine (a selective 5HT uptake inhibitor) suggesting a similar mechanism of action for both drugs. However, 4 hours after p-CPEA (50 mg/kg i.p.) mouse whole brain 5HT and 5-hydroxyindoleacetic acid (5HIAA) levels were increased to 156% and 180% of control respectively, while p-CA (20 mg/kg i.p.) has been reported to decrease brain 5HT and 5HIAA by 53% and 25% respectively (Fuller, R. et al., Neuropharmacol. 14, 739, 1975). Fluoxetine pretreatment (10 mg/kg, 0.5 hour before p-CPEA) prevented the 5HT reduction at 0.5 hr (due to release); however, it did not block the elevation of brain 5HT and 5HIAA at 2 and 4 hours after p-CPEA (50 mg/kg). Each i.p. injection of p-CPEA (50 mg/kg) produced the "serotonin behavioral syndrome" without development of tolerance. Repeated injection of p-CA produced tolerance to its behavioral effects.

In order to test for neurotoxicity, mice were injected with p-CPEA (50 mg/kg) and sacrificed 1 and 2 weeks later; brain 5HT and 5HIAA were normal at these times. In contrast, p-CA produces a prolonged reduction in brain 5HT and 5HIAA levels.

p-CPEA is taken up at nerve terminals by the serotonergic neuronal transport process and releases endogenous serotonin. Unlike p-CA, p-CPEA is not a neurotoxin and may increase tryptophan hydroxylase activity.

1863 PENTOBARBITAL-INDUCED ALTERATIONS OF ADENOSINE 3':5' CYCLIC MONOPHOSPHATE (cAMP) METABOLISM IN RAT BRAIN. M.L. Cohn and M. Cohn, Dept. Anes., Magee-Womens Hosp., Univ. Pittsburgh, Sch. Med., Pittsburgh, PA 15213.

Our previous findings that cAMP dose-relatedly regulates duration of narcosis led us to investigate whether brain cAMP concentrations are altered by anesthetics. However, cAMP measurements in either whole or specific brain structures failed to establish a relationship between cAMP brain content and state of narcosis. Here, we investigated in-vivo and in-vitro whether cAMP synthesis or degradation is altered by barbiturates. Male Sprague-Dawley rats were anesthetized with intraperitoneal sodium pentobarbital (50mg/kg); controls were untreated. Following sacrifice by either microwave radiation (MR) (5 sec. exposure) or decapitation (D), brains were immediately removed, homogenized in .4N perchloric acid (1ml/100mg of wet brain), centrifuged, neutralized and filtered. After D, brain cortex slices were incubated under aerobic conditions in Krebs-Ringer bicarbonate buffer pH 7.4 (30°C) with or without pentobarbital (10^{-6}M). Sequential aliquots of incubation mixture and brain extract samples were analyzed with our newly devised high performance liquid chromatographic method (Cohn et al, Pittsburgh Conference on Analytic Chemistry and Applied Spectroscopy, p. 620, 1979). Contrary to previous reports that in mammalian brain major metabolic products of ATP and cAMP are adenosine and adenine, our findings in untreated rats sacrificed by MR showed smaller concentrations of the two metabolites and much higher accumulations of deamination products inosine and hypoxanthine. Under hypoxic conditions (D) we found less inosine and hypoxanthine but a significant accumulation of adenosine. The shift in cAMP metabolism produced by pentobarbital, while similar, was more pronounced than that induced by D. In-vitro incubation studies revealed that pentobarbital reversibly inhibits deamination of 5'AMP, leading to adenosine accumulation with no concomitant rise of cAMP. Our in-vivo and in-vitro chromatographic evidence that barbiturates inhibit deamination in cAMP metabolic pathways provides a molecular basis for the 50-year old observation that anesthetics decrease brain ammonium concentrations. That pentobarbital increases adenosine, which allegedly regulates cerebral blood flow, may partially explain the barbiturates' therapeutic usefulness against ischemia and stroke. Recently, it was proposed that inosine and hypoxanthine are endogenous ligands of benzodiazepine receptors. Our earlier finding that, like barbiturates, diazepam-induced narcosis is dose-relatedly shortened by cAMP suggests that diazepam may also duplicate barbiturates' specific inhibition of deamination and subsequent lowering of the two metabolites' concentrations. Future investigations will verify our hypothesis.

1864 A SPECIFIC EFFECT OF MORPHINE IN THE HIPPOCAMPUS IN VITRO. William A. Corrigall and Mary Ann Linseman. Dept. Neurobiology, Addiction Research Foundation, Toronto, Ontario, M5S 2S1.

The acute effects of morphine sulphate on field potentials evoked in the isolated transverse hippocampal slice preparation from the rat were studied over a bath concentration range of 0.5 to 50 uM. Field potentials were elicited in the stratum pyramidale of CA1 by stimulation in the stratum radiatum. The field potential recorded in control medium generally showed a single population spike representing synchronous activation of the pyramidal cells. Morphine had a consistently stimulant effect on the response, manifest as a dose-related appearance/increase of a second, and occasionally subsequent, population spikes. This action of morphine appears to be stereospecific since it was consistently antagonized by naloxone (0.1 - 10 uM), and it could be duplicated by comparable doses of levorphanol but not of dextrorphan.

The size of the morphine effect was dependent on the input/output (I/O) function of the pyramidale field potential; that is, the effect was maximal at the top of the I/O curve, but it was generally small or absent near threshold.

Several experiments suggested that the effect was not produced at the level of the excitatory synaptic input to the pyramidal cells. Recordings in the stratum radiatum (the site of the synapses on the pyramidal neurons which are activated by radiatum stimulation) simultaneous with those in pyramidale showed that an increase in the population EPSP did not cause the increase in CA1 discharge. The effect was not dependent on the specific input pathway as it was also observed when the field potential was evoked via synapses on the basal dendritic tree by stimulation in stratum oriens. Synaptic input itself was not essential since the effect occurred when the pyramidal cells were driven antidromically by stimulation of the alveus.

The additional population spikes could result however from a decrease in recurrent inhibition upon the CA1 neurons, a presumed GABA-mediated effect. The morphine effect was indeed reversed by the addition of GABA (1 mM) to the bath. Picrotoxin (2.5 uM), a GABA antagonist, mimicked the effect of morphine.

These data are evidence for a specific, primary effect of morphine in the hippocampus, which at the cellular level may consist of a selective depression of the interneurons normally mediating recurrent inhibition to the CA1 pyramidal cells, resulting in net excitation of the latter.

1865 LESIONS OF THE SUBSTANTIA NIGRA REVEAL BENZODIAZEPINE RECEPTORS WITH AND WITHOUT γ-AMINOBUTYRIC ACID RECEPTOR LINKAGE. Tommaso Costa*, Agu Pert and Candace B. Pert. Biological Psychiatry Br., NIMH, Bethesda, MD 20205 (SPONSOR: L. K.Y. Ng)

Four weeks following the destruction of cell bodies in the substantia nigra by microinjection of 1 μg of kainic acid, specific [^{3}H]diazepam binding was reduced 60% in the lesioned side compared to the unlesioned control side. The ability of γ-aminobutyric acid (GABA) (10 μM) to enhance [^{3}H]diazepam binding was significantly reduced on the lesioned side. A parallel, but smaller (40%) decrease on the lesioned side was observed also for [^{3}H]-muscimol binding while the restricted conformation analog of GABA, 4,5,6,7-tetrahydroisoxazolo(4,5-c)pyridin-3-ol (THIP) was more potent in displacing [^{3}H]muscimol bound on the intact side than on the lesioned one. These data markedly contrast with the pattern of changes observed when the striato-nigral input is lesioned (Shibuya et al., Neuroscience Abst., this vol.). In this case, a dramatic increase in sensitivity of [^{3}H]diazepam binding to GABA receptors is accompanied by increased GABA receptors and decreased benzodiazepine (BZ) receptors.

Are the BZ receptors on cell bodies within the nigra closely and permanently coupled to GABA receptors while BZ receptors on terminals which project to the nigra are not associated with GABA receptors? This is unlikely since THIP, which labels the uncoupled form of the GABA receptor (Karobath et al., Nature, 278, 1979) is more potent in displacing GABA receptor ([^{3}H]muscimol) binding on the intact side.

An explanation consistent with all of our data is that the quantity of GABA/BZ-coupled receptors is a function of the ratio between free GABA receptors and free BZ receptors. This ratio is different for membranes obtained from various brain regions, and changes during altered states of sensitivity.

GABA's differential ability to enhance [^{3}H]diazepam binding (50-150%) depending on which brain region is examined (spinal cord > cerebellum > cortex) may be an approximate measure of the GABA-coupled BZ receptor.

1866 ON THE MULTIPLICITY OF BENZODIAZEPINE RECEPTORS AND THEIR DISTRIBUTION IN THE RAT BRAIN. Joseph Coupet and Vera A. Szucs-Myers*, American Cyanamid Co., Medical Research Division, Pearl River, NY 10965.

High affinity benzodiazepine binding sites in the mammalian brain have been described by many investigators. A high degree of correlation has been found between the binding affinities of a series of benzodiazepines and their potencies as anxiolytics, muscle relaxants and anticonvulsants. These findings strongly suggest that these sites may function as pharmacological receptors for the benzodiazepines. Is it possible that the diverse therapeutic effects of the benzodiazepines are mediated by the same receptor sites? Scatchard analyses of the binding of labelled benzodiazepines in various brain regions revealed a single population of binding sites. However, when we examined the dissociation curves ("off rates") for ^{3}H-diazepam from its binding sites, we uncovered biphasic lines of decline in the rat cerebral cortex and the hippocampus. The apparent half time (t-1/2) of the fast component was 1.5 - 2.0 minutes, and that of the slow component 8.0 minutes. In other brain regions ^{3}H-diazepam dissociated monophasically with a t-1/2 of approximately 5.0 minutes.

In an attempt to further characterize the "benzodiazepine receptors", we displaced ^{3}H-diazepam with an excess of unlabelled CL 218,872, a triazolopyridazine anxiolytic lacking sedative properties, and compared the results with those obtained with displacement by unlabelled diazepam or flunitrazepam. While the t-1/2 of the fast component was unaffected by CL 218,872, the t-1/2 of the slow component increased. These findings, taken together with other pharmacological data of CL 218,872 indicate: 1) that there exist two or more types of "benzodiazepine receptors in the rat brain; 2) that the "slow receptor type" may be associated with ataxia or sedation; and, 3) that pharmacologically active benzodiazepines have almost identical affinities for all receptor types, but have different rates of dissociation from each type of receptor.

1867 DEVELOPMENT OF TOLERANCE TO OPIATES AND OPIOID PEPTIDES IN CULTURES OF MOUSE SPINAL CORD WITH ATTACHED DORSAL ROOT GANGLIA. Stanley M. Crain, Bea Crain*, Tara Finnigan* and Eric J. Simon*. Depts. of Neuroscience, Physiol. and Neurology, Albert Einstein College of Medicine, Bronx, N.Y. 10461; (E.J.S.) Dept. of Medicine, New York University College of Medicine, N.Y. 10016.

Acute opiate-depressant effects on sensory-evoked dorsal-horn network responses of organotypic explants of fetal mouse spinal cord with attached dorsal root ganglia (Crain et al.,Br. Res. 133,'77; 157,'78) disappeared after chronic exposure to analgesic levels of morphine (1 μM) for > 2-3 days in culture at 35°C. (Drug exposures were begun about 1-3 weeks after explantation.) Characteristic dorsal cord responses could then be evoked by dorsal root ganglion (DRG) stimuli in the presence of morphine -- even after acute increases in concentration (up to 100-fold). Tolerance also developed after chronic exposure of cord-DRG explants to low concentrations (ca. 0.01 μM) of the enkephalin analog, [d-ala^2,MePhe^4,Met-(O)^5-ol]-enkephalin (Sandoz 33-824). The latter cultures showed cross-tolerance to met-enkephalin and opiates; dorsal cord responses could still be evoked even after acute exposure to high levels of morphine. Morphine-tolerant cultures also showed cross-tolerance to met-enkephalin and to the Sandoz opioid peptide (33-824).

The tolerant state did not develop if the cultures were incubated at lower temperature, 20°C, during exposure to 1 μM morphine for as long as 7 days. (Control 2-week-old cultures incubated in regular media at 20°C for 1 week showed no significant electrophysiologic deficits.) Furthermore, development of tolerance was partly antagonized by raising the Ca^{++} concentration of the medium to 10 mM during chronic exposure to 1 μM morphine. The latter results are consonant with our acute experiments showing that the depressant effect of opiates and opioid peptides on dorsal cord responses were often markedly reduced in the presence of high Ca^{++} in the culture medium (Crain et al., Br. Res. 157,'78).

The sensory-evoked dorsal-horn population responses in tolerant cultures often developed unusually large amplitudes during maintenance in 1 μM morphine or after acute introduction of naloxone. Explants chronically exposed to morphine continued to show evidence of tolerance for about 2 days after transfer to drug-free culture medium, but characteristic sensitivity to opiates returned during the subsequent few days. Organotypic cord-ganglion cultures provide, therefore, a valuable model system for analyses of cellular mechanisms underlying development of opiate tolerance and dependence in mammalian CNS tissues under flexible, controlled conditions in vitro.

1868 EFFECTS OF d-AMPHETAMINE ON DOPAMINERGIC NEURONS IN THE VENTRAL TEGMENTAL AREA OF THE RAT. M. Dalsass, D.C. German, R.S. Kiser, and S. Speciale. Depts. Psychiat. and Physiol., Univ. Tex. Health Sci. Ctr., Dallas, TX 75235.

Systemic d-amphetamine (d-A) can release dopamine (DA) from nerve terminals in the caudate-putamen and block the reuptake of this amine. This effect is accompanied by a decrease in the spontaneous firing rates of the substantia nigra (A9) DA neurons projecting to the caudate-putamen. Biochemical and electrophysiological data indicate that this decreased firing rate is mediated by a descending GABA-ergic projection from the caudate-putamen to the A9. For example, Bunney & Aghajanian (Arch. Pharmacol., 304, 255-261, 1978) showed electrophysiologically that picrotoxin, a GABA antagonist, reversed the d-A-induced depression in A9 impulse flow. Furthermore, after kainic acid lesions of the caudate nucleus, increased doses of d-A were needed to decrease A9 impulse flow, and picrotoxin failed to reverse the d-A effect. The present study sought to examine whether the medially adjacent DA neurons in the ventral tegmental area (A10), which project to the ventral portions of the caudate-putamen and nucleus accumbens, responded to d-A by a similar feedback mechanism.

Single unit activity was recorded from the A10 region in chloral hydrate anesthetized rats (400 mg/kg). DA neurons in this region are characterized by their slow (1-9 Hz) spontaneous firing rates, and long (>2msec.) action potential durations. Intravenous administration of d-A (1-1.5 mg/kg) produced a greater than 50% decrease in the firing rate of these neurons. Subsequent administration of picrotoxin (2-3.4 mg/kg) failed to reverse the effects of d-A while the DA antagonist, haloperidol (1-2 mg/kg) did. The same procedures were repeated with rats that received kainic acid (2 μg/μl) lesions of the ventral caudate/nucleus accumbens area. Histological examination of these regions showed massive cellular destruction which presumably affected descending pathways projecting to the A10 region. However, the A10 neurons responded to the same doses of d-A and haloperidol as in the normal rat. These findings suggest that the effects of d-A on A10 neurons are not mediated by a ventral caudate/nucleus accumbens feedback loop but perhaps by a direct action on A10 DA neurons. (Research supported by USPHS grants MH-27574, MH-30546, & MH-05831).

1869 α_2-ADRENERGIC RECEPTOR DESENSITIZATION: RECEPTOR UNCOUPLING FROM Ca^{++} CHANNEL IN RAT PAROTID CELLS. James N. Davis, Wendy Maury*, and Robert McDaniel*. VA Medical Center and Duke University Medical Center, Durham, N. C.

Parotid acinar cells are a particularly useful model for the study of α_2-adrenergic receptors since they have easily measured membrane receptor binding and a well-defined, Ca^{++} dependent response, the release of K^+. We previously described a type of α-adrenergic receptor desensitization that was mediated by a rapid alteration in the membrane receptor (Strittmatter et al., J. Biol. Chem. 252: 5478, 1977). This type of desensitization took 15 minutes to become complete, was voltage-dependent, occurred in mildly acidic (pH 6.5-7.0) conditions, and did not interfere with the muscarinic cholinergic response of these cells, also a Ca^{++} dependent K^+ release.

We now report a second type of α-adrenergic desensitization that occurs at physiological pH (7.4). Cells exposed to 100 μM epinephrine and then washed lose both their α-adrenergic and muscarinic cholinergic responses. This second type of desensitization is more rapid than the previously described receptor changes, being complete in 2-3 minutes and spontaneously reversing in 10 minutes. α-Adrenergic stimulation is required for the desensitization since epinephrine in the presence of excess phentolamine does not produce it. However when Ca^{++} is introduced into desensitized cells by the ionophore A23187, they release K^+ as well as washed controls showing that desensitization must prevent Ca^{++} entry. Desensitization can be elicited even in the absence of Ca^{++} (with EGTA) and is voltage-dependent. Although no cholinergic response is present, [^{3}H]-QNB binding to desensitized cells is the same as washed controls.

Our data demonstrate that α-adrenergic stimulation produces a heterologous desensitization of the adrenergic and cholinergic responses in parotid acinar cells. These data support experiments (Putney et al. J. Physiol. 268: 139, 1977) suggesting that these two receptors share the same Ca^{++} channel. We suggest that persistent α_2 stimulation leads to an uncoupling of the channel from both its adrenergic and cholinergic receptors. Since many nerve terminals have both α_2-adrenergic and muscarinic cholinergic receptors, this type of desensitization may play an important role in synaptic communication.

1870 EFFECTS OF β-ADRENERGIC DRUGS ON APOMORPHINE-INDUCED MODIFICATION OF BEHAVIOR IN MONKEYS AND CHICKENS. B. Delbarre and M. Goustard*,(SPON: R.W. Keller, Jr.), Laboratoire Ch. Exp. Fac. Medicine 37032, Tours, France and Laboratoire d'Ethologie Comparee, 91530, Saint-Cheron, France.

Drugs with β-adrenergic actions are known to affect mood and behavior. For example, propranolol, a β-adrenergic blocker, has been used as a therapeutic agent in the control of psychotic symptoms. Recently, we showed that clenbuterol, a β_2 adrenoreceptor stimulant, has antidepressant activity (Delbarre et al., Mol. Biol. and Pharmacol. of Cyclic Nucleotides 255-258, 1978). In the present investigation, we studied the effects of clenbuterol and DL propranolol on the behavior of monkeys (Macaca Fascicularis) treated intramuscularly (IM) with apomorphine (HCL) 0.4 mg kg^{-1}. Five to thirty minutes after administration, apomorphine produces hyperactivity, increased fearful reactions to observers and stereotyped behavior such as chewing, biting, licking, self-picking, self-grooming and vocalizations. Clenbuterol 5 mg kg^{-1} or DL propranolol 5 mg kg^{-1} administered IM ten minutes before apomorphine significantly attenuated or suppressed the apomorphine-induced behavioral modifications. In chickens IM apomorphine 0.1 mg kg^{-1} induced hypermotility and pecking. At the same dose-range, clenbuterol and DL propranolol antagonized the actions of apomorphine. Similarly, we have shown that neuroleptic drugs blocked apomorphine-induced behavioral alterations in monkeys and chickens (Delbarre et al., Collegium Internat. Neuro-Psychopharmacol., 10th Congress, 1976; Goustard et al., J. Pharmacol. (Paris) 8: 4, 1977). Our evidence suggests that the psychotropic activity of β-adrenergic drugs may be easily and reliably evaluated by testing the ability of these agents to block apomorphine-induced behavioral alterations in monkeys and chickens.

1871 ELECTROPHYSIOLOGICAL CORRELATES OF NORMAL AND HALOPERIDOL-INDUCED IMMOBILITY IN RATS. Marc De Ryck* and Philip Teitelbaum. Psychol. Dept., Univ. of Illinois, Champaign, ILL 61820.

Wakeful immobility in rats (n=10), chronically implanted with bipolar electrodes in somatosensory cortex (SSC) and hippocampus (H), was accompanied by low voltage fast activity (desynchronization, DESYNC) in SSC and large amplitude irregular activity in H. However, between periods of wakeful immobility and prior to the onset of slow wave sleep (SWS--i.e., large amplitude slow waves in SSC and H), intermittent hypersynchrony mixed with DESYNC appeared in SSC. This activity consisted of spindle-shaped bursts of biphasic spike or spike-wave discharges with frequencies of 7-10 spikes/sec and durations of 1-30 sec. Spike amplitudes (.3-2.2 mV), which always exceeded wave amplitudes (.2-.7 mV), were 2.5-13 times larger than the background DESYNC. SSC spiking spindles occurred in apparently awake but immobile rats and were associated with head bobbing in phase with the spike discharges together with fine whisker tremor. SSC spiking spindles in rats may represent an EEG correlate of a distinct immobility state occurring between wakeful immobility and SWS. Similar "twilight states" have been reported in cats and monkeys by Sterman, Rougeul and their associates.

.5-5 mg/kg haloperidol (HAL) produced catalepsy/akinesia accompanied by a dose-dependent increase in occurrence of SSC and H large amplitude slow waves similar to those observed in normal SWS. Thus, at these dosages, HAL predominantly produces somnolent immobility. At higher dosages (10-15 mg/kg), this SWS pattern was replaced, often abruptly, by almost continuous SSC spiking spindles (e.g., during 65-97% of a 30 min. period). Cholinergic agents (.5 mg/kg physostigmine, 8 mg/kg arecoline) completely abolished HAL-induced SSC spiking spindles and produced continuous DESYNC. Likewise, anticholinergic drugs (10 mg/kg atropine, .5 mg/kg scopolamine) abolished HAL-induced SSC spindles, but replaced them by continuous large amplitude slow waves (synchronization, SYNC). When anticholinergic and cholinergic agents were sequentially injected in rats with HAL-induced SSC spindles, the shift from cortical SYNC to DESYNC passed through a stage in which spiking spindles temporarily reappeared. In contrast to their effect on HAL-induced SSC spiking spindles, neither cholinergic nor anticholinergic agents suppressed petit mal or grand mal seizures associated with very high dosages of HAL (20-45 mg/kg). Thus, to the extent that SSC spiking spindles represent a dopaminergic-cholinergic imbalance, their reversal by both cholinergic and anticholinergic drugs suggests that this EEG correlate of normal immobility and HAL-induced akinesia depends on a narrow range of dopaminergic-cholinergic interactions. Supported by NIH Grant RO1 NS 11671.

1872 REGULATION OF β-ADRENERGIC RECEPTORS AND cAMP ACCUMULATION IN VITRO IN SLICES OF RAT CEREBRAL CORTEX. Mark D. Dibner and Perry B. Molinoff. Dept. of Pharmacology, Univ. of Colorado Med. Ctr., Denver, CO 80262.

The effects of incubating slices of rat cerebral cortex with the β-adrenergic agonist isoproterenol (ISO) on β-adrenergic receptor density and on catecholamine-stimulated cAMP accumulation were investigated. Exposure of slices to ISO led to a 40% decrease in receptor density (as measured by Scatchard analysis of IHYP binding). The effect of ISO was complete by 3-5 min and had an EC50 of 10 μM. In contrast, ISO-stimulated cAMP accumulation decreased by approximately 75% as measured by a protein binding assay. The effect of ISO on cAMP accumulation was more rapid (complete by 0.5 min) and had an EC50 of approximately 0.01 μM. Thus, incubation with ISO under appropriate conditions led to decreases in β-adrenergic receptor mediated cAMP accumulation without changing receptor density. The effects of ISO on receptor density and on ISO-stimulated cAMP accumulation were blocked by coincubation with the β-adrenergic receptor antagonist sotalol. The cAMP effects appeared to be receptor specific since PGE_1 stimulation of cAMP was not decreased following incubation with ISO nor was IHYP binding decreased following incubation of slices with PGE_1. Incubation with ISO did not significantly alter the IC50 for displacement of IHYP binding by either agonists or antagonists. Lastly, the observed decreases in β-adrenergic receptor numbers could be slowly reversed by reincubation of slices in the absence of ISO or rapidly reversed by incubation of homogenates with guanine nucleotides before binding.

1873 LEAD-INDUCED HYPERACTIVITY IN MICE AND BLOOD-BRAIN BARRIER FUNCTION. Floyd R. Domer and Carlos Wolf*, Dept. of Pharmacology, Tulane Univ. School of Medicine, New Orleans, La. 70112.

The offspring from CD-1 mice were exposed to 0.5% sodium or lead acetate in the drinking water from time of birth. After weaning, locomotor activity was evaluated. Individual mice were placed in a box which had the bottom marked off into two-inch squares. The numbers of squares crossed during a 10-minute period of observation was recorded. These observations were made three times at weekly intervals. The lead-exposed mice were hyperactive and smaller than the sodium-exposed mice. Amphetamine and caffeine caused a decrease in locomotor activity of the lead-exposed mice whereas methylphenidate and pemoline caused an increase in locomotor activity of the lead-exposed mice. The permeability of the blood-brain barrier (BBB) was evaluated by the intravenous injection of either radioactive technetium ($^{99m}TcO_4^-$) or radioiodinated human serum albumin (I^{131} RISA) sixty minutes prior to sacrifice. A blood sample was obtained by cardiac puncture and the brain was dissected out. The content of radioactivity in the brain relative to that of the blood was the criterion for judgment of the permeability of the BBB. When technetium was used to assess BBB function permeability was decreased by amphetamine, caffeine and pemoline and increased by ephedrine and methylphenidate in the lead-exposed animals relative to sodium-exposed animals. When RISA was used to assess BBB function permeability was increased by amphetamine (1 mg/kg) and decreased by amphetamine (3 mg/kg), methylphenidate (20 mg/kg) and ephedrine (40 mg/kg) in the lead-exposed mice relative to the sodium-exposed mice. It was concluded that lead-induced hyperactivity is not a valid model for evaluating drugs for use in children with hyperactivity or minimal brain dysfunction. In addition, changes in permeability of the BBB to technetium and RISA caused by the drugs are opposite. This suggests that different mechanisms are responsible for the BBB for the two probes.

1874 EFFECTS OF LSD AND 2-BROMO-LSD ON VISUALLY EVOKED ACTIVITY OF SINGLE CORTICAL NEURONS IN THE CAT. A. Dray and G.G. Somjen Dept. Physiology, Duke Univ. Med. Center, Durham, N.C. 27710.

Systemic or local administration of LSD causes complex changes in the discharge pattern of visual cortical neurons when these are activated by physiological optical stimulation (Rose & Horn, 1977, Expt. Brain Res. 27, 71; Hilmy et al. 1977, Neurosci. Abst. 3 562; Fox & Dray, 1979, Brain Res. 161, 107). To determine whether these changes are related to the hallucinogenic properties of LSD the actions of this drug have been compared with the supposed non-hallucinogenic analogue 2-bromo-LSD(BOL). Data were collected from single neurons in the striate cortex of anesthetized, immobilized cats. Drugs were administered intravenously or locally by microelectrophoresis. Visual stimulation usually consisted of an optimally orientated illuminated light bar moving back and forth across the receptive field. Systemic LSD either enhanced or depressed visually evoked responses. These effects were clearly dose related, enhancement being observed with low doses (0.1-10 ug/kg) and depression more frequently at higher doses (10-25 ug/kg). Accompanying this were changes in neuronal receptive field properties, directional selectivity and unstimulated background discharges. Such effects were observed on cells with both simple and complex receptive fields. Electrophoretic LSD produced similar dose dependent effects suggesting a direct action of LSD on the visual cortex. Unexpectedly systemic BOL (10-25 ug/kg) also produced similar effects to LSD. However comparisons on the same neurones suggested that it was some 20-100 times less active in producing enhancement of visually evoked activity but equipotent in producing depression. Electrophoretic BOL rarely produced changes in evoked activity, possibly due to inadequate expulsion from micropipettes. These results suggest that enhancement of visually evoked activity is an important action of LSD related to its hallucinogenic properties and that BOL in higher doses should produce visual disturbances in the cat (Fanchamps, 1978, Handb. Exp. Pharm. 49, 567).

1875 SLOW POTENTIATION OF CA1 HIPPOCAMPAL SLICE FIELD POTENTIALS AND ACUTE EFFECTS OF LOW-DOSE ETHANOL. Dominique Durand and Peter Carlen. Neurobiology Lab of the Addiction Research Foundation Clinical Institute, Playfair Neuroscience Unit, Toronto Western Hospital, University of Toronto, Toronto, Canada.

Field potentials were recorded from CA1 hippocampal neurons in the in vitro transverse hippocampal slice preparation. Orthodromic stimulation of the stratum radiatum at low frequency (.1 to .2 Hz) induced a slow but steady increase in the size of the field potential (2 to 10 fold in 30 to 60 min.). Input/Output (I/O) curves of the population spike recorded at 10 min. intervals over a 30 to 60 min. period showed a definite increase in amplitude and a shift to the left. This decrease in the threshold of the response cannot be attributed to an increased afferent volley since the size of the presynaptic spike remained constant.

Because of this slow potentiation, effects of low-dose ethanol (50 mM to 100 mM) were difficult to assess. However, after stabilization of the response, ethanol was added to the bath. Ethanol at 100 mM consistently produced a reversible depression of the field potential of 25%. 50 mM had different effects: in a total of 13 slices, 7 showed a depression (5 to 20%) of the population spike (5 of which were accompanied by acute tolerance ie. return to baseline during ethanol perfusion); 4 slices showed an increase (50 to 10%) of the response, 3 of which were accompanied again by acute tolerance; 2 slices did not show any effects. The time course of the peak ethanol response was between 15 to 30 min. The response returned to baseline during the ethanol infusion after another 15 to 30 min. period.

These depressing effects of ethanol were reversible within 30 min. by switching back to the control solution and were accompanied by an increase threshold as shown by a shift to the right of the input/output curves recorded during the ethanol perfusion period. Because the ethanol-induced increase in the size of the population spike was correlated with shorter periods of stimulation before stabilization, we feel that this response could also be attributed to further potentiation of the field potential, the later "tolerance" to this increase being then the depressing effects of ethanol.

These initial results suggest that clinically relevant doses of ethanol (50 to 100 mM) are effective in vitro but further experiments are necessary to understand these acute physiological changes.

1876 **SPECIFIC PHOSPHOPROTEINS IN THE FUNCTION OF OPIATE RECEPTORS.** **Yigal H. Ehrlich, Leonard G. Davis and Peter Keen*. Univ. of Mo.-Columbia, Sch. of Med., Mo. Inst. of Psychiatry, 5400 Arsenal St., St. Louis, MO. 63139**

We have reported that preparations containing synaptic membranes from the neostriata of morphine-dependent rats demonstrate a 50% decrease in endogenous phosphorylative activity compared to preparations from placebo treated controls. Examination by SDS-gel electrophoresis revealed that this decrease was directed specifically towards membrane phosphoproteins designated F and H (M.W. 47K and 15-20K, respectively; Life Sci. 23: 137, 1978). Subsequent studies in our laboratory have demonstrated that high concentrations of alkaloid opiates (0.5-5mM) and low concentrations of enkephalin and β-endorphin (10^{-8}-10^{-4}M) selectively inhibit in-vitro the phosphorylation of the same proteins (F and H) affected by long-term morphine in-vivo (Davis and Ehrlich, Adv. Exp. Med. Biol., in-press). We have hypothesized then that the membrane-bound enzymatic machinery for the phosphorylation of proteins F and/or H may be linked functionally, and perhaps also physically, to opiate receptors. Therefore, we have extracted our membranes with the non-ionic detergent Brij-36T. This treatment was reported by Simon, et al (Science, 190: 389, 1975) to extract stereospecific opiate-binding-sites from synaptic membranes. When synaptic membranes were first incubated with γ-^{32}P-ATP and then extracted with Brij-36T, close to 100% of the phosphorylated protein F and some of the H co-extracted with the opiate receptor. Moreover, the Brij extract and the membrane-residue retained phosphorylative activity. Endogenous phosphorylation of protein F was in evidence only in the extract. Chromatography of the Brij extract by gel filtration (Biogel-A1.5m) yielded macromolecular protein complexes that contained protein-bound [^{3}H]etorphine and the endogenous phosphorylation systems. Furthermore, concentrations of Brij-36T which were shown by Simon et al (1975) to distort the opiate binding site, caused selective inhibition of the endogenous phosphorylation of F and H, without affecting the endogenous phosphorylation of other proteins in synaptic membranes. Finally, opiate-inhibited phosphorylation of F and H was accompanied by altered activity of adenylate cyclase in the same preparations. Preliminary experiments indicate possible cause-effect relationships between these systems. The results suggest that the function of opiate receptors may involve complex interactions between opioid-peptides, their binding sites, and membrane-bound systems that phosphorylate specific phosphoproteins. Supported in part by a grant from the Epilepsy Foundation of America to Y.H.E., and by intramural funds from the MIP.

1877 EFFECTS OF CHRONIC INSTILLATION OF DOPAMINERGIC DRUGS INTO SPECIFIC SITES. Everett H. Ellinwood, Jr., George Dougherty, Ron E. Pruitt and M. Marlyne Kilbey, Dept. Psychiatry, Behav. Neuropharmacology Sect., Duke Univ. Med. Ctr., Durham, NC 27710

Several hypothesis relating Dopamine system mechanisms to the effects of dopamine agonists and antagonists have been proposed for experimental models of clinical disease ranging from dyskinesia to psychosis. Most frequently chronic drug induced behavioral changes, e.g., stimulants and neuroleptics are considered mainly in terms of post-synaptic receptor changes rather than the interaction of neuronal with synaptic mechanisms. This report will review data from several studies in which dopamine system sites, e.g., either unilateral substantia nigra and caudate are chronically treated with dopamine agonists or antagonists instilled via cannulae connected to Alza osmotic minipumps, then tested for post-treatment responsivity to apomorphine and amphetamine. For example, preliminary data analysis indicates that chronic amphetamine into the caudate leaves a residual state where animals rotate contralateral following i.p. amphetamine, yet show no rotational preference to apomorphine. This implies a pre-synaptic mechanism. On the other hand, chronic L-Dopa instillation into the substantia nigra renders animals that rotate ipsilateral to apomorphine which is in keeping with a subsensitive neuronal soma dopamine receptor mediating an inhibition of firing rate. In general, our results are consistent with a significant pre-synaptic role for residual chronic drug effects.

1878 CORRELATION BETWEEN STEREOTYPED BEHAVIOR AND DOPAMINE RECEPTOR BINDING IN AN ANIMAL MODEL OF TARDIVE DYSKINESIA. Jeremy Z. Fields, Chinwuba R. Okafor*, Bruce I. Diamond, & Richard L. Borison. Dept. Pharmacol., Chicago Med. Sch. & Mt. Sinai Hosp., Chicago IL 60612

Anticholinergic agents such as Cogentin(COG) and Artane(ART) are often coadministered with antipsychotic drugs to reduce extrapyramidal side-effects. These side-effects are thought to result from a shift in the functional balance between acetylcholine (ACh) and dopamine(DA) in the striatum(ACh> DA). It has recently been suggested that these anticholinergics may, in addition, promote the future development of neuroleptic-induced tardive dyskinesia(TD)(DA> ACh). To understand how this might occur, we tested the effects of these drugs in an animal model of TD. Chronic haloperidol(HAL)(i.p.,0.5mg/kg,14 days) produced a "sensitization" of striatal DA activity: stereotyped behavior(StB), induced by a challenge dose of apomorphine(APO)(0.25 mg/kg) 4 days after HAL withdrawal, was increased 5 to 6 fold while the number of DA receptors(DAr)(3H-spiroperidol binding) was increased 1.3 to 1.5 fold. Muscarinic cholinergic receptors(AChr) (3H-QNB binding) did not change in any of these studies(it is interesting that a DA antagonist increased the number of DAr but the cholinergic antagonists did not increase the number of AChr).

If either COG or ART(0.5 mg/kg) are coadministered with HAL (but not if they are given alone), there is a further small but significant increase in StB. No significant parallel increase in DAr could be detected. Amantadine(AMAN)(25 mg/kg), another anti-parkinsonian agent(believed to act as an indirect DA-mimetic) in combination with HAL, reduces the StB and decreases DAr binding. When APO(0.5 mg/kg) was coadministered chronically with HAL, the StB is significantly reduced while the HAL-induced increase in DAr is completely blocked. Chronic APO alone, in this paradigm, produced little change in either StB or in DAr.

Our data indicate that although there is not a 1 to 1 correspondence between StB and DAr, qualitatively, both parameteres change in parallel fashion. It has been shown clinically that the administration of DA-mimetics antagonizes the abnormal movements in TD. We have now shown experimentally that the conjoint treatment of a neuroleptic with a DA-mimetic produces not only an antagonism to the neuroleptic-induced behavioral hypersensitivity, but also reverses neuroleptic-induced increases in DAr.

Thus a more clinically rational treatment choice for neuroleptic induced extrapyramidal side-effects would be the DA-mimetic agent AMAN, rather than the anticholinergics COG or ART.

1879 ASSESSMENT OF ANTICONVULSIVE EFFECT OF DIAZEPAM IN PENTOBARBITAL DEPENDENT MICE. B. A. Flint and I. K. Ho, Dept. Pharmacol. & Toxicol., Univ. Miss. Med. Ctr., Jackson, Miss. 39216.

The effect of diazepam administration on the threshold for pentylenetetrazol (PTZ) or audiogenic induced convulsions in pentobarbital dependent mice was assessed. Male ICR mice were rendered dependent on pentobarbital by the subcutaneous implantation of a 75-mg pentobarbital pellet (acid form).Control animals received placebo pellets. After three days of pellet implantation the pellets were removed and animals were administered saline or diazepam, 1 mg/kg, i.p. Six hours following pellet removal CNS hyperexcitability was evaluated by two different methods. At least three different doses of PTZ were administered s.c. to separate groups of animals. The percent of mice having a clonic convulsion within five minutes was recorded. A second method used for assessing CNS hyperexcitability was by administering at least three different subconvulsive doses of PTZ s.c. and after five minutes challenging each group with an audiogenic stimulus. Mice were administered the audiogenic stimulus by placing them in an audiogenic seizure box equipped with a two inch in diameter bell. The percent of mice having a tonic convulsion within thirty seconds after the initiation of the audiogenic stimulus was recorded. Diazepam was observed to increase significantly the ED50 for PTZ and audiogenic induced convulsions. The involvement of the GABA system related to the observed increase in ED50 for PTZ in diazepam administered animals was evaluated. The GABA levels in pentobarbital dependent animals was significantly lower than that of the placebo control mice. A further decrease in GABA was also noticed to occur in dependent mice that convulsed after the administration of PTZ as compared to those that failed to convulse. The GABA level in diazepam treated pentobarbital dependent mice was significantly elevated as compared to non-treated pentobarbital dependent animals. Also, the activity of L-glutamate-1-decarboxylase measured in dependent mice that convulsed was significantly lower than those of non-convulsed dependent mice. Thus, it was shown that diazepam is effective in increasing the ED50 for PTZ and audiogenic induced convulsions in pentobarbital dependent animals. Also, an observed decrease in GABA levels seemed to be associated with the PTZ and audiogenic induced convulsive response increase in pentobarbital dependent mice. Therefore, it is possible that the GABA system is involved in the increased hyperexcitability observed at six hours after pellet removal in pentobarbital dependent mice (Supported by Grant DA-01403 from the National Institute on Drug Abuse).

1880 MORPHINE ENHANCES AND DIAZEPAM SUPPRESSES THE NEUROTOXICITY OF SYSTEMICALLY ADMINISTERED KAINIC ACID. Terry A. Fuller and John W. Olney. Washington Univ. School of Med., St. Louis, MO 63110.

Systemically administered kainic acid (KA) induces wet-dog shakes (WDS), convulsions and acute neuronal necrosis in various brain regions, particularly the hippocampus and olfactory cortex. Since WDS is a behavioral phenomenon observed in rats undergoing naloxone-precipitated withdrawal from opiates, we explored in a previous study, the effects of naloxone pre-treatment on KA-induced WDS and found that naloxone conferred a mild protective action in relation primarily to WDS but also to the convulsions and brain damage induced by KA. Ben-Ari et al., (Br. Res., 165, 362-365, 1979) found that the anticonvulsant, diazepam suppressed convulsions and blocks the "distant" hippocampal degeneration associated with local injections of KA into the amygdala. Here we report that morphine augments and diazepam suppresses both the convulsions and brain damaging effects of systemically administered KA.

When adult male Sprague-Dawley rats were given 7 mg/kg KA subcutaneously (sc), only 1 of 14 (7%) exhibited convulsions and sustained acute damage to the hippocampus and olfactory cortex. When the same dose of KA was preceded by injection of morphine, 10 mg/kg sc, 10 of 10 animals (100%) convulsed and sustained hippocampal and olfactory cortical damage. When 29 rats were injected with 12 mg/kg KA sc, 27 (93%) exhibited convulsions and the typical pattern of brain damage, but when this dose of KA was preceded by 20 mg/kg diazepam sc, the pattern of brain damage was characteristically modified with pathological changes being mild and only detectable in one brain region (CA3 hippocampus). The severe convulsions typically observed in rats treated with 12 mg/kg KA were eliminated but the incidence of WDS was not reduced by diazepam pre-treatment.

Our findings suggest that KA-induced convulsions and brain damage are closely associated phenomena; morphine augments both effects and diazepam suppresses both. The suppressant action of diazepam differs from that of naloxone in that WDS were influenced by naloxone but not diazepam. Additional research will be required to adequately clarify the mechanisms and receptors involved in the modification of KA neurotoxicity by these agents. Support by NIH grants NS-09156, DA-00259, ES-07066, a Huntington's Chorea Fdn. grant and RSD Award MH-38894 (JWO).

1881 METABOLIC CORRELATES OF TOLERANCE TO ETHANOL IN TWO SPECIES OF DROSOPHILA. F. Garcin[1], S. Radouco-Thomas[1], S. S. Chawla*[1], J. M. Perron*[2] and C. Radouco-Thomas[1]. Unité de Recherche sur l'Abus des Drogues et de l'Alcool, Hôp. St-François d'Assise, Dépt. Pharmacol., Faculté de Médecine[1] and Dépt. Biol., Faculté des Sciences[2], Université Laval, Québec, Canada.

Two sibling species of drosophila were used: Drosophila Melanogaster (Colmar) and Drosophila Simulans (Villeurbane). In a first set of experiments, adult individuals of both species were submitted to ethanol selection pressures according to the method of David et al (1974). For each generation, the 50% lethal ethanol concentration (LC_{50}) was determined. Concentrations of ethanol ranging from 6 to 20% (Drosophila Melanogaster) and from 1 to 10% (Drosophila Simulans) were used.

In a second set of experiments, the animals were exposed to ethanol (LC_5) during the developmental stages and submitted in adulthood to the same selection pressures as mentioned above.

In the two sets of experiments the specific activity of alcoholdehydrogenase (ADH) was determined spectrophotometrically in the whole body and the separated head (brain) of adults. The enzymatic polymorphism was revealed by polyacrylamide gel electrophoresis (Borner 1974).

In the flies submitted to selection in adulthood without prior ethanol exposure, the ethanol tolerance (LC_{50}) increased from generation to generation. The tolerance increase seemed to be parallel in both species although the initial tolerance was lower in Drosophila Simulans than in Drosophila Melanogaster.

In flies exposed to ethanol during all the developmental stages the selection pressure seemed to be more efficient. The concomitant changes in ADH electrophoretic pattern and specific activity are discussed for both experiments.

David, J., Fouillet, P. and Ariens, M.J. Arch. Zoologie expérim. 1974, 115: 401-410.

1882 PHYSICAL DEPENDENCE TO FK-33,824 [Tyr-dAla-Gly-MePhe-Met-(O)-ol], A SYNTHETIC METHIONINE ENKEPHALIN ANALOGUE, IN THE CHRONIC SPINAL DOG. P. E. Gilbert* and D. R. Jasinski. NIDA Addiction Research Center, Lexington, KY 40583.

FK-33,824 is a pharmacologically active peptide with some pharmacologic actions in the chronic spinal dog that resemble those of morphine (Gilbert and Jasinski, Fed. Proc., 1979). To confirm that FK-33,824 is a morphine-like drug, a direct addiction study was done in the chronic spinal dog. FK-33,824 was infused through an indwelling jugular catheter every 4 hr in a dose of 0.35 mg/kg/infusion in five chronic spinal dogs. The animals were stabilized at this dose of FK-33,824 for 2 weeks prior to the beginning of precipitation and suppression experiments. Throughout the study, 1 to 5 min after each drug infusion the dogs vomited. (This action of FK-33,824 was also observed in other dogs that received the drug only one time in acute studies.) Tolerance did not develop to this effect of FK-33,824, nor could the vomiting be blocked by the prior administration of 1.0 mg/kg of naltrexone in nondependent dogs. Naltrexone precipitated an abstinence syndrome in animals receiving FK-33,824 chronically. This abstinence syndrome resembled the naltrexone precipitated abstinence syndrome in morphine-dependent dogs. The most prominent signs of precipitated abstinence were stepping, salivation, mydriasis, tachycardia and tachypnea. Naltrexone was only about 1/8 as potent in precipitating an abstinence syndrome in FK-33,824-dependent dogs as it was in morphine-dependent animals. The dogs began to show signs of withdrawal abstinence approximately 4 hr after their last infusion of FK-33,824. Withdrawal from FK-33,824 had a more rapid onset and earlier peak (10-12 hr) than withdrawal from morphine. Both FK-33,824 and morphine suppressed withdrawal abstinence in 12-hr abstinent FK-33,824-dependent dogs. In conclusion, the chronic administration of FK-33,824 produces physical dependence in the dog. Additionally, the emetic effects of FK-33,824 are probably due to interactions at a non-opioid receptor since this action of FK-33,824 is not antagonized by doses of naltrexone, which precipitates an abstinence syndrome in dogs receiving FK-33,824 chronically and antagonizes the miotic and flexor reflex depression produced by single doses of FK-33,824.

1883 DEVELOPMENT OF OPIATE MECHANISMS IN THE GUINEA PIG SMALL INTESTINE IN RELATION TO THE ONTOGENY OF NEURONS KNOWN TO BE COMPONENTS OF THE ENTERIC NERVOUS SYSTEM. Alan R. Gintzler*, Taube P. Rothman and Michael D. Gershon. (Spon. K. Pfenninger.) Dept. of Anatomy, Columbia Univ., College of P&S, New York, New York 10032.

The development of opiate mechanisms in the guinea pig small intestine has been studied with reference to the development of transmitter mechanisms of neurons known to be components of the enteric nervous system. At 25 days' gestation, neurons and a primitive neuropil could be found in the enteric mesenchyme. At this time markers for two enteric neurotransmitters could be demonstrated, i.e., synthesis of ^{3}H-acetylcholine (^{3}H-ACh) from ^{3}H-choline, and specific axonal uptake of ^{3}H-5-hydroxytryptamine (^{3}H-5-HT). This early gut also showed high affinity, stereospecific binding of ^{3}H-diprenorphine that was antagonized by levallorphan but not dextrophan. Thus, opiate receptors are detectable in the gut as soon as neurons can be identified. Neuronal precursors, however, are probably present prior to 25 days. Putative serotonergic precursors were recognized by their uptake of ^{3}H-5-HT into cell bodies as early as day 20. Adrenergic innervation appeared gradually between days 32 and 48. Functional innervation of the longitudinal layer of smooth muscle was established much later in ontogeny. Spontaneous tone and a tetrodotoxin-sensitive, 5-HT-induced relaxation of the muscle were detected at day 42 (neither norepinephrine nor ATP mediate this effect). Contraction in response to ACh appeared at day 48 and responses to electrical stimulation were elicited at days 50-56. Acute and chronic (tolerance-dependence) effects of opiates were also apparent by day 56. The early appearance of opiate receptors is consistent with their being associated with either cholinergic or serotonergic neurons or both. Moreover these early opiate receptors suggest that opiates or endogenous substances that act on opiate receptors might have effects not revealed by standard indices of opiate actions. Supported by NIMH Grant #DA10772.

1884 CHOLINERGIC INTERACTIONS WITH STIMULANT-INDUCED MOTILITY. Larry P. Gonzalez and Everett H. Ellinwood, Jr., Dept. Psychiat., Behav. Neuropharm. Sect., Duke Univ. Med. Ctr., Durham, NC 27710

Recent evidence has implicated the involvement of striatal cholinergic (Ch) interneurons in a feedback regulation of activity in the nigrostriatal dopamine (DA) pathway. Since psychomotor stimulants are believed to act primarily through their effects on central DA activity, Ch modulation of DA neurons might play a role in mediating the effects of stimulant drugs. The present study examined the effects of altered Ch activity on behavioral stereotypy resulting from the administration of psychomotor stimulants. To determine the involvement of regulatory feedback mechanisms, a comparison was made between the effects of altered Ch activity on stereotypy resulting from treatment with the direct receptor stimulant apomorphine and effects resulting from agents which alter pre-synaptic DA release (amphetamine and methylphenidate). Altered feedback regulation of presynaptic DA activity would be expected to interfere with the effects of those stimulants acting pre-synaptically to a greater extent than with the effects of a direct receptor stimulant. The subjects were 258 male, Sprague-Dawley rats, 200-250 g. The measurement of stereotyped movements was performed in a Stoelting activity monitor, modified to permit quantification of restricted repetitive behaviors. This apparatus produced an analog signal with a frequency of oscillation equal to the frequency of occurrence of movements within the activity monitor. Twenty min. after an i.p. injection of either saline, physostigmine, neostigmine, scopolamine, or methylscopolamine, subjects received a second i.p. injection of either saline, amphetamine, methylphenidate, or apomorphine. Amphetamine, methylphenidate, and apomorphine produced dose-related increases in movement frequencies between 1 and 15 Hz, with a significantly greater increase in 8 Hz movements. We have previously demonstrated a significant correlation between such movements and the occurrence of stereotyped sniffing. Physostigmine significantly reduced the effects of all three stimulants. The effects of low doses of the stimulants were facilitated by scopolamine, but higher doses were not. Neostigmine and methylscopolamine did not alter stimulant-induced motility. These results indicate an involvement of central Ch neurons in the mechanisms by which stimulants alter behavior. The finding that apomorphine-induced motility is also affected by alterations in Ch activity suggests that these effects may not involve feedback regulating mechanisms, but rather suggests a more direct involvement of Ch neurons in the mediation of stimulant-induced behavioral effects.

1885 EFFECTS OF PICROTOXIN AND PHYSOSTIGMINE ON ETHANOL-INDUCED INHIBITION OF HIPPOCAMPAL UNIT ACTIVITY. Larry A. Grupp. Department of Pharmacology, University of Toronto and Addiction Research Foundation, Toronto, Canada.

We have previously demonstrated that high doses of ethanol inhibit spontaneous cell firing in the dorsal hippocampus of the awake rat. This report deals with the interaction of ethanol with each of two agents which increase the responsivity of hippocampal neurons by different mechanisms. Picrotoxin, a gaba antagonist may, in part, produce an increase in neuronal excitability by disinhibition, while physostigmine, an acetylcholinesterase inhibitor, may increase the excitatory cholinergic tone by maintaining high levels of acetylcholine.

Rats chronically prepared with hippocampal microelectrodes, fronto-cortical EEG electrodes and a jugular catheter, were pretreated intravenously either with picrotoxin (0.5 or 1.0 mg/kg) or physostigmine (0.15 mg/kg) 15 min prior to the infusion of ethanol (800 mg/kg). Recordings were taken for the entire pretreatment and ethanol periods (15 min each) and for a 15 min baseline period preceding the drug infusions.

Picrotoxin pretreatment increased unit firing rate above baseline levels, produced a reduction in heart rate and induced epileptiform (spike and wave) activity in the frontal cortex. The subsequent administration of ethanol produced an inhibition of firing which did not differ in degree from that obtained without pretreatment, although the final firing level achieved was considerably higher than that in the absence of any pretreatment. Cortical EEG was briefly normalized to low amplitude fast activity before reverting back to spike and wave activity, and heart rate reduction appeared to be reversed.

Physostigmine pretreatment produced decreases and increases in firing rate, yielded an essentially activated EEG, but did not decrease heart rate appreciably. The administration of ethanol for those units enhanced by the pretreatment brought about a quantitatively similar inhibition in rate to that obtained in the absence of pretreatment although final firing levels were again higher than in the absence of pretreatment. Those units inhibited by the pretreatment did not appear to show any further rate reduction following ethanol. Cortical EEG following ethanol showed little change from the activated mode, while heart rate also remained unaffected. Control experiments with neostigmine ruled out changes secondary to either cardiovascular or peripherally mediated effects.

These data indicate that the manipulation of hippocampal responsivity either by interfering with gaba-mediated inhibition or by augmenting cholinergically-mediated excitation does not alter the degree of firing depression produced by ethanol. (Supported by the Addiction Research Foundation of Ontario).

1886 VINYL GABA ALTERS AMPHETAMINE STEREOTYPY IN RATS. John Hammerstad, Lisa Gronke, John Nutt*, and Daniel Casey*. Depts. of Neurol. and Psych., U. Oregon Health Sci. Cent., Portland, OR 97201.

Initial studies of GABA-dopamine interactions in basal ganglia suggested that a striatonigral GABA system is inhibitory to the nigrostriatal dopamine pathway. However, direct injections into substantia nigra or systemic administration of GABA agonists have produced facilitation rather than inhibition of motor behaviors thought to be mediated by the nigrostriatal dopamine system. As part of a study of the role of GABA in an animal model of tardive dyskinesia, we made some further observations on this unexpected phenomenon by examining the effect of vinyl GABA, an irreversible catalytic inhibitor of GABA transaminase, on amphetamine stereotypy in the rat.

Eighteen hours after administration of vinyl GABA (1,000 mg/kg i.p.), control and treated animals (300 gm, male S-D rats) were given saline or dextroamphetamine (2 mg/kg). After two hours of behavioral observation, the animals were sacrificed and brains quickly removed and frozen for biochemical studies. In comparison with control animals, the vinyl GABA treated animals demonstrated an increase in the sniffing, gnawing stereotypy thought to be mediated through the neostriatal dopamine system while locomotor activity mediated by mesolimbic striatum was totally abolished. Striatal homogenates showed a 2-3 fold increase in GABA, a 42% inhibition of GABA transaminase activity and a 27% reduction in succinic semialdehyde activity. This dual action of elevated GABA on amphetamine stereotypy suggests differing interactions between GABA and dopamine systems in neostriatum and mesolimbic striatum. The results also provide additional evidence that treatments intended to increase GABA activity augment motor behavior mediated by neostriatum. Additional data, including results of GABA and dopamine binding in animals treated with neuroleptics, will be presented.

1887 ACTION OF CLONIDINE ON DOPAMINOCEPTIVE NEURONS OF THE SNAIL BRAIN
John C. Hancock, Department of Pharmacology, East Tennessee State University, College of Medicine, Johnson City, Tennessee 37601.

The action of clonidine (10^{-6} to 10^{-3}M) was studied on identified dopaminoceptive neurons in the abdominal ganglion of the snail, Helix aspersia. Standard microelectrode techniques were used to establish presynaptic, postsynaptic and local anesthetic effects of clonidine. On cell RPal (Judge, S.E. et.al. Comp. Biochem. Physiol., 61: 475-481, 1978), clonidine caused a hyperpolarization of the cell membrane, a decrease in input resistance and an inhibition of spontaneous firing. The membrane response to clonidine was less than that caused by dopamine (10^{-7} to 10^{-3} M) or methoxamine (10^{-7} to 10^{-3}M) but greater than that caused by isoproterenol (10^{-6} to 10^{-3}M). Disruption of synaptic transmission by elevating the extracellular Mg^{++} concentration did not alter the responses to these drugs. Dihydroergotamine (DHE: 10^{-6} to 10^{-3}M) but not chlorpromazine (10^{-3}M) or haloperidol (10^{-3}M) blocked the responses to clonidine, dopamine, methoxamine and isoproterenol on the post synaptic membrane. Stimulating the left pallial nerve evoked an inhibitory potential of long duration preceeded by an EPSP (ILD-E) in cell RPal. Stimulating the anal nerve evoked an antidromic potential followed by multiple firing. DHE but not chlorpromazine blocked all synaptically evoked potentials without affecting the antidromic potential. Clonidine (10^{-6} to 10^{-3}M) produced a progressive decrease in the synaptically evoked potentials without affecting the antidromic potential. For threshold stimulation, complete block of the ILD required 15 ± 1.7 min while blockade of the ILD-associated EPSP required 31 ± 1.8 min. For supra maximal stimuli, blockade of the ILD required 31 ± 1.7 min while blockade of the ILD-associated EPSP required 67 ± 1.5 min. Blockade of multiple firing accompanying stimulation of the anal nerve required 61 ± 1.9 min. Following complete blockade of the synaptic potentials by clonidine, the cell membrane was normally responsive to dopamine (10^{-7} to 10^{-3}M).

The results in elevated Mg^{++} demonstrate that clonidine has a direct post synaptic action on dopaminoceptive neurons to produce a dopamine-like response. The blockade of the responses to clonidine, dopamine, methoxamine and isoproterenol by DHE suggests that all of the drugs act on a dopamine receptor mediating inhibition. The failure to affect the antidromic potential eliminates the possibility of a local anesthetic action. The effect of clonidine to block synaptic potentials without affecting the cell response to dopamine suggests that clonidine has a presynaptic action to inhibit dopamine release.

1888 Dexamphetamine Increases Striatal Single Unit Activity in Freely Moving Rats.
Eric L. Hansen* and James G. McElligott (Spon: E. Geller) Department of Pharmacology, Temple Univ. School of Medicine, Philadelphia, PA 19140.

In awake freely moving rats, dexamphetamine (5 mg/kg, i.p.) significantly increased ($p < .001$) the firing rate of a group of individual striatal neurons (n = 13) by 100% during periods of drug-induced locomotion and stereotyped behavior. Individual cells increased their firing rate for periods ranging from 1 to 4 hours. However, the group as a whole had significantly elevated firing rates over the entire four hour time when contrasted with the preinjection rate. A group of saline (i.p. injection) control cells (n = 5) manifested no change in rate over a similar comparison period. This result agrees with a previous multi-unit recording study in freely moving rats which found that dexamphetamine (1-10 mg/kg, i.p.) caused small populations of striatal neurons to increase their average rate of discharge. In contrast, dexamphetamine has been reported to cause increases, decreases, or bi- and tri-phasic changes in firing of individual striatal neurons in immobilized, artificially respired rats. The discrepancy between data derived from freely moving and immobilized animal emphasizes the hazards of inferring neuronal correlates of dexamphetamine-induced behavior from experiments on immobilized non-behaving animals.

1889 BENZODIAZEPINE RECEPTORS IN PRIMARY CULTURES OF CEREBRAL CORTEX.
T.K. Harden and K.D. McCarthy*, Dept. of Pharmacology, Univ. of North Carolina, School of Medicine, Chapel Hill, N.C. 27514.

Benzodiazepine receptors were studied in primary cultures of rat cerebral cortex using ^{3}H-flunitrazepam (^{3}H-FNT) as a radioligand. Cultures containing mixed populations of neurons and glia were prepared from 18 day gestation rats and grown for 4 days. Scatchard analysis of ^{3}H-FNT binding to membrane fractions obtained from these cultures revealed a single high affinity binding site with a Kd (≈ 1.4 nM) identical to that observed in membrane preparations of adult cerebral cortex. Clonazepam, diazepam, oxazepam, and chlordiazepoxide inhibited the binding of ^{3}H-FNT with apparent Ki values (0.3, 8, 20, and 800 nM, respectively) that were similar to those determined for adult cerebral cortex. A variety of other non-benzodiazepine psychoactive drugs had little or no effect on binding at concentrations of competing drug up to 100 μM. Cultures grown for 4 days possessed the greatest amount of ^{3}H-FNT binding (101 ± 6 fmol/dish) and the highest specific activity of receptors (230 fmol/mg protein). Increasing the duration of the culture period resulted in a decrease in the number of binding sites per dish (day 8 = 44 ± 4 fmol; day 11 = 27 ± 4 fmol; day 15 = 13 ± 2 fmol). The decrease in ^{3}H-FNT binding sites coincided with a similar diminution in the number of neuronal elements as determined by (1) phase contrast microscopy, (2) transmission and scanning electron microscopy, and (3) veratridine-stimulated Na^+ uptake. In contrast, the number of glial cells and amount of protein per culture increased markedly over the same time period. When neuron-containing cell clusters in 3 day cultures were separated from the glial cell bed by physical agitation, greater than 90% of the ^{3}H-FNT binding sites were recovered in the cell cluster fraction. Growth of cultures in the presence of antimitotics resulted in virtual elimination of glial cells from the cultures with a much smaller reduction in the number of neurons. Under these conditions the number of ^{3}H-FNT binding sites was 60-70% of that observed in control cultures. Specific binding of ^{3}H-FNT was not detectable in pure astroglial cultures or in mixed glial cultures prepared from newborn rat cerebral cortex. The data indicate that primary cultures of rat cerebral cortex may serve as a useful model system for the study of benzodiazepine receptors. Preliminary results suggest that specific ^{3}H-FNT binding sites in these cultures may reside primarily on neuronal elements.

1890 EFFECTS OF ETHANOL ON SYNAPTOSOMAL CALCIUM TRANSPORT.
R. Adron Harris and William F. Hood. V.A. Med. Center and Dept. Pharmacol. U. Missouri, Columbia, MO 65212.

Effects of ethanol and related drugs on synaptosomal calcium transport were investigated using the K^+ depolarization-stimulated uptake of ^{45}Ca by intact synaptosomes (Blaustein, J. Physiol 247:617,1975) and the ATP-dependent sequestration of ^{45}Ca by intra synaptosomal organelles (Blaustein et al.,J. Gen. Physiol. 72: 15,1978) isolated from whole brain. In vitro addition of ethanol (EtOH), acetaldehyde (Acet)or pentobarbital (PB)inhibited calcium transport by both of these processes in a dose-dependent fashion:

Drug	$-K^+$	$+K^+$	ΔK^+	-ATP	+ATP	ΔATP
	nmol Ca/mg protein/1 min.			nmol Ca/mg protein/ 5 min.		
Control	3.0	8.0	5.0	0.3	1.3	1.0
Ethanol						
50 mM	3.0	7.1	4.1	0.3	1.3	1.0
200 mM	2.9	6.4	3.5*	0.3	1.2	0.9
800 mM	2.9	4.9*	2.0*	0.2	0.9*	0.7*
Acetaldehyde						
100 mM	1.9	4.4*	2.5*	0.2	0.6*	0.4*
Pentobarbital						
0.5 mM	2.6	4.8*	2.2*	0.4	1.2	0.8*

*Significantly different from control $p<0.01$

Results are from rats; similar effects were obtained in mice. The effects of these drugs were reversed when the membranes were centrifuged and resuspended in drug-free buffer. The effects were apparent as soon as 1 min. after drug addition and persisted at least 60 min. Ethanol inhibited the depolarization-dependent uptake equally over a range of assay temperatures (0°to 37°) but inhibited the ATP-dependent uptake only at higher temperatures.

Mice ingesting an ethanol-containing (7%v/v)liquid diet for seven days displayed altered synaptosomal calcium transport as compared to pair-fed controls. Depolarization-dependent and ATP-dependent transport were reduced by about 25% and 15%,respectively, by chronic alcohol exposure and the inhibitory effects of ethanol and pentobarbital added in vitro were reduced by chronic alcohol ingestion. Data from several strains of mice suggest that this effect is correlated with the development of tolerance to the behavioral effects of ethanol. In summary, the depolarization-dependent uptake was more responsive to alcohol than the ATP-dependent storage of calcium. These processes may be related,respectively,to the inhibition of depolarization-stimulated neurotransmitter release observed with moderate concentrations of ethanol and the increased resting release of neurotransmitter produced by high concentrations of ethanol. Both processes reflect the mechanisms responsible for ethanol tolerance and should prove useful for the study of these mechanisms. Supported by the National Council on Alcoholism and the Veterans Administration.

1891 THE RESPIRATORY AND CARDIOVASCULAR EFFECTS OF SINGLE AND MULTIPLE INJECTIONS OF MORPHINE IN THE DECEREBRATE RABBIT. A.H. Hassen and E.W. Riehl.* Div. of Allied Health and Life Sciences, University of Texas at San Antonio, San Antonio, Texas 78285.

Seventeen New Zealand rabbits (male, wgt. 2.3-3.7 kg) were used in a study of the respiratory and cardiovascular effects of morphine. During ether anesthesia, animals were decerebrated at the level of the superior colliculus and the trachea, femoral artery and femoral vein were cannulated. Upon completion of surgery, ether was removed and a minimum of one hour was allowed to elapse prior to the administration of morphine. Respiratory frequency and blood pressure were monitored. Heart rate (HR) and mean arterial pressure (MAP) were derived from direct measurements of blood pressure. Maximum changes occurred within 15 minutes of the intravenous administration of morphine. Results were stable over 30 minutes. In one group of animals, morphine was administered as a single, 6 mg/kg, injection. A second group received three, 2 mg/kg, injections, administered 30 minutes apart. Measurements before and thirty minutes after the single, 6 mg/kg, injections are shown in Table 1. Measurements before and thirty minutes after each of three, 2 mg/kg, injections are shown in Table 2. All values are MEAN±S.E.

TABLE 1.

	Control	6 mg/kg
Resp. Freq. (Breaths/Min)	46.5±5 N=5	23±6
H.R. (Beats/Min)	251±18.5 N=5	229±11
MAP (mmHg)	85±6.5 N=5	77±6

TABLE 2.

	Control	2 mg/kg	2 mg/kg	2 mg/kg
Resp. Freq. (Breaths/Min)	45±2.5	28±2.5 N=12	21±2	21±3
H.R. (Beats/Min)	281±11	253±14 N=10	241±15	243±14
MAP (mmHg)	82±5	73±4 N=10	70±4	72±6

Control injections of 1 ml phosphate buffered saline elicited small, transient, changes in blood pressure. Naloxone terminated the morphine response. These data demonstrate that respiratory frequency in the decerebrate rabbit is depressed to a greater degree than either heart rate or blood pressure. A single, 6 mg/kg, administration of morphine is found to be less effective than three, 2 mg/kg, injections. It is noted that the second and third injections are less effective than the first; the third injection producing little or no change. (Supported by NIDA Grant DA 01753-01).

1892 CYCLIC AMP AND OTHER ADENINE NUCLEOTIDES INHIBIT CA++-DEPENDENT POTENTIALS IN SYMPATHETIC POSTGANGLIONIC NEURONS. B.K. Henon and D.A. McAfee, Division of Neurosciences, City of Hope National Medical Center, Duarte, CA 91010, USA.

Previous studies in this laboratory have demonstrated that α-adrenergic agonists inhibit the inward Ca^{++} current in postganglionic sympathetic neurons of the rat. This results in depression of three Ca^{++}-dependent potentials: the shoulder on the repolarizing phase of the action potential, the hyperpolarizing afterpotential (HAP), and the Ca^{++} spike. Cyclic AMP has been implicated in both the mediation of α-adrenergic responses and in the control of Ca^{++} metabolism. Thus, we have examined the effect of several adenine nucleotides on Ca^{++}-dependent potentials recorded intracellularly from the rat superior cervical ganglion (in vitro).

Cyclic AMP depressed the HAP by 14% (n=4) at 0.01 mM and by 25% (n=9) at 1.0 mM. Dibutyryl and 8-Bromo cyclic AMP (n=3) also decreased the HAP about 25% at 1 mM. A number of other parameters were measured in the presence of 1 mM cyclic AMP. The duration of the HAP was reduced from 400 msec to about 250 msec. The action potential amplitude was only slightly reduced (1-3%), but its shoulder was significantly decremented. The input resistance was not affected. The Ca^{++} spike elicited in 1 μM TTX and 10 mM TEA was depressed by cyclic AMP, and this effect was not blocked by the α-antagonist, phentolamine, indicating that the effect of cyclic AMP was not due to release of endogenous catecholamines. Cyclic AMP hyperpolarized the postganglionic neurons (9 of 21 trials), but the effect was inconsistent and not dose dependent.

The phosphodiesterase (PDE) inhibitor Ro 20-1724 mimicked but did not potentiate the cyclic AMP effect on the HAP. In contrast, theophylline, a structurally dissimilar PDE inhibitor, caused a large increase in the magnitude and duration of the HAP. It is possible that theophylline has effects on Ca^{++} mechanisms unrelated to its PDE activity.

Adenosine (1 mM) reduced the HAP amplitude by 22% (n=4) and had a similar effect to cyclic AMP on the action potential amplitude and shoulder. 5'AMP also reduced the HAP (24%, n=4).

While cyclic AMP mimicked the effects of α-agonists on the Ca^{++}-dependent potentials, adenosine and 5'AMP also showed some of these effects. Thus, it is possible that cyclic AMP acts extracellularly on adenosine receptors or that adenine nucleotides act nonspecifically to antagonize Ca^{++}-dependent processes. These experiments, then, do not critically test the hypothesis that α-adrenergic actions are mediated by cyclic AMP. They do demonstrate that cyclic AMP has electrogenic actions. (Supported by NS-05820 and BRSG to C.O.H.)

1893 DIFFERENTIAL SENSITIVITY OF TWO TESTS OF DOPAMINERGIC FUNCTION TO ANTICHOLINERGIC ACTIVITY. W. F. Herblin. Central Research & Development Department, E. I. du Pont de Nemours & Company, Wilmington, DE 19898.

Evaluation of the interaction of scopolamine HBr with four neuroleptics on apomorphine-induced rearing in mice has revealed a consistent effect. Scopolamine HBr at about 3 mg/kg p.o. will double the dose of neuroleptic required to produce 50% inhibition of the rearing. This indicates that the apomorphine-induced rearing is 5-10 times less sensitive to anticholinergic activity than is amphetamine-induced turning in rats with unilateral lesions of the substantia nigra. In the latter test, the ED_{50} of neuroleptics is doubled by about .3-.5 mg/kg p.o. scopolamine HBr. It is thus possible that amphetamine-induced rotation is mediated predominantly by the striatum in which a strong cholinergic-dopaminergic balance is known to exist, while the apomorphine-induced rearing is mediated by the mesolimbic system in which the cholinergic function has been found to be considerably weaker.

1894 IN VIVO DETERMINATION OF ENDOGENOUS BIOGENIC AMINES IN RAT BRAIN USING HIGH PERFORMANCE LIQUID CHROMATOGRAPHY AND PUSH-PULL CANNULAE. J.N. Hingtgen*, C.C. Loullis, P.A. Shea and M.H. Aprison. Institute of Psychiatric Research and Depts. of Psychiatry and Biochemistry, Indiana U. School of Medicine, Indianapolis, IN 46223

In previous studies from these laboratories we have demonstrated that increases in total 5-hydroxytryptamine (5-HT) levels in specific brain areas (as well as increases in 5-HT levels in nerve ending fractions) were correlated with the disruption of food-reinforced behavior in pigeons and rats following the administration of L-tryptophan or D, L-5-hydroxytryptophan (5-HTP). One limitation in these experiments is that the trained animal must be sacrificed to permit the neurochemical determinations. Combining the methods of push-pull cannulation with those of high performance liquid chromatography (HPLC), we have measured a number of biogenic amines in the perfusate of freely moving rats. In an initial study, the hypothalamus was chronically implanted with a push-pull cannula and was perfused with 0.9% NaCl. Fifteen minute samples were collected through the push-pull cannula (flow rate: 25 μl/min) and 100 μl were injected on the HPLC without any extraction or prepurification procedure. Simultaneous determination of the levels of norepinephrine, dopamine, 5-HTP, 5-HT, and 5-hydroxyindole acetic acid (5-HIAA) in the perfusate was accomplished by means of HPLC with electrochemical detection. The HPLC system utilized a C-18 reverse phase column coupled with a glassy carbon detector and employed a modified version of the methods of Shea and Jackson (TRANS. AMER. SOC. NEUROCHEM. 10: 183, 1979). Results indicate that this combination of push-pull perfusions and HPLC assay methods can provide a simple, rapid, and sensitive technique for the in vivo simultaneous determination of the compounds released from discrete brain areas. In preliminary studies, in which 50 mg/kg D, L-5-HTP was injected (s.c.) into rats implanted with push-pull cannulae, significant increases in 5-HTP, 5-HT and 5-HIAA were measured over time using these methods. This technique could provide a useful tool in the assessment of neurochemical changes in brain during ongoing steady-state behaviors or during the disruption of behavior following administration of drugs, precursors, or other perturbations. (Supported in part by Research Grant MH-03225-20 from NIMH; Postdoctoral Grant PHS-TO1- MH 10695-13 from NIMH; and Indiana Dept. of Mental Health Grant 178-679-005 and Indiana Attorney General's Fund.

1895 Brain Serotonin and Spontaneous Locomotor Activity Changes Following Oral Tryptophan. K. Hirsh, L. DiMarco*, R. Pomerantz*, H. Cuzzone*, J. Springstead*, R. Ali* and D. Chou. General Foods Corporation Technical Center, Tarrytown, New York 10591.

It has been shown (1) that L-tryptophan (L-T) 0.03, 0.1, 0.3, 1.0 and 3.0g/Kg, p.o. in a 10% acacia vehicle produced a dose dependent trend toward depression of spontaneous locomotor activity (SLA) in mice. The effect was statistically significant at the two highest doses. In an effort to help define the mechanism of this action we studied the possible involvement of the brain serotonergic system. We determined the endogenous brain serotonin (5-HT) levels one hour after oral administration of the above doses of L-T, D-tryptophan (D-T) and the two combined, DL-tryptophan (DL-T) in 180 mice. The whole brain and brain stem, excluding the cerebellum, was dissected out over ice, after cervical dislocation. 5-HT was extracted using the butanol method and assayed fluorometrically. The results showed that brain 5-HT increases in a dose dependent manner as shown in the following table after oral L-T administration. It can be seen that brain 5-HT level reached a plateau at 0.3 g/Kg. At this dose L-T did not significantly reduce the SLA. At higher doses although brain 5-HT did not rise further, the SLA was more and more depressed. It is possible, based on this evidence alone that a non-serotonergic mechanism is involved in L-T effect on SLA. Further support for this contention comes from our results with D-T and DL-T. D-T by itself changed neither the brain 5-HT level nor the SLA. However, when combined with L-T it competitively inhibited depression of SLA (1) while brain 5-HT levels were raised in a manner identical to that observed after L-T alone. In summary we have demonstrated, in mice, an uncoupling of the rise in brain 5-HT level from SLA depression after L-T both in terms of the dose required to evoke these changes and in terms of the production of one response (increased 5-HT level) without the other (depressed SLA) through the use of a competitive inhibitor (D-T).

1896 INTERACTION OF DIBUTYRYL CYCLIC AMP WITH THE EFFECT OF MORPHINE AND METHIONINE-ENKEPHALIN ON SPONTANEOUS AND EVOKED NEURONAL FIRING IN RAT MESENCEPHALIC RETICULAR FORMATION (David A. Hosford and Henry J. Haigler, Department of Pharmacology, Emory Univ., Atlanta, GA 30322)

Morphine sulphate and methionine-enkephalin (met-enkephalin), administered microiontophoretically (MI) into the rat mesencephalic reticular formation (MRF), produced different effects on spontaneous neuronal firing and on firing evoked by a nociceptive stimulus (NS: foot pinch) (Hosford and Haigler, Fed. Proc. 38: 740, 1979). The effects of the drugs on spontaneous firing did not correlate with their effects on firing evoked by a NS (evoked firing). Since cyclic AMP(cAMP), administered i.v., antagonized morphine-induced analgesia in mice (Ho et al, J. Pharmacol. Exp. Ther. 185: 347, 1973), we administered dibutyryl cAMP (dBcAMP), a phosphodiesterase resistant analog of cAMP, MI to determine if it antagonized the effects of MI morphine and MI met-enkephalin on neuronal firing in the rat MRF.

After male Sprague-Dawley rats (220 to 370 grams; n=65) were anesthetized with chloral hydrate (400 mg/kg i.p.), a scalp incision was made, and a hole was drilled in the skull. A five-barrel micropipette, containing 10 mM met-enkephalin, 50 mM morphine sulphate and 0.5 m dBcAMP in three of its four side barrels, was lowered into the MRF. The central barrel of the micropipette was used for recording neuronal firing and the fourth side barrel was used as a current "balance" barrel. All neurons tested (n=48) responded to the NS with a significant ($p<.01$: 1 way ANOVA) increase in firing. As described previously (Hosford and Haigler, 1979) there were three classes of neurons: a). MI morphine blocked evoked firing, MI met-enkephalin did not (n=4); b). MI met-enkephalin blocked evoked firing, MI morphine did not (n=2); c). both drugs blocked evoked firing (n=1). In all of these neurons (n=7) MI dBcAMP antagonized the blockade of evoked firing induced by both morphine and met-enkephalin. Morphine and met-enkephalin may block the increase in neuronal firing evoked by a NS via the common mechanism of inhibiting intraneuronal production of cAMP. The effect of dBcAMP on spontaneous firing was excitatory ($p<.01$: 1 way ANOVA) in some neurons (n=17), but not in others (n=19), and it was not correlated with the dBcAMP antagonism of the morphine or enkephalin blockade of evoked firing. This may reflect differing actions of cAMP in pre- and post-synaptic neuronal elements. 1897 LATERALIZED PERIORAL SENSORIMOTOR FIELD ACTIVATED BY INTRANIGRAL GABAergic DRUGS AND BY SYSTEMIC APOMORPHINE AFTER 6-OHDA NIGRECTOMY. J.P. Huston, B. Nef*, G. Papadopoulos* and H. Welzl*. Institute of Psychology III, University of Düsseldorf, Düsseldorf, FRG.

Unilateral injection of the GABA agonist muscimol (20 ng in 0.1 µg saline) into the substantia nigra of rats caused contralateral turning as well as an asymmetry in responsiveness to tactile stimulation. I.e. contralateral to the side of the injection touching of the lip, cheek or vibrissae elicited a reflex that consisted of a withdrawal of the lip, followed by a quick orientation towards and biting of the probe.

Unilateral injection of the GABA antagonist picrotoxin (200 or 300 ng in 0.1 µl saline) induced rotation in the direction ipsilateral to the injected hemisphere, and higher ipsilateral responsiveness.

We observed that systemic injection of apomorphine clearly primes the biting reflex to tactile stimulation of the perioral area in intact rats and guinea pigs. The apomorphine-primed perioral biting reflex is blocked on the side ipsilateral to the substantia nigra lesioned by 8 ug of 6-OHDA. I.e. apomorphine primed the perioral biting reflex contralateral to the 6-OHDA lesioned substantia nigra during periods of contralateral turning. Injection of d-amphetamine in these animals induced ipsilateral turning and increased responsiveness to tactile stimulation on the side ipsilateral to the lesioned substantia nigra, but did not prime the perioral biting reflex.

These experments demonstrate: (a) transient reversible asymmetries in sensorimotor responsiveness correlated with direction of pharmacologically induced turning, and (b) a neuropharmacological basis of the perioral biting reflex, probably involving substantia nigra mediated dopaminergic-GABAergic systems.

1898 N-DIPROPYLACETATE INDUCES A PREFERENTIAL INCREASE IN NERVE TERMINAL GABA IN VIVO. M.J. Iadarola, A. Raines and K. Gale*. Dept. of Pharmacology Georgetown Univ. Schools of Medicine and Dentistry, Washington D.C. 20007.

N-Dipropylacetate (DPA) and amino-oxyacetic acid (AOAA) produced dose related elevations of brain GABA as well as protection against maximal electroshock seizures (MES 150 mA, 0.2 sec, 60 hz) in rats. The ED_{50} for DPA in MES (200 mg/kg) caused a 15% increase in whole brain GABA. In contrast, AOAA, 20 mg/kg, increased whole brain GABA by 60% but only produced a 10% protection in MES (at ED_{50} for MES, AOAA, 60 mg/kg, elevated GABA over 3 fold). In view of the modest effect of DPA on brain GABA levels we were interested in determining whether the GABA increase produced by this drug in vivo is associated with nerve terminals. For this purpose we developed a surgical transection technique to unilaterally sever all connections between substantia nigra (SN) and the forebrain. This resulted in the complete destruction of GABAergic fibers afferent to substantia nigra (SN) leaving glial cells and neuronal perikarya intact. One week postoperatively, GABA concentration in the SN of the transected hemisphere was 10-20% of control. In the SN largely devoid of GABAergic nerve terminals, AOAA, 30 mg/kg, produced a marked (2-fold) increase in GABA content. In contrast DPA, 300 mg/kg, did not change the GABA content in the GABA-denervated SN. Since DPA and AOAA had similar effects in the intact SN (25% increase in GABA), it appears that the elevation of GABA produced by DPA is dependent upon the presence of GABAergic nerve terminals, whereas AOAA primarily elevates GABA in non-nerve terminal components.

As we have previously reported (Iadarola et al., Soc. for Neurosci. 444, 1978 and J. Neurochem. in press) an an analysis of GABA increases in several brain regions revealed that areas which were most affected by DPA were among those least affected by AOAA.

Taken together, our experiments suggest that the antiseizur efficacy of these drugs correlates with their ability to raise GABA in nerve terminals in specific brain regions and not with increases in GABA concentrations in whole brain. We have obtain ed additional support for this conclusion by examining the effects of ℵ-vinyl GABA (a specific and irreversible GABA transaminase inhibitor) on MES as well as on GABA concentrations in various brain regions and in the GABA denervated SN.

1899 OPIOID HYPERMOTILITY IN RATS: DIFFERENTIAL EFFECTS OF PUTATIVE μ, κ AND σ RECEPTOR AGONISTS. Edgar T. Iwamoto. Department of Pharmacology, University of Kentucky, Lexington, KY 40536.

Sprague-Dawley male rats were acclimated to a lucite observation cage; body movements were recorded observationally, and horizontal activity was recorded using a motility meter (Optovarimex). In agreement with previous data (Martin and Sloan, 1977, Handb. Exp. Pharmacol, Vol. 45/I, Springer-Verlag, p. 49), 0.25, 0.5, 1.0 and 2.0 mg/kg s.c. of the putative agonist, morphine sulfate, induced grooming-chewing stereotypies, and increased locomotor and rearing behavior; periods of motionlessness separated the morphine-induced hyperactivities. Saline-injected animals exhibited infrequent exploration or slept. Forward locomotion and grooming were also induced by 62.5 μg/kg levorphanol or 5 mg/kg l-pentazocine, but not after corresponding doses of dextrorphan or d-pentazocine. Ketazocine (2.5, 5, 10 mg/kg s.c.), the prototype κ agonist, depressed locomotion and produced antinociception, sedation, decreased respiratory rate, loss of corneal reflex and Straub tail; grooming behavior and catalepsy were not elicited. Naloxone, 0.1 mg/kg i.p., antagonized the hyperactivity syndromes induced by morphine and levorphanol, and the sedation induced by ketazocine. SKF-10,047, the prototype σ receptor agonist, induced continuous sniffing and locomotion (2.5, 5, and 10 mg/kg s.c.) that was antagonized only by large doses (>20 mg/kg s.c.) of naloxone. Both morphine and SKF-10,047 induced ipsilateral turning in the 6-hydroxydopamine circling behavior model suggesting possible indirect activation of the nigrostriatal pathways. Thus, μ, κ and σ prototypes induce separate locomotor syndromes in the rat with differential sensitivity to naloxone antagonism; with respect to locomotor activity in rats, additional support for the concept of multiple opioid receptors is provided (Martin et al. JPET 197:517, 1976).

The research described in this report conforms with the 'Guide for the Care and Use of Laboratory Animals' prepared by the Committee on Care and Use of Laboratory Animals of the Institute of Laboratory Animal Resources, National Research Council, DHEW Publication No. (NIH)78-23. 1900 BEHAVIORAL HYPERSENSITIVITY WITH APOMORPHINE: PREVENTION BY L-DOPA. Vernice Jackson, Carl Miller*, ALN Prasad*, Stuart Snider*, and Stanley Fahn. Dept. Neurology, College of P & S, Columbia University, New York, NY 10032.

Intermittent stimulation of dopamine receptors by dopamine agonists such as apomorphine may cause behavioral hypersensitivity. To test this possibility we administered the following drugs: 1a) unoperated rats received apomorphine, 1 mg/kg i.p. once weekly for four weeks; 1b) some also received daily doses of L-dopa 250 mg/kg + carbidopa 25 mg/kg p.o.; 2a) substantia nigra-lesioned rats received apomorphine i.p. once weekly; 2b) some substantia nigra lesioned rats received daily doses of L-dopa + carbidopa.

The unoperated and the lesioned groups developed behavioral hypersensitivity manifested by a gradual increase in motor activity and stereotyped behavior during the four weeks. This occurred more rapidly in lesioned rats. The unoperated and lesioned rats receiving L-dopa exhibited significantly less motor activity and stereotyped behavior than those not receiving L-dopa.

We believe that the more continuous stimulation of dopamine receptors in rats treated with L-dopa prevented the development of behavioral hypersensitivity during intermittent apomorphine injection.

1901 EFFECTS OF HYDERGINE® ON PERIPHERAL BLOOD ALCOHOL LEVELS. Francine Joiner*, David Fenimore* (SPON: T. Samorajski). Dept. Biol., Texas Woman's Univ., Houston, TX 77030.

Female C57BL/6J mice with a mean age of 9 months in groups of 6-8 animals were used in these experiments. In the first experiment, mice were given a single dose of ethanol (2 g/kg) or a combined dose of ethanol (2 g/kg) and dihydroergotoxine mesylate (DHET: active substance of Hydergine) (2.0, 4.0, or 8.0 mg/kg). In experiment No. 2, mice were maintained on daily doses of ethanol only (2 g/kg) or ethanol plus DHET (2, 4, or 8 mg/kg) for a period of 21 days. Blood samples were collected from each animal on the 21st day of the experiment following the last dose of ethanol or ethanol plus DHET. In the third experiment, mice received 2 mg/kg ethanol, 15 minutes apart. One group received DHET first and the other, ethanol. Blood samples (100 μl) from a cut of the tail were collected at 5, 15, 30, 60, 120, and 180 minutes after ethanol only or DHET plus ethanol treatment. Samples were analyzed by headspace gas chromatography. Results indicated: (a) Acute treatment with combined oral doses of ethanol and DHET decreased blood alcohol levels in a dose-dependent manner. (b) Chronic administration of ethanol plus DHET reduced blood alcohol levels. (c) Blood alcohol levels were lower when ethanol was given 15 minutes before DHET than when DHET was given 15 minutes before ethanol.

1902 EEG AND POWER SPECTRAL EFFECTS OF NARCOTIC AGONISTS IN THE RAT CONTRASTED WITH THOSE PRODUCED BY MIXED AGONIST-ANTAGONISTS AND PURE ANTAGONISTS. Sarala Kareti*, J. Edward Moreton and Naim Khazan. Dept. Pharmacol. and Toxicol., Univ. of Maryland, Sch. of Pharmacy, Baltimore, MD 21201.

Rats were prepared with chronic cortical and temporalis muscle electrodes. Continuous recording of the electroencephalogram (EEG) and electromyogram (EMG) was made for two days before and continued for two days after acute intravenous administration of physiological saline or moderate doses of the narcotic agonist morphine (10 mg/kg), the agonist-antagonists nalorphine (5 mg/kg), cyclazocine (2 mg/kg), and buprenorphine (1 mg/kg) and the pure antagonists naloxone and naltrexone (5 mg/kg each).

During the quiet awake state of the control period, the characteristic low-voltage, high-frequency EEG yielded a power spectrum with minimal amount of power mainly in the 0-10 Hz band. The narcotic agonist morphine first produced a behavioral stupor associated with intermittent high-voltage, slow-wave EEG bursts. This stage was followed by a more intense behavioral stupor and continuous EEG slow-wave activity. The agonist-antagonists nalorphine, cyclazocine, and buprenorphine produced a morphine-like behavioral profile and EEG synchrony. However, the pure antagonists naloxone and naltrexone exerted no discernable effect on EEG or behavior.

In an attempt to further delineate similarities and differences between the above EEG effects, these EEGs were subjected to power spectral analysis using the Nicolet MED-80. It was found that during behavioral stupor associated with continuous EEG high-voltage slow activity, a distinction between the pure agonist and the mixed agonist-antagonists could be made using the EEG power spectra. Morphine produced EEG synchrony whose power spectrum occupied mainly the 0-7 Hz frequency band. However, synchronous EEG produced by nalorphine and cyclazocine demonstrated a more condensed lower frequency activity which peaked at 1-3 Hz. On the other hand, the pure antagonists naloxone and naltrexone exerted no effect on either direct EEG or the EEG power spectra.

Furthermore, the agonist-antagonist buprenorphine produced behavioral stupor and continuous EEG high-voltage slow activity at the 1 mg/kg dose level, and a power spectrum similar to that produced by morphine. Earlier studies have shown that at the 1 mg/kg dose, buprenorphine displays an agonistic activity.

These findings suggest that narcotic agonists, agonist-antagonists, and pure antagonists exhibit characteristic EEG power spectra which may correlate with their different pharmacologic profiles. (Supported by NIDA Grant DA 01050.)

1903 CROSS-TOLERANCE BETWEEN ETHANOL AND MORPHINE. J.M. Khanna*, H. Kalant*, A.D. Le* and J. Mayer* (SPON: Y. Israel). Dept. Pharmacol., Univ. of Toronto, and Addiction Research Foundation, Toronto, Canada M5S 1A8.

Adult male Wistar rats were fed chronically a liquid diet providing 35% of the calories as ethanol (12-14 g/kg ethanol daily), while pair-fed controls received the corresponding diet with alcohol replaced by an equicaloric concentration of sucrose. Rectal temperatures, after test doses of ethanol or morphine, were measured in several groups of rats at various times during chronic ethanol treatment. The fall in rectal temperature after a challenge dose of ethanol (3.0 g/kg) was significantly lower in the alcohol group than in controls, indicating tolerance to ethanol-induced hypothermia as a result of chronic ethanol treatment. They also developed cross-tolerance to the hypothermic effect of morphine (15 and 30 mg/kg), whereas no cross-tolerance to the hyperthermic effect of morphine (5 mg/kg) was seen. Administration of morphine (30 mg/kg i.p.) for 3 days resulted in tolerance to morphine hypothermia and also cross-tolerance to ethanol-induced hypothermia.

In other experiments, guinea pigs were treated by subcutaneous implantation of morphine (4 x 75 mg) or placebo pellets for 3 days. Longitudinal muscle/myenteric plexus preparations obtained from the morphinized animals showed tolerance to the inhibitory effect of morphine on the electrically evoked contraction, as measured by parallel shifts in the log dose response curves. The extent of shift was approximately 1.8 log units. The same preparations were cross-tolerant to ethanol, showing a shift of about 0.8 log units in the LDR curves. Similar results were found in preparations, obtained from naive guinea pigs, preincubated with morphine in vitro (40 x 10^{-6} M for 18 hrs) before testing.

These studies fit with our hypothesis that tolerance and cross-tolerance among drugs develop to drug effects rather than to drug per se. Therefore drugs sharing a common effect, even by different mechanisms, might show cross-tolerance for that effect.

1904 DIFFERENTIAL EFFECTS OF "DOPAMINERGIC AGONISTS" ON MEASURES OF DOPAMINERGIC FUNCTION. C.D. Kilts*, D.A. Smith*, M.G. Ondrusek, R.B. Mailman, R.A. Mueller and G.R. Breese. Departments of Psychiatry, Pharmacology and Anesthesiology, University of North Carolina School of Medicine, Chapel Hill, North Carolina 27514.

Apomorphine (APO) and the ergot derivatives lergotrile (LERG) and bromocriptine (BROM) increase locomotor activity of rats, an effect presumed to be related to a stimulation of dopaminergic activity. However, these drugs differ in how they affect locomotor activity in terms of potency (APO > LERG > BROM); latency to onset (LERG > BROM > APO); and duration (LERG = BROM > APO). Studies conducted utilizing 6-hydroxydopamine or α-methyltyrosine-pretreated animals indicate that inherent differences exist in the mechanisms underlying the locomotor increases evoked by APO, LERG and BROM. In addition to these behavioral assessments, the present study investigated several biochemical measures that have been hypothesized to reflect dopaminergic activity. The relative potency of these drugs in competing for ^{3}H-spiroperidol binding sites in a total particulate fraction of rat striata was BROM > APO = LERG. BROM was also more potent than LERG in displacing ^{3}H-spiroperidol (0.5-0.7 nM) from rat striatal membranes when the agonists were injected (i.p.) 2 hr before sacrifice. Micromolar concentrations of APO, but not BROM or LERG, stimulated basal adenylate cyclase activity in homogenates of rat striata. The in vitro stimulation of striatal adenylate cyclase activity by dopamine (5 μM) was antagonized by these drugs (LERG > APO > BROM) suggesting that these compounds are partial antagonists of this enzyme. In addition, it has been demonstrated that none of these drugs altered striatal cyclic AMP content in vivo. Therefore, these data are inconsistent with the postulate that cyclic AMP mediates the locomotor increases caused by APO, LERG and BROM. (Supported by USPHS Grants HD-10570, HD-03110, ES-01104 and MH-00013.)

1905 THE EFFECTS OF METOPRINE ON HISTAMINE-INDUCED HYPOTHERMIA. Michael C. Klein* and Sheldon B. Gertner* (Spon:A.G.Gona). Dept. Pharmacol. N.J. Med Sch. (CMDNJ) Newark, N.J. 07103.

Considerable data have accumulated to implicate histamine as a neurotransmitter within the central nervous system (CNS). However its precise physiologic function is still obscure. Central injections of histamine into the ventricular system or the anterior hypothalmus have resulted in a dose dependent fall in body temperature in rats which could be antagonized by histamine receptor antagonists (Brezenoff, H.E., and Lomax,P., Experientia, 26: 51,1970; Lomax,P., and Green, M.D., Prog. Brain Res., 42: 252,1975). Furthermore, systemic injections of histidine, the amino acid precursor of histamine or central injections of specific histamine receptor agonists have also induced significant hypothermic effects (Green, M.D., et al., Life Sci., 16: 1293, 1975; Cox, B., et al., J. Thermal Biol., 1:205, 1976).

Such data may implicate a functional role for histamine involving central thermoregulation. To further investigate this possibility male Sprague-Dawley rats were sterotaxically implanted with stainless steel canulae in the lateral ventricles (i.c.v.). One week later conscious animals were placed in restraining cages and injected (i.c.v.) with metoprine [2-4-diamino-5-(3,4 -dichlorophenyl)-6-methylpyrimidine] (10^{-5} molar). This drug has been demonstrated to be one of the most potent in vivo inhibitors of histamine N-methyl transferase (Duch, D.S., et al., Biochem.Pharmacol., 27: 1507,1978), the major and probably only significant metabolizing enzyme of histamine within the C.N.S. One hour later animals were injected (i.c.v.) with varying concentrations of histamine HCl (1-5ug). All experiments were conducted in a walk-in environmental chamber maintained at 20-22°C. Basal temperature was recorded by a thermistor probe inserted approximately 6 cm. into the rectum and gently taped to the tail.

Metoprine, in the doses used, significantly attenuated the histamine induced fall in body temperature (1-3°C) as well as reduced its duration of action (which was usually 2 to 3 hours). Central injections of metoprine alone, in the same doses, had no significant effects on body temperature. These paradoxical findings suggest that although metoprine may be a potent histamine N-methyl transferase inhibitor, it may also posess histamine receptor blocking activity. We are currently investigating the mechanism of this action. (Supported by grant #170000 GSBS,NJMS).

1906 Erythrosin B (Food, Drug, and Cosmetic Red No. 3) Inhibits Dopamine Uptake In Rat Caudate Synaptosomes: A Kinetic Study. J. Lafferman*, E. Silbergeld, NINCDS, NIH, Bethesda MD 20014 (SPON: R. Irwin)

Artificial food colors have been hypothesized to cause hyperkinetic behavioral disorders in certain children (Am. J. Nurs. 75, 797 (1975); Why Your Child Is Hyperactive (Random House, 1975)). A neurochemical study was undertaken to determine if erythrosin B has any properties of a central excitatory agent; we report here on its effects on synaptosomal dopamine metabolism. Synaptosmes were prepared as the P2 pellet from rat caudate and erythrosin B was added in vitro. Erythrosin B inhibited ^{3}H-dopamine uptake by synaptosomes with an IC_{50} equal to 45uM. The Michaelis-Menten kinetic constant (Km) decreased from 33.6nM to 13.5 nM and Vmax was decreased from 310 to 90 pmol/gram wet weight/5 min. From a Lineweaver-Burk plot of uptake kinetics, the type of inhibition observed is characteristic of uncompetitive or coupling inhibition. Uncompetitive inhibition of dopamine uptake by erythrosin B in vitro suggests that in the presence of dye, dopamine has a higher affinity for the transport carrier and the carrier-dopamine complex has a decreased efficacy of transporting dopamine across the synaptosomal membrane. One possible mechanism for this would be through an action by erythrosin B on sodium interactions with the carrier moiety.This is consistent with the lipophilic (Proc. Natl. Acad. Sci. 744, 2914 (1977)) and anionic nature of erythrosin B,to dissolve into the lipid membrane and to attract cations. In studies of synaptosomal ^{22}Na influx, it was found that erythrosin B increases sodium influx at concentrations around 0.5 uM. The results suggest that erythrosin B may be neuroactive if it acts similarly in vivo. An increase of dopaminergic transmission by the inhibition of dopamine removal from the synaptic cleft is consistent with hyperkinetic behavior which has been hypothetically associated with artificial food colors.

1907 AN ENDOGENOUS BARBITURATE/PICROTOXININ-LIKE SUBSTANCE IN MAMMALIAN BRAIN? Fredrik Leeb-Lundberg, *Christian Napias, *and Richard W. Olsen. University of California, Riverside, CA 92521.

α-Dihydropicrotoxinin (DHP) binding to mammalian brain membranes was inhibited by small amounts of the 100,000 x g supernatant fraction obtained from the same homogenate, and also by some purines and pyrimidines. Furthermore, DHP binding was inhibited by pharmacological concentrations of benzodiazepines, both depressant and excitatory. [^{3}H] DHP binding to fresh rat cerebral cortex membranes was measured by a centrifugation assay, giving a K_d of 2-3 μM and a B_{max} of 4 pmol/mg protein. Binding was highly enriched in the synaptosomal and light microsomal fractions; it was inhibited by biologically active picrotoxinin analogs, barbiturates (both depressant and excitatory), cage convulsants (Ticku et al. Mol. Pharm. 14, 381 [1978]; Life Sci. 22, 1643 [1978]; Neuropharm. 18, 315 [1979]), and by pyrethroid insecticides (Leeb-Lundberg, Napias and Olsen, in preparation). All of these drugs appear to have physiological effects involving Gamma-amino butyric acid (GABA) receptor-regulated Cl^- channels. The high affinity binding sites for these drugs (some K_d values in nM range) suggest the possibility of an endogenous ligand in brain. DHP binding was inhibited 50% by 50 μg of supernatant protein from rat cortex homogenate, assayed 10 min at 0° without preincubation, using 1 mg/ml membrane protein, [^{3}H] DHP at 10 nM, 29 Ci/mmol, in 0.1M NaCl, 20 mM HEPES, 1 mM CaCl2, pH 7.0. 50% inhibition of DHP binding was also obtained with 100 μM hypoxanthine and cytosine (but not several other bases nor nicotinamide at 1 mM, and by 1 μM benzodiazepines, including diazepam, flunitrazepam, nitrazepam and the convulsant analog RO5-3663. These results suggest that picrotoxinin/barbiturate binding sites might be receptor sites for endogenous ligands such as purines and pyrimidines (which also interact with high affinity binding sites for benzodiazepines) and that these substances may share some pharmacological actions at the level of Cl channels in GABA-mediated inhibitory synapses. Supported by NSF Grant BNS 77-24414 and NIH Grant NS-00224.

1908 KAINIC ACID-INDUCED NEUROLOGICAL SYNDROME: PARTIAL REVERSAL BY BACLOFEN AND OTHER PUTATIVE GABA-MIMETICS. Jeffrey Liebman, Patrick Bernard*, Richard Sobiski*, Gary Pastor* and Karen Dawson*. Research Dept., Pharmaceutical Div., CIBA-GEIGY Corp., Summit, NJ 07901

Kainic acid (KA) selectively destroys certain types of neurons when injected systemically or in various rat brain regions. This action is hypothesized to occur through a synergistic interaction with endogenously released glutamic acid, although not all reports are consistent with this proposal (Nadler, Life Sci. 24: 289, 1979). Because baclofen (BF) has been reported to reduce the release of glutamic acid in vitro (Potashner, Canad. J. Physiol. Pharmacol. 56: 150, 1978) it was of interest to evaluate the possible interaction of BF with KA. The effects of gamma-butyrolactone (GBL) and naloxone (NX) were also examined.

In the present experiments, KA (10 mg/kg i.v.) was administered to rats, which were then observed for 90 min afterwards by "blind", experienced observers. Wet dog shakes became apparent approximately 20-25 min after injection. At 30-35 min, hypersalivation was noted and was usually followed several min later by clonic seizures usually involving the jaw and forelimbs. KA also elicited a unique behavior, persistent scratching of the face with the hind legs. The ability of test drugs (i.p.) to antagonize its effects was evaluated by pretreating rats 30 min prior to i.v. KA.

BF (10-20 mg/kg) reduced the incidence of KA-induced clonic seizures. This effect contrasted strikingly with its inability to prevent metrazol- or electroshock-induced seizures. Similarly GBL (30, 100 or 300 mg/kg) selectively antagonized KA-induced seizures. Hypersalivation was reduced by the highest doses of BF (20 mg/kg) and GBL (300 mg/kg) tested. Hindleg scratching was antagonized by low doses of BF (3 mg/kg and up) and by high doses of GBL (300 mg/kg). None of these treatments altered the incidence of wet dog shakes. NX (3 and 30 mg/kg) failed to alter any of these KA-induced signs. Intrastriatally administered KA in rats reliably reduces striatal choline acetyltransferase levels, presumably by destroying striatal cholinergic neurons. BF (20 mg/kg i.p. at 1 hr before and again 2, 5 and 8 hr after intrastriatal KA, 0.5 μg, 1 μl) totally failed to antagonize this neurochemical effect of KA.

These results indicate that BF and GBL, which are not effective in traditional models of anticonvulsant activity, ameliorate the convulsant action of KA, as well as other induced neurological effects. The inability of BF and GBL to reverse KA-induced wet dog shakes and striatal choline acetyltransferase depletion suggests that the effects of KA may be mediated by multiple neurochemical substrates having differential susceptibility to various antagonists.

1909 A CONTROLLED RELEASE IMPLANT FOR CHRONIC ADMINISTRATION OF COCAINE. D.R. Liston*, C.D. Ebert*, S.W. Kim*, and J.W. Gibb (SPON: L.W. JARCHO). Department of Biochemical Pharmacology and Toxicology and Department of Pharmaceutics, University of Utah, Salt Lake City, Utah 84112.

The effects of chronic drug exposure can differ substantially from those of acute administration. Depending on the properties of the drug, either tolerance or sensitization to drug effects may result from chronic administration. Chronic studies on the effects of rapidly metabolized drugs, such as cocaine, present several technical problems, e.g., repeated injection requires either high doses or short dose intervals, the former causing wide variations in plasma drug concentrations while the latter can be technically inconvenient. Utilization of constant i.v. infusion requires some constraint of the animal. We are evaluating a sustained release drug delivery system composed of hydrogel polymers for the chronic administration of cocaine HCl. Advantages of the hydrogel system include suitable release kinetics for hydrophilic drugs and a high degree of tissue compatibility. In vitro release kinetics were determined for the polymeric, monolithic device emersed in twice-distilled water at 22°C. For gels equivalent to those implanted into test animals, typical first-order release kinetics were observed with a release rate of 8 mg/hr at 2 hours and 0.6 mg/hr at 36 hours. Subcutaneous placement in rats of gels containing a total dose of approximately 500 mg/kg cocaine HCl produced an increase in locomotor activity, followed by a progression to moderate stereotypic behavior within 6 hours after implant. Stereotypy continued for at least 36 hours. Preliminary biochemical experiments have indicated that tyrosine hydroxylase activity in the neostriatum is not altered 36-40 hours after implant. Current in vitro experiments with a combined polymeric device composed of a hydroxyethylene methylacrylate/cocaine HCl core encapsulated in a methoxyethyl methacrylate outer layer indicate that zero-order release kinetics can be achieved with cocaine for over ten days. This delivery system appears applicable to a wide range of drugs whose chronic delivery may be interesting and otherwise technically difficult. (Supported by USPHS grants GM 07579 and DA 00869.)

1910 BIPHASIC INTERACTION OF DIRECT-BUT NOT INDIRECT- ACTING GABA AGONISTS AND ANTAGONISTS WITH DOPAMINE-MEDIATED EVENTS. K. G. Lloyd and P. Worms *, Dept. of Neuropharmacology, Synthélabo-LERS, 31, Ave P. V. Couturier, F 92220 Bagneux, France

The control by GABA neurons of nigrostriatal dopamine (DA) -utilizing neurons has been demonstrated using both biochemical and behavioural methods. Thus, at anticonvulsant doses GABA-mimetics decrease striatal DA release, block apomorphine stereotyped behaviour and potentiate neuroleptic (eg haloperidol)-induced catalepsy. GABA-receptor antagonists have the opposite effects. However, in view of recent observations that DA agonists have biphasic actions in these test systems, purportedly due to dose-dependent pre-versus post-synaptic actions, we have investigated the interaction of a wide dose-range of GABA agonists and antagonists on DA-mediated events. For these studies catalepsy was measured utilizing the 4-cork test in male albino rats after an injection of 0.6 mg/kg i.p. of haloperidol. Stereotypies were rated in male albino mice after 0.5 mg/kg, s.c. of apomorphine. Direct acting GABA mimetics (SL 76 002, muscimol) showed a clear-cut biphasic action : haloperidol-induced catalepsy was antagonized and apomorphine stereotypies enhanced at low doses (12.5 mg/kg i.p. for SL 76 002 ; 0.25 mg/kg i.p. for muscimol, $p < 0.01$ vs reference compound alone in both cases) and markedly potentiated catalepsy and diminished stereotypies at high doses (100 mg/kg, i.p. for SL 76 002 ; 2.0 mg/kg i.p. for muscimol, $p < 0.01$ vs haloperidol alone). Accordingly, bicuculline (a direct GABA receptor antagonist) increased haloperidol-induced catalepsy at low (0.03 mg/kg, i.p.) doses and antagonized catalepsy at higher (0.3 mg/kg, i.p.) but still nonconvulsant doses. In contrast, agents (AOAA, gamma-acetylenicgaba) which indirectly (by means of inhibition of GABA-transaminase) increase GABA synaptic activity only potentiated catalepsy. Also inhibition of GABA synthesis by allylglycine only demonstrated an antagonism of haloperidol catalepsy. These results demonstrate that changes of GABA receptors has a biphasic curve whereas alteration of GABA levels has only a monophasic dose-response. This might be due either to the differential morphological arrangement of pre-versus post-synaptic GABA receptors and/or the existence of extra-synaptic GABA receptors which respond to injected GABA agonists or antagonists but which are relatively insensitive to alterations in the synaptic concentrations of this neurotransmitter.

1911 BEHAVIORAL EFFECTS OF CENTRALLY ADMINISTERED CYCLIC GMP. Irwin N. Lourie*, Michael M. Krieger* and Nagendran S. Thampi. Res. Dept., Norristown State Hospital, Norristown, PA 19401.

Intracerebroventricular (ICV) cannula were implanted in 92 day old male NSH Sprague-Dawley derived rats. Following a two week recovery period subjects were conditioned to a novel environment for one hour daily until behavior stabilized (after eight days). On subsequent days and 30 minutes after the ICV administration of either saline or dibutyryl cyclic 3',5' guanosine monophosphate (dbcGMP) animals were observed for one hour. Behavioral observations reported consisted of five consecutive one minute samples taken at the beginning of the assay. Behavior observed consisted of two types. Normal exploratory measures were made in which the following showed dbcGMP related effects: dynamic activity (forward motion) (DA), vertical exploratory activity (VE), total exploratory time (TE), and habituation rate (HR). Atypical behavior could be described by catatonia (C), wet dog shakes (WDS), convulsions (CON), and characteristic cholinergic effects. Dose range was 5 to 100 µg with all doses administered in 10 µl of saline with an n of 5 to 7 subjects per dose.

There are four observable dose responsive effects of dbcGMP on exploratory activity. At doses between 5 and 10 µg there is a 40% decrease in DA without any decrease in TE, indicating a specific effect on motor activity sparing the motivational component. Between 10 and 100 µg there is a biphasic dose response on these same measures ranging from depression at 10 µg, excitation at 50 µg, and subsequent depression at 100 µg. Concomitant with the depressed phase is an effect seen with neuroleptics and certain amygdaloid lesions: a two-fold increase in exploratory habituation rates. A fourth effect is a linear log dose response decrease in VE activity with complete suppression at 100 µg. Appearance of atypical behavior begins to occur at 100 µg or with repeated dosing. WDS and C are reversible but CON behavior is invariably irreversible leading to extensive brain damage and death. The multiplicity of effects of dbcGMP and its effectiveness at low doses seems to suggest a complex modulatory role for this substance in neural mechanisms.

1912 ^{3}H-SPIROPERIDOL BINDING SITES IN HUMAN CAUDATE AND PREFRONTAL CORTEX, M.E. Maguire, A.C. Andorn*, and L.E. Weber*. Departments of Pharmacology and Psychiatry, Case Western Reserve University, School of Medicine, Cleveland, OH 44106.

The examination of ^{3}H-spiroperidol (^{3}HSP) binding in rat striatum has shown the existence of two binding sites with different pharmacologies (Andorn and Maguire, Soc. for Neurosci. IV:504, 1978). The high affinity site (K_D=20pM) exhibits a pharmacology that is classically dopaminergic, while the second site (K_D=2nM) appears pharmacologically to be an α-adrenergic receptor even though dopamine is presumably the transmitter. Our data to date suggest that properties of ^{3}HSP binding and the associated pharmacology are similar in postmortem human caudate. Examination of human prefrontal cortex suggests only a small amount (if any) of a high affinity site, while the density of a lower affinity binding site is comparable to that seen in the caudate. However, the pharmacology of this lower affinity site differs markedly from the pharmacology of either of the caudate sites. Although neuroleptic potency was similar, and apomorphine and serotonin were potent competitors (apomorphine > serotonin), dopamine and norepinephrine competed only at mM concentrations. Our prefrontal cortical data is similar to data recorded by others in frontal cortex and not only suggests that the prefrontal cortical site is not the same site as those observed in the caudate but that it is primarily serotonergic.

We obtained postmortem tissue samples from a male schizophrenic in whom no tissue or fluid concentrations of psychotropic agents could be detected at autopsy, ^{3}HSP binding studies on prefrontal cortex and caudate show marked changes in affinities for agonists and antagonists. The differences in binding make it difficult to determine if a change in density also exists in prefrontal cortex although there are no immediately apparent differences between normal or unmedicated schizophrenic caudate. It is premature to speculate on the clinical relevance of these observations. (NSF PCM 77-24693 and NIH GRS RR05140A2)

1913 A PHYLETIC STUDY OF BICUCULLINE-SENSITIVE GABA RECEPTOR BINDING. E. Mann* and S.J. Enna (SPON: I. Butler). Depts. Pharmacol. and of Neurobiol. and Anat., Univ. Texas Med. Sch., Houston, Tx. 77025

γ-Aminobutyric acid (GABA) appears to be an inhibitory neurotransmitter in both vertebrates and invertebrates. In addition, recent studies have indicated that there may be present, at or near this receptor site, a modulator(s) of GABA binding, which can be removed by the detergent Triton X-100, and which may play a role in the mechanism of action of the benzodiazepines. The present study was undertaken to describe the pharmacological, biochemical and kinetic properties of the GABA receptor in a variety of species in an attempt to better define these characteristics. For the study, ^{3}H-GABA receptor binding was studied in membrane fractions prepared from vertebrate whole brain or invertebrate cephalic ganglia using a previously published proedure (Enna and Snyder, Mol. Pharm. 13:442, 1977). Specific GABA receptor binding was defined as the amount of ^{3}H-GABA displaced by unlabeled bicuculline (0.1 mM). In tissue not treated with Triton, a significant amount of bicuculline-displaceable ^{3}H-GABA binding was detected in the brains of all 9 vertebrate species studied, with the hagfish, the oldest vertebrate, binding over twice as much ^{3}H-GABA as the spiny dogfish, the net oldest species. All other vertebrates bound similar amounts of ^{3}H-GABA, being one-third to one-fourth that observed in the hagfish. In contrast, after Triton-treatment, the hagfish displayed the least amount of bicuculline-sensitive ^{3}H-GABA binding and, under these conditions, the amount of binding observed increased in an evolutionary fashion. Kinetic analysis indicated that Triton treatment enhanced binding in all vertebrates, except the hagfish, by increasing the affinity of the receptor for GABA. No measurable bicuculline-sensitive GABA receptor binding was noted in any invertebrate studied, suggesting that the receptors in these species are relatively insensitive to this antagonist.

These results suggest that bicuculline-sensitive GABA receptors are present in the brains of all vertebrates and that during the course of evolution there developed a Triton-sensitive substance (s) whose presence modifies the kinetic properties of this receptor site. This data, taken together with a previous report (Nielsen et al, Brain Res. 141:342, 1978) indicating a lack of benzodiazepine receptor binding in the hagfish, is further circumstantial evidence that these drugs may interact with a Triton-sensitive modulator(s) at the GABA receptor. (Supported in part by USPHS grants NS-13803 and an RCDA NS-00335 (S.J.E.))

1914 LITHIUM ANTAGONISM TO CLOZAPINE-INDUCED LEUKOPENIA. Philip J. Maple*, Bruce I. Diamond, and Richard L. Borison (SPON: C.M.Combs) Dept. Anesthesia, Mt Sinai Hosp., Chicago, Il 60606

Among neuroleptics, clozapine is unique because it fails to produce extrapyramidal side-effects and it has little demonstrated dopamine blocking activity. The clinical use of this drug in Europe has firmly established its use as a potent antipsychotic. Moreover, clozapine's lack of extrapyramidal system actions precludes its producing tardive dyskinesia. At present, this drug has been taken off the market due to its ability to produce agranulocytosis. We have now conducted studies to test whether lithium can reverse clozapine-induced agranulocytosis. Subjects were white male Swiss mice (25-30 g) which received daily injections of either saline, clozapine (15 mg/kg), lithium chloride (45 mg/kg) or the combination of lithium and clozapine. We found that after three weeks of treatment, that those animals receiving lithium showed a mild leukocytosis to 110% of control values. In contrast, animals receiving clozapine showed a marked leukopenia to 41% of control values, whereas animals receiving lithium-clozapine in combination showed a less drastic reduction of white blood cell count to 55% of control. Moreover, nine weeks after initiation of treatment, there was a recovery of white blood cell count to 64% of baseline values in animals receiving lithium and clozapine. Those animals receiving lithium achieved serum concentrations of 1.2 meq/l. The mechanisms underlying the hematologic actions of lithium remains to be fully elucidated, however lithium has been demonstrated to stimulate granulopoiesis, and it is suggested that it increases production of granulocytes rather than redistributing the granulocytes from the bone marrow to the circulation. In our experiments we have demonstrated both the leukopenic actions of clozapine, and its antagonism by conjoint treatment with lithium. These studies would suggest that combined therapy using lithium and clozpine may prove a clinically safe and rational treatment for schizophrenia.

1915 COMPARISON OF THE PATTERN OF MORPHINE-INDUCED CHANGES IN CORE TEMPERATURE AND MOTOR ACTIVITY IN THE RAT. Gregory E. Martin, Nan L. Papp* and G. Rufus Sessions Merck Institute for Therapeutic Research, West Point, PA 19486 and Walter Reed Army Institute of Research, Washington, D.C. 20012.

Restraining a rat in a plastic cage attenuates morphine-induced increases in core temperature (CT) whether morphine is given i.p. or intracerebrally (i.c.). Perhaps, the blockade of increased locomotor activity (LMA) is the action which results in the attenuated rise in CT. The purpose of the present experiments was to compare the time course of morphine-induced increases in LMA and CT in the rat following the drug's i.p. or i.c. administration.

Two measures of LMA were used. One was in a circular open field (OF) and the other was confinement motor activity (CMA) which records activity when the rat rears on its hind legs. OF counts were totaled at 15-min intervals following the injection of morphine in male rats, whereas CMA counts were totaled at 30-min intervals. CT was measured at 15 or 30 min intervals. Morphine was given i.p. in doses of 5, 15 and 30 mg/kg. It was given i.c. into the pre-optic anterior hypothalamus (POAH) in doses of 10, 20 and 50 µg. There was also a control group given the vehicle solution by each route.

In comparing the pattern of LMA and CT changes following i.p. morphine treatment, the time interval in which motor activity was greatest either preceded (2/6 treatments) or was coincident with the greatest recorded CT (4/6). In the OF test, the peak level of activity was recorded 30-60 min before the peak CT after the 30 and 15 mg/kg doses of morphine, whereas the 5 mg/kg dose and all dose levels in the CMA test elicited peak CT and LMA during the same time interval. Examination of the LMA vs time and the CT vs time curves reveals a marked similarity between the two functions following each dose of morphine given i.p. Although an increase in CT was observed following the i.c. microinjection of morphine, the increase in CT preceded the increase in LMA activity in 5/6 treatment groups. On the other hand, the peak periods for LMA and CT were coincident in 3/6 treatment groups, while the peak LMA followed the peak CT in 2/6 treatments and preceded it in 1/6.

These data indicate that a causal relationship may exist between the increase in LMA and the rise in CT observed following the i.p. administration of morphine. If true, this may partially explain the action of restraint on morphine-induced changes in CT. Since the increase in CT preceded the increases in LMA following the POAH injections of morphine, LMA is probably not crucial to the initiation of this hyperthermic response, but may contribute to its prolongation.

1916 KETAMINE BINDS TO BRAIN OPIATE RECEPTORS. Lawrence H. Matt*, Gopi A. Tejwani* and Joseph R. Bianchine. Dept. of Pharmacology, College of Medicine, The Ohio State University, Columbus, OH 43210.

Ketamine hydrochloride (2-[o-chlorophenyl]-2-[methylamino] cyclohexanone hydrochloride) is a short-acting, anaesthetic analgesic with unique side-effects including ataxia, catalepsy, and epileptiform EEG's. The mechanism by which ketamine causes analgesia and its "dissociative" anaesthesia is unclear. To determine whether an interaction with the endogenous opioid system might be part of the mechanism by which this drug acts, we have performed opiate binding assays to discover if ketamine displaces the stereospecific binding of [^{3}H]-naloxone to the opiate receptor.

The assay system we used is essentially the same as that described by Pert and Snyder (PNAS 70: 2243, 1973). Briefly, after killing a rat by decapitation, we excised the brain and removed the cerebellum from the brain. We then homogenized the brain in 50 mM Tris-HCl, pH 7.4. Two ml aliquots of the brain homogenate were incubated with various concentrations of drug in the presence of [^{3}H]-naloxone (45,000 cpm) for 3 hrs at 0 C. Stereospecific binding was taken to be the binding of [^{3}H]-naloxone in the presence of 1 µM dextrorphan minus its binding in the presence of 1 µM levorphanol. Under these conditions, ketamine was approximately as effective as morphine in displacing [^{3}H]-naloxone from opiate receptors. Preliminary results suggest that the ID_{50} 's of both ketamine and morphine are about 10 nM. (This work was supported by gifts from Mrs. Marion Colwill and Mr. Max Weiss.)

1917 DOES THE LEVEL OF SOUND STIMULATION AFFECT THE NEUROTOXICITY OF KAINIC ACID IN THE GUINEA PIG COCHLEAR NUCLEUS? Douglas E. Mattox*, Robert L. Gulley, and Stephanie Bird. (SPON: M. Vaughan) Dept. Surg. (Div. of ORL) and Anat., University of Texas Health Science Center, San Antonio, TX 78284 and Neuroscience Research Program, Jamaica Plains, MA.

Kainic acid causes a selective degeneration of neurons in the cochlear nucleus which receive primary auditory input. In this study kainic acid, 0.5 g in phosphate buffered saline, was injected in the brain stem adjacent to the cochlear nucleus of adult guinea pigs. At short time periods, this dose of kainic acid causes only a minimal amount of neuronal loss in the rostral anteroventral cochlear nucleus (Bird and Gulley, 1979). Animals injected with kainic acid were placed in a sound-reducing auditory chamber for four hours. Previous studies in this acoustic environment have shown that auditory activity is sufficiently reduced to produce significant morphological changes in the presynaptic terminals after 24 hours (Gulley, Mattox, and Ulrich, personal observation). Control animals received either an injection of phosphate buffered saline followed by four hours of sound reduction or 0.5 g of kainic acid followed by four hours of exposure to ambient noise. Neuronal degeneration in the cochlear nucleus was observed in animals injected with kainic acid after both sound deprivation and exposure to ambient noise. The amount of neuronal degeneration was identical in both groups. No degeneration was observed in sound-deprived animals injected with buffer. Zaczek et al (1978) described attenuation of the effect of kainic acid by various anesthetics which limit neuronal excitation. Our data suggest that, in the cochlear nucleus, decreased sound-evoked activity does not protect postsynaptic neurons from minimally toxic doses of kainate. This observation supports the findings in the cochlear nucleus that presynaptic terminals are not essential to mediate kainate neurotoxicity (Bird and Gulley, '79).

1918 STUDIES ON PHENCYCLIDINE (PCP) LOCALIZATION IN RAT BRAIN Richard C. Meibach, Stanley D. Glick, and Saul Maayani.* Department of Pharmacology, Mount Sinai School of Medicine, New York, New York 10029.

The deoxyglucose technique as described by Sokoloff, et al. was used in an attempt to define the possible sites of action of PCP by determining its effects upon glucose metabolism. Rats were injected with PCP (5mg/kg) IP, 40 minutes prior to administration of 25 µCi of ^{14}C-deoxy-d-glucose (DDG) (specific activity 40 Ci/mmole). Examination of the autoradiograms revealed a striking effect of PCP upon local cerebral glucose metabolism. Major increases were limited to limbic system structures, particularly those involved in the Papez circuit. These included the hippocampus (molecular layer of the regio superior), subicular cortex, anterior and posterior cingulate cortices, and anterioventral thalamic nucleus. Decreases were noticeable only in auditory structures most notably in the inferior colliculus. In order to quantify the autoradiographic data, experiments were repeated using tritium labeled DDG and counting freshly dissected brain parts in a liquid scintillation counter. The results of these experiments confirmed the autoradiographic data in that the anterior cingulate gyrus had a 26% increase in glucose metabolism while the inferior colliculus reflected a 46% decrease. Other structures which reflected increases in glucose utilization but were not readily apparent in the autoradiograms included the frontal cortex and striatum.

The distribution of PCP within the brain was determined following injection of ^{3}H-PCP. Surprisingly, the distribution closely paralleled that of DDG changes, with the anterior cingulate having the greatest uptake.

These results suggest the possibility that PCP may act primarily on the limbic system and could possibly account for the fact that PCP abuse is often associated with severe emotional disturbances.

1919 EFFECTS OF AMANTADINE ON RAT PLASMA PROLACTIN LEVELS. H.Y. Meltzer and V.S. Fang. Depts. of Psychiatry and Medicine, Univ. of Chicago Pritzker Schl. of Medicine, Chicago, Ill. 60637.

Amantadine (A) is an anti-parkinsonian drug whose mechanism of action is uncertain. There is much evidence against the suggestion that it acts via enhancement of dopamine (DA) release or inhibition of DA uptake. It has also been proposed (Cox and Tha, Eur. J. Pharmacol., 30, 344, 1975) that A may increase receptor sensitivity to serotonin (5-HT). We have investigated these hypotheses by studying the ability of A to influence the increase in rat prolactin (PRL) secretion induced by haloperidol (H) a dopamine antagonist, and 5-hydroxytryptophan (5-HTP), the precursor of 5-HT. We have previously shown that drugs which release DA and/or block its reuptake such as d-amphetamine and methylphenidate antagonize the H- and 5-HTP-induced increases in plasma PRL. A in doses of 50 and 100 mg/kg ip markedly enhanced the increase in plasma PRL produced by 5-HTP 100 mg/kg ip (168± SE 18 ng/ml; 168±36 ng/ml and 78±21 ng/ml respectively). On the other hand, A 50, 100 and 150 mg/kg did not potentiate the increase in PRL produced by H. These results suggest A does enhance 5-HTP activity and does not enhance DA release or block its reuptake. Studies concerned with a specific increase in 5-HT receptor sensitivity following treatment with A will be reported.

1920 SUPERSENSITIVITY AND INCREASED NUMBER OF OPIATE RECEPTORS IN CEREBRAL HEMISPHERES OF RATS WITH HEREDITARY DIABETES INSIPIDUS. Rita B. Messing, Beatriz J. Vasquez, Henk Rigter*, Robert A. Jenser Joe L. Martinez, Jr., J.C. Crabbe, Jr.*, and James L. McGaugh. Dept. of Psychobiol., Univ. of Calif., Irvine, CA 92717.

This study investigated opiate receptors in rats with hereditary hypothalamic diabetes insipidus (Brattleboro strain). These rats have no detectable brain or neurohypophyseal vasopressin. They also have deficiencies in brain endorphins and impaired tolerance development to opiates. Therefore, ^{3}H-dihydromorphine (DHM) binding kinetics were examined in 6 brain areas of rats homozygous for the mutant autosomal gene determining diabetes insipidus (HO-DI rats). DHM binding of these rats was compared to binding in rats heterozygous for diabetes insipidus (HE-DI rats) and normal rats. Washed membranes were pre-incubated at 35°C in 0.05M tris HCl buffer, pH 7.4 with 100 nM of either dextrorphan or levorphanol. ^{3}Samples were then incubated with one of 7 concentrations of ^{3}H-DHM ranging from 0.2 to 13 nM, and stereospecifi binding was determined at each concentration. Apparent dissociation constants (K_D's) and receptor concentrations (B_{max}'s) for each brain region were obtained from Scatchard plots of the data.

BRAIN REGION	APPARENT K_D(nM)		B_{max}(fmol/mg protein)	
	Normal	HO-DI	Normal	HO-DI
Ant. Cortex	3.77	1.54**	80.9	63.9
		6.17+		140.5*
Amygdala	0.94	0.73	20.9	34.0**
Striatum	4.59	2.90**	84.8	127.2
Hypothalamus	6.90	5.16	179.3	123.7
Thalamus	2.84	2.32	50.2	39.6
Midbrain	9.17	7.81	275.2	292.2*

+p<0.02 different from high affinity site.
* and **: p<0.02, p<0.01 respectively, different from normal.

Higher receptor concentrations and affinities for DHM were observed in all assayed areas of the cerebrum (anterior cortex, amygdala and striatum) of the HO-DI as compared to normal rats (see table). In contrast, in assayed areas of the brainstem affinity or number were found between HO-DI and normal rats (see table). In general, ^{3}H-DHM binding kinetics in cerebral hemispheres of HE-DI rats were intermediate to those of HO-DI and normal rats, but HE-DI rats had significantly fewer opiate receptors in the thalamus and midbrain when compared to normal rats.

Our findings suggest that opiate receptor differences between HO-DI and normal rats may be involved in impaired tolerance development of Brattleboro rats. Supported by USPHS AG00538 and MH12526, NSF BNS 76-17370 and the McKnight Foundation (JLMcG).

1921 **HALOTHANE EFFECTS ON SENSORY EVOKED PHOTIC RESPONSES RECORDED SIMULTANEOUSLY FROM RETICULAR FORMATION, THALAMUS AND CORTEX IN FREELY MOVING ANIMALS.** **Luis J. Moreno* (SPON. W.S. Fields) The University of Texas Medical School at Houston, Houston, TX 77025.**

Sensory evoked potentials were recorded simultaneously in response to sensory stimulation from three areas within the central nervous system which have been postulated to be involved in mechanisms of general anesthesia. Permanent semimicroelectrodes (62 μm in diameter) were implanted stereotaxically under pentobarbital (50 mg/μg) anesthesia in the brainstem reticular formation (MRF), ventral posterior nucleus of the thalamus (VPL) and the somatosensory cortex (SC), 5-8 days prior to the experimental day. Experiments were performed on 12 male albino Sprague-Dawley rats (250-350 gr). The present investigation was initiated to establish an electrophysiological measurement to identify the acute effects of several concentrations of halothane (0.25; 0.5; 1.0; 1.5; 2.0 and 2.5%) on sensory evoked field potentials.

The averaged photic evoked responses consist of a positive deflection (P_1), a negative deflection (N_1), followed by a positive (P_2), negative (N_2), and a positive wave (P_3). Only the N_2 components were evaluated in terms of the amplitude and latency because of the consistency within and between animals. The response amplitude of the recording from the SC was the most sensitive to halothane treatment and demonstrated suppression with the lower dose (0.25%). The degree of suppression was dose-related, i.e., with increased dose of halothane the amplitudes were suppressed more and more. The lowest dose of halothane (0.25%) induced excitation of the responses obtained from the MRF and exhibited dose-related suppression with increasing halothane doses (0.5%-2.5%). The VPL responses were affected only from the second dose of halothane (0.5%) and also exhibited dose-related suppression. In all three structures the suppression of the responses was accompanied with shifting the latency response to the right. Differences in the degree of these shifting between the three structures were observed. In conclusion, halothane induced different effects on the three structures investigated in the present study, and were remarkably different from those obtained following pentobarbital treatment (Dafny, 1978, Exper. Neurol., 59:263).

1922 DOPAMINE ANTAGONIST ACTIVITY OF A NOVEL ANTIPSYCHOTIC COMPOUND EN285. Paul R. Myers, Greg R. Christoph*, and Rebecca S. Knight*. Central Research & Development Department, E. I. du Pont de Nemours & Co., Inc., Wilmington, DE 19898.

Neurochemical and electrophysiological methods were used to study the dopamine antagonist properties of EN285, a chemically novel methanodibenzocycloheptapyrrole. EN285 was an effective antagonist of rat striatal dopamine-sensitive adenylate cyclase with an $I_{50} = 6 \times 10^{-7}$ M against 1×10^{-4} M dopamine. Half maximal stimulation of adenylate cyclase activity as measured by cAMP production was observed at 6×10^{-6} M dopamine with maximal stimulation at 1×10^{-5} M dopamine. Trifluoperazine showed 50% inhibition at 1×10^{-7} M. The potency of EN285 is similar to that of chlorpromazine ($I_{50} = 6 \times 10^{-7}$ M; Clement-Cormier et al., J. Neurochem, 25, 1975) in this assay. In electrophysiological experiments, rats were anesthetized with chloral hydrate. Single dopamine-containing neurons in the pars compacta of the substantia nigra were identified on-line by their firing rate (2-7 spikes/sec) and spike duration (> 2 msec) characteristics. EN285 (up to 0.4 mg/kg, i.v.) had little or no effect on spontaneous firing rate. In rats whose nigral cell discharge rate had been reduced 40-60% by d-amphetamine pretreatment, EN285 (0.1-0.4 mg/kg, i.v.) reversed the amphetamine-induced depression in a dose-dependent fashion. The present work demonstrates that EN285 has central dopamine antagonist properties.

1923 ETHANOL SPECIFICALLY POTENTIATES GABAERGIC NEUROTRANSMISSION IN FELINE CEREBRAL CORTEX. Joannis N. Nestoros. Dept. Anaesthesia Research, McGill Univ., 3655 Drummond St., Montreal PQ H3G 1Y6.

Since ethanol is the oldest known "anxiolytic" agent, and since anxiolytic benzodiazepines and barbiturates are known to potentiate GABAergic neurotransmission, the following questions were asked: 1) Does ethanol potentiate the inhibitory effect of GABA on single neurons in the feline cerebral cortex? 2) If there is such a potentiation, is it specifically exerted on inhibitions evoked by GABA or does it involve inhibitions evoked by other postulated neurotransmitters, such as glycine, serotonin and dopamine? The experiments were performed on cats anaesthetized with chloralose, fluothane or methoxyflurane. Control experiments were performed using the "isolated cerebrum" unanaesthetized preparation. The drugs were applied utilizing standard microiontophoretic techniques. The degree of inhibition of single cortical units induced to fire submaximally by Na-L-glutamate was measured from peristimulus histograms generated by the extracellularly recorded spikes.

It was found that ethanol released from micropipettes (0.3 M in 165 mM NaCl) by "electro-osmosis" (by removing the retaining current or by ejecting currents up to 10 nA) or applied intravenously (0.2-2.0 mg/kg) potentiated strongly the inhibition of neuronal firing produced by iontophoretically-applied pulses of GABA, whereas it had no effect on inhibition produced by pulses of glycine, and had an antagonistic effect on the inhibition produced by pulses of serotonin or dopamine. Furthermore, ethanol applied by "electro-osmosis" or intravenously in the same doses potentiated strongly the inhibition of neuronal firing evoked by electrical stimulation of the surface of the cerebral cortex. This electrically-evoked cortical inhibition is believed to be mediated by endogenous GABA, and was found in these experiments to be prolonged in the presence of nipecotic acid, and to be antagonized by bicuculline and picrotoxin, but not strychnine. Ethanol in the aforementioned electro-osmotic and intravenous doses frequently decreased spontaneous firing as well as the firing evoked by Na-L-glutamate. However, this always occurred at doses higher than those affecting the inhibitions under study and precautions were always taken to use doses of ethanol that did not interfere with Na-L-glutamate evoked firing.

When tested on the same neurons, the effects of ethanol on GABA pulses and electrically-evoked cortical inhibition were identical with the effects of flurazepam and chlordiazepoxide, except that the effects of benzodiazepines lasted longer.

The above findings may have implications for the etiology and treatment of alcoholism.

Supported by the Medical Research Council of Canada.

1924 ETHANOL PROLONGS THE TIME COURSE OF RECURRENT INHIBITION IN THE HIPPOCAMPUS IN RESPONSE TO COMMISSURAL FIBER ACTIVATION. S.A.Newlin, E.D.French*, T.Berger, F.E.Bloom. Alcohol Research Center, The Salk Inst., La Jolla, CA 92037.

Ethanol (3g/kg) was found to increase the period of recurrent inhibition recorded in hippocampal pyramidal neurons consequent to commissural fiber activation. This increase in the length of inhibition may be due to increased excitability of pyramidal neurons in the presence of ethanol.

Single unit responses were measured in CA_1 and CA_3 areas of the dorsal hippocampus using 3M NaCl-filled glass microelectrodes. On-line computer-generated post-stimulus-time histograms provided a measure of the degree of inhibition of spontaneous firing following stimulation. Stimulating current was delivered through a bipolar stainless steel electrode positioned in the contralateral hippocampus. Pyramidal neurons, as identified by firing pattern, responded to commissural fiber stimulation with an initial excitatory response followed by a cessation of activity lasting from 10-300 msec. As previously reported (Spencer and Kandel, Exper.Neurol.,1961) increasing intensities of stimulus voltage produced longer periods of recurrent inhibition. However, after a single i.p. injection of ethanol (3g/kg), the stimulus response curve for the period of recurrent inhibition was shifted to the left and upward, indicating an increase in the time course for inhibition with a given stimulus current. This increase in the time of recurrent inhibition could be due to any of several mechanisms, including: 1) an increased activation of pyramidal neurons which then activate more inhibitory interneurons; 2) an increased activation of inhibitory interneurons or increased transmitter release by inhibitory interneurons in the absence of increased activation of pyramidal neuron activity; 3) a change in pyramidal cell responsiveness to inhibitory synaptic input.

Our findings that iontophoretic application of ethanol (1-3M) on to CA_1 and CA_3 hippocampal neurons increased spontaneous firing rate in the majority (54%) of cells tested would be consistent with an hypothesis of increased pyramidal neuron excitability after ethanol. Moreover, an analysis of field potentials evoked by commissural stimulation revealed that the size of the population EPSP did not change while the size of the population spike was affected in the presence of ethanol.

1925 OPIATE ANALGESIA: EVIDENCE FOR MEDIATION BY A SUBPOPULATION OF OPIATE RECEPTORS. Gavril W. Pasternak, Steven R. Childers and Solomon H. Snyder. Depts. Neurology and Pharmacology, Memorial Sloan-Kettering Cancer Center and Cornell Univ. Med. College, N.Y., N.Y. 10021 and Depts. Pharmacology and Exp. Therapeutics and Psychiatry, Johns Hopkins Med. Sch., Baltimore, Md. 21205.

Animal responses to several different types of opiate analgesics have suggested multiple classes of receptors (Martin et al, JPET 197 517, 1976) and binding studies performed with opiates of high specific activity have demonstrated two distinct binding sites with differing affinities for narcotics (Pasternak and Snyder, Nature 253 563, 1975). In the present study, a novel narcotic antagonist, naloxazone, which appears to block irreversibly high affinity binding sites in vivo has been used to investigate the pharmacological relevance of the two receptor binding sites. Opiate binding in membranes from mice pretreated in vivo 24 hr earlier with naloxazone (200mg/kg) is decreased about 40% despite extensive washing techniques shown to remove reversibly bound ligands. Naloxone-treated controls (200mg/kg) show no decrease. Scatchard analysis of the decreased binding in the naloxazone-pretreated mice demonstrates loss of virtually all high affinity binding with almost no effect on the affinity or number of low affinity binding sites. The rate of return of high affinity binding suggests that in vivo turnover of high affinity receptors takes about 3 days. Sixteen hours after pretreatment with naloxone (200mg/kg) or saline, groups of mice tested for morphine (12mg/kg) analgesia in the tail-flick assay showed an increased latency of 90±4% (n=13) and 91±5% (n=8) respectively of the maximal measurable latency. By contrast, the naloxazone-pretreated group (200mg/kg) whose high affinity binding sites were blocked demonstrated only an 18±6% (n=13) increase in latency, suggesting prevention of analgesia seen in the control groups. When groups of mice similarly pretreated with naloxazone naloxone, or saline were given high (lethal) doses of morphine (500mg/kg), mortality (7/8, 7/8, 8/8 respectively) was the same in all groups. This mortality is opiate specific since the administration of naloxone immediately before the lethal dose of morphine prevents the mortality. Thus, blockade of only high affinity binding sites prevents opiate analgesia while offering no protection from opiate mortality. This mortality is probably a combination of cardiovascular and respiratory effects. These studies suggest that the different classes of receptors mediate different pharmacological functions and suggest the possibility of drugs specific for a single class of receptor.

1926 RAT BRAIN STRIATAL SYNAPTOSOMES BECOME RELATIVELY UNRESPONSIVE AT "OPTIMAL" pH CONDITIONS FOR MEASURING DOPAMINE FORMATION. Robert L. Patrick and Michael T. Rendel*, Neuroscience Sect. Div. Biol. Med. Sci., Brown Univ. Providence, RI 02912.

The rate of dopamine formation in rat brain striatal synaptosomes markedly increases as the pH is lowered from 7.2 to 6.2. Compared to pH 7.2, synthesis was increased 80% at pH 6.6 and 160% at pH 6.2. This increase in synthesis is accompanied by a significant increase in apparent Km for tyrosine as well as in apparent Vmax. Although these kinetic changes are similar to those produced by the depolarizing agent veratridine, it does not appear that synthesis is stimulated at pH 6.2 via synaptosomal depolarization since (1) synthesis stimulation still occurs at pH 6.2 in a calcium-free medium, in contrast to the calcium-dependency of synthesis stimulation observed with veratridine and (2) tyrosine uptake is not inhibited at pH 6.2, in contrast to the inhibition of tyrosine uptake produced by veratridine.

In order to study how the regulatory properties of synaptosomal preparations may vary according to pH, we have examined the effects of various stimulatory and inhibitory agents at pH 7.2, 6.6 and 6.2. The effects of three stimulatory agents (veratridine, amphetamine and phenylethylamine) were significantly diminished at pH 6.2 compared to pH 7.2. Their effects at pH 6.6, however, were quite similar to those at pH 7.2. The effects of two inhibitory agents (dopamine and tyramine) were also significantly antagonized at pH 6.2 compared to 7.2, while their effects at pH 6.6 were similar to those at 7.2. These results suggest that caution must be exercised in choosing an appropriate "optimal" pH for studying synaptosomal synthesis regulation, but it is possible to increase activity by altering pH without necessarily altering the regulatory properties of the system.

1927 A GENERAL METHOD FOR AUTORADIOGRAPHIC VISUALIZATION OF BRAIN RECEPTORS IN VITRO. Candace B. Pert and Miles Herkenham. Biological Psychiatry Branch and Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205

Previous autoradiographic visualization studies have involved either injection of reversible radioactive ligands into animals with subsequent work-ups developed for diffusable substances ("in vivo") or incubations "in vitro" with ligands which form covalent bonds. Since highly specific ligands which form covalent bonds with receptors are not always available, we developed a method for in vitro labeling of receptors which features a fixation procedure of general applicability.

Rats were decapitated, their brains were rapidly removed, frozen on dry ice, cut into 25 micron sections in a cryostat (-12°C), pressed lightly onto slides, and maintained at 4°C for several days. Batches of slides were incubated at 4°C in 200 mls of sodium phosphate buffer (0.05 M, pH 7.4) containing bacitracin (500 µg/ml), aprotinin (1 TIU unit/ml), 100 mM sodium chloride and [^{3}H]diprenorphine (1 x 10^{-8} M) for 10 min. Slides were quickly dipped into five serial washes of 0.2% albumin at 0°C and a final wash of distilled water at 0°C and rapidly frozen with dry ice. After lyophilization overnight, sections were fixed by overnight exposure to concentrated gluteraldehyde vapors in a sealed dish. Finally, the slides were washed in a series of five 10-min rinses in 1 mM glycine (pH adjusted to 7.4) and two washes in distilled water at room temperature. The clean dried slides were dipped in the darkroom into Kodak NTB-2 emulsion (1:1 dilution) and processed by traditional autoradiographic methods.

Slides available at 2 weeks of exposure showed tissue preservation consistently comparable to conventionally fixed tissue, very low background grain counts, comparable low levels in white matter and striking clusters of grains overlying several brain areas previously determined to be enriched in opiate receptors, e.g., striatal patches, amygdaloid nuclei, inferior colliculus and locus coeruleus. Longer exposures will be necessary for low-power visualization of receptor distributions.

We monitored specific binding by processing alternate sections incubated in saturating concentrations of the appropriate non-radioactive drug, cutting out the part of the slide containing the section, and counting it by liquid scintillation spectrophotometry. "Cold" displacer reduced control binding on alternate sections by 80% or more for a number of ligands including [^{3}H]-diazepam and [^{3}H]D-Ala^2-met-enkephalinamide, and this specific binding was maintained throughout all steps of the fixation procedure. The presentation will emphasize how variations of the ligand and incubation conditions on alternate slides can be used for visualization of various receptors and receptor subtypes.

1928 D-AMPHETAMINE REDUCES STRIATAL SUBSTANCE P CONCENTRATION BY PRESYNAPTIC RELEASE OF DOPAMINE. D. J. Pettibone and R. J. Wurtman. Dept. Nutrition and Food Science, M.I.T., Cambridge, MA 02139.

We have previously shown that the acute administration of d-amphetamine, a drug that releases striatal dopamine (Besson et al., Brain Research, 32:403, 1971), reduces substance P immunoreactivity in the rat striatum, 2-4 hrs post-injection (Pettibone, Wurtman and Leeman, Biochem. Pharmacol., 27:839, 1978). We suggested that the reduction might be mediated by activation of dopaminergic receptors. This report further characterizes the effect of amphetamine on striatal substance P and shows its dependence on adequate striatal dopamine concentrations.

The intraperitoneal administration of d-amphetamine sulfate to male, Sprague-Dawley rats (175 g) causes a dose-dependent reduction in substance P immunoreactivity within the striatum; a 10mg/kg dose reduces substance P from 1.37 to 0.97 pmoles/10 mg tissue ($p < 0.01$), 2 hrs post-injection. Substance P levels of substantia nigra or hypothalamus are unaffected. The amphetamine-induced reduction in striatal substance P is blocked in animals pretreated with haloperidol (1,3, or 10mg/kg i.p.). Similarly, when striatal dopamine levels are reduced 70-75%, either by injections of α-methyl tyrosine methyl ester (225mg/kg i.p.) or by lesions of the nigrostriatal tract (induced by intranigral injections of 8µg 6-OHDA), the effect of amphetamine is prevented.

These data indicate that the mechanism by which d-amphetamine reduces striatal substance P content involves the presynaptic release of dopamine from the terminals of nigrostriatal neurons. They raise the possibility that striatal dopamine release may normally participate in the regulation of neuronal substance P concentrations in this brain region. 1929 MORPHINE-LIKE EFFECTS OF CLONIDINE ON THE EEG AND BEHAVIOR IN THE DOG. Wallace B. Pickworth, Lawrence G. Sharpe and Vaikunth N. Gupta*. National Institute on Drug Abuse, Addiction Research Center, Lexington, Kentucky 40583

Clonidine, an alpha adrenergic agonist, has several effects similar to those of the opiates. We have compared the effects of morphine (0.5, 1.0 and 2.0 mg/kg) and clonidine (11, 33 and 100 µg/kg) on the EEG and behavior of the intact unrestrained beagle dog prepared with chronic electrodes for recording cortical and hippocampal EEG. EEG, heart rate, temperature and respiratory rate were recorded during a 2 hr experiment while the dogs were in a dimly lit sound-attenuated chamber. Their behavior was observed on a video monitor. Drugs were injected intravenously over 10 min from a pump outside the chamber. Morphine and clonidine caused cortical EEG synchrony which was more evident in parietal than occipital recordings. EEG-behavioral dissociation (EEG synchrony during a non-sleeping posture) was evident after all doses of morphine and after 33 and 100 µg/kg of clonidine. Also, both drugs increased total sleep. The increase was dose related after morphine, whereas the sleep after clonidine was maximal after the 33 µg/kg dose.

Spectral analysis of the EEG in clonidine treated dogs indicated that the effect of the drug was maximal at 15 min. The cut off frequency (half-power point) was increased from 6 to 10 Hz in the parietal and occipital EEG by clonidine. The drug increased power in the 4-8 Hz region while it decreased power in the 0.5-4 Hz band. The later effect was especially evident in recordings from the parietal cortex.

Morphine and clonidine caused behavioral sedation, ataxia, staring and vomiting as well as decreases in temperature, heart and respiratory rates. Catalepsy was more evident after morphine than clonidine. Naloxone (30 µg/kg) pretreatment antagonized the EEG and behavioral effects of morphine (1 mg/kg) but not those of clonidine (33 µg/kg). These data are consistent with the proposal that morphine and clonidine act upon different receptors in neural pathways which mediate these EEG and behavioral effects.

1930 POSSIBLE DISRUPTION OF GABAergic NEURAL FUNCTION IN ADULT MICE TREATED AS NEONATES WITH MONOSODIUM GLUTAMATE. William J. Pizzi, James R. Unnerstall* and June E. Barnhart. Department of Psychology, Northeastern Illinois University, Chicago, IL 60625.

Mice, treated as neonates with monosodium L-glutamate(GLU), exhibit a sequalae of somatic and behavioral deficits as adults due to the neurotoxic effects of GLU on the developing nervous system. We have recently shown that neonatal GLU-treated mice are more susceptible to pentylenetetrazol (PTZ) induced convulsions as adults. In order to explore this phenomenon, we have compared the differential response of GLU-treated and control mice to convulsants purported to act via differing pharmacological mechanisms.

Subjects were male HA:ICR mice born in our laboratory and housed with their dams until weaning at 29 days of age. Experimental animals were injected for 10 consecutive days (days 2-11 postpartum) with a gradually increasing dose of monosodium L-glutamate (2.2-4.4 mg/g body weight). Control subjects received equivalent volumes of equimolar NaCl.

All animals were tested between 90-120 days of age. The convulsant potencies of 3-mercaptopropionate (3-MP), an inhibitor of gamma-aminobutyric acid (GABA) synthesis, and bicuculline-HCl (BIC), a GABA receptor blocker, were determined according to the method of Litchfield & Wilcoxon (1949) using the least-squares criterion. A positive response was defined as a generalized clonic convulsion with loss of righting reflex. All agents were administered intraperitoneally using a 500 ul syringe.

GLU-treated mice were significantly more susceptible to 3-MP induced convulsions than controls (GLU: CD_{50}=19.59 mg/kg; NaCL: CD_{50}=31.02 mg/kg; Potency Ratio (PR)=1.58). The response of the GLU-treated animals to 3-MP was greater than the response obtained with PTZ (GLU: CD_{50}=38.7 mg/kg; NaCL: CD_{50}=49.6 mg/kg; PR=1.28). GLU-treated animals were less sensitive to BIC-induced convulsions (GLU: CD_{50}=5.89 mg/kg; NaCL : CD_{50}=4.06 mg/kg; PR=1.45).

The findings that GLU-treated animals are more sensitive to 3-MP and that they show a decreased sensitivity to BIC-induced convulsions suggests a disruption of normal GABAergic transmission in these animals. It is possible that GLU, administered during a critical period of neurochemical development, may permanently interfere in GABA synthesis and metabolism. Decreased GABA production may lead to altered sensitivity or increased numbers of GABA receptors, thus explaining the decreased sensitivity of GLU-treated animals to BIC.

1931 REGIONAL LOCALIZATION OF ^{14}C-METHADONE IN RABBIT BRAIN AFTER INTRACEREBROVENTRICULAR ADMINISTRATION: EFFECT OF NALOXONE PRETREATMENT. Donald A. Powell, Nandkumar S. Shah, Jane D. Yates* and Deborah A. May*. Ensor Fdn. Res. Jab., WM. S. Hall Psychiat. Inst. and V.A. Hosp., Columbia, S.C.

Albino rabbits were anesthetized (Ketamine, 55 mg/kg + chlorpromazine, 5 mg/kg, i.m.) and a cannula was implanted into the lateral ventricle. Seven days after surgery, a 50 µl Merles solution containing 96 µg + 1.47 µCi 2-^{14}C-methadone was introduced into cerebroventricular system. This dose exerted no noticeable behavioral effects. Following decapitation at 0.25, 1 or 2 hr, several brain areas were assayed for ^{14}C-methadone. ^{14}C was unevenly distributed in various regions reaching peak levels within 15 min. The superior colliculus, tegmentum, pons, hypothalamus, caudate, inferior colliculus, septum-nucleus accumbens, and medulla contained from 1.3 to 5.8 µg/g while olfactory tubercle, cortex, cerebellum, hippocampus and superior colliculus contained less than 1.0 µg/g. ^{14}C-methadone considerably declined at 2 hr. With few exceptions, pretreatment with naloxone (10 mg/kg i.p., 15 min) produced no significant effects on methadone levels in several brain regions examined at 15 min after methadone administration; only statistically significant differences were: marked decreases in inferior colliculus, superior colliculus and hypothalamus, a samll decrease in the thalamus, a large increase in the caudate and a small increase in cerebellum. At later time intervals, most noticeable differences in methadone levels in naloxone pretreated rabbits were the decreased levels in hippocampus and the increased levels in medulla. (Supported in part by the Ensor Research Foundation and V.A. Institute Funds Project No. 7155-03).

1932 THE EXCITATORY PORTION OF THE BIPHASIC RESPONSE OF CENTRAL NEURONS TO IBOTENIC ACID. E. Puil, Depts. of Anaesthesia and Pharmacology, University of British Columbia, Vancouver, B.C., Canada. V6T 1W5

At the last meeting of this Society, Puil and Krnjevic reported (Neurosci. Abst. 4:431, 1978) that microiontophoretic applications of ibotenate, a conformationally restricted analogue of glutamic acid, characteristically produced a biphasic effect in cerebral cortical neurons, as in spinal neurons: a strong excitation followed by a powerful, more prolonged inhibition of L-glutamate- and especially of acetylcholine-evoked discharge. As in the case of the potentiation of responses of neurons to L-glutamate by acetylcholine, the potentiation of L-glutamate-evoked firing by subthreshold amounts of ibotenate could be prevented by concurrent, extracellular application of methohexital.

Since the long latency of onset and afterdischarge of the excitatory responses of cortical neurons to ibotenate appeared to be more prominent in cats anaesthetized with diallylbarbiturate than with methoxyflurane, the effects of DL-ibotenate in cerebral cortical neurons were examined both extra- and intracellularly using parallel micropipette assemblies (triple barrel glued to single barrel at intertip distances of ~80µm) in cats with their forebrain isolated by leucotomy during brief anaesthesia with halothane. The most typical response of pre- and post-cruciate cortical neurons to iontophoresis of DL-ibotenate in this unanaesthetized preparation, was a strong excitation with a slow time course and afterdischarge more like the effect of acetylcholine than that of L-glutamate, while the subsequent inhibitory phase appeared to be much less prominent than that found in the previous studies. With intracellular recording, the excitation caused by ibotenate was seen to be related to a depolarizing action and to an ability of the isoxazole to increase the rate of rise of EPSPs evoked by bipolar electrical stimulation of the cortical surface or of the n. ventralis lateralis thalamus/internal capsule region with a tungsten microelectrode. The depolarization produced by ibotenate was in several cases associated with a rise in membrane resistance as measured from the increased amplitude of hyperpolarizing pulses injected through the recording barrel. In spinal motoneurons of cats anaesthetized with diallylbarbiturate, a similar, less pronounced depolarizing action of ibotenate was observed without important changes in membrane resistance. These data are consistent with the possibility that the excitatory portion of the biphasic response of central neurons to DL-ibotenate, which is dependent on the state of anaesthesia, is due at least in part to an action similar to that exhibited by acetylcholine, i.e., through a reduction in membrane permeability to K^+ relative to Na^+.

1933 CORTICAL SENSORY EVOKED POTENTIALS AND THE ANESTHETIC DOSE OF HALOTHANE IN FREELY BEHAVING RATS. L.S. RABE*, B.M. RIGOR*, L. MORENO*, N. DAFNY. Depts. of Neurobiol. & Anat. and Anesthes., Univer. of Texas Med. Sch. Houston, TX 77025

This study was designed to assess the effect of different doses of halothane on the averaged evoked response (AER) of freely behaving rats since halothane is one of the most commonly used gaseous anesthetics in this country. Stainless steel semimicroelectrodes (60 µm in diameter) were implanted under pentobarbital anesthesia in the visual and auditory cortices of rats several days prior to experimentation, along with a bipolar stimulating electrode surrounding the sural nerve. Four sets of AER's to both acoustic and visual stimuli (32 repetitions) were taken as controls and then following increasing doses of halothane at 0.25%, 0.5%, 1.0%, and 2.0% administered by a vaporizer, (Fluotec 3). At each dose the sural nerve was stimulated to determine onset of anesthesia. The amplitudes of the AER's were analyzed peak to peak and consisted of an initial positive-negative spike (P_1-N_1) followed by a larger positive-negative-positive-negative wave (P_2-N_2-P_3-N_3). The results indicate that the auditory averaged evoked response (AAER) is a more sensitive measure for detecting halothane's effect on cortical areas than the visual averaged evoked response (VAER). In general, the AAER from the auditory cortex was the most affected by the halothane averaged over all doses (59%). The later components (P_2,N_2,P_3,N_3) were more responsive (i.e. had the greatest number of animals with a significant change) than the early components. The effects of halothane on the individual components (P_1,P_2,N_2) showed dose related patterns of responsiveness. The next most responsive set of AER's was the AAER from the visual cortex, (52%), then the VAER from visual cortex, (44%), and the least responsive was the VAER from the auditory cortex, (38%). This last set was the only one not to exhibit increasing responsiveness in the later components. All areas showed dose-related patterns of responsiveness on one or more components. The results from the sural nerve stimulation were that the dose level of 0.5% was the lowest dose at which the rats showed no pain-evoked response to stimulation. In all sets of recordings at this dose (0.5%), the N_2 component showed an increase in amplitude over controls while other components showed mixed responses. These results indicate a relationship between anesthetic dose and cortical AER's and suggest clinical applications for monitoring level of anesthesia.

1934 DIFFERENTIAL DOSE-DEPENDENT EFFECTS OF D-AMPHETAMINE AND APOMORPHINE ON SPONTANEOUS NEURONAL ACTIVITY IN THE RAT NEOSTRIATUM AND NUCLEUS ACCUMBENS. George V. Rebec and Kenneth S. Zimmerman*. Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

Increasing doses of d-amphetamine produce a shift in the firing pattern of neurons in the neostriatum that has been implicated in the dose-dependent transition in behavior from locomotion to focused stereotypy (Rebec and Segal, Brain Res., 1978, 150: 353). To further elucidate the neuronal mechanisms underlying the amphetamine behavioral response, we extended our dose analysis to the nucleus accumbens. We also characterized the dose-dependent changes in firing rate produced by apomorphine. Unit activity, recorded from immobilized, locally anesthetized rats (350-450g), was amplified and displayed by conventional means. All drugs were injected via an in-dwelling intraperitoneal catheter.

Although low doses of d-amphetamine (1.0-2.5 mg/kg) and apomorphine (0.5-1.0 mg/kg) produced a qualitatively similar depression of neuronal activity in the neostriatum and nucleus accumbens, increasing the dose caused dramatic regional differences in firing rate. Thus, whereas neurons in the neostriatum responded to 7.5 mg/kg d-amphetamine with a prolonged increase in unit activity, the same dose produced a mirror-image inhibition in the nucleus accumbens. Increasing the dose of apomorphine (4.0 mg/kg), on the other hand, typically inhibited neuronal activity in the neostriatum but increased firing rate in the nucleus accumbens. The dose-dependent effects of d-amphetamine and apomorphine in both brain sites were reversed by either haloperidol (2.0 mg/kg) or clozapine (20-40 mg/kg).

The results indicate that the amphetamine- and apomorphine-induced behavioral transition from locomotor activity to stereotypy may be mediated, in part, by a differential dose-dependent effect on unit activity in the neostriatum and nucleus accumbens.

1935 ENANTIOMERIC INFLUENCES IN NEUROLEPTIC BINDING TO THE DOPAMINE RECEPTOR. Timothy A. Robert, Ernest A. Daigneault and Andrea N. Hagardorn*. Department of Pharmacology, College of Medicine, East Tennessee State University, Johnson City, Tennessee 37601.

The stereoselectivity of the dopamine (DA) receptor has been recognized for some time. Antagonists such as cis-thiothixene, a geometric isomer, and (+) butaclamol, an optical isomer, are more potent both in vivo and in vitro than their corresponding antipodes. The unique properties of enantiomers make them particularly useful for studying receptor interactions. Differences in potency of DA antagonism between optical isomers is exclusively a function of relative affinities determined by a single recognition parameter at the receptive site. A series of optical isomers of phenothiazine derivatives was examined for the ability to displace ^{3}H-DA and ^{3}H-spiroperidol (SP) from crude homogenates of calf caudate nucleus. Levorotatory methotrimeprazine was most effective at displacing both ^{3}H-DA and ^{3}H-SP with IC_{50} values of 2×10^{-6} and 9×10^{-8}M respectively. The corresponding IC_{50}'s for the dextrorotatory isomer were 3×10^{-5} and 9×10^{-6}M. In contrast, the dextrorotatory forms of other phenothiazine derivatives such as promethazine were more effective at displacing ^{3}H-SP. Upon comparing the ratios of *d*- and *l*- IC_{50} values for displacing ^{3}H-DA and ^{3}H-SP by methotrimeprazine, a large difference was observed. The receptor population labeled by ^{3}H-SP exhibits a six-fold higher stereospecificity than that labeled by ^{3}H-DA. These results provide direct evidence suggesting non-equivalence of ^{3}H-DA and ^{3}H-SP receptors in the calf caudate.

Resolved phenothiazines were the generous gifts of Wyeth Laboratories, Inc. and Rhône-Poulenc.

1936 EFFECT OF CHRONIC D-AMPHETAMINE OR β-PHENYLETHYLAMINE ON DOPAMINE BINDING IN RAT STRIATUM AND LIMBIC SYSTEM. Harold A. Robertson, Department of Pharmacology, Dalhousie University, Halifax, N. S., Canada. B3H 4H7.

D-amphetamine, a dopamine (DA)-releasing agent, produces a psychosis in man that is difficult to distinguish from paranoid schizophrenia and which is effectively controlled by neuroleptic drugs. β-Phenylethylamine (PEA), a sympathomimetic amine found in mammalian tissues, is structurally similar to amphetamine, the only difference being that PEA lacks a methyl group on the α-carbon of the side chain. PEA, like amphetamine, produces stereotyped behavior in rats and it has been suggested that PEA may be involved in the aetiology of schizophrenia. It was therefore of interest to know the effects of chronic PEA treatment on DA receptors in the CNS.

Male Wistar rats (200 g) were injected i.p. with saline, d-amphetamine sulphate (5 mg/kg) or β-phenylethylamine-HCL (50 mg/Kg) daily for 22 days. On day 24, animals were killed, tissue pooled from 2 rats and DA receptor binding assays (using 0.2 nM 3H-spiroperidol) were carried out on striatum and the meso-limbic system. The meso-limbic system consisted of pooled nucleus accumbens and olfactory tubercule.

Chronic treatment with either PEA or d-amphetamine produced an increase in specific 3H-spiroperidol binding in both striatum and meso-limbic system.

TREATMENT	SPECIFICALLY-BOUND 3H-SPIROPERIDOL (Fmol/mg protein ± SEM, N=4)	
	Striatum	Mesolimbic System
Saline	82.6 ± 3.3	69.2 ± 2.9
D-amphetamine	102.0 ± 3.5**	87.0 ± 0.6**
β-phenylethylamine	96.6 ± 3.2*	87.2 ± 3.6**

*P < 0.05, **P < 0.01, compared to saline

Recent work has demonstrated increased 3H-spiperone and 3H-haloperidol binding in caudate nucleus and nucleus accumbens of schizophrenic patients (Lee et al, Nature 274: 897, 1978). Rats treated with chronic amphetamine also show enhanced behavioral reactivity to directly acting dopamine agonists (Klawans et al, J. neurol. Sci. 25: 283, 1975). It appears therefore that chronic amphetamine treatment or chronic PEA treatment can produce changes in DA-receptor sensitivity similar to those seen in schizophrenic patients. This finding supports the contention that β-phenylthylamine may be useful as an animal model for schizophrenia. Finally there appears to be no differentiation between extrapyramidal and limbic areas in terms of the changes in DA-receptor binding and this too is in agreement with findings in schizophrenic patients.

Supported by the Canadian MRC.

1937 PRE- AND POSTSYNAPTIC ACTIONS OF RIGID ANALOGS OF DOPAMINE. D.B. Rusterholz, D.B. Goodale, J.R. Flynn*, J.P. Long*, T. Lee* and J.G. Cannon*. Dept. Pharmacology, Coll. Med., Univ. of Iowa, Iowa City, IA 52242.

In order to investigate the structural requirements of dopamine receptors that mediate postsynaptic events as compared to dopamine receptors that mediate presynaptic events, the relative potencies of a series of 18 structural analogs of dopamine were determined in two models. The test series included derivatives of phenethylamine, 2-aminotetralin, benzo[f]quinoline and ergoline.

The agonist potencies of the test compounds at postsynaptic dopaminergic receptors were evaluated using the rotating-rat model of Ungerstedt, et al. (Brain Res. 24, 485, 1970) with the modification that a smaller volume of 6-OH-DA was used in making the unilateral substantia nigra lesions. Contralateral circling behavior was recorded automatically for one hour following s.c. administration of the drug. Potencies were calculated relative to apomorphine using a parallel line bioassay.

Presynaptic receptor agonism was assessed by measuring the drug-induced inhibition of DOPA accumulation in rat striatal samples following administration of gamma-butyrolactone and a DOPA decarboxylase inhibitor. The method of Walters and Roth (N.S. Arch. Pharm. 296, 5 1976) was followed with the modification that NSD1015 was used as the DOPA decarboxylase inhibitor and DOPA was determined using high performance liquid chromatography with electrochemical detection. Potencies relative to apomorphine were calculated using a parallel line bioassay.

Seven compounds were found inactive in one or both preparations, leaving 11 members of the test series with measurable potencies in both models. Although several agents appeared to have some degree of selectivity, a comparison of the rank ordering of the potencies of the test substances by the two models revealed a strong similarity: Spearman's correlation coefficient = .78 ($p<0.01$). These data suggest that the structural requirements of the receptors mediating rotational behavior and inhibition of DOPA accumulation are similar and therefore may involve only one receptor type.

1938 ADENOSINE AS A MEDIATOR OF THE EFFECTS OF LITHIUM AND OTHER PSYCHOTROPIC DRUGS. A. Sattin, E. Einterz* and N. Whicker*, Institute of Psychiatric Research, Dept. of Psychiatry, Indiana Univ. Sch. Med., Indianapolis, IN 46223.

The accumulation of cyclic AMP in chopped brain tissue has served historically as a useful tool for identifying neurotransmitters and their interactions by examining the effects of the test substances upon the tissue content of cyclic AMP. The most striking example of this was the discovery that adenosine activates adenylyl cyclase, that adenosine receptors interact with biogenic amine receptors, and that activation of adenosine receptors is antagonized by methylxanthines (A. Sattin and T.W. Rall, Molec. Pharmacol. 6: 13-23, 1970). Desipramine (T. Kodama et al., BBA, 252: 165-170, 1971) and other tricyclic drugs (M. Huang and J. Daly, J. Med. Chem. 15: 458-462, 1972) have adenosine like effects on cyclic AMP accumulation in chopped cerebral cortex. This has been confirmed and correlated with the effects of a series of antidepressant drugs applied iontophoretically to rat cerebral cortical neurons in vivo (A. Sattin et al., Life Sci. 23: 2621-2626, 1978). Mediation of the drug effects by adenosine was based upon prevention of increase in cyclic AMP in vitro by theophylline and potentiation of the inhibitory effects of the tricyclic drugs by adenosine in vivo. The tricyclic drugs produce decreases in the chopped tissue content of ATP and increases in the content of 5'-AMP and adenosine. The increase in the tissue content of adenosine is sufficient to account for the observed increase in cyclic AMP. This work has now been extended to mice in vivo.

In order to enhance the effect of the drugs on the adenosine compounds chronically drug treated mice were stressed with an electroconvulsive seizure, then allowed to partially recover before freezing in isopentane. The most striking effects were seen following 5 μ equiv./g of LiCl x 7 days in SEC X DBA hybrid mice (60 days old). Five saline-injected control mice gave values for adenosine and cyclic AMP of 3.48 ± 0.28 and 2.64 ± 0.38 (SEM) nmoles/g respectively in whole forebrain. The respective values for ATP, ADP and 5'-AMP were 8.49 ± 0.71, 1.34 ± 0.16 and 0.49 ± 0.04 μmoles/g. The ATP content is more than twice the previously reported value for intact brain and indicates the efficacy of this freeze-fixation method. Following Li^+ treatment ATP increased 50% and ADP increased over 3-fold. Ninety sec. following onset of ECS ATP was still less than half the lithium control and increases were observed in adenosine (10-fold), cyclic AMP (3-fold) and 5'-AMP. A dose-response analysis and an exploration of other post ECS times will be discussed in relation to the possible involvement of adenosine in therapeutic and/or toxic effects of Li^+. (Supported by MH 31137 and the State of Indiana).

1939 INTERACTION OF GABA MIMETICS WITH CENTRAL CHOLINERGIC NEURONS. Bernard Scatton* and Giuseppe Bartholini* (SPON: M. Le Moal). Synthélabo (L.E.R.S.), Research Department, 58, Rue de la Glacière, 75013 PARIS, FRANCE.

The effect of the GABA mimetic agents muscimol and SL 76 002 ({α(chloro-4 phenyl) fluoro-5 hydroxy-2 benzilidene-amino} -4 butyramide) on acetylcholine (ACh) levels were investigated in various regions of the rat brain.

Muscimol (0.2 to 7.5 mg/kg i.p.) and SL 76 002 (10 to 400 mg/kg i.p.) induced a dose-related increase in striatal ACh levels. As ACh esterase activity was not affected by muscimol, SL 76 002 or its metabolites (10^{-4}M) the increase in ACh concentration probably reflects a decreased release of ACh. This effect is unlikely to be connected with an interaction of the GABA agonists with ACh receptors as SL 76 002, its metabolites and muscimol (5 x 10^{-4}M) do not affect the binding of ^{3}H-quinuclidinylbenzylate in rat brain membrane preparations. The enhancement of striatal ACh levels is also unlikely to be the consequence of GABA mimetic-induced changes in dopaminergic transmission : thus, these compounds caused a similar modification of striatal ACh levels after 6-hydroxydopamine induced degeneration of the nigro-striatal dopaminergic pathway. Moreover, SL 76 002 and muscimol increased striatal ACh levels to a similar extent after administration of haloperidol (2 mg/kg) or apomorphine (5 mg/kg). In addition after unilateral transection between substantia nigra and striatum, GABA mimetic agents retain their ability to increase striatal ACh content. Finally, striatal ACh levels were increased after intrastriatal infusion of GABA (750 ng) or muscimol (75 ng). These data suggest that striatal ACh neurons may receive a direct GABAergic inhibitory influence.

GABA also appears to affect ACh neurons in other ACh-rich brain areas. Thus, muscimol (7.5 mg/kg) or SL 76 002 (400 mg/kg) increased ACh levels in the frontal cortex, olfactory tubercle, nucleus accumbens and interpeduncular nucleus. However, the percentage increase was smaller in the latter areas than in striatum. In contrast, no change of ACh levels was observed in the septo-hippocampal system.

The present results suggest that GABA affects brain cholinergic cells in discrete brain areas.

1940 BEHAVIORAL EFFECTS OF THE NOVEL DOPAMINE AGONIST SK&F 38393. Paulette E. Setler, Joseph McDevitt* and Tsuneo Fujita*. Smith Kline & French Laboratories, Philadelphia, Pennsylvania 19101.

SK&F 38393 (2,3,4,5-tetrahydro-7,8-dihydroxy-1-phenyl-1H-3-benzazepine) is a dopamine agonist which, in the central nervous system, selectively activates dopamine receptors linked to adenylate cyclase (Setler et al., Eur. J. Pharmacol. 50:419, 1978). The complex interactions of SK&F 38393 with anticholinergic drugs suggest that the behavioral effects of this agonist may not accurately reflect the consequences of activation of cyclase-coupled dopamine receptors. SK&F 38393 produces contralateral rotation when injected systemically or into the dopamine-depleted caudate nucleus in rats with a unilateral 6-hydroxydopamine-induced lesion of substantia nigra. In non-lesioned rats intra-caudate injection of SK&F 38393 produces rotation only when the rats are given a systemic injection of a muscarinic antagonist such as scopolamine. SK&F 38393 which, unlike most dopamine agonists, does not produce stereotyped behavior in intact rats, does produce stereotypy in rats with either unilateral or bilateral depletion of dopamine and causes a mild form of stereotypy in intact rats also given scopolamine. Another animal model in which SK&F 38393 produces a form of stereotyped behavior is the 6-8 day old rat, which may have a functionally weak central cholinergic system. SK&F 38393 also has little effect on the symptoms induced by a combination of reserpine and α-methyl-p-tyrosine. When given with scopolamine, however, SK&F 38393 reverses the postural and motor effects of acute catecholamine depletion.

SK&F 38393 produces few overt effects in intact rats, but behavioral effects traditionally associated with dopamine agonists may be seen in rats with denervation supersensitivity of dopamine receptors or in rats with reduced central cholinergic function. This may indicate a pharmacologic effect of SK&F 38393 on cholinergic function which masks the effect of dopamine receptor activation. Alternatively, these unmasked behaviors could represent a weak activation of another type of dopamine receptor not coupled to adenylate cyclase. This activation would be observable only when the dopamine receptors are made more sensitive by denervation or suppression of cholinergic activity.

1941 EVIDENCE THAT AMPHETAMINE-INDUCED MYDRIASIS IN THE DOG IS DUE PARTLY TO INHIBITION OF THE EDINGER-WESTPHAL NUCLEUS (EW) BY A MUSCARINIC CHOLINERGIC INPUT. Lawrence G. Sharpe and Wallace B. Pickworth. NIDA Addiction Research Center, Lexington, Kentucky 40583.

Amphetamine produces pupillary dilation in several species by the simultaneous activation of sympathetic and inhibition of parasympathetic impulses which reach the dilator and sphincter pupillae of the iris. Recent evidence showed that microinjections of cholinergic muscarinic agonists in the EW caused mydriasis in the dog, suggesting that the pupilloconstrictor neurons receive tonic muscarinic inhibitory input (Sharpe and Pickworth, SN Meeting, 1978). The purpose of this study was to test the hypothesis that amphetamine produces mydriasis partly through an increased release of acetylcholine (ACh) in the EW to inhibit the pupillary light reflex path.

Five dogs were acclimated to a sling restraint. Atropine N-methyl nitrate or haloperidol (2.73nmol in 1.0 µl) were injected via chronically indwelling cannula in a region of the oculomotor nuclear complex that yielded pupilloconstriction to electrical stimulation. Thirty minutes after the antagonist microinjection, amphetamine (1.0 mg/kg) was infused intravenously for 10 min. Pupillary diameter was measured photographically before and for 2 hr after the infusion.

That microinjections of atropine, but not haloperidol, produced pupilloconstriction, is consistent with the hypothesis that the EW receives tonic muscarinic inhibitory input. Pretreatments with microinjections of atropine, but not haloperidol, partially and significantly antagonized amphetamine-induced mydriasis when compared to saline pretreatment (area under time action curve, $P = 0.01$, $t = 4.35$, 4 df).

Because we have previously shown that when microinjected into the EW (1) catacholamines produce miosis, (2) cholinomimetics produce mydriasis and (3) amphetamine produces no change in pupillary diameter, we conclude that EW is not the site of action of this portion of amphetamine-induced mydriasis. One explanation is that amphetamine may increase ACh release in the EW indirectly by increasing first the release of catecholamines distant from the EW to excite the cell bodies of those cholinergic inhibitory pathways leading to the EW.

1942 BENZODIAZEPINE BINDING IN SUBSTANTIA NIGRA; INCREASED STIMULATION BY GABA AFTER STRIATONIGRAL LESIONS. Haruo Shibuya*, Karen Gale* and Candace Pert. (SPON: J. Neale) Nat'l. Inst. Mental Health, Bethesda, MD 20205 and Dept. of Pharmacol., Georgetown U. School of Med. and Dent., Wash. DC 20007.

Striatonigral GABA-containing pathways were unilaterally destroyed by a discrete electrolytic lesion in the crus cerebri, rostrolateral to substantia nigra (SN). Four weeks postoperatively, the GABA concentration of the SN from the lesioned hemisphere dropped to below 40% of that on the intact side. At this time, specific [^{3}H]diazepam binding (per mg protein) in the SN on the lesioned side was significantly reduced (by 40%) when compared with either the intact contralateral SN or with SN from unoperated control rats.

Addition of GABA (10^{-6} to 10^{-5}M) to benzodiazepine binding assay preparations has been shown to increase benzodiazepine binding by increasing the apparent affinity of the benzodiazepine site for its ligands (Tolman et al., Nature 274: 383, 1978). We observed that the [^{3}H]diazepam binding sites remaining in the SN of the lesioned side exhibited an enhanced response to the addition of GABA to the binding assay. In membranes from the SN of the unlesioned side, 10^{-7}M GABA did not stimulate [^{3}H]diazepam binding, while the same GABA concentration elicited a significant increase (37%) in [^{3}H]diazepam binding to membranes from the SN of the lesioned side. At 10^{-6}M, GABA elicited a 30% enhancement of [^{3}H]diazepam binding in the intact SN and a 77% enhancement of [^{3}H]diazepam binding in the SN from the lesioned hemisphere.

Acute depletion of GABA by injection of isoniazid (400 mg/kg i.p. 1 hr. prior to sacrifice, which results in a 60-70% decrease in nigral GABA) had no significant effect on the ability of GABA to enhance [^{3}H]diazepam binding in SN. Thus it is unlikely that a reduced tissue level of GABA per se can account for the augmentation of the GABA effect on benzodiazepine binding. Instead, the effect which we have observed is most likely a result of the chronic loss of GABA or GABAergic terminals after the lesions.

It has been previously shown that 2-4 weeks after electrolytic lesions of the striatonigral pathways, there is an increase in the amount of high affinity binding sites for [^{3}H]GABA in SN (Guidotti et al., Brain Research, in press). Our observation that these same lesions result in an enhancement of the effect of GABA on benzodiazepine binding suggests that one population of benzodiazepine receptors in SN may be closely coupled to GABA receptors in such a way that supersensitivity of GABA receptors manifests itself on the binding of benzodiazepine receptors as well.

1943 IN VITRO BINDING STUDIES WITH 3H-N-METHYL ASPARTATE. S. Robert Snodgrass (SPON: L. W. Kneisley), Dept. of Neuroscience, Children's Hospital Medical Center, and Dept. Neurology, Harvard Medical School, Boston, MA 02115

What is the "endogenous ligand" for excitotoxins such as kainic acid (KA)? Do the large number of excitotoxins all bind to the same receptor? N-methyl-D-aspartic acid (NMDA) is one of the most potent excitants known. McCulloch, Watkins, and others have suggested that NMDA and KA act at different kinds of receptors. Evans et al (Experientia 33:489, 1977) reported that micromolar concentrations of Mg^{++} antagonized NMDA excitation in frog and rat spinal cord, but not that due to KA or glutamate (glu). They suggested that these Mg^{++} effects were probably post-synaptic as they were not reversed by Ca^{++}.

Binding of 3H-NMDA (80 Ci/mmol, New England Nuclear Corp.) to membrane fractions from rat and mouse brain was studied. The binding was greater in buffers lacking Na^{+} ion and 50 mM Tris acetate or Tris citrate, pH 7.2, were routinely used. Incubation with 1.7 nM 3H-NMDA was for 2 min at room temperature and was terminated by filtration through GF/B glass fiber filters. Non specific binding was estimated with 62 uM nonradioactive NMDA. Binding was found to be saturable, with a Kd of 9.8 nM estimated for mouse cerebellar membranes. No evidence of metabolism of the NMDA was detected by TLC with butanol-acetic acid-water (3:1:1). The binding was not altered by Ca^{++} but was decreased in a dose-dependent manner by Mg^{++}. The IC_{50} for this Mg^{++} inhibition was estimated at 450 uM. Using the same membranes, buffer, and 3H-KA, no effect of Mg^{++} could be detected.

As with other amino acid ligands, binding reaches equilibrium very quickly. KA and glu were weak inhibitors of NMDA binding, while DL-homocysteic acid and D-aspartate (asp) were more potent antagonists. For both glu and asp, the "unnatural" D-isomers had greater potency than the L-isomers. DL-α-aminoadipate was able to block NMDA binding with a potency similar to that of DL-homocysteic acid and D-asp. In parallel studies, nonradioactive NMDA was a poor displacer of KA binding. The number of binding sites for NMDA appears to be somewhat less than the number of KA sites, although both show significant regional variation and the number of binding sites for 3H-L-glutamate, in Na^{+} free media is 8-10 fold greater. The binding sites for KA and NMDA differ in several important ways and it is likely that there are at least two separate receptors which bind excitotoxins. They differ in sensitivity to Mg^{++} ions as first noted in physiological studies.

1944 THE EFFECTS OF CHOLINE AT THE MUSCARINIC CHOLINERGIC RECEPTOR IN BRAIN. Robert C. Speth and Henry I. Yamamura. Department of Pharmacology, University of Arizona Health Sciences Center, Tucson Arizona 85724.

Choline is both a precursor and a metabolite of acetylcholine (ACh). Until recently, little thought was given to the possibility that choline might also interact with cholinergic receptors. We have tested choline for its ability to inhibit specific [^{3}H]-quinuclidinyl benzilate [QNB] binding to muscarinic cholinergic receptors in brain. Choline inhibited [^{3}H]QNB binding with an IC_{50} value of 1.3 mM which is about 1000 fold less potent than ACh (IC_{50}=1.5 μM). Respective K_i values for choline and ACh were 0.34 mM and 0.39 μM.

One mM choline competitively inhibited [^{3}H]QNB binding, shifting the K_D apparent of [^{3}H]QNB from 45 pM to 109 pM with no effect on the maximal binding capacity. The effects of choline appear to be specific to cholinergic receptors since one mM choline did not significantly affect the binding of [^{3}H]spiroperidol or [^{3}H]-flunitrazepam to their receptors on brain membranes. The slopes of log-logit plots for the inhibition of [^{3}H]QNB binding by various cholinergic substances were; 0.44 for ACh, 0.73 for oxotremorine, 0.82 for choline and 1.09 for atropine. Since muscarinic agonists typically have slopes of <1, this suggests that choline may act as an agonist at muscarinic receptors in brain. Brain concentrations of choline are reported to be 15 to 30 μM, however at cholinergic synapses, the choline concentrations may be much higher. If so, it is possible that choline may interact with cholinergic receptors under normal conditions.

1945 EFFECTS OF MORPHINE (MS), METHIONINE-ENKEPHALIN (ME) AND SUBSTANCE P (SP) ON NEURONAL FIRING IN THE NUCLEUS RETICULARIS GIGANTOCELLULARIS (NRGC) OF THE RAT. (D. D. Spring* and H. J. Haigler, Dept. of Pharmacology, Emory Univ., Atlanta, GA 30322)

The NRGC and surrounding areas (i.e., raphe magnus and nucleus reticularis paragigantocellularis) are responsive to nociceptive stimuli (Morrow and Casey, Adv. in Pain Res. and Ther. 1: 503, 1976). Microinjections of low doses of morphine and enkephalins into the NRGC produce analgesia (Akaike et al, Jap. J. of Pharmacol. 27: 548, 1977; Akaike et al, Neuropharmacol. 17: 775, 1978). Enkephalin and SP containing neurons are found in the region of the NRGC (Hokfelt et al, Proc. Natl. Acad. Sci. 74: 3081, 1977). Since the NRGC and surrounding areas are apparently involved in nociception and analgesia, we microiontophoretically administered MS, ME and SP in these areas to determine the effects on spontaneous neuronal firing and neuronal firing evoked by a nociceptive stimulus (i.e., foot pinch).

Male Sprague-Dawley rats (220-350 gms) were anesthetized with halothane and surgically prepared with a tracheal cannula, paralyzed with gallamine triethiodide; the pCO_2 in the expired air was maintained between 3.5-3.7%. Local anesthetics were administered around all wound edges and on the sterotaxic ear bars. In some experiments, chloral hydrate (80 mg/kg) was periodically administered through a tail vein. A five-barrel micropipette was lowered into the brain through a hole drilled in the skull. The micropipette contained 10 mM ME, 50 mM MS, and 3 mM SP in three barrels; a fourth barrel, filled with 4 M NaCl, was used as a current balance barrel; the central barrel, filled with 2 M NaCl and FG, was used to record single unit activity. Most neurons tested with the nociceptive stimulus responded with a significant ($p<0.05$:1-way ANOVA) increase in firing. Iontophoretically-applied MS and ME usually had no effect on spontaneous firing and failed to block the increase in evoked firing elicited by the nociceptive stimulus. SP had no effect on spontaneous firing; however, in 2 of 18 cells it potentiated the evoked firing. These data do not support the hypothesis that SP is a neurotransmitter in the NRGC of the rat. Systemically-administered MS (2.0-8.0 mg/kg) blocked the increase in firing produced by the nociceptive stimulus but high currents (up to 100 nA) of iontophoretically-applied MS and ME did not. The effect of MS administered systemically was blocked by naloxone (1.0-2.0 mg/kg). Systemically administered morphine apparently acts at sites other than the NRGC to block the increase in neuronal firing evoked by a nociceptive stimulus. MS and ME do not have a direct effect in the NRGC since neither substance blocked evoked firing. (Supported in part by NIDA Grant 1-RO1-DA-01344-03.)

1946 EFFECTS OF UNILATERAL 6-HYDROXYDOPAMINE ADMINISTRATION ON DOPAMINE RECEPTORS IN RAT CORPUS STRIATUM. D.A. Staunton*, B.B. Wolfe, P.M. Groves and P.B. Molinoff. (SPON: W. Hahn) Dept. of Pharmacol., Univ. of Colo. Med. Ctr., Denver, CO 80262

Destruction of the nigrostriatal bundle leads to biochemical, neurophysiological and behavioral alterations in animals. This forms the basis of a model for Parkinson's Disease in humans. Previous research utilizing this paradigm revealed that such lesions lead to an increased sensitivity of striatal neurons to iontophoretically applied dopamine (DA) as well as to an increased binding of ^{3}H-haloperidol to striatal membranes. An increased maximal stimulation of DA-sensitive adenylate cyclase in striatal homogenates from denervated striata has been observed in some studies. In the present experiments, 6-hydroxydopamine (6-OHDA; 8 μg) was injected unilaterally into the nigrostriatal bundle of male Sprague-Dawley rats weighing approximately 150 g. The animals were sacrificed at 1, 2, 3, 5, 14 and 28 days post-lesion and the corpus striata were removed for biochemical analyses. Striatal DA content was reduced by greater than 95% within 2 days following 6-OHDA administration. Nonspecific ^{3}H-spiroperidol binding was defined as the binding in the presence of 2 μM (+)-butaclamol or 10 μM (±)-ADTN. No change in the binding of ^{3}H-spiroperidol was observed 1 or 2 days after lesioning. However, the density of ^{3}H-spiroperidol binding sites was increased by 25-50% in the denervated striata 5 or more days following 6-OHDA treatment. Basal and DA-stimulated adenylate cyclase activity were measured in fresh striatal homogenates from the same animals. Maximal stimulation of enzyme activity occurred in the presence of 100 μM DA. There was no change in either basal or DA-stimulated cyclase activity on the first post-operative day. At longer time points, the ratio of stimulated (100 μM DA) to basal activity was increased by 30-40% on the lesioned side, with no change in the EC50 value. These results demonstrate that lesions of the nigrostriatal pathway lead to similar time-dependent increases in the density of DA receptors and in DA-stimulated adenylate cyclase activity. Increased ^{3}H-spiroperidol binding appears to develop concomitantly with the earliest appearance of apomorphine-evoked contralateral rotational behavior. The present results support the hypothesis that the destruction of the nigrostriatal DA pathway results in a time-dependent development of denervation supersensitivity and that changes in DA receptors are at least partially responsible for the increased sensitivity. Supported by the USPHS (NS 09199).

1947 IS REWARD BEHAVIOR MEDIATED BY AN ENDOGENOUS OPIATE SYSTEM? Elliot A. Stein and Joseph Zerneskie* Department of Biology, Marquette University, Milwaukee, WI 53233.

One of the least investigated, and most unknown aspects of addictive behavior concerns the neuroanatomical and physiological bases of the craving-euphoric effect. Since this behavior is in ways, similar to intracranial self-stimulation(ICSS), it would be of interest to determine if both phenomena are mediated by a set of common central structures. One line of evidence pointing to such a commonality is the remarkable overlap between opiate receptor density with those sites supporting ICSS. If the endogenous opiates play a role in hedonic behavior, then it is conceivable that animals might self-administer opiates into those brain areas subserving reward behavior and containing opiate receptors. To test this hypothesis, male Holtzman rats were stereotaxically prepared with 26 g guide cannulae aimed at various subcortical sites. Following a 2 day recovery period, a 33 g injection cannula is lowered into the brain and the rat is placed into a rectangular plexiglass chamber with a pedal placed at each end. One pedal is arbitrarily chosen as the active one such that each press results in a single drug injection. The alternate pedal serves as a control for non-specific general behavioral activation. Drug doses were 0.1 and 0.5 ug/inj.(volume=10 nl/inj. with delivery time at 280 msec). Experiments were performed overnight for 20 hours.

The highest rates of self administration (in approx. descending order) have been seen for lateral ventricle, lateral hypothalamic area, amygdala and preoptic area. Considerably lower rates were found for the periventricular gray and septum. Finally no significant presses were seen for cortex, cerebellum, reticular formation or fourth ventricle. Preliminary results indicate that 5 ug/inj Met-Enkephalin is also self-administered into LH while 4.5 ug/inj B-Endorphin resulted in an increase in total presses for both pedals.

These results point towards a commonality of reward sites within the central nervous system and are discussed with respect to the role of opiates and the endogenous opiate system in hedonic behaviors. (Supported by grants from the NIDA, Pharmaceutical Manufacturing Association Foundation and the Marquette University Committee on Research)

1948 POWER SPECTRAL ANALYSIS OF REM SLEEP EEG IN THE RAT SELF-ADMINISTERING NARCOTICS. George F. Steinfels, Gerald A. Young and Naim Khazan. Dept. Pharmacol. and Toxicol., Univ. of Maryland Sch. of Pharmacy, Balto., MD 21201

In a previous study we used power spectral analysis to demonstrate that the behavioral states of sleep, REM sleep and wakefulness in the rat are associated with different EEG power spectra (Young et al, 1978a). In a subsequent study we examined the EEG power spectra of the first REM sleep episodes after self-injections of morphine and the last REM sleep episodes before the next injections (Young et al, 1978b). We found that the mean peak EEG frequency during the first REM sleep episodes was higher than that during the last episodes. A similar finding has been reported during methadone self-administration (Steinfels et al, 1978). The present study has extended these findings to include REM sleep EEG power spectral changes occurring throughout the interinjection intervals during self-administration of morphine, methadone, &-alpha-acetylmethadol (LAAM) and the two active N-demethylated metabolites of LAAM, nor-LAAM and dinor-LAAM.

Adult female Sprague-Dawley rats were implanted with chronic cortical and temporalis muscle electrodes and intravenous (iv) cannulas for drug administration. Tolerance and physical dependence were induced by automatic hourly iv injections of increasing doses of morphine. Rats were then trained to lever press to self-administer morphine (10 mg/kg/inj) on an FR-20 schedule of reinforcement (Khazan et al, 1967). For some of the rats, morphine was then replaced with methadone (2 mg/kg), LAAM (1 mg/kg), nor-LAAM (1 mg/kg) or dinor-LAAM (1 mg/kg). At least one week was allowed for the establishment of stabilized self-injection patterns. EEG recordings were stored on FM tape, and, later, EEG samples of successive REM sleep episodes which occurred between self-injections were subjected to power spectral analyses using a Nicolet MED-80 system.

During self-administration of these narcotics, the first REM sleep episode in each interinjection interval had the faster peak EEG frequency. The peak EEG frequencies of successive REM sleep episodes declined in a linear fashion. Differences in the slopes of the linear EEG frequency declines reflected differences in the pharmacokinetic profiles between the narcotics. Lever pressing activity did not appear to be related to these EEG changes since similar EEG frequency changes were seen in rats which received automatically delivered morphine injections. Therefore, these decreases in peak EEG frequencies may reflect a decline in brain levels of the respective narcotic and/or changes in the CNS that precede "drug-seeking behavior." (Supported by NIDA Grant DA 01050.)

1949 STRESS BLOCKS NALOXONE INDUCED HYPOTHERMIA. Jane Stewart and Roelof Eikelboom*. Dept. Psych., Concordia Univ., Montreal, Canada, H3G 1M8.

The specific opiate antagonist, naloxone, produced marked hypothermia in unstressed drug-naive rats. Rectal temperature readings taken 45 min after 2.5, 5, or 10 mg/kg naloxone HCl revealed a significant, dose-dependent hypothermia (> 1^{o} C) in animals thoroughly familiarized with the experimental handling. In contrast, similar doses of naloxone given to experimentally naive rats, or to rats subjected to a specific noise stressor had little, if any, effect on rectal temperature. Because in this first experiment naloxone was administered after initial handling and temperature readings, a second experiment was done in which steps were taken to administer naloxone prior to the onset of stress induced by handling and insertion of the rectal probe. Under these conditions a dose-response suppression of the stress induced rise in body temperature was observed (see also Blässig, Höllt, Bäuerle and Herz, Life Sci. 23:2525, 1978). When similar experiments were carried out in hypophysectomized rats, naloxone produced marked hypothermia even in stressed rats, making it appear that it is pituitary secretions that mediate the masking effects of stress on naloxone induced hypothermia.

The fact that naloxone has hypothermic effects in unstressed intact rats and in hypophysectomized rats suggests that naloxone acts by antagonizing brain endorphin or enkephalin systems that normally participate in tonic thermoregulation. Furthermore, the observation that the hypothermic effect of naloxone is found in the relatively unstressed animal has led us to conclude that the frequent failure to find physiological or behavioral effects of naloxone in drug-naive animals arises, not from a lack of tonic effects of endogenous opioids in normal animals, but rather from the somewhat stressful conditions that characterize acute testing procedures in experimentally naive animals.

1950 INHIBITION OF ACETYLCHOLINE RELEASE FROM THE MYENTERIC PLEXUS BY MORPHINE OR BY DECREASED AVAILABILITY OF Ca^{2+}: DIFFERENCES IN THE KINETICS OF LABELLED ACETYLCHOLINE EFFLUX. John C. Szerb, Dept. of Physiology & Biophysics, Dalhousie U., Halifax, N.S., Canada.

The release of [^{3}H]ACh from guinea-pig myenteric plexus longitudinal muscle preparation (MPLM) evoked by 0.1 Hz stimulation measured in the absence of cholinesterase inhibition has an initial fast and a later slow component. Morphine (1 μM) slows down the initial fast efflux and decreases the releasable pool size but not the rate of the slow efflux (Down & Szerb, Br. J. Pharmac., in press). To see whether a decreased availability of Ca^{2+} for release could be responsible for the effect of morphine on the slow efflux, the kinetics of [^{3}H]ACh release evoked by supramaximal 0.1 Hz stimulation in the absence of cholinesterase inhibition was measured in Krebs containing reduced Ca^{2+} or oxotremorine (OT). During releasing stimulation the concentration of Mg^{2+} was raised to 9.6 mM to avoid the contracture of MPLM which by itself reduced the size of the releasable pool of [^{3}H]ACh. In the presence of 2.5 mM Ca^{2+}, 9.6 mM Mg^{2+} reduced the rate constant of the slow release from 0.023 to 0.017 min^{-1}. The rate constant was further reduced in the presence of 1.75 mM Ca^{2+} or of OT, without changing the size of the releasable pool of [^{3}H]ACh. The effect of OT but not of reduced Ca^{2+} was overcome by atropine. On the other hand, morphine reduced the releasable pool size but not the rate constant of release in the presence of 9.6 mM Mg^{2+}. Results suggest that morphine reduces the size of the releasable pool of [^{3}H]ACh by hyperpolarizing cholinergic neurons as observed by North & Tonini (1977). Because of this hyperpolarization a number of neurons will cease to be excited by field stimulation and their [^{3}H]ACh stores will not be available for evoked release. Those neurons which continue to fire in the presence of morphine will release their [^{3}H]ACh at the same rate as without morphine. On the other hand, reduced Ca^{2+} or OT does not decrease the number of neurons excited but each impulse releases less [^{3}H]ACh, hence the rate of release is slower. Results therefore suggest that reduced availability of Ca^{2+} is not responsible for the depression by morphine of the evoked slow release of [^{3}H]ACh from the MPLM.

1951 EFFECTS OF CHRONIC ETHANOL ON CHOLINERGIC AND NEUROLEPTIC BINDING SITES IN BRAIN. Boris Tabakoff, Jeremy Z. Fields, Paula L. Hoffman*, Marietta Munoz-Marcus*, and Chinwuba Okafor*. Dept.Physiol. and Biophys., Univ. Ill. Med. Ctr., & Dept. Pharmacol., Chicago Med. Sch., Chicago, IL 60612

We have previously noted that mice withdrawn from chronic feeding with ethanol were less affected by apomorphine and other dopamine(DA) agonists than control animals. The stimulation of striatal tyrosine hydroxylase activity by neuroleptics was also diminished in the ethanol-withdrawn animals. In the present studies we wished to examine the characteristics of the neuroleptic binding sites in the striatum of ethanol-withdrawn animals and also to examine the muscarinic cholinergic receptors, since the cholinergic systems may participate in the feedback regulation of tyrosine hydroxylase activity. Spiroperidol and haloperidol binding to tissue homogenates were used to investigate the properties of the neuroleptic receptor sites and quinuclidinyl benzylate(QNB) binding was monitored to assess the properties of the muscarinic cholinergic receptors. Ethanol was administered in a liquid diet and control animals received a similar diet in which sucrose was equicalorically substituted for ethanol. The number of QNB binding sites was unaltered in the striatum of ethanol-intoxicated mice(0 time of withdrawal) or at 8 hours after withdrawal, when animals display the most profound withdrawal symptoms. On the other hand, QNB binding in the hippocampus and cerebral cortex was significantly altered in the ethanol withdrawn mice(Table 1).

Table 1. QNB Binding in Control and Ethanol-Withdrawn Mice

	Control		Ethanol Withdrawn*	
Brain Area	K_D(pM)	R_{max}**	K_D(pM)	R_{max}**
Hippocampus(10)	62.6±16.1	596±72	72.3±22.7	703±87^{++}
Striatum(4)	90.8±24.3	981±72	95.6±5.1	888±187
Cortex(6)	74.2±18.9	566±25	76.7±15.9	645±64^{+}

*Withdrawn from ethanol for 8 hours
**fmol/mg protein: $^{++}$, $p<0.01$; $^{+}$, $P<0.1$

Haloperidol and spiroperidol binding were unaltered within the first 24 hours after ethanol withdrawal but further studies at extended time points are now in progress. The results of the binding studies could not explain the decreased pharmacologic effects of neuroleptics in ethanol-withdrawn mice. However, changes in QNB binding may indicate a compensatory response to the ethanol-induced inhibition of acetylcholine release in cortex and hippocampus.

1952 AGONIST INDUCED INCREASE IN BINDING AFFINITY OF [^{3}H]-MUSCIMOL TO CRUDE SYNAPTIC MEMBRANES OF RAT CEREBELLUM. Rebecca Thomas*, Adrienne Gordon, and Ivan Diamond. Department of Neurology, University of California Medical School, San Francisco, Calif. 94143.

Many investigators have observed specific binding of γ-aminobutyric acid (GABA) to crude synaptic membranes prepared from rat cerebellum. Binding appears to involve two sites, one of high affinity and one of lower affinity. Moreover, Toffano et. al. (P.N.A.S. 75 (8), 4024, 1978) have shown that there is a conversion from low affinity to high affinity sites by removal of an endogenous inhibitor of GABA binding. A major limitation in previous studies is that the ligand was incubated with membranes for up to 30 min. before measurement of the amount bound. In order to elucidate the mechanism of ligand binding to the GABA receptor it is necessary to study the kinetics of the binding reaction. We have therefore been using [^{3}H]-muscimol as a ligand. This GABA agonist has a 10-fold higher affinity for the receptor than GABA itself and a slow off-rate which permits the use of filtration methods to measure muscimol binding. We have observed a biphasic association of [^{3}H]-muscimol with time. Initially there is a rapid phase which is over in less than one minute. This is followed by a slower phase which appears to be linear for at least 20 min. This linear increase in binding correlates with a 2 to 4-fold increase in the affinity and a 50% increase in the number of specific muscimol binding sites. Since the only variable in these experiments is the time the membranes are exposed to [^{3}H]-muscimol, the data suggests that there is an agonist-induced change in binding affinity of the GABA receptor for muscimol.

In order to determine whether this agonist-dependent change in affinity of the GABA receptor is mediated by changes in the endogenous inhibitor or some other mechanism, we investigated the effect of this inhibitor on the agonist-dependent affinity changes. We prepared endogenous inhibitor from frozen membranes which were incubated at 37°C for 30 min. The membranes were then centrifuged at 48,000 x g for 10 min. The supernatant was used as a source of endogenous inhibitor. Membranes to be used for binding studies were washed three times with buffer to remove the released inhibitor. In agreement with others, we find that addition of the inhibitor results in a decrease in affinity for muscimol. However, our results also indicate that a 4-fold change in affinity constant is still induced by muscimol and is not affected by the presence or absence of endogenous inhibitor. It is possible that the agonist-induced change in affinity of the GABA receptor which we report here may account for the phenomenon of pharmacological desensitization of the GABA receptor.

1953 FAILURE OF SYSTEMICALLY ADMINISTERED MUSCIMOL TO ACT AS A GABA AGONIST. James R. Unnerstall* and William J. Pizzi. (SPON: D. Rowland). Department of Psychology, Northeastern Illinois Univ., Chicago, IL 60625.

Muscimol (MUS) is a potent agonist of the putative neurotransmitter gamma-aminobutyric acid (GABA) in vitro and when administered intracranially, in vivo. Systemically administered MUS is also pharmacologically active. However, it is unclear whether the behavioral and biochemical effects are due to the drug per se or to some active metabolite of MUS. While Naik et al. (1976 Neuropharm. 15, 479) and Matthews et al. (1978, Neurosci Abst 4, 428) describe a pharmacological profile for systemically administered MUS consistent with expectations for a GABA agonist, Maggi & Enna (Neuropharm, in press) report that MUS is rapidly metabolized after systemic administration, and that this metabolite is not localized to the GABA receptor. The Maggi & Enna report, along with an observation in our lab indicating that MUS pretreatment protected mice against strychnine induced convulsions, led to the present investigation. A pharmacological profile of MUS ability to protect against the convulsions induced by several chemical agents, which are purported to work by different mechanisms, was determined. The results do not support a GABA mimetic action of systemically administered MUS.

Male Ha:ICR mice, 90-120 days of age, were challenged by CD_{97} doses of bicuculline-HCl (BIC), strychnine-HCl (STRY), 3-mercaptopropionate (3-MP) or pentylenetetrazol (PTZ) following systemic administration of MUS. The ED_{50} of MUS was determined for each convulsant with the method of Litchfield & Wilcoxon (1949). A positive response was defined as a generalized clonic convulsion with loss of righting reflex. MUS was administered 30 minutes prior to the convulsant challenge. All agents were administered intraperitoneally using a 500 ul syringe.

At the highest dose of MUS tested (2.25 mg/kg), animals appeared sedated but maintained a righting reflex. At lower doses, MUS exerted an apparent protective effect against STRY-induced convulsions. However, this trend was reversed at higher doses. Yet, a dose-dependent increase in latencies was observed. On the other hand, MUS clearly exerted a dose-dependent protective effect against 3-MP induced convulsions (ED_{50}=1.36 mg/kg). MUS exerted no protective effect on convulsions induced by BIC or PTZ. In fact, MUS (1 mg/kg administered 30 minutes prior to the convulsant challenge) potentiated BIC & PTZ induced convulsions (BIC: CD_{50}=4.56 mg/kg; MUS+BIC: CD_{50}=3.95 mg/kg; potency ratio= 1.15). (PTZ: CD_{50}=53.92 mg/kg; MUS+BIC: CD_{50}=43.10 mg/kg; potency ratio = 1.25).

These data lend support to the evidence presented by Maggi and Enna demonstrating that systemically adm. MUS is independent of a specific pharmacological action at the GABA receptor.

1954 KAINIC ACID ADMINISTRATION INTO THE SEPTUM ACTIVATES HIPPOCAMPAL THETA RHYTHM WITHOUT ALTERING ACETYLCHOLINE CONTENT. M.R. Vasko, I.L. Crawford, C.N. Allen*. Depts. Pharmacology and Neurology, VA Med. Ctr. and Univ. Texas Hlth. Sci. Ctr. at Dallas, TX 75216.

The neuroexcitatory and neurotoxic actions of kainic acid (KA) in the brain are well established. Therefore, kainate may be a useful tool for the stimulation as well as the destruction of specific neuronal pathways. We studied the effects of low and high doses of KA on physiological and neurochemical parameters of the cholinergic system in the septal-hippocampal pathway. Rhythmic slow activity (RSA, 4-7 hz) was monitored in hippocampus as an index of cholinergic function. In addition, concentrations of acetylcholine (ACh) were measured in discrete brain regions following kainate administration.

Rats (300±25 gm) were implanted with an indwelling cannula guide directed at the medial septum. Bipolar recording electrodes were also implanted on the surface of the hippocampus, bilaterally. Animals were allowed 5 days to recover, then electrical activity was monitored before and after injections of saline or KA. For neurochemical studies, KA (1 and 1.5 µg in 1µl) was injected slowly using a sterotaxically implanted 26ga needle directed at the medial septum. Ten days after the KA injections, the animals were sacrificed by microwave irradiation (1.3 kw) focussed on the head. The brains were removed, dissected, and ACh assayed radiochemically using the enzyme choline kinase.

Low doses of KA (10ng in 1µl) injected into the area of the medial septum caused a rapid activation of RSA bilaterally with a complete loss of desynchronous activity. The RSA was observed in immobile, as well as, moving animals. The desynchrony was abolished for 12 mins. Saline injection (1µl) had no effect on the bursts of desynchrony that occurred at 15-25 sec intervals in control resting animals. High doses of KA (1µg) resulted in electrographic seizure activity characterized by spikes and followed by intermittent abnormal sharp and slow waves. One and 1.5 µg of KA injected into the septum had no significant effect on ACh concentrations in either the septum or the hippocampus. ACh levels in septum and hippocampus were 30.5±6.7 and 26.6±2.8 nmol/gm, respectively, following KA (1µg) as compared to 37.1 ±5.3 and 27.4±4.9 nmol/gm for controls. Minimal, if any, cytotoxicity was observed in the septum following these large doses of KA. The small dose (10 ng) had no demonstrable cytotoxic effects in the hippocampus. Our results show that KA can drive septal-hippocampal RSA at doses that do not produce cytotoxicity or neurochemical changes in ACh. (Supported by VA MRIS 8977 and NIH Service Award GM07062, NIGMS).

1955 THE EFFECT OF CYCLIC NUCLEOTIDES AND A PHOSPHODIESTERASE INHIBITOR ON OPIATE-INDUCED DEPRESSION OF TRANSMITTER RELEASE IN THE MOUSE VAS DEFERENS. Lauren V. Vitek* and R. A. North. Loyola University Medical Center, Maywood, IL 60153.

The amplitude of evoked excitatory junction potentials (e.j.ps) is a sensitive measure of the amount of transmitter released from nerve terminals. Opiates depress evoked transmitter release and hence decrease e.j.p. amplitude in the mouse vas deferens. One hypothesis of opiate action states that the acute effects of opiates are mediated by a decrease in cyclic adenosine-3',5'-monophosphate (cAMP) levels in neurons. According to this hypothesis, an increase in neuronal cAMP levels should prevent or reduce opiate effects. Intracellular recordings were made from smooth muscle cells of the mouse isolated vas deferens. The aim was to determine whether drugs that modify cAMP levels could alter opiate-induced depression of e.j.p. amplitude.

Both cAMP (1mM) and its dibutyryl derivative (dbcAMP; 1mM) decreased the amplitude of the evoked e.j.p. The phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine (IBMX; 50 or 500μM) increased e.j.p. amplitude; this effect exhibited tachyphylaxis. IBMX (50 or 500μM) and dbcAMP (250 or 500μM) together increased e.j.p. amplitude more than IBMX alone. Neither the cyclic nucleotides nor IBMX altered the resting membrane potential of smooth muscle cells. There was no change in the ability of normorphine to depress the e.j.p. amplitude in the presence of cAMP (1mM) or in the combined presence of IBMX (50μM) and dbcAMP (500μM). Similarly, the dose-response curve for D-ala^2-met^5-enkephalin-amide (DAEA) was not affected by the presence of IBMX (500μM) and dbcAMP (250μM).

The present findings do not support the hypothesis that a reduction in intracellular cAMP levels is an essential step in the inhibition by opiates of transmitter release.

1956 CHOLINERGIC MICROSTIMULATION OF THE PONTINE BRAIN STEM PROVOKES THE DESYNCHRONIZED SLEEP SYNDROME. Ennio Vivaldi*, Robert W. McCarley and J. Allan Hobson. Laboratory of Neurophysiology, Department of Psychiatry, Harvard Medical School, Boston MA 02115.

We have proposed that desynchronized sleep (D) results from the increase in activity of cholinergic gigantocellular tegmental field (FTG) cells and that their recurrent collaterals play an important role in the overall population effect. The fact that local delivery of the long lasting cholinergic agent carbachol to the FTG induces prolonged periods of D supports the idea of a cholinergic state generator mechanism situated in the pontine reticular formation. We have previously documented the similarity of the drug induced state to physiologically occurring D, and established that more confined and less disruptive techniques of drug delivery resulted in more consistent and specific results. It thus seemed possible to adapt the drug delivery system to the cellular level of analysis, and thereby to determine the minimum number of cells which, when activated, could generate the whole D syndrome. We now report preliminary experience with a micropipette system that combines behaviorally effective drug delivery with single unit recording capability.

Two cats were prepared for chronic EEG recording and painless head restraint. Glass micropipettes could then be stereotaxically introduced through a burr hole while sleep-wake behavior was observed and polygraphically monitored. When the tips were positioned at FTG coordinates (P 3.0, HC -7.0, L 1.5) and filled with a 1 M carbachol solution, currents of 300 nA of 10 minutes duration produced a state indistinguishable from D sleep but which lasted for up to 50 minutes, 5 to 10 times the duration of D seen in KCl control experiments.

In one experiment a carbachol micropipette was placed in the peribrachial region of the pons (P 3.0, HC -2.0, L 2.9) from which PGO burst cells may be recorded. Passage of current then induced a dramatic and abnormal state of continuous PGO wave activity without other signs of D sleep; the stereotyped clusters of waves persisted for 15 hours. A unit recorded through the drug-filled pipette showed the tight phase locking of firing and EEG waves that characterizes the PGO burst cell in physiological D sleep.

The microstimulation method thus promises to be a useful tool in our effort to understand the D sleep generator process.

1957 EFFECTS OF CHRONIC DESIPRAMINE TREATMENT AND α-ADRENERGIC DRUGS ON RAT BRAIN NORADRENERGIC NEURONS. W. Warnack, B.A. McMillen, D.C. German, and P.A. Shore. Depts. of Physiol., Psychiat., & Pharmacol., Univ. of Texas Health Science Center, Dallas, TX 75235

The purpose of the present experiment was to study the effects of acute and chronic desipramine (DMI) treatment on the electrophysiology and biochemistry of rat brain norepinephrine (NE) neurons. Locus coeruleus (LC) NE neurons normally fire 1.73 ± 0.14 Hz (N=44) in the chloral hydrate anesthetized rat. After acute DMI (1.25 or 10.0 mg/kg i.p.), LC impulse flow decreased to 0.50 ± 0.11 Hz (N=11) whereas after chronic DMI (5.0 mg/kg b.i.d., i.p., 7-9 days) LC impulse flow partially recovered (1.09 ± 0.24 Hz, N=12). Furthermore, after chronic DMI, LC impulse flow was markedly less sensitive to the acute effects of intravenous DMI. This tolerance to DMI's effects on LC impulse flow, despite continued NE uptake blockade, suggests lessened inhibition of NE neurons. Since the LC has α_2-receptors on cell bodies and/or dendrites which are inhibitory to impulse flow, the present results suggest an α_2-receptor subsensitivity. Consistent with this interpretation are biochemical data showing that both 25 and 250 μg/kg doses of clonidine were equally effective in decreasing whole brain MOPEG-SO_4 in control rats, but only the larger dose decreased it in 12 day DMI rats. To test the sensitivity of α_1-receptors (post-synaptic), prazosin (5.0 mg/kg) in a dose just sufficient to increase MOPEG-SO_4 in control rats was found to be similarly effective in 12 day DMI rats. These data suggest that α_2-receptors become subsensitive during chronic DMI treatment but α_1-receptors do not. (Research supported by USPHS Grants MH-27574, MH-30546, and MH-05831.)

1958 OCCURRENCE AND DISTRIBUTION OF RAT BRAIN 3,4-DIHYDROXYPHENYLETHYLENE GLYCOL (DHPG) DETERMINED BY GAS CHROMATOGRAPHY MASS FRAGMENTOGRAPHY. Jerry J. Warsh, Damodar D. Godse*, Siu Cheung* and Peter Li*. Dept. of Neurochemistry, Clarke Institute of Psychiatry, University of Toronto, Toronto, Canada, M5T 1R8.

In a number of species central nervous system (CNS) norepinephrine is preferentially metabolized to the glycol end products 3,4-dihydroxyphenylethylene glycol (DHPG) and 3-methoxy-4-hydroxyphenylethylene glycol (MHPG). While substantial research has been done on the occurrence and significance of MHPG in the CNS, less is known about the occurrence and biological importance of CNS DHPG. This situation stems from the lack of suitably sensitive and specific methods for quantitation of DHPG in biological samples. We describe here a sensitive and specific GC-MS assay for simultaneous determination of DHPG and MHPG in biological samples and its application to the study of DHPG in rat brain.

Formic acid homogenates of whole rat brain or brain areas were subjected to enzymatic hydrolysis with aryl sulfatase (16 h., 37°C, pH 5.9). Under basic conditions (pH 10-10.5), DHPG and MHPG were simultaneously acetylated and extracted into ethyl acetate containing acetic anhydride (0.5%). The acetylated glycol products were acylated with trifluoroacetic anhydride and quantitated by multiple ion mass fragmentography. For internal standards DHPG-$^2H_2$ was synthesized by reduction of 3,4-dihydroxymandelic acid with $^2H_2$-borane methyl sulfide, while $^2H_3$-MHPG was synthesized by the method of Karoum et al. (J. of Neurochem. 25, 653, 1975).

Whole rat brain DHPG (115 ± 2.6 ng/g) was of the same order of magnitude as brain MHPG (87.0 ± 1.8 ng/g). Unconjugated DHPG and MHPG accounted for 12% and 11%, respectively, of total brain DHPG and MHPG concentrations. Regional brain total DHPG concentrations varied from 963 ± 37 ng/g (n = 6) in hypothalamus and 450 ± 70 ng/g (n = 6) in septum to 76 ± 10 ng/g (n = 6) in the caudate. Total DHPG was significantly higher than MHPG in hypothalamus and septum (molar ratio of DHPG/MHPG = 6.9 ± 0.44 and 3.91 ± 0.31, respectively). Yohimbine (0.5-10mg/kg, i.p.) produced parallel linear increases in both forebrain total DHPG and MHPG. Ten mg/kg yohimbine i.p. resulted in 212 ± 6.1% (n = 8) and 250 ± 5.6% (n = 8) increases in forebrain total DHPG and MHPG, respectively. The present data suggest that in rat brain formation and efflux of conjugated DHPG may account for a major fraction of the metabolic clearance of brain norepinephrine.

1959 EFFECTS OF DIETARY CHOLINE AVAILABILITY AND CHRONIC NEUROLEPTIC ADMINISTRATION ON RAT STRIATAL NEUROTRANSMITTER RECEPTORS. Lynn Wecker, Robert C. Speth and Henry I. Yamamura. Departments of Pharmacology, Louisiana State Univ. Med. Ctr., New Orleans, LA 70112 and Univ. of Arizona Health Sci. Ctr., Tucson, AZ 85724.

Recent investigations indicate that the dietary availability of choline significantly alters the dynamic regulation of acetylcholine metabolism and modifies the responsiveness of central cholinergic neurons to pharmacological manipulation (Neurosci. Abst. 4:436,1978).These effects are generally believed to involve presynaptic synthetic mechanisms, but possible receptor-mediated effects have not been thoroughly investigated. Hence, the present study was designed to determine the effects of dietary choline availability on central muscarinic receptor characteristics. In addition, due to recent evidence indicating that chronic choline administration decreases dopamine agonist-induced stereotypy in rats treated chronically with neuroleptics (Life Sci. 22:1699, 1978), the effects of dietary choline availability on spiroperidol binding in striata were investigated in rats chronically treated with haloperidol. Rats were randomly divided into 3 groups and maintained for 3 weeks on:a standard choline diet (0.2% choline chloride), a choline deficient diet, or a choline supplemented diet (2.0% choline chloride). Animals in each dietary group were injected daily (ip) during the 3 week period with either saline or haloperidol (5 mg/kg) and sacrificed 24 hours following the final injection by decapitation. Striata were removed, homogenized and prepared for receptor binding studies.Muscarinic receptors were characterized by incubating brain samples, in the presence and absence of atropine, with ^{3}H-L-quinuclidinyl benzilate (QNB, 30-1000pM). Specific high affinity binding of ^{3}H-spiroperidol (SP, 30-300pM) was determined in the presence and absence of (+)-butaclamol.Preliminary results indicate that the affinity (K_D) of QNB binding is not altered by dietary choline availability, but a 10% decrease in Bmax was observed in striata from rats on the choline supplemented diet. SP binding in striata from rats maintained on the standard dietary regimen was characterized by a K_D of 71pM, whereas in choline deficient and choline supplemented rats,the K_D was 82pM and 61pM, respectively. The Bmax of SP binding was unaffected by dietary choline manipulation. Chronic haloperidol administration increased the Bmax of SP binding in all dietary groups by approximately 50%. Binding in choline supplemented rats was not differentially affected. Preliminary results suggest that the effects of dietary choline availability on central neurotransmitter mechanisms may be mediated by alterations at receptor sites and we are currently pursuing studies to further characterize the nature of the interactions. (Supported in part by an RSDA #MH-00095 to H.I.Y.)

1960 THERMODYNAMIC EVIDENCE FOR AN AGONIST-SPECIFIC CONFORMATIONAL CHANGE OF THE β-ADRENERGIC RECEPTOR. G.A. Weiland*, K.P. Minneman*, and P.B. Molinoff. (SPON: W. Wickelgren). Dept. of Pharmacol., Univ. of Colo. Med. Ctr., Denver, CO

The effect of temperature on the affinities of β-adrenergic agonists and antagonists was examined by the inhibition of specific ^{125}I-iodohydroxybenzylpindolol binding to turkey erythrocyte membranes. The affinities of agonists increased with decreasing temperature while antagonist affinities were almost entirely independent of temperature. With a decrease in temperature from 37°C to 1°C, equilibrium dissociation constants (Kd's) decreased 56- to 16-fold for full agonists but by less than 3-fold for antagonists. Intermediate decreases in Kd values were observed for partial agonists.

Thermodynamic analysis of the dependence of Kd on temperature demonstrated fundamental differences between agonist and antagonist interactions with the receptor. The binding of agonists was enthalpy-driven with highly unfavorable decreases in entropy (see Table). Antagonist binding, on the other hand, was entropy-driven with only small changes in enthalpy. The binding of partial agonists was associated with intermediate changes in thermodynamic parameters. The changes in enthalpy and entropy were closely correlated with the relative efficacies of the compounds in stimulating adenylate cyclase activity. The results are consistent with the following model: $L + R \overset{1}{\rightleftarrows} LR \overset{2}{\rightleftarrows} LR'$. In this model the binding of agonists or antagonists (step 1) is based on hydrophobic interactions (entropy-driven) with only negligible changes in enthalpy. Agonists, but not antagonists, induce a conformational change (step 2) resulting in a net decrease in entropy and an increase in adenylate cyclase activity. The energy which compensates for this decrease in entropy is provided by a greater decrease in enthalpy. Agonist specific changes in the affinity of the β-adrenergic receptor have been observed following cell disruption and membrane solubilization and in the presence of guanine nucleotides or divalent cations. The thermodynamic approach described here may prove helpful in understanding these changes. Since affinity is a function of changes in enthalpy and entropy, alterations in affinity will reflect changes in these parameters. Thus, thermodynamic analysis may be a useful tool in examining the molecular events involved in hormone receptor interactions. (USPHS NS 13289 and NS 09199).

	ΔH° (kcal/mole) Range	ΔS° (entropy units) Range
Agonists (3)	-18.9 to -13.4	-35.3 to -12.9
Partial Agonists (5)	-10.8 to - 4.1	-13.1 to + 6.7
Antagonists (12)	- 5.1 to + 3.9	+13.0 to +42.3

1961 IDENTIFICATION OF ^{3}H-CLONIDINE BINDING SITES IN RAT BRAIN. P. Weinreich, M. Titeler and P. Seeman. Department of Pharmacology University of Toronto, Toronto, Ontario M5S 1A8.

Previous work has shown that there are two α-adrenergic receptors than can be pharmacologically differentiated (Langer, 1973, 1977; Andén et al., 1976), into a high affinity (Langer, 1973) and a low affinity norepinephrine site. The high affinity site is thought to be located pre-synaptically (Langer, 1973). A current issue is whether or not the high affinity ^{3}H-clonidine binding site in the brain represents this same pre-synaptic adrenergic receptor (Titeler et al., 1978). To test this hypothesis a series of catecholamine derivatives were tested for their ability to compete with ^{3}H-clonidine binding; these binding data were compared with the pre-synaptic cardiac actions of these drugs (Long et al., 1979). The strong correlation between the pre-synaptic cardiac actions of these drugs and their ^{3}H-clonidine IC_{50}'s indicates that the binding site in the brain and the site of action of these drugs in the heart are pharmacologically very similar. Currently we are trying to localize this ^{3}H-clonidine binding site in the brain using specific noradrenergic fibre lesions. (Supported by OMHF and MRC).

1962 BINDING STUDIES WITH ALPHA AND BETA DIHYDROPICROTOXININ. W. F. White and S. R. Snodgrass. Dept. Neurosci. The Children's Hospital Medical Center, and Dept. Neurol. Harvard Med. Sch. Boston, MA 02115.

The potent convulsant picrotoxinin is known to be a noncompetative antagonist of the GABA receptor. Recently a receptor for picrotoxinin has been characterized by Olsen and his collaborators using the less potent analogue ^{3}H-α-dihydropicrotoxinin. We have investigated the binding characteristics of both the alpha and beta isomers of ^{3}H-dihydropicrotoxinin to membrane fractions prepared from rat brain and also to intact rat cerebral cortical neurons grown in tissue culture. These studies support the findings of Olsen's group on the binding and pharmacological characteristics of ^{3}H-α-dihydropicrotoxinin binding to membrane fractions. Thus we find a small but significant percentage (20%) of the total binding is displacable by excess picrotoxinin and thus is specifically bound to the picrotoxinin receptor. This binding is saturable and is antagonized by the cage convulsant isopropylbicyclophosphoric acid. A number of agents known to interact with the GABA receptor at the Na^+-independent GABA binding site including GABA and the benzodiazepines have no effect on the binding of ^{3}H-α-dihydropicrotoxinin nor do variations of either Na^+ or Cl^- concentration. The development of ^{3}H-α-dihydropicrotoxinin binding sites in the cortical culture system is similar to that reported in situ and parallels the development of other biochemical measures of GABA function in the cultures. We have also investigated the stereospecificity of binding using the beta isomer of ^{3}H-dihydropicrotoxinin. In these studies we find little difference in the binding characteristics of the two isomers. This result is somewhat surprising in light of the marked stereospecificity of binding at most receptors. While this result may indicate a functional equivalence of the two isomers at the physiological picrotoxinin receptor this interpretation must await an analysis of the relative potencies of the two isomers in eliciting convulsions and as antagonists of GABA transmission. Results on these two points will be presented.

1963 SELECTIVE BLOCK OF DEPOLARIZING ACTION OF GABA ON PRIMARY AFFERENTS BY PIRETANIDE. J. Martin Wojtowicz, Roger A. Nicoll. Dept. Pharm. Univ. California, San Francisco, CA 94143.

Using the isolated frog spinal cord in conjunction with sucrose gap recording from the spinal roots it was found that piretanide (10^{-5} - 10^{-3} M) blocked the depolarizing GABA action on the primary afferent terminals, whereas the hyperpolarizing effect of GABA on motoneurones was unchanged. The depolarizing action of β-alanine on primary afferents was also blocked while there was only variable and slight depression of glutamate responses. Piretanide also blocked the dorsal root potential (DRP) generated by ventral root stimulation and reduced the DRP generated by dorsal root stimulation without prolonging its time course. The ventral root potential generated by dorsal root stimulation was little affected by piretanide. The action of piretanide was essentially irreversible since little recovery was seen after washing for 3 hours.

It has previously been reported (Zeuthen et al., Nature 273, 678-680, 1978) that piretanide inhibits chloride transport in intestinal epithelial cells. To examine the mechanism for the GABA blockade in our preparation intracellular recordings from isolated dorsal root ganglia were initiated. Iontophoretic application of GABA produces a marked depolarization of the somata of the dorsal root ganglion cells. The depolarization is associated with a decrease in the membrane resistance and its equilibrium potential (E_{GABA}) is 50-60 mV. Following repeated GABA applications, E_{GABA} can be shifted towards the resting membrane potential suggesting that the ionic gradient responsible for the depolarization is being dissipated. Piretanide accelerates the shift in E_{GABA}. Since Cl^- is the major ion involved in the GABA response (Gallagher et al., J. Physiol. 225, 2-22, 1977), the effect of piretanide can be explained by an inhibition of the inward chloride pump. In addition, a reduction in the conductance change due to GABA occurred in the presence of this drug.

In summary, we have found that piretanide selectively blocks depolarizing GABA responses both by interferring with inward chloride pumping, and by reducing the chloride conductance change elicited by GABA. Such a selective drug should be valuable in separating pre- and postsynaptic inhibitory events. (Supported by GM23478 and RCDA NS00287).

1964 POWER SPECTRAL ANALYSIS OF EEG AFTER ETHANOL ADMINISTRATION: CORRELATION WITH ETHANOL BLOOD LEVELS. Daniel L. Wolf* and Gerald A. Young (SPON: Naim Khazan). Dept. Pharmacol. and Toxicol., Univ. of Maryland Sch. of Pharm., Balto., MD 21201

Dose-related effects upon EEG after acute intravenous ethanol administration were studied in the rat and compared with ethanol blood levels. One group of female Sprague-Dawley rats was implanted with chronic cortical EEG and temporalis muscle electrodes, and indwelling jugular cannulas for ethanol administration. Ethanol (1, 2, and 4 g/kg, i.v.) was given and EEG and behavior were continuously monitored. Analysis of slow-speed EEG polygraph tracings revealed that ethanol had a dose-related effect to increase the duration of individual episodes with high voltage EEG. Peak increases in duration of EEG synchrony occurred at approximately 1.5, 3.0, and 7.0 hours after the 1, 2, and 4 g/kg doses of ethanol, respectively. The synchronized pattern observed in the EEG after ethanol was subjected to off-line power spectral analysis utilizing a Nicolet MED-80 minicomputer. Power spectral densities were determined at 0.1 Hz intervals in the 0-25 Hz range. Power spectral analysis of ethanol-induced EEG synchrony revealed dose-related increases in power in the 0-4 Hz band. Peak increases in 0-4 Hz band spectral power occurred at the same time as peak increases in duration of high voltage EEG episodes. Dose-related decreases in spectral power in the 4-8 Hz and 8-13 Hz bands were observed soon after infusion, but these changes occurred to a much lesser degree. These results indicate that ethanol caused a general shift of the EEG to lower frequencies. Comparison of ethanol-induced EEG synchrony to control slow wave sleep EEG further revealed that ethanol power spectra differed significantly from sleep power spectra in both power and frequency distributions.

A second group of rats bearing only jugular cannulas received the same ethanol treatment. Serial blood samples were withdrawn and the ethanol content determined. The peak blood level occurred at the end of the infusion and was proportional to dose, while the time to eliminate one-half of the peak was 1.3, 2.3, and 6.0 hours for the 1, 2, and 4 g/kg doses, respectively.

Peak changes in EEG spectral power were manifest at a time when approximately 70% of the respective peak ethanol blood level had been eliminated. From these results we conclude that ethanol induces EEG patterns distinct from those observed in the control sleep state and that the peak responses in the EEG synchrony are preceded by, and do not coincide with, the peak levels of blood ethanol. (Supported by NIAAA Grant AA 03659.)

1965 ALPHA ADRENERGIC RECEPTOR SUBTYPES AND CYCLIC AMP ACCUMULATION IN MOUSE CEREBRAL CORTEX. B.B. Wolfe, J.B. Kleiner* and P.B. Molinoff. Department of Pharmacology, University of Colorado Medical Center, Denver CO 80262.

The pharmacological specificity of catecholamine-stimulated cyclic AMP accumulation in mouse cerebral cortex was determined. Both α and β-adrenergic receptors increase cyclic AMP accumulation in slices of cerebral cortex. The difference between the maximal stimulation in the presence of l-epinephrine (EPI) and that in the presence of l-isoproterenol (ISO) was used as a measure of α-adrenergic receptor stimulated cyclic AMP accumulation. Cortical slices from male HS mice from a colony maintained at the University of Colorado were used as a tissue source. These mice were chosen on the basis of the large α-adrenergic component of cyclic AMP accumulation. Typical values for cyclic AMP accumulation were: Basal 25 pmol/mg; l-ISO 150 pmol/mg; l-EPI 500 pmol/mg. The Ki and Kact values were determined for a number of drugs including l-EPI, d-EPI, phentolamine, indoramin, prazosin, yohimbine, clonidine and WB-4101.

Radioligand binding utilizing both (^{3}H)-WB-4101 and (^{3}H)-clonidine was also examined. These ligands appear to bind primarily to α-1 and α-2 receptors respectively. The Kd values of a variety of agonists and antagonists were determined for the inhibition of both (^{3}H)-WB-4101 and (^{3}H)-clonidine binding. The values obtained with (^{3}H)-clonidine did not correllate with Ki or Kact values obtained in studies of cyclic AMP accumulation while the data obtained in studies with (^{3}H)-WB-4101 more closely resembled the cyclic AMP data. The results suggest that α-adrenergic receptor stimulated cyclic AMP accumulation in mouse cerebral cortex is not associated with the α-2 receptor as measured by (^{3}H)-clonidine binding but may be associated with the α-1 receptor as measured by (^{3}H)-WB-4101 binding.

To further examine this question neonatal mice were treated with 6-hydroxydopamine during the first 4 days of life. This treatment resulted in a 70% increase in α-adrenergic receptor stimulated cyclic AMP accumulation in slices of adult mouse cerebral cortex. This was accompanied by a 50% increase in the density of (^{3}H)-WB-4101 binding sites with no significant change in the density of (^{3}H)-clonidine binding sites. Supported by NS13289 and NS09199.

1966 ^{3}H-PERGOLIDE BINDS TO DOPAMINE RECEPTORS IN MAMMALIAN BRAIN. David T. Wong,* Frank P. Bymaster,* Penny T. Lane,* Donald Kau* and Edmund C. Kornfeld.* (Spon: L. Lemberger). The Lilly Research Laboratories, Indianapolis, IN. 46206.

Pergolide, (8β)-8-[(methylthio)methyl]-6-propylergoline, is a potent new dopamine agonist. Pergolide caused turning in rats with unilateral nigrostriatal lesions, lowered serum prolactin, and decreased dopamine turnover in rat brain (Fuller et al., Life Sci. 24, 375, 1979). Pergolide also inhibited the binding of ^{3}H-dopamine and ^{3}H-spiperone in bovine striatal membranes with inhibitor constants (Ki values) of 7.6 and 12 nM, respectively (Wong et al., XI Int'l Congress Biochem. 1979 Abs.).

Specific binding of ^{3}H-pergolide has been demonstrated in corpus striatum and olfactory tubercle of bovine and rat brains. About 70% of the specific binding was localized in the P_2 fraction (crude synaptosomes) of the striatal homogenate of rat brain. Scatchard analysis revealed a single component of ^{3}H-pergolide binding sites with a dissociation constant (Kd value) of 2.8 nM and receptor number of 370 fmole/mg protein in bovine striatal P_2 membranes. The corresponding values for the rat striatal P_2 membranes were 3 nM and 653 fmole/mg protein. Dopamine agonists (apomorphine and the aminotetralin derivatives, M-7 and TL-II-160) were potent inhibitors of ^{3}H-pergolide binding in rat striatal membranes with Ki values of 3.4, 19 and 11.3 nM, respectively. The dopamine antagonist, d-butaclamol, blocked ^{3}H-pergolide binding with a Ki value of 13 nM while its pharmacologically inactive isomer, l-butaclamol, was 1/20 as effective. Dopamine was a relatively weak inhibitor of ^{3}H-pergolide binding (Ki=1125 nM). Since pergolide was over 100-fold more potent in the inhibition of ^{3}H-dopamine binding than dopamine was in the inhibition of ^{3}H-pergolide binding, we conclude that pergolide binds more tightly to the receptors than does dopamine. Binding of ^{3}H-pergolide increased in striatal membranes from rats made supersensitive to apomorphine and pergolide after nigrostriatal lesions with 6-hydroxydopamine or after chronic administration with haloperidol. All of these studies suggest that pergolide produces its dopaminergic responses in vivo by acting on the postsynaptic receptors for dopamine.

1967 REGIONAL BRAIN GLUCOSE UTILIZATION FOLLOWING INTRASTRIATAL INJECTIONS OF KAINIC ACID IN RATS.
G. F. Wooten and R. C. Collins. (Spon. William M. Landau); Dept. Neurol., Wash. U. Med. Sch.; St. Louis, MO 63110

Intrastriatal injections of kainic acid (K.A.) (0.2-3.8 nmol in 0.4 µl of buffered normal saline) resulted in a dose-dependent increase in glucose utilization in the ipsilateral striatum 1-2 hours after injection as determined by ^{14}C-2 deoxyglucose autoradiography. Quantities of K.A. (1.9 and 3.8 nmol) sufficient to cause extensive lesions of the striatum resulted in a marked increase in glucose utilization in deeper layers of the overlying frontal neocortex 1-2 hours after injection. 1 week after injections of 1.9 or 3.8 nmol of K.A. the ipsilateral striatum showed a reduction in glucose utilization associated with a similar reduction in the number of neuronal cell bodies and choline acetyltransferase activity. Even at the lowest K.A. concentrations (0.2 nmol) there was a marked increase in glucose utilization 1-2 hours after injection in ipsilateral globus pallidus, substantia nigra, nucleus accumbens, septum, and ipsilateral greater than contralateral hippocampus; while at the higher concentrations (1.9 and 3.8 nmol) glucose utilization was markedly increased after 1-2 hours in ipsilateral olfactory cortex, pyriform cortex, and ventral tier nuclei of the thalamus as well.

Autoradiographs following intrastriatal injection of 1 µCi of ^{3}H-K.A. in 0.4 µl of normal saline revealed that all detectable tritium remained highly localized in the striatum for at least 2 hours after injection.

These results demonstrate that K.A. causes an increase in glucose utilization in the striatum and in some adjacent as well as far distant brain structures within 2 hours of intrastriatal injection. It appears that the increase in glucose utilization in distant sites may be mediated via direct anatomical connections with the striatum along multisynaptic pathways rather than by diffusion or rapid axonal transport of K.A..

1968 DISTRIBUTION OF PHENYTOIN IN RABBIT BRAIN: IN VITRO STUDY.
T. Yanagihara, Dept. of Neurol., Mayo Clinic and Mayo Med. School, Rochester, MN 55901.

Intracerebral distribution of phenytoin, a commonly used anticonvulsant, has been investigated in the past after systemic or intracranial administration, by incubation with isolated subcellular fractions, and by binding with proteins or lipids extracted from brain. These investigations have shown variable results ranging from covalent binding of phenytoin to macromolecules to reversible binding, and from binding to brain proteins to lipids. At certain periods after systemic administration, nerve cells contained more phenytoin than neuroglial cells. In the present investigations, therefore, binding characteristics of phenytoin were further investigated in vitro by incubation of brain slices or isolated synaptosomes in the presence of 0.25 µM to 100 µM of [^{3}H]phenytoin. Subcellular fractions were subsequently prepared by sucrose density centrifugation, and neuron-enriched and glia-enriched fractions and synaptosomes by Ficoll-density gradient centrifugation. Synaptic subfractions were separated by osmotic shock and subsequent sucrose density gradient centrifugation.

Among subcellular fractions, purified nuclei and microsomes showed high concentration (per protein unit). However, these high activities could be easily reduced by washing in an isotonic sucrose solution. The highest concentration was obtained in the supernatant. There was no significant difference between the neuronal and neuroglial fraction after an incubation period for 30 min. The uptake of phenytoin by isolated synaptosomes did not show high affinity kinetics. Further separation of synaptic subfractions revealed the highest concentration in the soluble fraction. The concentration of the membrane-enriched and other particulate fractions were similar. The uptake to tissue slices or synaptosomes were not saturable within the concentration of phenytoin investigated here. Phenytoin was bound to macromolecules up to 90% in the supernatant fraction. In synaptosomes, a similar extent of binding was observed in the soluble fraction when they were investigated by ultrafiltration technique. However, the bound phenytoin was easily dissociated from macromolecules (proteins) by passing through a Sephadex G-25 column. On the other hand, phenytoin remains bound to serum proteins after the same treatment. The present investigation indicated binding of phenytoin to brain subcellular elements and proteins but did not show any specific high affinity uptake or binding. Binding to brain proteins showed even a lesser degree of affinity than binding to serum proteins. However, more specific binding may exist if the binding characteristics are tested with certain specific proteins. (Supported by the grant NS-52327 from NIH)

1969 THE NEUROPHARMACOLOGY OF A NOVEL γ-AMINOBUTYRIC ACID ANALOG, KOJIC AMINE.
George G. Yarbrough, Michael Williams and Dean R. Haubrich. Dept. of Neuropharm., Merck Institute for Therapeutic Research, West Point, PA 19486.

Kojic amine (KA; 2-aminomethyl-5-hydroxy-4H-pyran-4-one), a compound which shares some structural features and pharmacological properties with γ-aminobutyric acid (GABA) and muscimol, has been examined in a variety of test systems for GABAmimetic activity. In several in vitro central nervous system receptor binding assays employing rat brain membrane preparations, KA exhibited selective activity to displace ^{3}H-muscimol but with a relatively high IC_{50} of 4.4 µM. Iontophoretically applied KA exerted a pronounced (comparable to GABA on the basis of ejection currents) inhibition of the firing of cerebellar Purkinje cells and spontaneously active or glutamate-activated neurons in the cerebral cortex. The inhibitory effects of KA, which were longer lasting than those of GABA, were antagonized by bicuculline and enhanced in the presence of 2,4-diaminobutyric acid. On the isolated amphibian (Bufo marinus) spinal cord, KA was less than 1/3 as potent as GABA in depolarizing primary afferent terminals. In this preparation KA caused a marked decrease in the dorsal and ventral root potentials evoked by electrical stimulation of an adjacent or corresponding dorsal root. KA is a poor substrate for GABA uptake systems into rat brain synaptosomes, has no effect on GABA release in vitro and does not inhibit GABA transaminase activity. Altogether, these data suggest that KA does have some GABAmimetic actions but also exerts other pharmacological effects as well.

1970 METHADONE AND UNDERNUTRITION: A COMPARATIVE STUDY OF THEIR EFFECTS ON BRAIN DEVELOPMENT.
Ian S. Zagon and Patricia J. McLaughlin. Dept. Anatomy, The M.S. Hershey Medical Center, The Pennsylvania State University, Hershey, PA 17033.

The effects of maternal methadone exposure (5 mg/kg methadone-HCl; METH), undernutrition (18 pups/litter; UND), or a combined methadone-undernutrition (METH-UND) treatment, administered during lactation, on body and brain development were studied in 21- and 60-day old Sprague-Dawley rats. At weaning (day 21), the body weights of METH, UND, and METH-UND animals were reduced 19%, 48%, and 58%, respectively, from control levels. METH rats had the most pronounced deficits in brain weight at 21 days; brain weights were reduced 31%, 12%, and 16% from controls in the METH, UND, and METH-UND groups, respectively. Brain/body weight ratios were elevated in the UND and METH-UND groups, suggesting a brain-sparing effect in these rats. Brain length was significantly reduced in METH and METH-UND pups at weaning, while cerebral width was subnormal in METH and UND rats. In comparison to the reductions in brain DNA content of UND and METH-UND rats (9% and 15%, respectively, of control values), 21-day old METH pups had the most marked deficit (43%), while protein contents were 50%, 21%, and 23% lower than controls for rats in the METH, UND, and METH-UND groups, respectively. At 60 days of age, male rats of all experimental groups had subnormal body weights, but female rats were comparable to controls. METH rats were similar to controls in brain weight and brain dimensions on day 60, while METH-UND rats were subnormal in brain weight (25%) and brain length (15%); UND animals had marked reductions in brain length (16%) and cerebral width (6%). Brain DNA and protein contents and concentrations of animals in the METH and UND groups were lower than controls at sexual maturity, with deficits ranging from 6% to 30%. UND rats also had abnormal reductions in brain RNA content (15%) and concentration (17%) at 60 days. METH-UND rats had the fewest number of biochemical alterations, with reductions in DNA (16%), RNA (26%), and protein (25%) contents recorded; these appear to be associated with the decreased brain weights noted at this time. These results suggest that the constellation of neurobiological effects observed in rats subjected to methadone differ from those found in nutritionally-deprived offspring. The magnitude of structural and biochemical changes that occur during preweaning neuro-ontogeny appear to be greatest in methadone-treated offspring, while the most pronounced disturbances in postweaning development are associated with undernutrition. Furthermore, combined exposure to methadone and undernutrition does not produce a cumulative response.

1971 OPPOSED EFFECTS OF MUSCIMOL AND PICROTOXIN ON BRAIN STIMULATION REWARD: A ROLE FOR GABA. Peter Zarevics* and Paulette E. Setler (SPON: W. D. Matthews). Smith Kline & French Laboratories, Philadelphia, Pennsylvania 19101.

Rats were trained in a two-lever intracranial self-stimulation (ICSS) paradigm. Responses at the first lever delivered brain stimulation which was decreased in magnitude after every 5 responses. Responses at the second lever reset the current available to its original value. The current level at which the reset responses occurred was defined as the "reward threshold." The rate of responding at each current level during the stimulate-reset sequence was also determined. This paradigm, therefore, allowed simultaneous rate-independent and rate-dependent assessment of ICSS.

Decreased reward, as demonstrated by an elevated "reward threshold," was produced in a dose-related manner by the GABA blocking agent, picrotoxin. Similar effects could be produced by making each stimulation train less rewarding, i.e. by reducing the amount of charge delivered per stimulation. Conversely, increased reward, as indicated by a lower "reward threshold," was produced in a dose-related manner by the GABA-mimetic agent, muscimol, or by increasing the amount of charge delivered by each stimulation. Response rates were not significantly changed at any stimulation intensity following treatment with either drug.

These data suggest that the effects of picrotoxin and muscimol on ICSS are due to changed perception of reward and not to altered performance of the lever pressing task. An important role for GABA in the mediation of reward needs, therefore, to be considered.

NEUROTRANSMITTERS

1972 ^{3}H METARAMINOL UPTAKE IN ISOLATED CEREBRAL MICROVESSELS. Toshiko Abe*, Kozo Abe* and Maria Spatz. Lab. Neuropath. Neuroanat. Sci., NINCDS, NIH, Bethesda, MD 20205.

Norepinephrine, which doesn't cross the blood brain barrier, can be taken up and metabolized in isolated cerebral microvessels showing features of both extraneuronal and neuronal uptake. In order to elucidate further the monoamine's uptake in cerebral microvessels, we investigated the uptake of ^{3}H metaraminol, a norepinephrine analogue which is neither metabolized by MAO nor COMT.

The capillary uptake of ^{3}H metaraminol increased with the time of incubation (30 sec-15 min). The uptake was found to be saturable, because it could be inhibited by addition of unlabeled metaraminol in increasing concentrations to the incubation media containing the labeled substance. The accumulation of ^{3}H metaraminol in the capillaries was stimulated by K^{+} and Na^{+} and inhibited by ouabain, KCN, DPN, adrenergic blocking agents (imipramine, propranolol, dichloroisoproterenol and phentolamine). Moreover, the ^{3}H metaraminol capillary uptake was competitively inhibited by arterenol, 5-hydroxytryptamine and cross inhibited by dopamine, 6-hydroxy dopamine, 5-hydroxydopamine, L-dopa but not by normetanephrine or metanephrine.

These results indicate that ^{3}H metaraminol is taken up by K^{+} and Na^{+} dependent carrier-mediated mechanism (which may be shared by other monoamines) in the cerebral microvessels. This process appears to be similar to the one described for neuronal monoamine uptake especially since extraneuronal uptake of amines was reported to be insensitive to metaraminol but sensitive to normetanephrine and metanephrine.

1973 TRANS-SYNAPTIC EFFECTS OF CHRONIC DORSAL RAPHE STIMULATION ON NEUROTRANSMITTER-SYNTHESIZING ENZYMES. E. Andersen*, N. Dafny, and Z. Gottesfeld. Dept. of Neurobiology and Anatomy. Univ. of Texas Medical School, Houston, TX 77025.

Relatively little is known about the role of neuronal activity in the regulation of neurotransmitter synthesis in the central nervous system. The present work demonstrates the effect of prolonged electrical stimulation of the dorsal raphe (DR) on choline acetyltransferase (ChAT), a cholinergic marker enzyme, and on glutamate decarboxylase (GAD), a GABAergic marker. The brain areas which were tested have been previously shown to receive DR projections. They include caudate nucleus (CN), substantia nigra pars reticulata (SNR), medial habenula (MH), lateral habenula (LH), superior colliculus (SC), ventral tegmental area (VTA), interpeduncular nucleus (IP) and the nucleus of the diagonal band of Broca (NDBB). The stimulation was performed in freely moving animals.

Male Sprague-Dawley rats (200 g) were stereotaxically implanted with chronic electrodes in the DR. After recovery from surgery, the animals were stimulated for 20 minutes daily (20Hz, 6V, 0.2 msec pulse) for 13 days. Sham animals were chronically implanted and were handled identically, but did not receive electrical stimulation. Shortly after the last stimulation, the animals were decapitated, and the brains were quickly removed and frozen on dry ice. Coronal brain sections were cut alternately (60μm and 300μm) in a cryostat at -8°C. The thin sections were stained with 0.1% thionine for microscopic verification of implantation sites and were used as a guide for accurately dissecting discrete areas from the thick sections.

The enzymes ChAT and GAD were assayed in the various brain regions. The activity of ChAT was found to increase by 148% in the LH, 93% in the NDBB, 49% in the VTA, and by 22% in the IP, but did not change in CN, SNR, MH, or SC. GAD activity did not change in the VTA, CN, SNR or IP.

The results suggest that the increase in the activity of ChAT following chronic DR stimulation takes place transynaptically, and that it is modified by serotoninergic neurons located in the DR.

1974 IMMUNOCYTOCHEMICAL LOCALIZATION OF [LEU^{5}]-ENKEPHALIN AND SUBSTANCE P IN RELATION TO NORADRENERGIC NEURONS IN AREA POSTREMA. D.M. Armstrong, V.M. Pickel, R.J. Miller, T.H. Joh, D.J. Reis. Lab. of Neurobiol., Dept. of Neurol. Cornell Univ. Med. College, New York, NY 10021. (RJM) Dept. of Pharmacol. and Physiol. Sci., Univ. of Chicago, Chicago, IL 60637.

The Area Postrema (AP) in rat contains intrinsic cells which stain with dopamine beta hydroxylase (DBH) and are presumably noradrenergic (Torack et al, Brain Res. 61:235, 1973). We sought to determine by light microscopic immunocytochemistry whether the AP includes dopamine and adrenaline containing cells in addition to the noradrenergic ones. The presence and distribution of the peptides substance P (SP) and enkephalin, which are associated with catecholaminergic neurons in other regions of the brain (Pickel et al, Brain Res. 160:387, 1979), were also examined. Specific antisera to the catecholamine synthesizing enzymes, tyrosine hydroxylase (TH), DBH, and phenylethanolamine N-methyltransferase (PNMT),and to peptides (Leu^{5})-enkephalin and SP were raised in rabbit. Antisera were localized by the peroxidase-antiperoxidase method in 22u Vibratome sections of rat brain fixed by vascular perfusion with 4% paraformaldehyde. TH and DBH but not PNMT were contained in cells of similar morphology throughout the rostrocaudal and dorsoventral extent of the AP. Similarly, cells with enkephalin-like immunoreactivity (ELI) were distributed throughout the AP. ELI containing cells were relatively sparse compared with those labeled with TH and DBH. Varicosities with ELI were present throughout the AP with a heavier concentration ventrolaterally. Unlike ELI, the reaction product for SP was absent in cells and only seen in varicosities located predominantly in the ventrolateral portion of the AP. A few scattered processes containing SP were present in the central AP, although much less dense than the terminals showing ELI. In addition, neuronal perikarya staining with TH, DBH, SP, and ELI were present in lateral regions adjacent to the AP. We conclude the AP in the rat contains intrinsic noradrenergic and enkephalinergic cells. The terminal varicosities in the AP may be derived from these intrinsic cells as well as neuronal perikarya found lateral to the AP. The AP may be a site of interaction of both catecholaminergic and peptidergic neuromodulators.

1975 AMFONELIC ACID AND AMPHETAMINE EFFECTS ON SYNAPTOSOMAL DOPAMINE FORMED FROM PHENYLALANINE. S. P. Bagchi, T.M. Smith* and P. Bagchi* Rockland Research Institute, Orangeburg, N.Y. 10962

Nonamphetamine stimulants amfonelic acid (AA) and cocaine (CO) mimic the central effects of amphetamine (AMT) and all three appear to exert their effects via catecholamines. Reserpine (Res) depletion of brain catecholamines does inhibit the central effects of the nonamphetamines but not of amphetamine. To distinguish between the actions of AMT and those of AA, we have studied the effects of these two drugs alone and in combinations with Res on the synaptosomal (P_2) synthesis/release of dopamine (DA) from phenylalanine (Phe) precursor. P_2 from rat caudate nucleus was incubated with ^{14}C-Phe in tris buffer (pH 7.4) with NaCl (125 mM), KCl (5 mM), $MgCl_2$ (15 mM), pargyline (0.08 mM), glucose (10 mM) and sucrose (0.32 M). After 10 minutes of incubation (37°), the mixture was filtered through a 0.8 mμ Millipore filter to separate the synaptosomes from the medium and the separated fractions were analyzed for labelled DA and synaptosomal level of ^{14}C-Phe. The results show that the addition of either Res, AMT or AA enhanced the release of synaptosomally formed labelled DA into the medium. Res (1.8 micromolar) concomitantly inhibited the total synthesis of labelled DA. AMT and AA in 0.9 to 18 micromolar concentration range stimulated the synthesis and their synthesis and release enhancing effects were comparable. In other experiments, AMT and AA, each in a combination with Res, were incubated with P_2 and labelled DA synthesis/release determined. The results show that both AMT and AA were able to enhance further the synaptosomal release heightened by Res. However, AMT (plus Res) was markedly effective in stimulating the total synthesis of labelled DA over that observed in the presence of Res alone but AA (plus Res) was ineffective. Furthermore, AMT had a greater synthesis stimulating effect in the presence than in the absence of Res. None of the drugs had any significant effect on the synaptosomal level of ^{14}C-Phe substrate. Other results show that the effects of CO on the DA synthesis/release were similar to those of AA. The results suggest that the action of AA and CO may differ from that of AMT on the Res responsive intrasynaptosomal DA pool at the site of phenylalanine hydroxylation. (Kindly supported by the Dept. of Mental Health, State of New York).

1976 IN VITRO EFFECTS OF pH AND PHOSPHORYLATION ON NEOSTRIATAL TYROSINE HYDROXYLASE FROM CONTROL AND HALOPERIDOL TREATED RATS. Charles Bakhit* and James W. Gibb (SPON: W. Stevens). Department of Biochemical Pharmacology and Toxicology, University of Utah, Salt Lake City, Utah 84112

We have recently shown that the haloperidol-induced increase in the activity of tyrosine hydroxylase (TH) is pH dependent (Fed. Proc., 38, 805, 1979). This activation of TH occurs at the higher pH spectrum but not at the optimum pH for TH. A decrease in Km of TH after haloperidol treatment is seen at pH 6.5 but no change is observed at pH 6.0 for the pteridine cofactor. It is possible that haloperidol may produce its effect by causing a phosphorylation of the enzyme. In an attempt to understand the relationship between pH, phosphorylation and the haloperidol-induced effect, neostriatal TH activity from control and haloperidol-treated (1 mg/kg) rats was assayed under normal and phosphorylating conditions at different pH values using the Nagatsu method, with 6 MPH_4 as the cofactor. The apparent Vmax and Km of TH were determined at two pH values, 6.0 and 6.5. As reported previously, haloperidol treatment caused a decrease in Km with no change in Vmax for the cofactor at pH 6.5, but at pH 6.0 haloperidol did not induce a change in the Km or Vmax of TH. With phosphorylating conditions at pH 6.5, TH from haloperidol-treated rats showed an increase in apparent Vmax, and a return of the Km to control value; the haloperidol-induced activation was no longer observed and the kinetics of enzyme were the same as that for normal rats. In control rats, with phosphorylating conditions at pH 6.5, an increase in Vmax of the enzyme was observed but no change in Km occurred. In contrast, neostriatal TH from control animals assayed at pH 6.0 under phosphorylating conditions showed a decrease in apparent Km but no change in Vmax. However, it should be noted that the activity of the phosphorylated enzyme at pH 6.5 is still less than the activity of TH under optimum pH conditions. These results indicate that the haloperidol-activated enzyme can be further activated by phosphorylation, which causes a return to control kinetics. Furthermore, the kinetics of phosphorylated TH from normal rats at its in vitro optimum pH are different than those at higher pH conditions. (Supported by USPHS grants GM 07579 and DA 00869.)

1977 CHARACTERISTICS OF THE GLUTAMATE RECEPTOR FUNCTION OF BRAIN SYNAPTIC MEMBRANES AND OF THE PURIFIED BINDING PROTEIN. R. Belieu, E. Michaelis, M. Michaelis, and H. Chang*. Dept. of Human Development, Univ. of Kansas, Lawrence, Kansas 66045.

Previous studies from this laboratory have shown that brain synaptic membranes possess high-affinity, Na^+-independent glutamate (Glu) binding sites which have many of the characteristics of the physiologic receptor for L-Glu (Michaelis et al., 1974). In addition, it was demonstrated that this high affinity Glu recognition function was associated with a glycoprotein which was solubilized from the membranes and purified to near homogeneity (Michaelis, 1975). However, since all previous studies were conducted in hypotonic, Na^+-free media, it was considered necessary to examine the behavior of this Glu recognition function of synaptic membranes under more physiological conditions of ionic composition of the incubation medium and of temperature of incubation. A microfuge centrifugation binding assay (Michaelis, 1979) was employed in the measurement of Glu binding to isolated brain synaptic membranes prepared according to the method of Kanner (1978). L-(^{3}H)-Glutamate binding to these membranes was determined either in 10 mM KPO_4 buffer or in a Krebs buffer medium. For a single batch of membranes the binding activity under these two conditions was almost identical. Pretreatment of the membranes with the organomercurial p-chloromercuribenzylsulfonate (PCMS) did not affect Glu binding, even though this type of treatment does block 85% of Glu transport carrier activity.

Glutamate binding to the synaptic membranes measured in either phosphate or Krebs and at either 25° or 37° exhibited a very rapid phase of association kinetics followed by a slower phase of binding. Half-maximal association to the rapidly-binding sites at 25° occurred in 37 - 40 sec and in 15 - 20 sec at 37°. On the basis of the kinetics of this binding interaction, the K_D was estimated to be 80.06 nM. Equilibrium binding assays revealed multiple binding equilibria with apparent K_D's equal to 60 - 70 nM, .200 - .295 μM, and 3.40 μM. The most effective displacing agent for bound L-(^{3}H)-Glu was L-aspartate. The potent neuroexcitatory agent kainic acid was only a weak antagonist of Glu binding to the synaptic membranes regardless of whether such binding was measured in phosphate or Krebs media.

All of the above observations on the Glu interaction with the synaptic membranes were found to hold true also for Glu binding to the purified protein, including the lack of sensitivity to PCMS, the presence of multiple binding equilibria, and the absence of any appreciable effect of kainic acid. (Supported by GM-22357 and Institutional Biomedical Research Support Grant RR-50706.)

1978 DL-α-AMINOADIPATE ANTAGONIZES POSTSYNAPTIC ASPARTATE RESPONSES IN CULTURED MURINE SPINAL CORD NEURONS. Gregory K. Bergey*, Michael R. Martin and Manfred Hermes*. (SPON: Phillip G. Nelson). Laboratory of Developmental Neurobiology, NICHD and Laboratory of Neuro-Otolaryngology, NINCDS, Bethesda, MD 20205.

The effects of D,L-α-aminoadipate (DLAA) on the responses to iontophoretically applied amino acids were studied using cultured dissociated fetal mouse spinal cord neurons. Intracellular recordings were obtained from spinal cord neurons grown in culture for five to ten weeks and responses to iontophoretically applied excitatory (asparate, ASP and glutamate, GLU) and inhibitory (glycine, GLY and γ-aminobutyric acid, GABA) were obtained in the presence of tetrodotoxin blockade of spontaneous electrical activity.

DLAA at DC iontophoretic currents of less than 100 nA rapidly and reversibly reduced the responses to 100 ms (0 to 100 nC) iontophoretic pulses of ASP an average of 87% (n = 23). The plot of mean antagonism of ASP by DLAA was an exponential curve with 50% reduction of the control response occurring with 20 nA of DLAA. Log-log plots of ASP dose-response curves showed no change in slope (m = approx. 1) with DLAA, indicating no alteration of ASP receptor cooperativity by DLAA. In contrast to the effects of DLAA on ASP, GLU responses were reduced an average of only 22% (n = 12) by DLAA currents of 80 - 100 nA. No attenuation of GABA (n = 9) or GLY (n = 10) responses was seen with similar DLAA currents. At the iontophoretic currents used (0-100 nA) DLAA produced no change in membrane potential or membrane conductance. The L-isomer (LAA) produced no antagonism of ASP or GLU (n = 4), confirming reports that the D-isomer is the active dicarboxylic acid antagonist.

These results provide additional evidence that D- and DLAA are useful antagonists of dicarboxylic amino acid putative neurotransmitters, most particularly ASP. No presynaptic effects of ASP or GLU were seen, presumably DLAA antagonism occurs at the postsynaptic membrane. This antagonism occurs in the absence of observable direct effects of DLAA.

1979 THYROTROPIN-RELEASING HORMONE MODULATES THE RESPONSE TO SEVERAL NEUROTRANSMITTERS IN SOMATOSENSORY CORTEX OF CAT. D. J. Braitman, C. R. Auker, and D. O. Carpenter. Neurobiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Synaptic modulation, the nonlinear summation of responses to two transmitters, has been described for a variety of putative neurotransmitters including the neuroactive peptides. Thyrotropin-releasing hormone (TRH, Glu-His-Pro), a peptide present in mammalian cortex, has been reported to specifically enhance the excitatory action of acetylcholine (Ach) on cerebral cortical neurons (Yarbrough, European J. Pharmacol. 48: 19-27, 1978) although Winokar and Beckman (Brain Res. 150: 205-209, 1978) were not able to confirm these results in a small sample of cells.

A number of questions need to be answered concerning the role of TRH as well as neuromodulators in general. (1) Can TRH have both a direct and modulatory effect on the same cell? (2) Is the modulatory effect of TRH specific for the Ach response? (3) If TRH modulates the response of one neurotransmitter on a given cell, does it also modulate the response of other neurotransmitters on that same cell? (4) Does TRH modulate specific response, e.g., the slow excitation frequently seen with Ach and histamine (Hist)? (5) Does TRH exert its effect on all cortical cells or only on specific populations of cells?

We have studied the modulatory effects of TRH on pyramidal tract (PT), nonpyramidal tract (NPT), and unidentified cells in somatosensory cortex (area 4) of cloralose-anesthetized cats with seven-barreled microelectrodes. In each electrode, the center barrel was filled with 2M NaCl for recording single-neuron activity. Each of the other barrels was filled with Ach, Hist, glutamate (Glu), or aspartate (Asp) for ionophoretic application. One barrel was filled with TRH for microionophoretic and/or pressure injection.

The following experimental findings are pertinent to the questions posed above: (1) TRH had a direct excitatory effect on only five of 32 cells tested. In three of these cells there was no modulation of the Ach response. (2) TRH modulated some responses to glutamate, histamine, and aspartate as well as to acetylcholine. In all instances of TRH modulation of Asp the response to Asp was enhanced. The response to Ach was enhanced in four cells and inhibited in one. Hist response was enhanced in two cases and inhibited in one. TRH modulation of Glu was always inhibitory. (3) In one of nine cells tested, TRH was found to enhance the excitatory response to both Ach and Hist. In five other cells, TRH altered the response to one transmitter but not another. (4) TRH potentiated both slow and fast excitatory responses, but not in all cases. In addition, it inhibited four fast excitatory Glu responses and two slow excitatory responses by Ach and Hist. (5) The excitatory Ach response on NPT cells was never potentiated by TRH. All TRH inhibition was on NPT cells. Our results indicate that TRH can modulate both fast and slow excitatory responses and responses to other neurotransmitters as well as Ach on two identified populations of cortical neurons.

1980 IMMUNOCYTOCHEMICAL AND AUTORADIOGRAPHIC LOCALIZATION OF THE γ-AMINOBUTYRIC ACID SYSTEM IN FROG RETINA. C. Brandon, D.M.K. Lam*, and J.-Y. Wu. Departments of Cell Biology and Ophthalmology, Baylor College of Medicine, Houston, Texas 77030.

Several lines of evidence have implicated GABA as a neurotransmitter in the retina of the frog. Graham (Brain Res. 36, 476-479 (1972)) showed levels of GABA and its synthetic enzyme (glutamate decarboxylase, GAD) to be highest in the inner plexiform layer (IPL), and Voaden et al (ibid 67, 115-132 (1974)) demonstrated the presence of a high-affinity uptake system for GABA in horizontal cells and certain amacrine cells. Using a specific antiserum to the mouse brain enzyme (Brain Res. 65, 277-285 (1974)) and a Protein A-Peroxidase-Antiperoxidase (A-PAP) technique, we have examined the GABA system in the frog retina by immunocytochemistry and autoradiography.

Frog (Rana pipiens) retinas were fixed by immersion in 1% formaldehyde containing 0.1% glutaraldehyde or 0.055% acrolein in 0.12M sodium phosphate buffer, pH 7.3. Tissue chopper sections (100um thick) were treated sequentially with rabbit anti-GAD serum (1:200 dilution), protein A (50ug/ml) and PAP; all incubations were carried out in PBS containing 0.1% ovalbumin to minimize non-specific staining.

GAD-positive reaction product was observed to form five discrete laminae within the IPL. The laminae adjacent to the inner nuclear layer (INL) and the ganglion cell layer were the most dense; three evenly-spaced lighter bands were observed between them. In addition, occasional cell bodies lying within the inner third of the INL, presumably amacrine cells, were filled with immunochemical reaction product. Slender, single processes were often seen descending from these cell bodies into the IPL.

For GABA uptake studies, retinas were incubated in vitro with ^{3}H-GABA in frog ringer, then fixed in glutaraldehyde and processed for autoradiography. Grains were observed over horizontal cells, amacrine cells, and ganglion cell bodies.

These results suggest that a family of amacrine cells in the frog retina uses GABA as a neurotransmitter. Ultrastructural analysis of the detailed synaptic relationships of these GAD-containing neurons, thought to be involved in the formation of complex receptive field properties, will be presented.

1981 A SYNAPTOSOMAL PREPARATION FROM THE GUINEA PIG ILEUM. Clark A. Briggs*, Rose A. Schulz*, and Jack R. Cooper (Spon: James W. Maas). Dept. of Pharmacology, Yale Univ. School of Med., New Haven, CT 06510.

The myenteric plexus of the guinea pig ileum has characteristics which make it a choice mammalian tissue for the study of neuronal activity. Although part of the peripheral nervous system it bears a remarkable similarity--morphologically, functionally and neurochemically--to the central nervous system (CNS). Perhaps the best known example is the similarity in potency for a wide range of narcotics in inducing analgesia in the CNS and in inhibiting acetylcholine (ACh) release from the myenteric plexus. This similarity of the ileum to the CNS, coupled with the observations that a number of neurotransmitters and neurohormones have been shown to affect the release of ACh, prompted us to develop a synaptosomal preparation from this tissue.

After a considerable number of trials, the following procedure was adopted: Using 250-350g Hartley guinea pigs, strips of myenteric plexus-longitudinal muscle were prepared from the entire ileum, except for the terminal 12cm, by a minor modification of the method of Paton and Vizi. High affinity choline uptake was used as a marker for synaptosomal activity during the isolation. After mincing, the strips were homogenized in 0.32M sucrose-3mM sodium phosphate buffer, pH 7.2, first by Ultra-Turrax homogenization at low speed, followed by Teflon-glass homogenization. A crude fraction ("P_2") containing most of the synaptosomal activity was prepared by initially centrifuging at 1,000g for 10 min. followed by centrifugation of the supernatant at 17,000g for 20 min. The synaptosomal fraction was prepared by applying the P_2 to a discontinuous sucrose-Metrizamide gradient containing 3mM sodium phosphate buffer, pH 7.2; this was centrifuged at 86,000g for 30 min. in an SW50L rotor to yield a synaptosomal band with a 7 to 8 fold enrichment compared to the P_2 fraction. Recovery of activity amounted to 40 to 50%. Electron microscopy of the fraction revealed a fairly homogeneous synaptosomal population with some membrane contamination but no free mitrochondria.

Synaptosomal activity was indicated by a high affinity choline transport system which displayed sodium and temperature dependence and inhibition by hemicholinium-3 and hypo-osmotic shock. In addition, a calcium dependent release of [^{3}H]-ACh, synthesized by preincubation with [^{3}H]-choline, was also demonstrated when the preparation was depolarized with K^+ or veratridine.

In preliminary experiments we have shown an inhibition by oxotremorine of [^{3}H]-ACh release from this preparation.

1982 **MUSCARINIC MODIFICATION OF VOLTAGE-SENSITIVE CURRENTS IN SYMPATHETIC NEURONS.** **D. A. Brown* and Paul R. Adams. Dept. of Physiol. and Biophys., University of Texas Medical Branch, Galveston, Texas, USA.**

Bullfrog sympathetic ganglion cells in vitro were impaled with two microelectrodes (30-40 MΩ, filled with 3 M KCl) and voltage-clamped. In most cases the ganglia were trypsinised and the Ringer supplemented with 10 mM magnesium chloride. A pure muscarinic agonist, dl-muscarine, was applied by bath-perfusion (10 μM) or by iontophoresis. The agonist produced a voltage-sensitive inward current, which was very small (≤0.1 nA) at holding potentials more negative than -50mV and increased to 2-4 nA at holding potentials up to -20mV. Control steady-state current voltage (I/V) curves showed strong rectification at membrane potentials below -60mV. Currents following long (up to 0.5 sec) hyperpolarizing command-steps comprised an ohmic step followed by a slow inward relaxation (time constant ~100msec) in the rectifying range of membrane potential, with an appropriate slow inverse relaxation on restoring the holding potential. The reversal potential of the slowly relaxing currents was near -80 mV. Also, the ohmic current stepping back from a hyperpolarized level was less than that seen at the onset of the hyperpolarizing step. Thus these slow inward currents probably represent deactivation and reactivation of the cell's potassium conductance. Muscarine (i) reduced the rectification of the steady-state I/V curve, (ii) reduced the slow current relaxations following hyperpolarizing voltage-steps and (iii) reduced the slope of the instantaneous I/V curve (measured from ohmic current steps) at depolarized membrane potentials (-20 to -40 mV) by up to 70%. In contrast, the slope of both steady-state and instantaneous I/V curves at more hyperpolarized levels (≤-60 mV) was usually unchanged. Further, muscarine did not clearly reduce the currents generated by small (10-20 mV) depolarizing voltage steps. These observations suggest that muscarine's main action is to inhibit that component of the cell's potassium conductance that becomes evident at a restricted range of potentials around -35 mV, with diminishing effect at more depolarized or more hyperpolarized potentials. **(Supported by NIH grant NS-14984 and a travel grant from the Wellcome Foundation.)**

1983 ACUTE AND CHRONIC ALCOHOL ADMINISTRATION ALTER GABA RECEPTOR SENSITIVITY IN INBRED STRAINS OF MICE. Troie Burch* and Maharaj K. Ticku Dept. Pharmacology, Univ. Texas Health Sci. Ctr., San Antonio, TX 78284.

The molecular basis of action of alcohol (ethanol), and the neuronal components involved in its tolerance, physical dependence and withdrawal are not known. Ability of alcohol to enhance γ-aminobutyric acid (GABA) mediated transmission has been reported (Davidoff, R.A. Arch. Neurol. 28:60, 1973), and GABA mimetics have been reported to reduce ethanol withdrawal symptoms, while GABA antagonists produce symptoms similar to those seen during alcohol withdrawal (Goldstein, D.B., JPET 186:1, 1973). We have examined the interactions of acute alcohol with GABA receptors in DBA (alcohol avoiding) and C57 (alcohol preferring) mice, and of chronic alcohol in C57 mice. DBA and C57 mice like rat brain bind GABA to two classes of binding sites. DBA mice have significantly higher affinities (K_{D1} = 13 nM; K_{D2} = 91 nM) and lower binding capacities (B_{max1} = 713 fm, B_{max2} = 3187 fm) compared to C57 mice (K_{D1} = 27 nM, K_{D2} = 135 nM; B_{max1} = 1421 fm; B_{max2} = 3798 fm) for the two binding sites. Acute alcohol (4 g/kg) produced a significant increase in the binding capacity of the low affinity GABA binding site in both C57 (12%) and DBA (23%) mice, without significantly altering other binding parameters. These results suggest that acute alcohol ingestion may produce a possible facilitatory effect on GABAergic transmission, which may be responsible for alcohol induced behavioral depression. Chronically treated C57 mice (2 weeks on 10% ethanol) exhibited a single class of GABA binding site with an apparent affinity of 89 ± 12 nM and a binding capacity of 2471 ± 360 fm/mg protein. The complex effects of chronic alcohol ingestion on both the affinity and the binding capacities of GABA receptor sites may represent an offsetting neuronal mechanism to the continuous depressant effects of alcohol. These results suggest a possible role of GABA receptor sensitivity in the neuropharmacological actions of alcohol and also in the development of its tolerance.

1984 RELEASE OF ENDOGENOUS EPINEPHRINE, NOREPINEPHRINE, AND DOPAMINE FROM RAT HYPOTHALAMUS IN VITRO. Susan K. Burgess* and Richard E. Tessel* (SPON: Ronald T. Borchardt). University of Kansas, Lawrence, Kansas, 66045.

The presence and distribution of both epinephrine (EPI) and its synthesizing enzyme, PNMT, in the hypothalamus and brainstem suggest the existence of anatomically distinct adrenergic neurons in brain. Comparative measurements of in vivo pharmacological alterations in EPI, norepinephrine (NE), and dopamine (DA) contents and the activities of their synthesizing enzymes have suggested that EPI-containing neurons may be pharmacologically and biochemically distinct as well. To further characterize these neurons, we examined the ability of amphetamine and two depolarizing agents, veratridine and KCl, to release endogenous EPI, in comparison with NE and DA, from minced hypothalamus in vitro. Release of endogenous amine may be a more accurate indication of relevant synaptic events than the conventional isotope-tracer release technique, which presents particularly severe difficulties (e.g., non-specific tracer uptake) with the relatively sparse EPI neurons.

Minced hypothalamic tissue was exposed to the releasing agent for 30 minutes at 37°C in physiological medium. After centrifugal separation of tissue and media, the catecholamines in each fraction were analyzed by HPLC with electrochemical detection. Data are expressed as % release [media content ÷ (tissue + media contents) X 100], and as pmol/mg protein. In no case was control release above 10%. Each of the three agents released the three catecholamines in a dose-dependent way and each agent was essentially equipotent with respect to release of EPI, NE, and DA. Approximate EC50's are: K^+, 45mM; veratridine, $3X10^{-6}$M, and d-amphetamine, $3X10^{-5}$M. Maximal release after K^+ depolarization was: EPI, 50.3±8.5%; NE, 57.9±3.9%; and DA, 64.0±5.4%, representing respectively 0.98±.21 pmol/mg, 42.6±3.4 pmol/mg, and 13.0±1.1 pmol/mg. K^+-induced release was strongly Ca^{++} dependent for all three catecholamines. Veratridine at 10^{-4}M released EPI (46.5±1.9%) and NE (51.6±3.4%) less than it did DA (65.4±5.1%), (representing 1.33±.19 pmol/mg, 62.8±7.6 pmol/mg, and 19.3±1.4 pmol/mg). Veratridine release was largely blocked by $5X10^{-7}$M tetrodotoxin. Amphetamine also preferentially released DA. At 10^{-3}M amphetamine, EPI release was 47.4±5.3%, NE was 36.5±2.3%, and DA was 78.2±2.0%, or 1.04±.25 pmol/mg, 27.7±2.3 pmol/mg, and 15.5±1.5 pmol/mg respectively. Amphetamine induced release was not Ca^{++} dependent.

The data suggest that EPI is stored in nerve terminals and can be released by both exocytotic and non-exocytotic mechanisms.

(Supported by USPHS # NIDA-01614 and grants from the University of Kansas.)

1985 AMYGDALOID KINDLING IS ASSOCIATED WITH MUSCARINIC CHOLINERGIC RECEPTOR REDUCTIONS IN THE DENTATE GYRI OF BOTH HIPPOCAMPAL FORMATIONS. Mary Constant Byrne* and James O. McNamara. Div. Neurology, Duke Univ. and VA Med. Center, Durham, N. C. 27710

Kindling refers to the phenomenon whereby periodic electrical stimulation of the brain at current levels too low to induce a behavioral response initially, ultimately produces a motor seizure. Once established, this enhanced sensitivity to electrical stimulation is permanent. Increasing evidence indicates that modification of neural circuitry remote from the stimulating electrode is essential to kindling. Pharmacological studies suggest that the interaction of acetylcholine with muscarinic cholinergic receptors contributes to the development of kindling. We previously reported significant reductions in muscarinic cholinergic receptors in the stimulated amygdala and both hippocampi in animals sacrificed 12-18 hours following completion of amygdaloid kindling. The goal of these studies was to define the distribution of the muscarinic receptor declines within the hippocampi. Electrical stimulations were administered at hourly intervals to the right amygdala of Sprague-Dawley rats until a single Class 5 kindled seizure consisting of rearing and falling was elicited. Animals were sacrificed 18-24 hours following kindling with paired controls (electrode implanted but not stimulated). Both hippocampi were removed and dissected into three principal parts: dentate gyrus, CA3, and CA1 regions. Membranes were prepared from each area and specific binding (atropine displaceable) of muscarinic receptors measured under equilibrium conditions using [^{3}H] quinuclidinyl benzilate (QNB). The mean values ± SEM (N=10) of specifically bound QNB (femtomoles/mg protein) were: right dentate 684±45 control (C); 583±55 kindled (K); left dentate 658±51 C; 542±48 K; right CA3 551±26 C; 492±33 K; left CA3 614±35 C; 568±49 K; right CA 1 563±37 C; 570±38 K; left CA 1 585±29 C; 581±29 K. Statistically significant reductions (paired t-test) were present in the dentate gyri on both sides (right $p < .01$, left $p < .0025$) but not in other regions. Scatchard analysis demonstrated these reductions in QNB binding to be due to decreased numbers of binding sites without alterations in the affinity of the remaining receptors for QNB. The cholinergic innervation of the dentate gyrus arises from neurons situated in the medial septal region. These muscarinic receptor reductions may reflect altered septal cholinergic regulation of neuronal excitability in the dentate gyri following kindling. The dentate gyri of both hippocampi may represent sites of remote neuronal alterations which contribute to the development of kindling established in the amygdala.

1986 COMBINED IMMUNOCYTOCHEMISTRY AND AUTORADIOGRAPHY AFTER IN VIVO INJECTIONS OF ANTIBODY AND ^{3}H-LABELED COMPOUNDS: LOCALIZATION OF COEXISTENT PUTATIVE TRANSMITTERS AND TRANSMITTER-RECEPTOR SYSTEMS IN THE NERVOUS SYSTEM. Victoria Chan-Palay. Dept. Neurobiology, Harvard Medical School, Boston, MA 02115.

In vivo injections of characterized antibodies into selected areas of the central and peripheral nervous system allow direct visualization of neurons and their connections by subsequent anterograde or retrograde transport of antigen-antibody complexes (Chan-Palay 1979, Chan-Palay, Palay, Wu 1979). Further experiments indicate that another novel approach for transmitter localization is achieved by combined immunocytochemistry and autoradiography after in vivo injections of an antibody and a radioactively labeled substance. Examples will be illustrated from several systems. Studies after injections of ^{3}H-serotonin and monoclonal antibody to Substance P indicate that some neurons in the medullary raphe system contain both serotonin uptake systems and Substance P immunoreactivity, whereas other neurons contain one of the two putative transmitter substances tested for (Chan-Palay 1979). Other investigations into the spinal cord, retina and cerebellum have been made using injections of ^{3}H-muscimol; ^{3}H-isoguvacine; ^{3}H-nipecotic acid or ^{3}H-GABA together with antibody against glutamic acid decarboxylase, the synthetic enzyme for γ-aminobutyric acid (GABA). The cellular locations of GABA synthesis together with the uptake and transport systems for GABA, and muscimol and isoguvacine receptor binding sites are revealed. The method involves in vivo injections in the 0.025-0.05 µl range of undiluted antibody and ^{3}H-labeled substance, fixation by perfusion with formaldehyde fixatives with minimal glutaraldehyde, serial vibratome sectioning, reaction by the indirect peroxidase-antiperoxidase technique and revelation with diaminobenzidine/hydrogen peroxide. Following the immunocytochemical procedures the sections are processed for high resolution autoradiography. The major steps for ensuring or controlling for cytochemical specificity and sensitivity in terms of antigen, antigen-antibody complexes, radioactive label through tissue preservation and subsequent preparations have been taken in each of the studies enumerated. They include the use of injections with antibody pretreated with antigens in excess, normal or preimmune sera; controls for serotonin uptake; and the use of GABA uptake inhibitors, agonists and antagonists. The fundamental scheme of simultaneous injection of multiple labels, one radioactive, another an antibody for the detection of multiple transmitter systems, opens avenues for future investigation of chemically specific cells and their connections.

1987 LOCALIZATION OF DOPAMINE-SENSITIVE ADENYLATE CYCLASE IN THE RAT OLFACTORY TUBERCLE. A.C. Church*, B.S. Bunney and N.R. Krieger, Depts. of Pharmacology and Psychiatry, University of Pennsylvania Medical School, Philadelphia, PA., 19104, and Depts. of Psychiatry and Pharmacology, Yale University Medical School, New Haven, CT., 06510.

Numerous biochemical studies have demonstrated the presence of dopamine-sensitive adenylate cyclase (DSAC) within the central nervous system. The distribution of DSAC activity as a function of the neuronal layers of the olfactory tubercle has been described (Brain Res. 131:303, 1977). This region, because of its laminar organization, is particularly suited to neurochemical localization studies. Here we report the use of selective chemical lesions to localize DSAC within the rat olfactory tubercle. Stereotaxic injections were made directly into the tubercle with kainic acid (1µg in 1µl of artificial CSF) or with 6-OH dopamine (4µg in 1µl of saline with 0.1% ascorbate). Using male Sprague-Dawley rats (150g), unilateral injections were made with a 26 ga. needle over a 1 minute period. Animals were sacrificed 3 days later by decapitation, and the brain was rapidly removed and dissected. Homogenates of the olfactory tubercle were assayed for DSAC by the method of Kebabian et al. (PNAS 69:2145, 1972). The kainic acid lesion reduced the DSAC activity by 70-90% (n=4) as compared to values from sham lesioned or unlesioned controls. Homogenates of 6-OH dopamine treated tubercles did not differ in DSAC activity from untreated controls. The lesions were assessed by light and fluorescence microscopy. Sections from kainic acid treated tubercles showed extensive neuronal losses with increased numbers of glial cells. Sections from 6-OH dopamine treated tubercles appeared normal under the light microscope. Examination of 6-OH dopamine treated tissue by glyoxylic acid-induced-histofluorescence established the loss of dopaminergic terminals. The marked decrease of DSAC accompanying the selective loss of neurons (kainic acid treatment) but not accompanying the loss of dopaminergic terminals (6-OH dopamine treatment) suggests that this enzyme occurs in the neurons and not in the glia or in the dopaminergic terminals of this region. Our findings of a neuronal localization for DSAC in the olfactory tubercle parallel the findings of others in the caudate nucleus (Brain Res. 118:356, 1976; 127:235, 1977) and suggest a similar localization for this enzyme in the two regions. (Supported by Scottish Rite Schizophrenia Research Program, N.M.J., U.S.A. and N.I.H. Grant 1 R01 MH31820-01 PPR).

1988 PENTOBARBITAL AND DIPHENYLHYDANTOIN EFFECTS ON THE EXCITABILITY AND GABA SENSITIVITY OF RAT DORSAL ROOT GANGLION CELLS. Barry W. Connors. Dept. of Physiology, Duke Univ. Med. Center, Durham, N.C. 27710

The anesthetic pentobarbital (PB) and the anticonvulsant diphenylhydantoin (DPH) have each been reported to enhance the inhibitory response to GABA, and to have depressant effects on the excitability of a number of neuronal preparations. Dorsal root ganglion cells provide a simple neuronal system which exhibits a chloride conductance increase to exogenously applied GABA. Ganglia from adult rats were placed in a continuously perfused chamber (37°C) and intracellular recordings were made with 4M K-acetate microelectrodes. All drugs were bath-applied.

PB, at concentrations 0.4-2.0x10^{-4}M, reversibly potentiated the amplitude (up to 180±20% of control) and duration of the GABA response in a dose-dependent manner, without having any effect on the resting potential or input resistance. At 10^{-3}M PB, cells were slightly depolarized and showed a small conductance increase. This is probably an expression of the GABA-mimetic property of the drug (Nicoll. PNAS.72:1460.1975), and at this concentration the responses to GABA were profoundly depressed (20±15% of control), perhaps because of receptor desensitization. Additionally, PB (10^{-4}M) increased the accommodation to long current pulses in some cells, with little change in rheobase.

DPH, up to 2x10^{-4}M, did not affect the amplitude or the time course of the GABA response, nor did it change the resting potential or resistance. It did depress the amplitude and rate of rise of the action potential, as well as increase rheobase current. Repetitive firing was also inhibited. Ganglion cells have variable sensitivity to tetrodotoxin (TTX) (Yoshida et al. J. Neurophysiol. 41:1096. 1978), and the effect of DPH was much greater on those action potentials which could be potently inhibited by TTX. Veratridine, which increases resting sodium conductance, caused a slow depolarization which could be partially reversed by either TTX or DPH. Some spikes exhibited a plateau, which could be greatly prolonged by the addition of 5mM Ba^{++}. DPH had no effect on this presumed calcium component (Dunlap and Fischbach. Nature. 276:837.1978) of the spike.

It is concluded that PB and DPH act through entirely different mechanisms, in this preparation. PB may significantly potentiate inhibitory GABA responses in the central nervous system, as well as decrease repetitive firing of neurons. The properties of DPH are compatible with a TTX-like inhibition of resting and voltage-sensitive sodium conductances, with no visible change in GABA inhibition. 1989 INVESTIGATIONS OF THE SOURCE OF ENKEPHALIN IN THE RAT GLOBUS PALLIDUS USING KNIFE CUT, ELECTROLYTIC AND KAINATE LESIONS. Fernando M. A. Corrêa, Robert B. Innis, Lynda D. Hester*, Steven R. Childers and Solomon H. Snyder. Dept. Pharmacol., Sch. Med., Johns Hopkins Univ., Baltimore, MD 21205

The pentapeptides leucine- and methionine-enkephalin are believed to act as neurotransmitters at brain opiate receptors. Sensitive radioimmunoassay and immunohistochemical techniques have demonstrated that the globus pallidus contains the highest concentration of these opioid peptides in the rat brain. Cuello and Paxinos (Nature 271:178, 1978) have suggested that enkephalin in the globus pallidus of the rat is synthesized in the caudate-putamen and then axonally transported to the globus pallidus. They found that knife cuts between the globus and caudate-putamen eliminated enkephalin immunohistofluorescence in the globus, although knife cuts between the cortex and caudate-putamen had no effect. However, we have found too few enkephalin reactive cell bodies in the caudate of colchicinized rats to account for the very high concentration of enkephalin in the globus pallidus. In addition, the technical difficulties of making a knife cut between the caudate and globus raised the possibility that the enkephalin depletion following such cuts may not simply result from axonal transection. We have investigated the source of enkephalin in the globus by comparing effects of knife cuts, electrolytic and kainate lesions.

Large electrolytic lesions in anterior regions of the caudate do not decrease enkephalin immunohistofluorescence in the globus pallidus, suggesting that little enkephalin in the globus comes from the anterior caudate. Knife cuts between the caudate and globus eliminate enkephalin fluorescence in the region of astroglial proliferation adjacent to the knife cut. This result suggests that some of the decrease of enkephalin immunofluorescence is due to generalized tissue damage rather than interruption of a pathway from the caudate to the globus. The intensity of staining for enkephalin in the globus is so great that it is unclear whether there may not also be enkephalin containing cell bodies as well as fibers. Results from kainate lesions of the globus pallidus suggest that some of the enkephalin in the globus arises from intrinsic neurons.

A major limitation of the immunohistofluorescence technique is that it is not quantitative. For this reason we have attempted to correlate results from immunhistofluorescence and radioimmunoassay of the globus pallidus dissected free from surrounding brain tissue. 1990 EFFECTS OF ACETYLCHOLINE ON CULTURED MAMMALIAN CORTICAL NEURONS. Marc Dichter. Dept. Neurology, Harvard Medical School, Boston, MA 02115.

Rat embryo cortical neurons grown in dissociated cell culture develop morphological, electrophysiological and pharmacological properties similar to cortical neurons in situ and the neurons form new excitatory and inhibitory synaptic connections with one another. The cultures contain cholineacetyl transferase (CAT) and acetylcholinesterase (AChE), both of which start at very low values and increase dramatically during the second and third weeks in culture. Histochemical staining reveals that AChE is contained in approximately 5-15% of the neurons and not in non-neuronal cells. These AChE positive neurons exhibited no specific morphology.

Acetylcholine (ACh) applied by microperfusion at 1 to 500 µM produced no significant change in neuronal membrane potential, membrane conductance or action potential configuration. In approximately 50-70% of neurons, ACh produced a delayed (several seconds) and prolonged increase in spontaneous synaptic potentials, either excitatory or inhibitory, which was generated by a presynaptic mechanism. The ACh effect was blocked by concomitant application of tetrodotoxin, and therefore probably involved the activation of Na channels in axon terminals. The ACh effect was also blocked by atropine at 10-100 µM but not by nicotinic blocking agents.

It can be concluded that ACh does not act as either an excitatory or inhibitory synaptic transmitter between cortical neurons in vitro, but probably acts as a presynaptic modulator of ongoing neurotransmission.

1991 THE EFFECT OF RESERPINE ON THE UPTAKE AND RELEASE OF TRITIATED meta-TYRAMINE (m-TA) AND para-TYRAMINE (p-TA) IN RAT STRIATAL SLICES. L.E. Dyck* and A.A. Boulton, Psychiatric Research Division, University Hospital, Saskatoon, Sask., Canada S7N 0W8.

We have shown that slices of rat striatum preloaded with tritiated m-TA or p-TA can be induced to release labelled amine by 50 mM KCl and also by removal of calcium ions from the incubation medium. The latter confounds efforts to determine the calcium-dependency of the release process. Thus, to determine the source of released amine, we have examined the effect of 10 µM reserpine on the uptake of 10 nM m-TA-^{3}H, p-TA-^{3}H and DA-^{3}H and on the subsequent release stimulated by 50 mM KCl, calcium removal or unlabelled m-TA, p-TA or DA (10 µM). Pargyline (10 µM) was present at all times and release was studied by a rapid transfer technique. Presumably, release stimulated from reserpine-pargyline treated slices originates from cytoplasmic sites; whereas in pargyline treated slices, release could originate from vesicular sites as well. Reserpine is a well known depletor of endogenous stores of catecholamine and has been shown to reduce endogenous m-TA and p-TA, too. The uptakes of p-TA-^{3}H, m-TA-^{3}H and DA-^{3}H, expressed as fmol/mg slice/15 min, were 324 ± 20, 373 ± 17 and 332 ± 12 (mean ± S.E.M.) in the pargyline treated slices; and were significantly reduced ($P < 0.01$) to 219 ± 15, 216 ± 35 and 230 ± 9, respectively, in the reserpine-pargyline treated slices. Since reserpine reduced the total uptake, the amount released into each fraction was expressed as a percentage of the total of the amounts released into each fraction and the amount left in the slices at the end of the experiment. Reserpine attenuated the release of all three whether the stimulus was 50 mM KCl or calcium removal. It could be concluded, then, that both types of stimuli caused a release of m-TA-^{3}H and p-TA-^{3}H as well as DA-^{3}H from a vesicular site.

The effect of reserpine on release of tritiated amine by unlabelled amines (10 µM) was also investigated. The magnitudes of the releasing effects of the unlabelled amines on preloaded m-TA-^{3}H, p-TA-^{3}H and DA-^{3}H were similar, the release of m-TA-^{3}H by DA being the least. Reserpine had no effect on the amine-induced releases of m-TA-^{3}H, but it attenuated the amine-induced releases of DA-^{3}H. Reserpine did not alter the m-TA-induced release, potentiated the p-TA-induced release and attenuated the DA-induced release of p-TA-^{3}H. It could be concluded that m-TA-^{3}H is not released from vesicles by exogenous amine, p-TA-^{3}H is released from vesicles by DA only, and DA-^{3}H is released from vesicles by all three amines.

1992 ACTIONS OF ANTI-CONVULSANTS ON GABA-DEPOLARIZATIONS AND ACTION POTENTIALS RECORDED FROM A MAMMALIAN SENSORY NEURON. Joel P. Gallagher, Hiroe Inokuchi* and Patricia Shinnick-Gallagher, Dept. of Pharmacology & Toxicology, Univ. Texas Med. Br., Galveston, TX 77550.

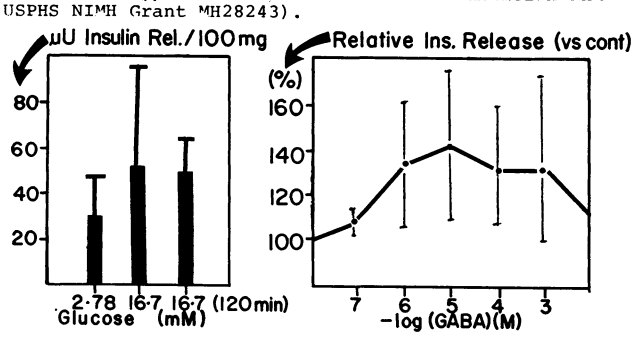
The knowledge that gamma-aminobutyric acid (GABA) is an inhibitory substance in the mammalian brain has resulted in a great amount of research to suggest that an alteration of the GABAergic system may be involved in the etiology or treatment of epilepsy. With this suggestion in mind, we have begun an investigation using three anti-convulsant drugs to examine their potential interactions with a GABA receptor which we have previously characterized on the cell body of cat dorsal root (sensory) ganglia (DRG). This in vitro system is especially suitable since interactions of drugs with receptors can be studied in the absence of synapses. Three structurally different anti-convulsants have been examined: phenobarbital (PB), phenytoin (DPH) and valporic acid (V). Two different types of active responses were recorded from impaled DRG cells: 1) a direct action potential (AP) was obtained by passing a brief cathodal pulse through the recording electrode; and 2) a membrane depolarization was obtained by iontophoretic application of GABA (GD). The AP and GD were recorded before and after superfusion of the anti-convulsants. It was possible to separate a general depressant effect (block of AP) from a specific GABA-receptor effect (alteration in time-course and/or amplitude of GD). PB at concentrations of 5×10^{-5}M to 2×10^{-4}M enhanced the amplitude and prolonged the half-fall of GD without altering AP. At 5×10^{-4}M to 5×10^{-3}M, PB had a dual action, altering the GD as in lower concentrations, but also depressing or completely blocking the AP. DPH (1×10^{-5}M to 1×10^{-4}M) did not affect the GD but either depressed or completely blocked the AP. At 2×10^{-4}M, DPH also depressed GD. V (1×10^{-4}M to 1×10^{-3}M) produced only a slight (10%) depression of GD, but did not affect AP. These results suggest that these three anti-convulsants employed in generalized epilepsy may produce their clinical efficacy by different mechanisms. (Supported by NIH Grant, NS 13727.)

1993 SOLUBILIZATION AND SEPARATION OF NEUROTRANSMITTER RECEPTORS IN THE BRAIN. Moshe Gavish, Ted Usdin, Raymond S. L. Chang, Solomon H. Snyder. Dept. Pharmacol., Sch. Med., Johns Hopkins Univ., Baltimore, MD 21205

Binding sites for neurotransmitter receptors in the brain have proved more difficult to solubilize than peripheral neurotransmitter and hormone receptors. Using a variety of detergents and techniques for assessing binding to soluble proteins, we have been able to solubilize several neurotransmitter receptors under conditions in which binding of the ligands is maintained in the soluble state. Receptors successfully solubilized include benzodiazepine receptors labled with ^{3}H-flunitrazepam, GABA receptors labeled with ^{3}H-muscimol, dopamine receptors labeled with ^{3}H-spiroperidol, histamine H_1 receptors labeled with ^{3}H-mepyramine and histamine H_2 receptors labeled with ^{3}H-cimetidine. Affinity chromatography utilizing supports to which appropriate drugs have been linked covalently has permitted extensive purification of some of these receptors. Molecular sieving techniques have enabled us to separate different populations of binding sites in order to ascertain possible interactions between various receptors. The possibility of multiply receptor sites for various transmitters has been explored by efforts to separate distinct macromolecular entities binding individual ^{3}H ligands.

1994 GABA RELEASE FROM, AND ACTION IN THE ENDOCRINE PANCREAS: EFFECT ON INSULIN AND GLUCAGON RELEASE. J.C. Gerber, III and T.A. Hare. Thomas Jefferson University, Philadelphia, PA 19107.

γ-Aminobutyric acid (GABA) is thought to be the major inhibitory neurotransmitter in the mammalian central nervous system (CNS). As in areas of the CNS, (where it is present at a level of 1-10 nMols/mg wet weight) it is also possible that GABA may act in an inhibitory or excitatory manner in peripheral systems. Using the sensitive (lower limit of sensitivity = 1 pMol) and specific (confirmed by GC/MS and radioreceptor assays) Ion Exchange/Fluorometric assay for GABA, we have recently reported (Fed. Proc. 38: 375, 1979) GABA's presence in various peripheral organs of the rat. Because GABA was present in isolated pancreatic islet tissue at a level roughly one-tenth that of brain (190 pMols/mg wet wt.) and at a similar level in catfish brockman bodies we have begun investigation of its role in endocrine pancreatic function by examining its relationship to insulin and glucagon secretion. We report here a significant ($p < 0.05$) increase in GABA release from perifused rabbit pancreata in response to 16.7 mM glucose as compared to 2.78 mM glucose. Rabbit pancreata were found to have a GABA content very similar to that of the rat. Further, GABA was found to facilitate insulin release into the perifusate with maximum insulin release occurring in response to 10^{-5}M GABA. Preliminary experiments suggest significant uptake of GABA into perifused pancreata. (Supported in part by the HD Foundation and USPHS NIMH Grant MH28243).



1995 INCREASED GLUTAMATE DECARBOXYLASE ACTIVITY FOLLOWING IN VITRO DEPOLARIZATION OF RAT BRAIN CORTICAL SLICES. Barry I. Gold, Barbara C. Bailey*, and Francis P. Huger* Dept. Pharmacology, Uniformed Services Univ. Sch. Med., Bethesda, MD 20014.

Changes in glutamate decarboxylase activity (GAD) in striatal slices have been reported following in vitro depolarizing stimuli (Life Sci. 22:187-194 [1978]; J. Neurochem. 32:883-888 [1979]). This report describes a persistent increase in GAD activity following in vitro depolarizing stimuli.

Rat frontal cortices were dissected fresh daily and two-hundred micron slices were prepared with a Sorval tissue chopper. The slices were suspended by vortexing in 5 ml of normal Krebs-Ringer-Phosphate medium (KRP), a high potassium KRP (K^+-KRP) or KRP containing 100 μM veratridine. Slices were preincubated 15 min at 37° and were recovered by filtration onto nylon mesh. Filtered slices were homogenized in Sorensen's buffer (10 mM, pH 6.5) containing 0.5 mM dithiothreitol and 0.5% (v/v) Triton X-100. The homogenates were centrifuged at 49000 g for 30 min and the supernatants aspirated and stored on ice for assay within two hours. GAD activity was estimated by the ability of the supernatants to liberate $^{14}CO_2$ from [1-^{14}C] glu.

Increased GAD activity was seen in supernatants prepared from high K^+- or veratridine-depolarized frontal cortex slices when assayed in the absence of added pyridoxal phosphate (PLP).

	PREINCUBATION MEDIUM		
	KRP	K^+-KRP	VERATRIDINE-KRP
GAD activity (nmoles/mg/15min)	4.9	11.2	5.9

These results are consistent with the hypothesis that GAD activity may be regulated by cofactor availability (Nature 266:847-548 [1977]). We also found, however, a twofold increase in GAD activity in supernatants prepared from K^+-depolarized slices assayed in the presence of saturating (50 μM) PLP concentrations. This would suggest that in vitro depolarization does not merely increase the saturation of GAD by PLP. Attempts to increase in vitro GAD activity by added calcium were unsuccessful. When supernatants prepared from fresh frontal cortex were assayed in the presence of several concentrations of $CaCl_2$, a slight inhibition (15%) was seen at 30 μM.

Experiments are in progress to study the mechanism by which depolarizing stimuli cause a persistent increase in GAD activity.

1996 REGULATION OF ACETYLCHOLINE RELEASE IN THE CAT CAUDATE NUCLEUS. Jay M. Gorell *, Michael J. Callahan *, and Eugene P. Schoener. Depts. of Neurology and Pharmacology, Wayne State Univ. Schl. Med. Detroit, MI 48201.

Adult cats were prepared under halothane anesthesia, and each had a push-pull cannula stereotaxically implanted in the right caudate nucleus. Wound edges and pressure points were infiltrated with lidocaine, and halothane was withdrawn. Gallamine was given IV and ventilatory support was provided to the conscious animal throughout each experiment. Caudate perfusion with normal saline was stabilized at 50 µl/min for one hour prior to collection of samples. Subsequent perfusates were collected during 10 - 15 min consecutive periods.

Basal samples were taken during the first 50 min of each experiment. Thereafter, atropine in saline was perfused at 10^{-6}, 10^{-5}, 10^{-4}, and 10^{-3} M for 50 min at each dose level. Finally, normal saline alone was perfused for 50 min. At the end of each collection period, the sample was stored at -80 C for later acetylcholine (ACh) assay. At the end of each experiment the perfusion site was marked for subsequent identification; verification of placement in the caudate nucleus was made in each case.

150 µl triplicates of each 10 - 15 min perfusate sample were assayed by a modification of a radioenzymatic method (Goldberg and Mc Caman, 1973).

Basal ACh release levels were 10.3 ± 0.3 nanomolar (6 cats; 23 samples). Sequentially perfused atropine 10^{-6} and 10^{-5} M produced no change, 10^{-4} M increased release 3.4 fold, and 10^{-3} M rapidly decreased ACh release to 26 % of basal levels. Saline perfused immediately after atropine 10^{-3} M rapidly increased ACh release beyond basal values.

These data suggest that probable post-synaptic muscarinic block occurs in the caudate with atropine 10^{-4} M, and that possible pre-synaptic cholinergic block occurs with atropine 10^{-3}M

This research was supported by a grant to the Dept. of Neurology, Wayne State Univ. by the Detroit General Hospital Research Corp.

1997 DEAFFERENTATION OF GABAERGIC PROJECTIONS TO THE HABENULA: IMMUNOCYTOCHEMICAL DEMONSTRATION. Zehava Gottesfeld, Christopher Brandon and Jang-Yen Wu. Dept. Neurobiol. and Anat., Univ. of Texas, Med. Sch. Houston, and Dept. Cell Biol., Baylor Coll Med., Houston, TX 77025.

Biochemical studies employing glutamate decarboxylase (GAD) as a marker have identified GABAergic neuronal elements in the medial (MH) and lateral (LH) habenular nuclei. GAD activity in the LH was higher than in the MH, and was partly attributed to GABAergic projections via the stria medullaris (SM) (Gottesfeld et al., Brain Research 130:184, 1977). The present work has been designed to accurately localize the GABAergic system in the habenulae by immunocytochemical visualization of GAD.

Unilateral high frequency lesions were placed stereotaxically in the SM of adult rats. Following 4 months survival the animals were anaesthetized and fixed via intracardiac perfusion with solutions containing periodate-lysine-paraformaldehyde (McLean and Nakane, J. Histochem. Cytochem., 22:1077, 1974). Coronal brain sections (50-100µm thick) were stained by the peroxidase-anti-peroxidase method of Sternberger (Petrali et al., J. Histochem. Cytochem. 22:782, 1974) as modified by Brandon et al., (PNAS, in press). Both the antigen (purified mouse brain GAD) and antiserum have been extensively characterized (Wu et al., J. Biol. Chem. 284:3029, 1973). The sections were embedded in Spurr's resin and observed by light and electron microscopy.

GAD-positive reaction product appeared within axon terminals, seen as punctate structures, in both habenular nuclei. The intensity of the stain was more striking in the LH, particularly in the mediolateral aspect of the nucleus, and was greatly diminished in the controlateral, lesioned side. Furthermore, the prolonged lesion seemed to cause marked shrinkage of the habenular complex. A dense, narrow streak containing GAD-positive axon terminals was observed underlying the ependyma within the MH. These nerve endings appeared in close contact with a single layer of large cell bodies which lined the third ventricle. These terminals were not affected by the SM lesion.

The disappearance of GAD immunochemical staining from the LH in response to SM lesions corroborates the biochemical data showing that the SM contains GABAergic projections to the LH. Also, it provides new information on the localization of GABAergic terminals in the habenular nuclei.

(Supported in part by BRSG-UTMSH to Z.G. and NS-13224 to J.-Y.W.)

1998 BLOCKADE OF GLUTAMATE EXCITATION AND GABA INHIBITION OF BRAIN STEM NEURONS BY CURARE. R. W. Greene* and D. O. Carpenter (SPON: M. I. Varon). Neurobiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014

Curare is a competitive antagonist of the nicotinic acetylcholine receptor, where it causes a shift to the right in the dose response curve, and will block the binding of α-bungarotoxin, a specific nicotinic receptor antagonist. Recent studies on Aplysia neurons in our laboratory have demonstrated, however, that two different types of response, due to conductance increases to Na^+ and Cl^-, respectively, are blocked by curare when these responses are elicited by any of nine neurotransmitters acting at different and specific receptors (J. Neurobiol. 8: 119, 1977). We suggested that these effects of curare are mediated by blockade of channels, not receptors. In these experiments we have investigated the effects of curare on the glutamate Na^+-dependent excitation and GABA Cl^--dependent inhibition of reticulospinal neurons of the brain stem of the cat to determine if these, like the comparable responses on Aplysia neurons, are blocked by curare.

The floor of the IV ventricle of cats was exposed by aspiration of the cerebellum, and recordings were made from antidromically identified reticulospinal units of the pontine medial reticular formation. We used seven-barrelled micropipettes, filled with saturated curare at pH 7, 1 M glutamate at pH 8, 1 M GABA, 1 M acetylcholine, picrotoxin (saturated), and 0.5 M NaCl, all at pH 4. The center barrel contained 2 M NaCl for recording. All the reticulospinal cells encountered were silent but could be driven with a constant background current of glutamate. The glutamate-induced excitation was completely and reversibly blocked when curare was applied by pressure injection or by ionophoresis. Sometimes this blockade was preceded by a brief period of increased excitation. The inhibitory actions of GABA were also reversibly blocked by curare, and the transient excitation that sometimes followed curare application probably reflects blockade of natural Cl^--dependent inhibitory potentials. Hill et al. (Brit. J. Pharmacol. 56: 9, 1976) have previously reported that the convulsant effects of curare may result from blockade of GABA and glycine inhibition.

Recent re-analysis of the actions of curare at neuromuscular junction (Manalis, Nature 267: 366, 1977) has shown a channel blocking effect here also. Ascher et al. (J. Physiol. 278: 207, 1978) have applied noise analysis to Aplysia excitatory responses to acetylcholine and have confirmed that curare blocks the channel. The present results suggest that 1) curare can block both Na^+ and Cl^- channels, 2) the ion channels of invertebrates and vertebrates are similar in at least this regard, and 3) blockade of a response by curare does not necessarily indicate that acetylcholine is the transmitter involved.

1999 PRIMARY VS. SECONDARY EFFECTS OF FIGHTING ON DOPAMINE UPTAKE IN ISOLATED MICE M.G. Hadfield, Dept. of Pathology, Medical College Virginia, Richmond, Virginia 23298

The present study was undertaken to separate primary effects on dopamine (DA) uptake produced by fighting from secondary effects that may accompany fighting such as those resulting from motor activity and sensory stimulation. To accomplish this aim, several controls were instituted including animals not exposed to fighting (resting controls), animals exposed to the fighting situation but not permitted to fight (stimulus controls) and animals exposed to stress and motor activity equivalent to that of fighting. To augment the power of the controls, DA uptake was studied in both the nigrostriatal (extrapyramidal) system which is known to modulate motor activity and the mesocortical system which is altered by stress. These two DA systems were also chosen because we have just reported that fighting significantly increases Km and Vmax for DA uptake in the mesorcortical system but not the nigrostriatal system, (VII Int. Mtg. ISN, 1979).

Isolated male ICR mice were placed for five minutes in a combat arena (fighting animals), in a chamber separated from the fighting arena by wire mesh (stimulus controls) or in a tumbling wheel containing cylinders the size of mice (motor/stress controls). The brains were then removed and synaptosome-rich homogenates of striatum and prefrontal cortex were respectively prepared and incubated with varying concentrations of ^{3}HDA. Uptake values were obtained by liquid scintillation counting from which Km& Vmax were calculated (Michaelis-Menten analysis). Each group of experiments was repeated 7-9 times and were compared with matching resting controls by "t" test.

The stumulus control animals showed an increase in Km& Vmax for DA uptake in the mesortical terminals, though of lesser magnitude than that noted in the fighting animals. This group alone also showed a decrease in Km and Vmax for DA uptake in the striatum. The motor/stress controls showed modest increases in values for the uptake constants in the pre-frontal cortex and no change in the striatum.

Fighting, witnessing fighting as a spectator (stimulus controls) and motor activity and pummeling similar to that experiences during fighting (motor stress controls)--all represent forms of stress which alter the neurotransmitter activity (uptake) of the mesortical DA system. Of these, fighting produces the greatest change, but it is interesting that significant changes in DA uptake are produced in the protected stimulus controls. Thus, there may be no specific primary effect of fighting, alone, on DA uptake. The decreased DA uptake in striatum noted in the stimulus controls may be related to inability to "act out" on a stress producing situation.

2000 EFFECTS OF SUBCORTICAL LESIONS ON NEOCORTICAL CHOLINERGIC MARKERS. Stanley L. Hartgraves*, Patricia L. Mensah, Peter H. Kelly. Dept. Physiol. and Biophysics and Dept. of Anatomy, Univ. of Southern California Sch. Med., Los Angeles, CA 90033.

Experimental evidence suggests there are cholinergic pathways to the neocortex. Undercutting of the neocortex in the cat causes a large decrease in choline acetyltransferase (CAT) (Hebb et al., 1963, Nature, 198, 692). Pepeu, et al. (1973, Brain Research, 57, 153) reported a decrease of acetylcholine in the neocortex of the rat following lesion of the septum. On the basis of horseradish peroxidase studies Divac (1975, Brain Research, 93, 385) has described direct projections to neocortex from neurons in the medial septum and globus pallidus region.

Here we have examined changes in the neocortex of CAT and [^{3}H] choline uptake, as markers of cholinergic neurons, one week after electrolytic lesions of the globus pallidus, medial septum and ventral thalamus. Pallidal lesions caused decreases of CAT by 58% and 42% in anterior and middle neocortical regions and a smaller decrease (by 23%) in the posterior cortex. In hippocampus CAT was unaltered. These lesions also decreased [^{3}H] choline uptake in anterior and middle neocortical regions by 35-40%. Septal lesions did not alter CAT in anterior or middle regions but caused decreases of 90% in hippocampus and 30% in posterior neocortex. Hippocampal [^{3}H] choline uptake was decreased 65% by this lesion. Lesions of the ventral thalamus caused no change in CAT activity in the regions studied (anterior and middle neocortex). These results are consistent with the hypothesis that the globus pallidus sends a diffuse network of cholinergic fibers to the neocortex, with preference to the anterior and middle regions, while the medial septal cholinergic innervation of neocortex is only to its posterior regions. Fibers from ventral thalamus contribute little or nothing to the subcortical cholinergic innervation of neocortex.

2001 RECEPTOR BINDING TO ASTROGLIA CELLS: THE QNB RECEPTOR. Fritz A. Henn[1], Barbara Oderfeld-Nowak*[1] and Robert Roskoski[2]. U. of Ia., Iowa City, Iowa 52242.

A preliminary study of QNB binding in astroglial and synaptosomal fractions of bovine caudate revealed an enrichment of QNB binding in astroglial cells. The enzymatic profiles of the fractions suggests that both choline acetyl transferase and glutamic acid decarboxylase are enriched in the synaptic fraction along with GABA or musimol binding. The muscarinic receptor ligand QNB appears to be enriched in astroglial cells. This enrichment is not large enough to account for all QNB binding, suggesting that the ligand may bind both glial and neuronal elements. This is analogous to the diazepam receptor which is clearly present in astroglia in the frontal cortex and neuronal elements in the cerebellum. Data on QNB binding has also been obtained on micro preparations of astroglia from rat hippocampus. These data support a glial localization as do lesion studies of hippocampus.

*Barbara Oderfeld-Nowak was an NIH Fogarty International Fellow.

2002 NEUROTRANSMITTER UPTAKE MECHANISMS IN DEVELOPING AND AGING CHICK IRIS. Douglas W. Hoffman*, Mario Marchi*, and Ezio Giacobini (Spon. S. Maxson) Dept. Biobehavioral Sci., University of Connecticut, Storrs, CT. 06268.

Age-related changes in the characteristics of accumulation of norepinephrine (NE) and choline (Ch) in chick iris in vitro were studied throughout the lifespan of the animal. We have found a specific uptake for NE at 10 days of incubation (d.i.). At this point uptake is sensitive to ouabain, desmethylimipramine (DMI), cocaine and low sodium concentrations, but the $^{Q}10$ ($V_{37°}/V_{27°}$) value does not differ significantly from 1 until hatch (21 d.i.). The time course of development is different for each of these individual characteristics of the uptake process,suggesting that they are selectively sensitive to changes in energy metabolism and membrane composition during ontogenesis of the chick. The kinetic values for NE uptake appear to fall into two groups; 10 d.i. to 1 month after hatch (a.h.), K_m=13-19 uM, and 2 months a.h. to 2 years a.h., K_m=3.5-5 uM. The V_{max} increases steadily with age up to 2 years. Other age-related changes in NE uptake are variations in sensitivity to DMI at 2 years a.h., and the appearance and increase in metanephrine sensitivity after hatch.

NE uptake is compared developmentally with Ch uptake, which is first seen at the earliest time of innervation of the iris by cholinergic fibers (4 1/2 d.i., stage 24). The K_m for Ch uptake does not show the same age-related changes as the K_m for NE uptake, but does remain stable from 1 month a.h. to 5 and 7 years of age. The V_{max}, after increasing from 5 d.i. to 3 months a.h., declines at 5 and 7 years of age, paralleling changes in Ch and acetylcholine levels in the iris (see Giacobini et al., Marchi, et al., Abstracts, this meeting).

Changes in neurotransmitter uptake during development and aging reflect changes in the maturing nerve terminals. It is not yet clear if this is due to changes in molecular aspects of the uptake mechanism, or is in response to changes in the basic metabolic and structural processes of the developing and aging neuron.

2003 OSMOTIC LYSIS OF BOVINE CHROMAFFIN GRANULES IN ISOTONIC SOLUTIONS OF SALTS OF WEAK ACIDS AT LOW MEDIUM PH. Ronald W. Holz and Bruce Trock.* Dept. of Pharmacology, Univ. of Michigan Medical School., Ann Arbor, MI 48109.

Chromaffin granules have an intragranular pH of 5.5-5.7. The neutral form of weak acids such as acetic acid should be permeant and attain equal concentrations across the granule membrane. The negatively charged species should be relatively impermeant but should gain access to the granule interior by dissociation of the neutral species within the granule. The intragranular concentration of the charged species will then be determined by the local pH, the intragranular (and extragranular) concentration of neutral species, and the dissociation constant of the weak acid. One predicts that in isotonic solutions of weak acids, that granules would be stable when the medium pH is 7 because the negative species is excluded from the granule interior. When the medium pH is lowered, the intragranular concentration of both charged and uncharged species should increase. The granules should osmotically lyse and release their contents of catecholamines, ATP, and dopamine-β-hydroxylase (DBH) into the medium when the medium pH approaches the intragranular pH. Chromaffin granules in isotonic solutions of $K^+ CH_3COO^-$ (acetate), $K^+ CH_3CHOHCOO^-$ (lactate), and $K_2^+ OOCCH_2CH_2COO^-$ (succinate) are stable at pH 7 but release their contents of catecholamines, ATP and soluble DBH when the medium pH is less than 6. The effect is inhibited by increasing the osmolality of the solution with sucrose. Granules in isotonic solutions of salts of strong acids such as $K^+ CH_3SO_4^-$ (methylsulfate), $K^+ CH_2OHCH_2SO_3^-$ (isethionate), and K_2SO_4 are stable between pH 7.0-5.4.[2] These data provide further evidence that the intragranular pH is acidic. Supported by grants from the Michigan Heart Association and the NSF (#BNS-7824494).

2004 ACETYLCHOLINE METABOLISM IN THE NEMATODE ASCARIS. Carl D. Johnson* (SPON: A.O.W. Stretton). Dept. of Zoology, Univ. of Wisconsin, Madison, WI 53706.

We have been studying the distribution of choline acetyl transferase (CAT) and acetylcholinesterase (AChE) in the nematode Ascaris. The tissues of nematodes are arranged in three layers: hypodermis, muscle and gut plus gonad. The nervous system which contains some 250 cells is embedded in the hypodermal layer. In comparison to more complex animals it is a significant simplification that neither neurons nor neuronal processes extend into the muscle layer or into gut or gonads; therefore cholinergic enzymes found in these tissues cannot result from neuronal synthesis.

Among the neurons, we have previously described the selective localization of CAT in excitatory as compared to inhibitory motorneurons (Neuroscience Abstr. 4:197, 1978). Pharmacological experiments suggest that interneurons which drive excitatory motorneurons may also be cholinergic since their input is blocked by curare (I.S. Kass, unpublished results). CAT activity in neurons, however, represents only ~1% of the total activity in the animal. Most of the CAT is localized in the hypodermis and is particularly concentrated in the tip of the head. The function of ACh synthesized in hypodermis is not yet understood but if it is releasable it could provide additional, presumably tonic, excitatory input to muscle.

The muscle layer contains two forms of AChE separable by velocity sedimentation (5S and 13S) with different Kms for ACh (5S ~100 μm; 13S ~20 μM). They are also differentially affected by detergents; the 5S form is irreversibly inactivated by Na deoxycholate whereas the larger form is inhibited by TRX-100. Comparable forms of AChE in the nematode Caenorhabditis elegans have been shown by mutant analysis to be the products of separate genes. Analysis of the distribution of separable forms within different muscle regions reveals that the 5S form is high in the front half of the animal and declines posterior to the vulva. The 13S form is more evenly distributed. In the most common locomotory behavior in Ascaris waves of contraction are initiated at the vulva and move anteriorly, so the muscle region with high 5S activity is more active. Thus 5S AChE may be regulated by muscle activity.

Finally, both CAT and AChE have been located in gonads. CAT levels are high in the vas deferens and in the anterior end of the uterus whereas AChE is concentrated in the seminal vesicle and in the vagina. We are currently investigating the possibility that ACh may play a role in the activation or guidance of Ascaris sperm.

2005 ACTION OF KAINIC ACID IN THE TOAD AND GOLDFISH RETINA. Jochen Kleinschmidt*, Charles L. Zucker* and Stephen Yazulla*. (SPON: B. M. Twarog). Dept. Biology, SUNY Stony Brook, Stony Brook, NY 11794.

Kainic acid (KA) is an analog of L-glutamic acid (GLU) and has a potent neuroexcitatory and neurotoxic action in the goldfish retina. In order to investigate the mechanism of action of KA in the retina and to find out if it involves GLU receptors, we have studied the early neurotoxic effects of KA in isolated retinae of goldfish and toad (Bufo marinus). Retinae were isolated from dark-adapted animals and incubated in 200 μl of Ringer with and without KA and other agents for various times. After incubation, retinae were processed for routine histology and investigated by light and electron microscopy.

One of the earliest visible signs of KA neurotoxicity in the retina is the formation of clear, membrane bound vacuoles in the outer plexiform layer (OPL). Vacuoles are found within photoreceptor synaptic invaginations as well as more proximally in the OPL and appear to originate mostly from distal and proximal segments of horizontal cell dendrites. The extent of vacuolation in the OPL is graded with KA concentration and with length of incubation; half-maximal swelling occurs at 5μM KA for 15 min incubations, or at 5 - 10 min incubation for 20μM KA. In goldfish but not in the toad, rod-connected dendrites are less sensitive to KA than are cone-connected dendrites. KA-induced vacuolation in the OPL: (1) is not mimicked by other excitotoxic amino acids including 50mM GLU, by convulsants, or by a variety of agents which cause nonspecific cellular swelling elsewhere in the CNS or in other tissues, (2) is not blocked in zero Ca Ringer or by 20mM Mg or 2mM Co, precluding a presynaptic action via transmitter release from photoreceptor terminals, (3) is Na-dependent and is greatly reduced by 0.5mM pentobarbitone which at similar concentrations blocks Na-mediated synaptic excitation in other preparations.

These findings suggest that the action of KA in the OPL is specific, is the result of a direct action of KA on postsynaptic membranes, is mediated by a Na ionophore similar to synaptic ionophores, and appears to involve binding of KA to a receptor which either has a very low affinity for GLU or which readily desensitizes or inactivates to GLU but not to KA.

2006 INTRACELLULAR ACTIONS OF GABA, GLYCINE AND SOME RELATED AGENTS. K. Krnjević, A. Constanti* and A. Nistri*. Anaesthesia Research and Physiology Departments. McGill Univ. Montreal PQ Canada. H3G 1Y6.

GABA and glycine have well-known inhibitory actions when applied to many central neurons. There is good evidence that these are mediated by specific receptors, situated on the external surface of the neuronal membrane, which activate anion-permeable channels. Under normal conditions, the predominant ion involved is Cl^-, and since in central neurons the Cl^- equilibrium potential is usually more negative than the resting potential, both GABA and glycine have a hyperpolarizing action associated with a fall in membrane resistance.

There is some evidence, however, that GABA can depolarize glia (Krnjević and Schwartz, 1967, Exp.Br.Res.3,306) and that a depolarizing effect is superimposed on its predominant hyperpolarizing action on motoneurons (Krnjević et al.,1977, Can.J.Physiol. Pharmac. 55,653). These depolarizations (which have not been observed with glycine) could be due to electrogenic uptake of GABA in association with Na^+. If such electrogenic transport indeed takes place, one might expect it to be reversible, as in some cells that utilize electrogenic transport systems for neutral amino acids (Johnstone, 1979,Can.J.Physiol.Pharmac. 57,1). To test for this possibility, we have injected GABA and some related agents into lumbosacral motoneurons in cats under Dial, using balanced iontophoresis with the return current through a KCl- or K citrate-containing barrel of the 4-barrelled glass micropipettes.

The majority of cells into which GABA was injected (5-15 nA, for 10-100 sec) showed repeatably a small hyperpolarization (typically by 2-5 mV) which persisted for 1 min or more after the end of the injection, was not readily reversible by hyperpolarization, was not potentiated by an intracellular injection of a benzodiazepine, and was not associated with a fall in membrane resistance - on the contrary, intracellular injections of GABA often increased the input resistance.

These characteristics indicate that this hyperpolarizing action is probably not mediated by the "classical" external GABA receptors; apart from the surprising increase in resistance, they are consistent with a reversed electrogenic outward transport of GABA.

We conclude that if motoneurones indeed have Na^+ coupled neutral amino acid (and closely related) transport systems, only that for GABA (of the agents tested) seems to have the characteristics (rate, stoichiometry of Na^+-coupling, etc.) required for clear electrogenic manifestations of transport.

2007 CHLORIDE DEPENDENCE OF CHOLINE UPTAKE, ACETYLCHOLINE SYNTHESIS AND RELEASE. H.Ksiezak* and A.M.Goldberg. The Johns Hopkins Univ. School of Hygiene and Public Health, Baltimore, MD 21205.

The role of chloride (Cl^-) in the functioning of the cholinergic nerve terminal has only recently been described. Rossier et al. (J.Neurochem., 29:1007, 1977) demonstrated that lack of Cl^- inhibited the activity of choline acetyltransferase. Further, Kuhar et al. (J.Neurochem., 31:251, 1978) have shown that the sodium dependent high affinity choline transport is also Cl^- dependent. In addition, Gennaro et al. (J.Physiol., 280:237, 1978) demonstrated that propionate substitution for Cl^- in elevated K^+, depletes the frog neuromuscular junction of its synaptic vesicles content. We therefore examined the effects of propionate substitution for Cl^- on the uptake of choline, synthesis and release of ACh in rat brain synaptosomal preparations (P2 fraction). The kinetics of transport were studied over a range of choline concentrations 1-100 μM in 5 mM K^+ Krebs-Phosphate buffer (5 K-P) or in the same medium in which all Cl^- was replaced with propionate (125 mM; 5 K^+ Cl^- -free). In 5 K-P two components, high and low affinity uptake of choline, were observed. In 5 K^+ Cl^- -free medium only a low component could be detected and at 10 μM choline, the amount of newly synthesized ACh found in the pellet was reduced by 75%. However, in 35 K-P newly synthesized ACh was maintained but again only a low affinity component could be observed (Carroll and Goldberg, J.Neurochem., 25:523, 1975). The total amount of ACh (released plus remaining in tissue) was greatly increased by incubation in 35 K-P over 30 min. (270 to 690 pmol/mg prot.) but was only slightly increased in 35 K^+ Cl^- -free medium (235 to 290 pmol/mg prot.). In 35 K-P release of ACh was linear for at least 30 min. and was 400 pmol/mg prot. In 35 K^+ Cl^- -free medium release was also linear for 30 min. but was reduced to 200 pmol/mg prot. Therefore, the process of release in 35 K^+ Cl^- -free medium was not impaired but the amount of ACh released was reduced. Further, in K-P the tissue level was maintained for 30 min. while in the Cl^--free medium the tissue levels were greatly decreased. These results confirm and extend the observation and importance of Cl^- on the uptake of choline and/or synthesis of ACh. However, they do not allow a conclusion to be drawn as to whether the reduction in newly synthesized ACh was the result of a decrease in uptake of choline or in the synthesis of ACh. These results further suggest that the synthesis of ACh and the transport of choline are closely associated, and possibly even linked. They also raise the interesting possibility that propionate may be a useful agent in studying the mechanisms of release of ACh.

2008 ELECTRON MICROSCOPIC LOCALIZATION OF CHOLINERGIC MUSCARINIC RECEPTORS IN RAT BRAIN. Michael J. Kuhar, Naomi Taylor*, Nigel Birdsall* and Edward Hulme*. (SPON: K. Dismukes). Dept. of Pharmacol., the Johns Hopkins Univ. Sch. of Med., Balto., Md., and Mol. Pharm. Section, Natl. Inst. for Med. Res., Mill Hill, London, England.

Propylbenzilylcholine mustard (N-2'- chloroethyl-N- 2",3"-propyl-2-aminobenzilate, PBCM) is a potent, specific, irreversible cholinergic muscarinic antagonist. In its radiolabeled form, it can be used in autoradiographic studies to localize the receptor at the microscopic level. The goal of these studies was to utilize ^{3}H-PBCM to localize the muscarinic receptor at the electron microscopic level.

Rats were perfused with 30 ml 0.1% glutaraldehyde in buffer intracardially. The brains were rapidly removed and dissected in ice cold saline. Slices of hippocampal formation and cerebral cortex (350μ) were prepared with a tissue chopper and incubated with 5 to 25 nM concentrations of ^{3}H-PBCM in a Kreb's Ringer solution for 15-25 min at 30°C. Some slices were preincubated with 1 μM concentrations of QNB for 3 min and incubated further with ^{3}H-PBCM to obtain "blanks" for measurement of background values. Specific to nonspecific ratios of binding varied between about 2 to 5. The slices were rinsed with cold Ringer's solution 3 times, and further fixed with aldehydes and osmium. The slices were dehydrated with ethanol and embedded in TAAB resin.

Light microscopic autoradiography of 1μ sections revealed a limited penetration of drug into the tissue and, by grain counts, confirmed the specific to nonspecific ratios observed in biochemical studies. Preliminary electron microscopic autoradiography with thin sections (1-5 month exposures) revealed a significant fraction of grains over synapses in both the hippocampus and cortex. This fraction was reduced in the tissues treated with QNB. These preliminary studies suggest the possibility of studying the ultrastructural localization of muscarinic receptors. They were supported by USPHS grants MH25951 and MH00053, and a grant from the McKnight foundation.

2009 DIFFERENTIAL BINDING TO DOPAMINE AND NEUROLEPTIC RECEPTORS. J. Y. Lew* and M. Goldstein. New York University Medical Center, Department of Psychiatry, 550 First Ave., New York, N.Y. 10016.

To determine whether dopamine (DA) receptors with high affinity for DA agonists have different properties than those with a high affinity for DA antagonists, we have investigated the thermal stability of these receptors in calf striatum.

The exposure of striatal membranes to 53°C for 2 min. resulted in a decrease of the specific binding of H^{3}-spiroperidol (Spi) by 5-10%, while the specific binding of H^{3}-DA was decreased by 80-90%. Scatchard plot analysis revealed that the dissociation constant for H^{3}-Spi and for H^{3}-DA was the same in the thermal exposed membranes as in the control membranes. The maximum number of binding sites in thermal exposed membranes was decreased for H^{3}-Spi by approx. 10% and for H^{3}-DA by approx. 75%. Thus, the selective decrease in specific binding of H^{3}-DA suggests that thermal exposure results in an inactivation of DA receptors with high affinity for DA.

The potencies of DA agonists and DA antagonists to displace H^{3}-Spi from intact striatal membranes and from thermal exposed striatal membranes were investigated. The displacement of H^{3}-Spi by DA agonists is significantly reduced in the thermal exposed membranes while the displacement of DA antagonist is not altered.

Thus, thermal exposure of striatal membranes makes it possible to differentiate DA receptors with high affinity for DA antagonists (neuroleptic receptors) from those with high affinity for DA agonists. The results of this study indicate that neuroleptic receptors and DA receptors are two distinct molecular entities; one of them is thermal stable while the other is labile.

2010 RAT TRIGEMINAL MESENCEPHALIC NEURONS ARE RESISTANT TO BOTH EXCITATORY AND NEUROTOXIC ACTIONS OF KAINIC ACID. J.P. Lund and C. de Montigny, Centre de Recherche en Sciences Neurologiques, Université de Montréal, Montréal, Canada.

The "excitotoxic" hypothesis proposes that neurotoxic amino acids exert their toxic effect through neuronal excitation. Colonnier et al. (1979) have reported that neurons of trigeminal mesencephalic nucleus (NMT) of the cat survive kainic acid (KA) injections. In the present study, we confirmed the resistance of NMT neurons to the toxic action of KA in the rat and found addition that these neurons are not excited by iontophoretically-applied KA.

In the first series of experiments, 2.5 μg of KA in 5 μl of saline were injected in the vicinity of the pontine part of NMT on one side. 5 μl of vehicle was injected on the other side. Histological sections were prepared in a conventional manner. Ten and 14 days following KA injections all non-NMT neurons within a radius of 2 mm from the injection sites, including the relatively resistant cerebellar cortical granule cells, had disappeared. However NMT neurons remained and were comparable in number and appearance to those of the control saline-injected side. Thus, these observations in the rat confirm those of Colonnier et al. (1979) in the cat.

In the second series of experiments, the effect of iontophoretic application of KA was studied in NMT. This nucleus contains cell bodies of primary afferent neurons which innervate pressoreceptors around the teeth and muscle spindles in the jaw closing muscles. Sixty-three NMT neurons recorded were identified by mechanical stimulation of their receptors and tested iontophoretically. Thirty non-NMT neurons were tested with the same pipettes. A 0.1 M KA solution at pH 8.0 and a conventional iontophoretic technique with an automatic current "balance" were used. Recording sites were marked with fast green and verified histologically.

None of the NMT neurons responded to KA applied iontophoretically, even when currents of 100 nA or more were used, but all thirty non-NMT control neurons were activated when KA was applied with small currents (1-10 nA).

It is concluded that, in the NMT, the absence of both neurotoxic and neuroexcitatory effects of KA is consistant with the "excitotoxic" hypothesis. The results also suggest that KA requires the presence of receptors to exert both its neurotoxic and neuroexcitatory actions.

Supported by MRC grants MA-6444 (C. de Montigny) and to the Groupe de Recherche en Sciences Neurologiques (J. Lund).

2011 DESENSITIZING EXCITATORY RESPONSES TO PEPTIDES, PURINES, PROTONS AND DRUGS REVEALED USING CULTURED MAMMALIAN NEURONS. J.F. MacDonald, J.L. Barker, D.L. Gruol, L.M. Huang*, and T.G. Smith*. Lab. of Neurophysiology, NINCDS, NIH, Bethesda, Md. 20014

Spinal neurons derived from mouse embryos were grown in tissue culture for 4 weeks or more. Intracellular recordings using conventional and voltage clamp techniques, coupled with extracellular microiontophores or microperfusion were used to study the effects of leucine- and methionine-enkephalin, inosine, substance P, and flurazepam on neuronal membrane properties. 10 mM Mg^{++} was added to the recording medium to prevent spontaneous synaptic activity and allow clearer examination of pharmacologically induced membrane events. Iontophoresis of all of these substances evoked rapidly depolarizing, rapidly desensitizing excitatory responses on spinal neurons. Under voltage clamp the responses were associated with both an increase in inward current and membrane conductance. The responses extrapolated to an apparent reversed potential close to the peak of the spike (+20 mV), suggesting that they are due primarily to activation of sodium conductance. Responsive cells showed a non-uniform distribution of response amplitude over the cell surface.

Because iontophoresis requires charged molecules, which frequently necessitates acidification to pH 3, control pipettes containing HCl at pH 3-5 were also tested and occasionally such pipettes evoked entirely similar rapidly depolarizing, rapidly desensitizing excitatory responses. An increase in the frequency of cells responding to H^{+} ions was observed using pipettes containing 1M HCl (pH < 1). H^{+} ion excitation of spinal neurons may result from rapid titration of protein groups comprising membrane receptors or channels.

In order to ensure that the drug responses were not all due to iontophoresis of H^{+} ions, all of the substances were dissolved in bathing medium (1-10 μM) and applied to single neurons by pressure microperfusion. Rapidly desensitizing excitatory responses were evoked by all of the substances using this alternative method of application which eliminates any contribution of H^{+} ions.

Thus, evanescent excitation of central mammalian neurons is common to a wide variety of endogenous substances. A phenomenologically similar form of synaptic excitation has been reported in invertebrates. While the pharmacokinetics of flurazepam application would prevent drug-induced excitation in the intact animal, part of the therapeutic efficacy of the drug might be due to drug-induced desensitization of naturally occurring excitatory synaptic transmission. In this regard, cross desensitization between pharmacologically applied flurazepam and inosine occurs on these cultured neurons.

2012 BICUCULLINE HAS DIFFERENT ACTIONS ON MAMMALIAN SPINAL CORD AND FOREBRAIN NEURONS IN PRIMARY DISSOCIATED CELL CULTURES. R.L. Macdonald, A.B. Young, L.M. Nowak. Department of Neurology, University of Michigan Medical Center, Ann Arbor, MI 48109.

Convulsants such as bicuculline have been demonstrated to antagonize GABA-mediated inhibition in many in vitro and in vivo experimental preparations and it has been suggested that such antagonism forms the basis for their convulsant activity. We have investigated the action of bicuculline on forebrain and spinal cord neurons in primary dissociated cell culture and report that bicuculline produces paroxysmal depolarization in both neuronal systems but with a different ED_{50}.

Spinal cords and forebrains were removed from 13-14 or 14.5-15.5 day old fetal mice respectively and grown (as previously reported) in normal growth medium for four to sixteen weeks prior to electrophysiological study. Only neurons with spontaneous activity or with evoked action potentials were accepted for study. Paroxysmal depolarizing events (PDE) were defined as abrupt, randomly occurring depolarizations followed by volleys of action potentials and repolarization.

The percentage of forebrain neurons with PDE was a function of bicuculline concentration with about 20% at 100nM, 60% at 200nM and 100% at 500nM giving an ED_{50} for PDE of between 150 and 200nM. The PDE-bucuculline dose response curve was steep with PDE ranging from control levels to 100% over 8-500nM. Also as the bicuculline dose increased, time-to-peak, duration and frequency of PDE declined.

In spinal cord neurons, PDE was also produced by bicuculline but over a different dose range. PDE occurred in about 40% of neurons in 5μM, 80% in 20μM and 100% in 40μM bicuculline with a ED_{50} for PDE between 5 and 10μM. Again the PDE-bicuculline dose-response curve was steep with control to 100% range occurring between 1-40μM. Increasing doses of bicuculline decreased PDE duration, rise time and frequency as in forebrain neurons.

Thus, we have demonstrated that the ED_{50} for bicuculline-induced PDE is higher in spinal cord than in forebrain neurons in culture consistent with the similar shift in ED_{50} for bicuculline displacement of GABA-binding (see abstract Young and Macdonald). Furthermore, the entire PDE-bicuculline dose response curve overlaps the lower 20% of the GABA-displacement curve in both preparations. This demonstrates that displacement of GABA by bicuculline from binding sites occurs at bicuculline doses which are physiologically active in producing paroxysmal activity and supports the hypothesis that antagonism of GABA-mediated inhibition is involved in the production of paroxysmal depolarizing events.

2013 L-THREONINE ADMINISTRATION INCREASES GLYCINE CONCENTRATIONS IN THE RAT CENTRAL NERVOUS SYSTEM. Timothy J. Maher* and Richard J. Wurtman. Lab. Neuroendocrine Regulation, MIT 56-245, Cambridge, Mass. 02139, USA.

Glycine is produced by an enzyme, serine transhydroxy methylase (STHM) that can use either serine or threonine (THR) as substrate. We suspected that STHM might not be saturated with THR at normal brain THR levels; hence we examined the effect of exogenous THR on spinal cord and brain glycine levels. Male rats were killed 1 hour after receiving 0, 50, 100, 200, or 400 mg/kg THR i.p.. Cord and brain THR levels increased in a dose-dependent fashion after THR injection. The concentration of glycine in the spinal cord also significantly increased by 26% in rats receiving 400 mg/kg THR ($p<.01$) and by 17% and 16% in the 200 and 100 mg/kg groups ($p<.05$). Changes in brain glycine followed a similar pattern, but were not increased significantly. Doses of THR that increased cord glycine also tended to decrease its levels of the large neutral amino acid tyrosine; this indicates that THR did in fact compete with other large neutral amino acids for transport at the blood-brain barrier. THR administration (400 mg/kg) increased synaptosomal glycine levels in spinal cords by an average of 16% (from 8.53 to 9.90 nmol/mg protein), compared with a 26% increase in glycine concentrations seen in intact spinal cords.

These observations indicate that THR can be used to enhance glycine levels in rat spinal cord neurons, and also suggest that glycine synthesis may normally be influenced by plasma composition (that is, by the ratio of plasma THR concentration to the sum of the large neutral amino acid concentration).

2014 ASPARTATE AS THE TRANSMITTER OF THE AUDITORY NERVE. Michael R. Martin. LNO, NINCDS, NIH, Bethesda, MD 20205.

One criterion for establishing a transmitter role for a compound is to determine that a substance affecting the natural transmitter affects the putative transmitter in an identical fashion. There is substantial evidence that either glutamate or aspartate (or both) is the natural transmitter(s) of the auditory nerve Wenthold and Gulley, Brain Res. 138: 111, 1977; Martin and Adams, Neuroscience, in press). There is evidence that glutamate diethyl ester (GDEE) is a more selective antagonist of glutamate than aspartate and that the opposite is true for D-α-aminoadipate (DAA) (McLennan and Hall, Brain Res. 149: 541, 1978). Magnesium (Mg) has been shown to be effective in preferentially reducing aspartate and N-methyl-D-aspartate (NMDA, a structural analog of aspartate) responses (Davies and Watkins, Brain Res. 130: 364, 1977). In the present study the actions of the antagonists GDEE, Mg and DAA were compared on glutamate-, aspartate- and NMDA-evoked excitations and on synaptic responses on 11 chopper - type units in the anteroventral cochlear nucleus of the cat. The drugs were iontophoresed from seven barreled microelectrodes, with automatic current balancing control.

The effects of the antagonists GDEE and Mg were compared on glutamate and aspartate responses on 5 units and on glutamate and NMDA responses on 2 units. Neither antagonist was very effective in differentiating between glutamate and aspartate; both were depressed with a tendency for GDEE to depress glutamate and Mg to depress aspartate preferentially. NMDA was not affected by GDEE. In contrast, Mg blocked the NMDA response. Mg depressed and GDEE had no effect on synaptically-evoked responses on 1 of these units.

The effects of the antagonists GDEE and DAA were compared on glutamate and aspartate responses on 1 unit and on glutamate and NMDA responses on 4 units. Again, there was a slight preferential depression of glutamate over aspartate by GDEE while on the same unit DAA preferentially depressed the aspartate response. GDEE had little effect on NMDA responses. DAA at low iontophoretic currents blocked the NMDA response without having any substantial effect on glutamate. DAA depressed the synaptically-evoked responses while GDEE had no effect on any of these units.

The preferential depressions of aspartate, NMDA and synaptic responses by DAA and Mg were in contrast to the preferential depression of glutamate and the inability to affect synaptic responses by GDEE. The data are preliminary but suggest that aspartate or an aspartate-like substance is more likely to be the transmitter of the auditory nerve than glutamate. Further experiments are being conducted to substantiate these initial observations.

2015 GLYCINE AND PEPTIDES IN THE PROCESSES OF THE IDENTIFIED APLYSIA NEURONS R3-R14. D.J. McAdoo, C.H. Price, and M.H. McAdoo*. Marine Biomedical Institute and Dept. of Human Biological Chemistry and Genetics, Univ. Texas Medical Branch, Galveston, TX 77550.

Previous work has shown that the cell bodies of R3-R14, identified neurons in the abdominal ganglion of Aplysia, contain unusually high glycine concentrations and unique small peptides. These substances are candidates for release from R3-R14 as chemical messengers. We have recently located the terminals of the major axons of R3-R14 (Price and McAdoo, this meeting) and this has enabled us to do chemical analyses on nerves containing their preterminal processes. Using gas chromatography-mass spectrometry, we have found glycine concentrations in these nerves that are 10 times higher than in other nerves. By autoradiography, we have demonstrated a specific and rapid glycine uptake system in the axons and terminals of R3-R14.

SDS polyacrylamide gel electrophoresis demonstrated that there are small peptides in the axons and terminals of R3-R14 with molecular weights that are similar to those of the peptides found in the cell bodies. There are large quantitative differences between the gel patterns of peptides in the axons and cell bodies, consistent with peptide processing during axonal transport.

Statistical analysis of electron microscope autoradiographs demonstrated a highly significant association of axonally transported ^{3}H-glycine with the large osmophilic vesicles characteristic of R3-R14. Earlier work (Price et al., J. Neurobiol., in press) has shown that 80% of the radioactivity in such transport experiments is in molecular glycine, not protein. This is the first report of an association of a free amino acid with neuronal vesicles. As glycine is not osmophilic, the vesicles presumably contain peptides as well.

The presence of unique small peptides and high concentrations of free glycine in the R3-R14 terminal regions suggests that both could be released as chemical messengers, but neither case has yet been proven. Morphological studies have shown that R3-R14 have endings on vascular smooth muscle and secretory endings in neurohemal areas. These biochemical and morphological results suggest that R3-R14 may use multiple modes of signalling to their target tissues.

2016 SLOW EXCITATORY RESPONSE TO DOPAMINE IN APLYSIA. M. J. McCreery* and T. C. Pellmar (SPON: C. M. Woodbury). Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Previous reports have demonstrated a slow excitatory response in some neurons of Aplysia to iontophoretically applied serotonin (5-HT) and GABA. Gerschenfeld and Paupardin-Tritsch (J. Physiol. 243: 427, 1974) characterized a slow depolarizing response to 5-HT, the A' response. This response reached peak amplitude in 10-25 sec and was almost abolished when Na+ was replaced by Tris+. Unlike the fast excitatory response to 5-HT due to an increase in sodium conductance (A response), the A' response was unchanged by 10^{-4}M curare. Observation of a similar slow depolarizing response to GABA was made by Yarowsky and Carpenter (Br. Res. 144: 75, 1978) in L11 of the abdominal ganglion. The underlying mechanism of this response appeared to be a conductance increase to sodium and, like the A' response to 5-HT, was curare-insensitive.

We report here that some neurons in the abdominal and buccal ganglia of Aplysia, studied under current or voltage clamp conditions, exhibit a slow depolarizing response to iontophoretically applied dopamine. The duration as well as the time-to-peak of this response is much longer than that of the fast increased sodium conductance response to dopamine which has been observed by several workers. In contrast to the fast excitatory response which peaks in 1-3 sec and lasts 10-20 sec, this slowly developing depolarization peaks in 10-25 sec and lasts as long as 1-2 min. It is minimally affected by exposure to low-Cl^- seawater or to 10^{-3}M curare. The response amplitude is reduced when sucrose is substituted for NaCl. Although it has been difficult to ascertain a change in membrane conductance during the response, it behaves like a conductance increase to sodium in that the response amplitude decreases with membrane depolarization and extrapolates to zero amplitude at a potential between 0 mV and -20 mV.

These observations demonstrate another type of excitatory response to dopamine in Aplysia. The ionic mechanism of this response appears to be similar to the slow depolarizations already reported for 5-HT and GABA.

2017 ACh RELEASE FROM RAT CORTICAL SYNAPTOSOMES AND ITS RELATIONSHIP TO Na^+K^+-ATPase ACTIVITY. Edwin M. Meyer* and Jack R. Cooper. Dept. of Pharmacology, Yale Univ. School of Med., New Haven, CT 06510.

Since a number of problems exist with the vesicular theory of transmitter release, we are exploring the possibility that the release mechanism may involve H^+ generation at the presynaptic terminal via Na^+,K^+-ATPase activity. Accordingly, the efflux of [^{14}C]-acetylcholine (ACh) and [^{14}C]-choline from superfused rat cerebro-cortical synaptosomes was monitored continuously through an anthracene scintillator flow cell. The release of [^{14}C]-ACh but not that of [^{14}C]-choline was increased several fold by short (10-60s) exposures to 60mM K^+, 10^{-5}M veratridine, or electrical field stimulation (20V). Each of these treatments released [^{14}C]-ACh via a Ca^{2+} dependent, reversible mechanism. Ouabain (10^{-4}-10^{-3}M), a specific inhibitor of transport Na^+,K^+-ATPase, also increased [^{14}C]-ACh efflux from these cortical synaptosomes within several seconds of exposure; however, as would be predicted, ouabain-induced transmitter release was not dependent on the presence of extracellular Ca^{2+}. Synaptosomal Na^+,K^+-ATPase activity and [^{22}Na]-efflux were also measured via batch or superfusion techniques, and preliminary evidence from these experiments indicated that ACh-releasing agents or treatments also inhibited synaptosomal Na^+K^+-ATPase activity in a manner that temporally paralleled their action on [^{14}C]-ACh release. These preliminary results support a model which implicates changes in Na^+,K^+-ATPase activity as a trigger for neurotransmitter release.

2018 ROLE OF DOPAMINE AND ITS AGONISTS AND ANTAGONISTS IN CAROTID BODY CHEMORECEPTOR FUNCTION OF THE RAT. J. Mishra, H. N. Sapru, and A. Hess. Dept. Anat., CMDNJ-Rutgers Medical School, Piscataway, NJ 08854, Section of Neurological Surgery, CMDNJ-Med. School, Newark, NJ 07103.

In vivo studies on the inhibitory or stimulatory action of dopamine, its agonists and antagonists on the carotid bodies of cat, dog, rabbit and rat have produced variable and conflicting results. These might occur because of the differing types of anaesthesia employed and the varying levels of anaesthesia achieved in the experimental animals. In the present study, decerebrate as well as chloral hydrate (35mg/kg i. p.) anaesthetized rats were used to study carotid body chemoreceptor function. Injection of the dopamine agonist apomorphine (200µg/kg) by itself in the carotid artery close to the carotid body resulted in minimal excitation or no change in the carotid sinus nerve (CSN) activity or respiration. However, apomorphine potentiated the ventilatory as well as CSN response to NaCN (100µg/kg, i. a.). On the other hand, chlorpromazine suppressed the ventilatory and CSN response to NaCN. Chlorpromazine by itself had no significant effect on respiration and CSN activity. Dopamine (1-6µg/kg close to carotid body) produced by itself small or no excitation of respiration. Increasing the dose up to 10µg/kg did not produce any alteration in respiratory response. These results were confirmed in decerebrate rats, thus eliminating the variability, if any, due to anaesthesia. Injection of high doses of dopamine (20µg/kg), however, produced by itself increase in respiration. Severance of the ninth nerve bilaterally abolished all respiratory responses to exogenous neurotropic substances. To ascertain further that the respiratory response elicited in the present study was indeed mediated by the carotid body, the ventilatory response of the cat was compared to that of the rat. As previously demonstrated by others recording cat CSN activity, dopamine agonists inhibited, while antagonists stimulated respiration. It thus appears that dopamine and its agonists and antagonists have opposite effects on breathing responses of cat and rat, despite the similarities in morphology, innervation, neurotransmitter content, and presumed function of the carotid bodies of these different mammalian species.

2019 CYSTEINE UPTAKE IN CENTRAL NERVOUS SYSTEM: COMPARISON OF UPTAKE IN HOMOGENATE AND CRUDE SYNAPTOSOMAL PREPARATION OF DIFFERENT REGIONS OF THE BRAIN AND THE EFFECTS OF SOME INHIBITORS. C.H. Misra, R.C. Smith and J. Sammeta*

The nerve endings in the brain possess membrane transport mechanisms for the uptake of various substances. The compounds thought to act as transmitter characteristically are taken up by high affinity mechanism [(Logan, W.J. and Snyder, S.H., Nature, 234, 297 (1971)]. The accumulation of L-(^{35}S)-cysteine into synaptosomal preparation of rat cerebral cortex was carried out with the same high affinity uptake mechanisms. [Misra, C.H. and Smith, R.C., Society for Neuroscience. Abstract #1424, Vol 4, 448 (1978)]. The high affinity uptake system appears to be associated with a unique population of nerve terminals which can be separated from the other terminals that concentrate other synaptic transmitter. Therefore, we have examined a variety of amino acids, other putative transmitters, and drugs for their ability to inhibit the high affinity uptake of L-(^{35}S)-cysteine into crude synaptosomal preparation of rat cerebral cortex.

Twenty substances were tested as inhibitors of the uptake of L-(^{35}S)-cysteine in crude synaptosomal preparations (P_2) of rat cerebral cortex. Among cysteine analogous tested, only S-ethyl-L-cysteine had affinity for the uptake mechanism comparable to cysteine. L-(^{35}S)-cysteine uptake was also potentially inhibited by norepinephrine, dopamine, butaperazine, L-glutamic acid, L-aspartic acid, DL-Homocysteine and glutathione. L-(^{35}S)-cysteine uptake was examined in homogenate of cerebral cortex and other regions of the rat brain. The uptake of L-(^{35}S)-cysteine was also studied in the subcellular factions (P_1, P_2 and P_3) of the rat cerebral cortex homogenate. Accummulations of L-(^{35}S)-cysteine were in the order of crude synaptosomal fraction > nuclear fractions > microsomal fractions.

2020 GABA RECEPTOR BINDING IN BOVINE RETINA: EFFECT OF FREEZING TRITON X-100, and $NaClO_4$. Cheryl K. Mitchell* and Dianna A. Redburn. (SPON: E. Simon Sears). Department of Neurobiology and Anatomy. The University of Texas Medical School at Houston, Houston, Texas 77025.

Two different types of ^{3}H-GABA receptor binding assays were performed on retinal subcellular fractions. In one assay, fractions were pretreated by freeze-thawing, and exposure to Triton X-100 before incubation with ^{3}H-GABA and rapid centrifugation as described by Enna and Snyder (Brain Res. 115, 174-179, 1976). These pretreatments were reported to cause an apparent increase in GABA receptor binding in brain synaptosomal membranes: freezing (20°C, 24 hrs)=two fold increase; treatment with 0.05% Triton X-100=five fold increase. Two retinal synaptosomal fractions were assayed: the first was enriched in large photoreceptor cell terminals (the outer plexiform layer or the OPL fraction), and the second contained conventional sized terminals (the inner plexiform layer or IPL fraction). GABA receptors from both fractions showed similar Triton sensitivity as compared to brain, with maximal stimulation noted at 0.05% Triton concentration. However, unlike brain, freeze-thawing of the tissue prior to the assay had little affect on the apparent binding. In Triton treated material two binding sites were observed: a lower affinity site (K_D=330 nM) with the number of binding sites roughly equal in both fractions (10 pmoles/gm tissue), and a higher affinity site (K_D=38 nM) limited primarily to the OPL fraction.

In the second type of ^{3}H-GABA binding assay, $NaClO_4$ was included during the incubation period. Preliminary results indicate that, like Triton pretreatment, $NaClO_4$ increases the specific ^{3}H-GABA receptor binding in both IPL and OPL fractions. However, the two differences were noted: 1) the overall affinity of the GABA receptor sites is significantly lower than in Triton treated material, 2) more binding sites were observed in the IPL fractions after $NaClO_4$ treatment than with Triton treatment. Experiments to determine the pharmacological specificity of these sites are currently underway. (This study was supported by USPH Grant EYO 1655-03 and RCDA 1K04 EY 00088-02 to DAR.)

2021 β-ALANINE INHIBITION OF POTASSIUM INDUCED ^{3}H-γ-AMINOBUTYRIC ACID RELEASE FROM MOUSE CORTICAL SLICES. James V. O'Fallon and Joseph W. Harding. Dept. Vet. Microbiology/Pathology, Wash. State U., Pullman, Wa 99164.

Mouse cortical slices were preloaded with ^{3}H-γ-aminobutyric acid (GABA) and superfused with 115mM NaCl, 5mM KCl, 1.2mM $MgCl_2$, 1.2mM Na_2HPO_4, 5.0mM glucose, 10mM animooxyacetic acid (AOAA) and 40mM glycyglycine (pH 7.4). The introduction of 40mM KCl with 2.5mM $CaCl_2$ caused a release of ^{3}H-GABA which was 3-5 times higher than the spontaneous efflux rate. No significant release was seen in the absence of added $CaCl_2$. The release of ^{3}H-GABA was virtually eliminated by superfusion with 50μM β-alanine. β-Alanine added to the uptake medium alone had no effect on ^{3}H-GABA release. The introduction of 50μM 2,4-Diamino-n-butyric acid (DABA) had no effect on K^+-stimulated, Ca^{++} dependent release when introduced into both the uptake and superfusion mediums. 50μM glycine also had no effect whereas 50μM unlabeled GABA increased the spontaneous efflux rate of ^{3}H-GABA 3-4 fold but had no effect on K^+ induced release. In the absence of AOAA no K^+ induced release of ^{3}H-GABA was observed.

2022 BLOCKADE BY α-AMINOADIPATE OF THE NEUROTOXIC AND LH-RELEASING ACTIONS OF N-METHYL ASPARTATE. J.W. Olney, M.T. Price, T. Fuller, T. de Gubareff*, M. Anglim*, J. Labruyere* and V. Mitchell*. Washington University School of Medicine, St. Louis, MO 63110.

When administered subcutaneously (sc), the excitotoxic amino acids - glutamate (Glu), aspartate (Asp) and certain analogs - selectively penetrate a specific region of the endocrine hypothalamus, the arcuate nucleus (AH), and induce disturbances in neuroendocrine function. When neurotoxic doses are employed, AH neurons are destroyed and a permanent neuroendocrine deficiency syndrome results, which includes impaired reproductive capacity and reduced size of the gonads and accessory reproductive organs. Subtoxic doses induce reversible perturbations in endocrine functions, the most studied of which is a transient rise in serum luteinizing hormone (LH). Price et al. (Neuroendocrinol. 26, 352, 1978), who recently evaluated several of the more potent excitotoxins and found each to be effective in releasing luteinizing hormone (LH), considered N-methyl aspartate (NMA) the most promising for investigating the LH axis. When administered sc in nontoxic doses (15-40 mg/kg) to weanling or young adult male rats, NMA induces LH release by an action which is reversible, rapid of onset, brief in duration, and is dependent upon AH neurons, since rats bearing an excitotoxin-induced AH lesion do not respond to the LH-releasing action of NMA (Price, M.T., et al., Neurosci. Abstr., 1979).

We have proposed that both the AH neurotoxic and LH-releasing actions of NMA stem from excitatory interaction between NMA and synaptic receptors on the dendrosomal surfaces of AH neurons. NMA is thought to act primarily at "Asp-preferring" receptors and its excitatory action at such receptors is reportedly blocked specifically by the antagonist, α-aminoadipate (αAA). We will present evidence that αAA blocks both the LH-releasing and the AH neurotoxic activity of NMA, whereas GABA, a putative neuroinhibitory transmitter, blocks the LH-releasing but not the AH neurotoxic action of NMA. This suggests that αAA blocks NMA specifically at its AH excitatory receptor whereas GABA blocks at some other locus along this LH release pathway.

From these and other findings we are beginning to suspect that AH neurons are a major link in an LH release pathway that is driven by aspartergic excitatory input to synaptic receptors on the dendrosomal surfaces of AH neurons and is subject to GABAergic inhibition at some point between the AH neuronal perikaryon and median eminence storage terminals from which luteinizing hormone releasing hormone is secreted in response to aspartergic activation of the pathway. 2023 EVIDENCE FOR TWO-INTERCONVERTIBLE FORMS OF THE NICOTINIC ACETYLCHOLINE RECEPTOR FROM GOLDFISH BRAIN. Robert E. Oswald and John A. Freeman. Depts. of Biochem. and Anat., Vanderbilt Univ. Med. Sch., Nashville, TN 37232.

In the central nervous system of the goldfish, intracellularly recorded EPSP's elicited by the iontophoresis of ACh can be blocked by the application of α-bungarotoxin (α-Btx; J. A. Freeman, ARVO Abstracts, 1979), indicating that α-Btx is a useful probe for the nicotinic acetylcholine receptor (nAChR) in this system. We have previously reported some aspects of the kinetic and equilibrium analysis of ^{125}I-α-Btx binding to the goldfish nAChR as well as some of its molecular properties (R. E. Oswald and J. A. Freeman, J. Biol. Chem., 1979). In this report we present evidence for the presence and interconvertibility of two forms of ^{125}I-α-Btx binding sites.

Equilibrium binding studies using high specific activity ^{125}I-α-Btx (1 Ci/μmole) have demonstrated the presence of two distinct binding sites: A high affinity site with a K_D of 0.1 to 0.2 nM, and a low affinity site with a K_D of 6 to 10 nM. A Hill plot indicated the presence of apparent negative cooperativity, yielding a Hill coefficient of 0.89. Only one association rate constant was detectable; however, dissociation kinetics revealed the presence of two distinct components. When a 1000-fold excess of cold α-Btx was added to ^{125}I-α-Btx-nAChR complexes, approximately 20% of the sites dissociated with a half-time of 17 minutes and 80% with a half-time of 45 hours. The addition of d-tubocurarine (d-TC) and carbamylcholine produced the same dissociation kinetics as cold α-Btx when used in low concentrations (0.01 mM d-TC and 1 mM carbamylacholine). However, when high concentrations were used (0.05 to 1 mM d-TC and 25 to 100 mM carbamylcholine), the percentage of rapidly dissociating sites increased up to a maximum of 75% in a dose-dependent fashion without affecting the dissociation rate constant of either site. Because this effect occurs at concentrations of 10^4 to 10^5 fold higher than the K_I of each ligand (10^{-8} for d-TC and 10^{-6} for carbamylcholine), we believe that d-TC and carbamylcholine bind to an allosteric site which mediates a conformational change from a form of the nAChR having a high affinity for α-Btx to a form having low affinity for α-Btx. Thus, the goldfish brain seems to contain one type of α-Btx binding protein (the nAChR) with two interconvertible sites rather than two distinct binding proteins.

2024 GABA RECEPTORS: AUTORADIOGRAPHIC LOCALIZATION IN RAT CEREBELLUM. José M. Palacios*. W. Scott Young III and Michael J. Kuhar. Dept. of Pharmacol. The Johns Hopkins Univ. Sch. Med., Balto., Md. 21205

A new technique involving the in vitro labeling of mounted tissue sections has been used to localize GABA receptors at the light microscopic level. ^{3}H-muscimol (^{3}H-M) was incubated with mounted tissue sections and the binding kinetics of the drug had all of the characteristics associated with a GABA receptor. The binding was rapidly reversible (t1/2 at 2°C of 20 min), of a high affinity (Kd of 6-13 nM) and saturable(Bmax of about 200 fmol/mg tissue). The pharmacological specificity was also that of a GABA receptor. Specific ^{3}H-M binding was displaced by GABA (Ki about 10 mM), imidazole acetic acid (Ki about 100 nM) and (+) bicuculline (Ki about 10 μM). The binding was insensitive (-) bicuculline, picrotoxin and the GABA uptake inhibitor diaminobutyric acid. The specific to nonspecific binding was about 6:1.

Autoradiographic studies revealed a very high density of receptors over the granule cell layer, a low level over the molecular layer and negligible receptor binding over the white matter. These results were highly reproducible and found in several experiments. A similar distribution was observed in the cerebella of mice and guinea pigs. The results were same whether we used 1,5 or 30 nM concentrations of ^{3}H-M, and the same results were found when ^{3}H-GABA was used to label the receptors. While there were significant levels of receptors in all areas, these results suggest a high localization of GABA receptors to granule cells. This suggestion is confirmed by a variety of neurochemical studies in the literature and in press. For example, removal of granule cells by viral treatment or by utilization of mutant mice results in a 60-70% loss of GABA receptor binding in vitro. These results are compatible with the view that Golgi II cells as well as other cells are GABAergic.

High receptor densities were observed in many other regions of the rat brain as well. These include the substantia nigra zona reticulata, the dorsal lateral geniculate and parts of the dorsal horn of the spinal cord.

These autoradiographic studies can contribute to localizing elements of the GABAergic system in neuronal tissue. They are sensitive and provide light microscopic resolution. They could be valuable adjuncts to other histochemical methods for localizing GABA synthesizing enzymes and GABA uptake sites. These studies were supported by USPHS grants MH25951, MH00053.

2025 INVOLVEMENT OF CYCLIC AMP IN VOLTAGE-DEPENDENT CALCIUM CURRENT ELICITED BY SEROTONIN. T. C. Pellmar and D. O. Carpenter. Department Neurobiology, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

In neurons of the lower left quadrant of the abdominal ganglion in Aplysia californica, iontophoretic application of serotonin elicits an extremely slow, voltage-dependent calcium current (Pellmar and Carpenter, Nature 277:483, 1979). The transmitter-induced current, studied under voltage clamp conditions, has a time-to-peak of 10-30 sec and a duration of 1-4 min. The response is of maximum amplitude when the membrane potential is about +10 mV. At more depolarized and at more hyperpolarized membrane potentials, the amplitude is smaller. The transmitter-induced calcium current is not present at potentials more hyperpolarized than -40 mV.

In the abdominal ganglion of Aplysia, perfusion of serotonin produces an increase in cyclic AMP (cAMP) (Cedar and Schwartz, J. Gen. Physiol. 60:570, 1972). It has been proposed that serotonin mediates heterosynaptic facilitation by inducing a presynaptic calcium current through a cyclic nucleotide mechanism (Klein and Kandel, PNAS 75:3512, 1978; Shimahara and Tauc, J. Physiol. Paris 74:515, 1978). We tested the actions of cyclic nucleotides and phosphodiesterase inhibitors on this voltage-dependent calcium current. Perfusion of 10^{-5}M to 10^{-4}M cAMP or dibutyryl cAMP (dBcAMP) has little effect on the amplitude and duration of the voltage-dependent response to iontophoresis of serotonin. In some experiments, a slight and transient reduction in amplitude is observed. On occasion, cAMP and dBcAMP induce a transient inward current while the membrane potential is at a depolarized potential. Adenosine (10^{-5}M to 10^{-4}M) has similar effects, occasionally inducing an inward current and occasionally reducing the amplitude of the response to serotonin. The phosphodiesterase inhibitors isobutylmethylxanthine (IBMX) (1 mM), theophylline (2 mM), and RO 20-1724 (about 1 mM) all cause a reduction in the amplitude of the voltage-dependent calcium current elicited by serotonin. This action is reversible by washing with normal seawater.

Based on these preliminary data, it appears that cAMP does not mediate the action of serotonin to open calcium channels involved in the voltage-dependent response seen here. However, it is conceivable that the serotonin-activated conductances observed by others, including a presynaptic calcium conductance, may operate through a cAMP mechanism. The possibility that the cyclic nucleotides can modulate or directly induce a similar current cannot be excluded.

2026 TURNOVER OF BIOGENIC AMINES IN THE HYPOTHALAMUS OF RATS DURING PYROGEN FEVER. P. E. Penn+ and B. A. Williams*. NASA-Ames Research Center, Moffett Field, CA 94035

Many pharmacological studies have implicated the biogenic amines in the hypothalamus as playing a role in the production of fever, but few investigations of endogenous neurochemicals have been made during fever. Turnover rates of transmitters utilizing radioactive precursors may be one of the most accurate measurements of activity in brain regions. The present study was designed to measure the turnover of 5-hydroxytryptamine (5-HT), norepinephrine (NE) and dopamine (DA) in the hypothalamus of rats during pyrogen fever. Salmonella typhosa (Wyeth, 8 units) was previously found in our laboratory to produce a significant hyperthermia in most rats by 2.5 hours. This pyrogen (N=12) or saline control (N=8) was injected intraperitoneally and the rats killed 2.75 hours later. Rectal temperatures (Tr) were monitored continuously with thermocouples taped to the tail and recorded automatically every 3 minutes. Half of each group received an injection of radioactive precursors, ^{3}H-tryptophan (0.5 mCi) and ^{3}H-tyrosine (1.0 mCi), via an indwelling jugular catheter 60 minutes before killing, and the other half at 90 minutes. The rats were killed by near freezing in liquid nitrogen and the brains dissected in the cold. Turnover was measured by the method of Lane et al. (Life Sci 21, 1101, 1977). At the time of killing most of the pyrogen group showed a significant ($p<.02$) increase (mean ± s.e.m.) in Tr above pre injection levels (0.75 ± 0.13°C, N=10). The saline group showed no change (-0.025 ± 0.16, N=8), and the difference between groups was also significant. No significant differences were found in the levels of the amines between the pyrogen and saline groups. A significant difference was found in the specific activity of NE between the 60 minute pyrogen and saline groups (4.41 ± 0.41 vs 2.6 ± 0.51 dpm/pmole) but no change in ^{3}H turnover. This suggests an increased accumulation of ^{3}H-NE in the pyrogen group, but no change in utilization. An increased turnover of DA for the pyrogen group (44.5 vs 19.2 pmole/mg protein/hr) was found. However, DA is mainly a precursor in the hypothalamus and measurement was near the limit of sensitivity for the assay; these limitations must be considered in interpreting this data. The most significant finding was an increase in the turnover of 5-HT in the pyrogen group (41.3 vs 7.3 pmole/mg protein/hr), indicating a resynthetization rate of 77% of the total pool per hour. These results suggest that at the time point measured, an increase in the utilization of 5-HT in the hypothalamus is correlated with pyrogen fever. (+NRC Associate at NASA-Ames)

2027 AMINO ACID-DIRECTED ACCUMULATION OF CYCLIC NUCLEOTIDES IN RAT CEREBELLAR SLICES. M.A. Rea* and W.J. McBride (Spon: S.L. Morzorati). Depts. of Psych. & Biochem., Institute of Psychiatric Research, Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

Both the harmaline-induced increase in cerebellar climbing fiber activity and the intraventricular micro-injection of glutamate (Glu) cause 2.5 fold increases in rat cerebellar cyclic GMP content in vivo (Biggio and Guidotti, Brain Res. 107: 365, 1976). These findings have been presented as evidence in support of a role for Glu as the excitatory neurotransmitter released from climbing fibers. However, other data have been reported which suggest that aspartate (Asp) may be the climbing fiber transmitter (Nadi et al., J. Neurochem. 28: 661, 1977). Therefore, we undertook a study of the effects of Asp and Glu, as well as GABA and taurine (two suspected inhibitory transmitters) on the accumulation of cyclic GMP and cyclic AMP in rat cerebellar slices. Under the conditions employed in this study, which were adapted from those described by Schmidt et al. (Brain Res. 112: 113, 1976), the basal levels of cyclic GMP and cyclic AMP were 15.2 ± 0.5 and 20.2 ± 0.5 pmol/mg protein, respectively. Incubation of the slices for 15 min in the presence of either Asp or Glu (1 and 10 mM), or 55 mM K^+, resulted in a 2 to 2.5 fold increase in cyclic GMP content. Furthermore, the effects of both amino acids were potentiated by theophylline (1 mM) and dependent upon the presence of Ca^{++} in the medium, suggesting that both Glu and Asp stimulate cyclic GMP accumulation by a similar mechanism. Similarly, both Asp and Glu stimulated cyclic AMP accumulation. However, in this case, the increase caused by Glu (2 to 2.5 fold) was significantly greater ($p<0.05$) than that caused by Asp (1 to 2 fold). Furthermore, the Asp effect was blocked by theophylline and partially dependent upon the presence of Ca^{++} in the medium while the Glu effect was not, suggesting that the effect of these amino acids on cyclic AMP accumulation involve different mechanisms. Cyclic AMP levels were not altered by 55 mM K^+. GABA (10 mM) caused a 25% decrease in cerebellar cyclic AMP levels but had no effect on cyclic GMP levels. Taurine and alanine did not change cerebellar cyclic nucleotide levels at the concentrations used (1 and 10 mM). The finding that both Asp and Glu stimulate cyclic GMP levels by a similar mechanism and to approximately the same degree does not permit an interpretation which favors either amino acid as the climbing fiber neurotransmitter candidate. (Supported by NS 13925).

2028 SEROTONIN LOCALIZATION BY FLUORESCENT TECHNIQUES IN THE BRAINS OF NORMOTENSIVE AND HYPERTENSIVE RATS.
Richard Ross Rebert, James W. Ward*, and Stan Greenberg*.
Dept. Pharm., Coll. of Med. Univ. of South Alabama, Mobile, Al. 36688.

Brains of normotensive Wistar Kyoto (WKY) and spontaneously hypertensive rats (SHR) were treated according to the Falck-Hillarp method suggested by de la Torre (Dynamics of Brain Monoamines, Plenum, 1972) for histofluorescence of biogenic amines. The brains of these animals showed marked differences which depend on the degree of blood pressure change. WKY animals showed serotonin deposits in all cerebral areas of the brain not corresponding to those normally associated with serotonin deposition (i.e., the raphe system). The SHR animals showed a greater (2-3x) amount of serotonin in discrete granules spread throughout the brain. There is evidence of large amounts of serotonin in neurons and capillary endothelial cells of SHR rats. There are granule accumulations of serotonin which seem to be localized in glial cells. The majority of serotonin granules in the SHR animals, however, is within the neurons or the capillary endothelial cells. The disparity between the WKY and the SHR suggests that the brain tissues act in the hypertensive state as a storage area for serotonin, or there is an increased ability to take up serotonin. Parachlorophenylalanine (pCPA) does not seem to abolish the serotonin fluorescence in the brain to the extent that is has been reported in peripheral tissues. The presence of serotonin in discrete large granules within cells that in addition also fluoresce with norepinephrine suggests that the SHR animals may have cells capable of containing and storing both biogenic amines at the same time. Thus a cell which may have a designated function to release only one transmitter for action at specific receptor sites could possibly demonstrate a capability for release of "foreign" transmitters as well, whether the foreign transmitter possesses any action at postsynaptic sites remains a future question.

2029 INTERACTION OF GABANERGIC AND CHOLINERGIC SYSTEMS IN RABBIT RETINA. Dianna A. Redburn and Thyon Chentanez*. Department of Neurobiology and Anatomy, The University of Texas Medical School at Houston, Houston, Texas 77025.

Two synaptosome fractions were obtained from rabbit retina, one enriched in photoreceptor terminals (the outer plexiform layer, or OPL fraction), a second enriched in conventional sized terminals (the inner plexiform layer or IPL fraction). High affinity uptake sites for ^{3}H-GABA and ^{3}H-choline were highly enriched in the IPL fraction as compared to the OPL fraction. Uptake in both fractions was temperature and sodium dependent, and had similar affinities; however, the Vmax was four fold higher for ^{3}H-choline and three fold higher for ^{3}H-GABA in the IPL fraction. It is unlikely that the relatively minor GABAnergic and cholinergic components found in the IPL were associated with contaminating synaptosomes from the IPL fraction since these systems in OPL fractions displayed unique characteristics. Specifically, in OPL fractions, the ^{3}H-GABA uptake system was stimulated by addition of exogenous ACh. The stimulation was dose dependent and saturable at micromolar concentrations. Increases in endogenous levels of ACh by preincubation with choline or neostigmine also stimulated ^{3}H-GABA uptake specifically in OPL. The cholinergic stimulation was blocked by both nicotinic and muscarinic receptor blockers, however, nicotinic blockers were 10 times more potent as measured by IC_{50} concentrations. Nicotinic agonists, nicotine and DMPP mimicked the action of exodogenous and exogenous ACh. If the GABAnergic and cholinergic systems in the OPL are associated with photoreceptor elements then these data would be consistent with reports from other species which suggest that cholinergic cone terminals transmit directly to GABAnergic horizontal cell terminals within the cone triad. (The work was supported by USPH Grant EYO 1655-03 and RCDA IK04 00088-02 to DAR.)

2030 EFFECTS OF NEURONAL DELETIONS ON UPTAKE AND BINDING OF CEREBELLAR NEUROTRANSMITTER CANDIDATES. Brooks H. Rohde* and W.J. McBride, Depts. Psych. & Biochem., Inst. of Psych. Research, Indiana Univ. School of Medicine, Indianapolis, IN 46223.

Exposure of the cerebella to x-irradiation on a schedule from day 12 to 15 after birth (12-15X) causes a loss of late-forming granule cells while exposure to x-irradiation from day 4 to 15 (4-15X) causes the loss of granule, stellate, and basket cells. Injection of 3-acetylpyridine (3-AP) causes the loss of the climbing fiber input without apparently causing damage to other cellular elements in the cerebellum. The uptake of 1.0 µM (^{3}H)-glutamate (glu) and (^{3}H)aspartate (asp) was approximately 20% lower while the uptake of 1.0 µM (^{3}H)GABA and (^{3}H)taurine (tau) was unchanged in the crude synaptosomal fraction (P_2) isolated from the cerebella of 12-15X rats relative to control values. More detailed kinetic analysis of the uptake of (^{3}H)glu revealed that the K_m value was not changed but that the V_{max} value was 20% lower in the 12-15X rats relative to the control group. In the 4-15X group, decreases were seen in the P_2 uptake of 1.0 µM (^{3}H)glu (40%), (^{3}H)asp (30%) and (^{3}H)GABA (40%) relative to control values. Uptake of 1.0 µM (^{3}H)tau was not significantly different between the control and 4-15X groups. More detailed kinetic analysis of the uptake of (^{3}H)GABA revealed that the K_m value was not changed but that the V_{max} value was decreased by 40% in 4-15X rats relative to control values. The uptake of 1.0 µM (^{3}H)glu, (^{3}H)asp, (^{3}H)GABA and (^{3}H)tau into the P_2 fraction was not different for 3-AP injected animals relative to control values. Sodium-independent binding of 20 nM (^{3}H)GABA was reduced by 20% and binding of 20 nM (^{3}H)kainic acid was reduced by 29% in synaptic plasma membrane (SPM) preparations obtained from 12-15X group relative to control values. Sodium-independent binding of 1.0 nM (^{3}H)quinuclidinyl benzilate (QNB) was increased by 22% in 12-15X group while binding of 1.0 nM (^{3}H)dihydroalprenolol (DHA) was not different from control values. The data on uptake are consistent with the idea that glu may be the excitatory neurotransmitter released from the granule cells and that GABA may be the inhibitory transmitter released from the basket cells. However, on the basis of the uptake data, no conclusions may be drawn pertaining to the transmitter released by the climbing fibers. The decreased sodium-independent binding of (^{3}H)GABA and (^{3}H)kainate may indicate a loss of GABA and glutamate receptors in the granule cell deficient cerebella. Conversely, loss of granule cells does not appear to result in a decrease of either muscarinic or beta-adrenergic receptors. (Supported by NS 13925).

2031 SOMATOSTATIN AND SUBSTANCE P INHIBIT CATECHOLAMINE SECRETION FROM GUINEA PIG CHROMAFFIN CELLS. Lorna W. Role*, Robert L. Perlman*, and Susan E. Leeman, Department of Physiology, Harvard Medical School, Boston, MA 02115.

We have been studying the secretion of catecholamine from purified guinea pig chromaffin cells. The chromaffin cells are isolated by collagenase digestion of guinea pig adrenal glands, followed by isopycnic centrifugation through a 5%-25% (w/v) gradient of metrizamide. More than 90% of the cells in these preparations are viable chromaffin cells, as judged by fluorescence histochemistry and the exclusion of trypan blue. Purified chromaffin cells contain 400±50 nmol epinephrine (EPI)/mg protein (mean S.E.M., n=8). These cells accumulate [^{3}H]-l-norepinephrine (NE) by a high-affinity uptake system (apparent K_m=2µM). During a 10 min incubation at 37°C, the cells release 1%-3% of their stored EPI or their newly accumulated NE. Acetylcholine (ACh) causes a dose-dependent increase in the secretion of EPI and of NE; 100 µM ACh releases 10%-20% of the stored catecholamines from the cells. The peptides somatostatin and substance P inhibit the secretion of catecholamine from the chromaffin cells. In twelve experiments, somatostatin (10 µM) inhibited basal catecholamine release by up to 50%, and substance P (10 µM) inhibited basal release by up to 40%. These peptides also inhibit ACh-induced catecholamine secretion. Somatostatin (10-100 µM) inhibited catecholamine secretion produced by 100 µM ACh by about 55%. Half-maximal inhibition of ACh-induced catecholamine secretion was produced by 3 µM somatostatin. Substance P (10 µM) inhibited ACh-induced catecholamine secretion by about 40%. Chromaffin cells were extracted with 2M acetic acid. These extracts contain both immunoreactive somatostatin and immunoreactive substance P. The possible release of these peptides from the cells is being investigated.

2032 IRREVERSIBLE INHIBITION OF THE HIGH-AFFINITY CHOLINE CARRIER. B. Jane Rylett and E. Howard Colhoun*, Department of Pharmacology, University of Western Ontario, London, Ontario, Canada.

The high-affinity uptake of choline (HAUC) into cholinergic nerve endings would appear to be essential to, and the rate-limiting step in the synthesis of acetylcholine. A number of structural analogues of choline have been shown to compete with choline for this carrier, with some being incorporated into the nerve ending as false transmitters. The nitrogen mustard analogue of choline, choline mustard aziridinium ion (ChM Az), has affinity for this sodium-dependent high-affinity transport system causing inhibition of choline uptake into rat forebrain synaptosomes (Rylett and Colhoun, Can. J. Physiol. Pharm. 55, 769, 1977; Society for Neuroscience, 7th Meeting, abst. 1319, 1977). HAUC was found to be competitively inhibited in synaptosomes pre-incubated with ChM Az for 10 minutes at 37°C (controls at 0°C); the K_i value was calculated to be 2.63 µM. However, the inhibition produced by this compound increases progressively with time and shows an irreversible component insofar that inhibition of HAUC could not be reversed by washing the synaptosomes in inhibitor-free medium. Further evaluation of the kinetics of the inhibition of HAUC by the nitrogen mustard analogue revealed that when preincubation of synaptosomes with ChM Az was increased from 10 to 30 minutes before the measurement of HAUC the nature of the inhibition produced shifted from competitive to mixed competitive - noncompetitive type. This is indicative of a time-dependent decrease in the maximum velocity with which choline could be transported into the nerve terminals as well as an alteration in the apparent affinity with which the substrate choline binds to the carrier. A corresponding decrease in the K_i value was observed at the longer incubation time thus supporting the idea of a time-dependent development of an irreversible blockade of the high-affinity choline carriers. Analysis of the kinetics of the inhibition of HAUC into synaptosomes by ChM Az and the apparent irreversible binding of this nitrogen mustard analogue to the high-affinity choline carrier seems to provide an explanation for the mechanism of action of this compound at the presynaptic ending as well as important information about HAUC. Thus, the shift in the type of inhibition produced by ChM Az with increasing time could be indicative of an excess of carrier sites on the presynaptic membrane over those which are contributing to the control V_{max} measured. Inactivation of carrier sites by alkylation beyond a critical level could cause an initially competitive substrate to show a noncompetitive type of kinetics since sufficient carriers may no longer be functional to transport choline at the V_{max} rate.

2033 IMPORTANCE OF THE CHOLINERGIC PATWAYS OF THE SEPTAL AREA AND THE SUBFORNICAL ORGAN IN THE REGULATION OF THE SODIUM AND POTASSIUM RENAL EXCRETION. Wilson Abrão Saad, José V.Menani*, Luiz A.A.Camargo*, José Antunes-Rodrigues* and Miguel R.Covian*. Dept. Fisiol. and Patol. Sch. Dent. - UNESP - Araraquara - 14.800 - SP. Brasil

Evidence has been presented indicating that cholinergic stimulation of the hypothalamus and septal area play an important part in the regulation of sodium and potassium in the urine (Silva-Netto, C.R. et.al. J. Physiol. 72:917,1976 and Saad, W.A. et.al. Pharmacol. Biochem.Behav. 3:985,1975). Recent investigations have shown the importance of the subfornical organ in the control mediation of renal sodium and potassium excretion. (Saad, W.A.et.al. Cienc.Cult. 30:487,1978). The present report was undertaken to provide an analysis of the degree of intensity of participation in the septal area and the subfornical organ in this control. Male Holtzman rats weighing 250-320grams were used in these experiments. All animals had cannulae stereotoxically implanted in the septal area or in the subfornical organ. Carbachol was injected into these areas. The urine was collected over a period of 120 minutes and the concentration of Na^+ was determined by flame fotometry. The results are shown below.

	Carbachol (ug)						
	0.01	0.02	0.1	0.2	0.5		
Na^+	37.4	91.4	191.4	264.0	350.0	-	AS
(uEq/120')	61.4	120.2	286.9	563.7	820.9	-	OSF
K^+	55.4	83.6	88.0	135.0	133.2	-	AS
(uEq/120')	85.4	109.1	145.5	217.7	222.9	-	OSF

In conclusion, our findings show that the subfornical organ is more sensitive than the septal area in inducing renal eletrolites excretion. Further research is under way in our laboratory with the object of studing the interaction between, hypothalamus, septal area, and, subfornical organ in this regulation.

2034 REGIONAL HIGH-AFFINITY ^{3}H-CHOLINE ACCUMULATION IN CAT FOREBRAIN: SELECTIVE INCREASE IN THE CAUDATE-PUTAMEN AFTER CORTICOSTEROID PRE-TREATMENT. A. Sastre, D.K. Riker, T. Baker, R.H. Roth and W.F. Riker, Jr. Dept. Physiology, Johns Hopkins U. Sch. Med., Baltimore, MD 21205; Depts. Pharmacology, Cornell U. Med. College, N.Y., NY 10021, and Yale U. Sch. Med. New Haven, CT 06510.

The effect of acute and chronic gluco- and mineralocorticoid treatment on high-affinity ^{3}H-choline accumulation (HACA) was investigated in cat brain synaptosomes. HACA in forebrain synaptosomes was found to be Na^+- and energy-dependent, hemicholinium-3 sensitive ($K_i \approx 2.5 \times 10^{-9}$ M), and of high-affinity (K_T = 0.43 - 0.63 µM). The rank order of regional HACA at 0.04 µM choline (4 min at 37°C) was: caudate-putamen > anterior perforated space (incl. olfactory tubercule, n. accumbens and islands of Calleja) > hippocampus-fornix > prefrontal neocortex. HACA in caudate-putamen synaptosomes was significantly elevated 37 - 75% after daily treatment for one week with either triamcinolone diacetate (8 mg/kg), hydrocortisone acetate (4 or 32 mg/kg), or deoxycorticosterone (32 mg/kg), but not with 11α-epicortisol (8 mg/kg), a biologically inert epimer of hydrocortisone. Treatment-induced increases in caudate-putamen HACA were attributable to an increase (45 - 53%) in the maximum transport velocity (V_{max}) and not in the apparent transport constant (K_T), as determined by Eadie-Hofstee and double-reciprocal analyses.

Significant increases in HACA were not seen in the hippocampus-fornix, anterior perforated space or prefrontal cortex. Acute treatment of cats with a single intravenous dose of methylprednisolone sodium succinate (90 mg/kg) produced 75 - 83% increases in HACA in caudate putamen and hippocampus-fornix three hours after treatment. At 24 hours HACA was increased (70 and 76%) in the caudate-putamen and anterior perforated space. Increases in HACA found in the caudate-putamen after in vivo treatment could not be produced by in vitro addition of steroids or alterations of the Na^+/K^+ environment. We conclude that the velocity of high-affinity transport of choline into cat brain synaptosomes is strongly and selectively increased in the caudate-putamen after acute or chronic gluco- or mineralocorticoid treatment. The possible explanations for this selectivity will be discussed with reference to neurochemistry and neuropharmacology of the caudate-putamen. Supported by NINCDS grant NS-01447 to W.F.R., Jr. and post-doctoral research fellowships NS-00832 to A.S. and NS-05406 to D.K.R.

2035 EPINEPHRINE IN THE BRAIN OF PRIMATES AND RATS: EFFECT OF STRESS. A. Sauter*, K. Ueta*, T. Asano*, J. Pearson and M. Goldstein. Departments of Psychiatry and Pathology, New York University Medical Center, 550 First Avenue, New York, New York 10016.

Using high pressure liquid chromatography we have measured epinephrine (E) levels in the African green monkey and in the rat. In both species relatively high E levels were found in the C_1 and C_2 regions of the medulla oblongata and in the hypothalamus (especially ventromedial areas which include mamillary bodies, suprachiasmatic N., median eminence, lateral N.). In the monkey relatively high levels of E were also found in the thalamus (anterior N.) and in the epithalamus (habenula), while smaller levels were found in the substantia nigra and in the inner segment of the globus pallidus.

A similar regional distribution of E was observed in two human post-mortem brains. Thus, the distribution of E in human and non-human primate brain is wider than that in the rat.

To determine whether brain E participates in regulating some responses to stress we have studied the effects of immobilization stress in rats on central E and norepinephrine (NE) levels. Exposure of rats to stress results in a significant decrease of E and NE levels in the hypothalamus and in the C_1 and C_2 regions of the medulla oblongata. Stress produces a greater % decrease of E levels than of NE levels. These results suggest that E neurons are involved to a greater extent than NE neurons in some responses to stress or that the synthesis rate of brain E is slower than that of NE.

2036 ELECTROPHYSIOLOGICAL AND PHARMACOLOGICAL CHARACTERISTICS OF SEROTONIN RECEPTORS ON A NEURONAL SOMATIC CELL HYBRID. William G. Shain and Joseph E. Freschi* (SPON: A. Kobrine). Neurobiol. Dept., Armed Forces Radiobiol. Res. Inst., Bethesda, MD 20014.

The electrophysiology and pharmacology of serotonin (5-HT) responses on a cell line (TCX11) derived from the fusion of mouse neuroblastoma cells (N18TG2) with mouse sympathetic ganglion cells (Greene, L. et al Proc. Nat. Acad. Sci. USA 72: 4923, 1975) were studied. Dopamine (DA) and 5-HT elicit depolarizing, conductance increase responses in these cells (Myers, P.R., J. Cell. Physiol. 91: 103, 1977). The purpose of this study was to characterize the 5-HT response and compare the properties of the 5-HT and DA responses to determine if they are mediated through different receptors. Iontophoresis of 5-HT caused a rapid depolarization of the hybrid cell membrane potential associated with an increase in membrane conductance (Gm). The response rapidly desensitized with repeated pulses of 5-HT. These same results were obtained when DA was iontophoresed, but the cells were 10 to 100 times more sensitive to 5-HT than to DA. When equal pulses were used, the responses to 5-HT and DA appeared mediated by different receptors when examined for reversal potentials, cross desensitization, and antagonist specificity. However, when the iontophoretic pulses were adjusted to give responses of similar amplitude, different results were obtained. DA and 5-HT cross-desensitized. Reversal potentials determined for both DA and 5-HT on the same cell were equal and varied from 0 to +15 mV. Perfusion of the cells with low-sodium medium reduced the 5-HT and DA responses and shifted the reversal potentials in a similar manner. Possible antagonists were bath applied in concentrations of 10 to 100 uM. No drug has been found that blocks one response and not the other. The following drugs blocked both responses: (+)-tubocurarine, chlorpromazine, bulbocapnine, phentolamine, metergoline, bromo-LSD methiothepin, cyproheptadine, cinnanserin, and mersalate. Phentolamine, bromo-LSD, and cyproheptadine, applied by blunt micropipette, caused a depolarization and increase in Gm. The absence of this effect during bath application was presumably due to rapid desensitization. Since the drugs that were only bath applied may have had similar agonist effect, we have not characterized the nature of the blockade mediated by any of these drugs. Pharmacology will be reexamined by establishing dose-response curves of DA and 5-HT in the presence of varying concentrations of test drugs. In addition, the effects on membrane potential and conductance will be assessed by applying the test drugs by micropipette. The 5-HT response of TCX11 appears similar to that on a number of autonomic neurons (e.g., Wallis, D. J. and North, R.A. Neuropharm. 17: 1023, 1978) and on several neuroblastoma clones and neuroblastoma x glioma hybrids (MacDermot, J. et al. Proc. Natl. Acad. Sci. USA 76: 1135, 1979). It is impossible to know how similar the 5-HT receptors are on these various preparations until more detailed pharmacology is performed on all of them.

2037 MICROIONTOPHORETIC STUDIES WITH L-DOPA AND SOME PUTATIVE NEUROTRANSMITTERS ON THE NEURONS OF CAUDATE NUCLEUS OF RAT. J. N. Sharma* and Stanley Fahn (SPON: A.S. Perumal) Department of Neurology, College of Physicians and Surgeons, Columbia University, New York, New York 10032

To investigate the mechanisms of action of L-dopa in Parkinson's disease the effects of microiontophoretic application of L-dopa and its metabolites and dopamine (DA) were studied on spontaneously firing and on glutamate-induced excitatory responses of caudate nucleus (CN) neurons. It was observed that while DA had only inhibitory effect and blocked the glutamate excitatory responses, L-dopa at lower dosage potentiated, whereas at higher dosage blocked the glutamate responses. The interaction between two metabolites of L-dopa, i.e. 3-O-methyldopa and 4-O-methyldopa on glutamate excitatory responses was also studied. Like L-dopa, 3-O-methyldopa, though at lower dosage potentiated the glutamate responses, at higher dosage failed to modify the same. The other metabolite, 4-O-methyldopa, did not have any effect on glutamate responses. On the other hand 3-O-methyldopamine and 4-O-methyldopamine had only blocking effect on the glutamate excitatory responses. The results suggest that L-dopa does not only act by being converted to DA at nigrostriatal nerve terminals, but may also be having its own pharmacological effects one of which may be modification of glutamate responses which has been suggested to be an excitatory neurotransmitter at the cortico-caudate nerve terminals. It is possible that the present observation may be related to the "on-off" phenomenon of patients on chronic L-dopa therapy for Parkinson's disease. Furthermore, the metabolites of DA though less potent also appear to have significant and predominantly inhibitory role in the functioning of CN. It is postulated that the CN neurons have excitatory and inhibitory modulations by cortico-caudate and nigro-striatal neuronal pathways which are glutaminergic and dopaminergic in nature.

2038 IMMUNOCHEMICAL STUDIES OF ANTI-CATFISH GAD IgG. Y. Y. Thomas Su*, Jang-Yen Wu and Dominic M. K. Lam*. (Spon: D. D. Louie) Baylor College of Medicine, Houston, TX 77030

L-Glutamic acid decarboxylase from catfish brain has been purified to homogeneity by the combination of ammonium sulfate fractionation, gel filtration, calcium phosphate gel and preparative polyacrylamide gel electrophoresis. The purity of the enzyme was established by showing that in several gel electrophoresis systems the enzyme migrated as a single band which contained all the enzyme activity. The antibody against purified enzyme was obtained from rabbit after injection of 80 µg of the enzyme. Double immunodiffusion test using this antibody against crude extract showed a sharp precipitin band. The precipitin band from this study showed enzyme activity. The inhibition of the enzyme by antibody was studied. About 65% of the enzyme was inactivated after 4 days incubation of 12 µg of enzyme with 19.2 µg of antiserum. The inhibition of the same amount of the enzyme by 1.64 µg to 19.2 µg of antiserum increased from about 2% to 65% after 4 days of incubation. The enzyme activity presented in precipitate,however, increased to about 80% of the total enzyme activity remained in the reaction mixture. Microcomplement fixation of the antibody and the enzymes from different species were also studied.

Supported in part by the Retina Research Foundation(Houston), NIH grants EY 02423 and NS 13224 and a grant from Huntington's Chorea Foundation in memory of Mrs. Ruth Berman.

2039 NOVEL GABA RECEPTORS REVEALED ON CULTURED NEURONS. M.K. Ticku, J.L. Barker, J.F. MacDonald and A. Huang*. Dept. of Pharmacology, University of Texas Health Center, San Antonio, Texas; Lab. of Neurophysiology, NINCDS, NIH, Bethesda, Md. 20205.

Neuroblastoma-glioma hybrid cells (108CC15) respond to iontophoretically applied GABA with a rapidly depolarizing, rapidly desensitizing excitatory response which is insensitive to conventional GABA antagonists. To test for the presence of GABA receptors on these cells we measured GABA binding to these cells using centrifugation assays. Binding was measured under Na^+-free conditions, after freeze-thawing and extensive washing of the particulate fraction of homogenates of the hybrid. Specific binding, determined as the difference in the amount bound in the absence and presence of 100 M GABA, represented 80% of the total binding. GABA binding was rapid, reaching equilibrium within five minutes. Binding was saturable and Scatchard analysis revealed the presence of two classes of binding site. The high affinity site had a Kd of 10 nM and binding capacity of 200 fmoles/mg protein, while the low affinity site had a Kd of 63 nM and binding capacity of 500 fmoles/mg protein. Tritated GABA binding was displaced by agonists like GABA, muscimol, isoguvacine and THIP, but very poorly by (+) bicuculline and not by picrotoxin or GABA uptake blockers like nipecotic acid.

The agonist specificity suggests the presence of post-synaptic GABA-like receptors on this clone line. The inability of conventional GABA antagonists to block pharmacologic responses or to displace specifically bound GABA suggest that there may exist a subpopulation of GABA receptors coupled to membrane conductances that are functionally excitatory.

2040 CYCLIC AMP ACCUMULATION IN INTACT CELLS: FACTORS DETERMINING THE DOSE-RESPONSE CURVE FOR AGONISTS. Giancarlo Tonon* and G. Alan Robison. Dept. of Pharmacology, U. of Texas Med. School, Houston, TX 77025.

The accumulation of cyclic AMP (cAMP) in cultured BHK cells in response to β-adrenergic agonists is being studied as a model system for the study of neurotransmitter action in general. Using the adenine prelabeling technique, the following points have been established.

1. In the presence of methylisobutylxanthine (MIX), the level of cyclic AMP rises rapidly in response to epinephrine (EPI) or isoproterenol (ISO), reaching a peak at the same time regardless of the concentration of agonist, during which time the cells become tachyphylactic.

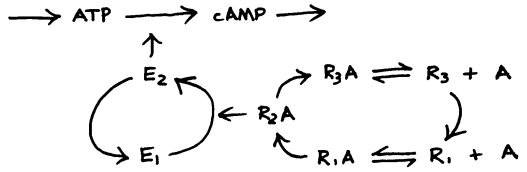
2. Increasing MIX from 0 to 2.0 mM inhibits both PDE and the rate of efflux, and predictably shifts the peak response to the right.

3. The dose-response curve depends not only on the number of agonist molecules per cell and the volume in which these molecules are dispersed, but also in an important way on when the response is measured. At higher agonist concentrations the relationship between dose and response is actually reversed when the response is measured at later times, i.e., the dose-response curve is bell-shaped.

4. The equilibrium binding curve for agonists is shifted several orders of magnitude to the right of the dose-response curve, even though there is no evidence in these cells for the existence of spare receptors.

5. There is a 15 to 30 second lag between the time a supramaximal concentration of propranolol is added and the time the effect can be observed, when the antagonist is added after the agonist.

These and other observations can be understood in terms of a recently developed model (Federation Proc. 38: 532, 1979), the general features of which are shown below.



The general features of this model should be applicable to neuronal and glial cells as well as to fibroblasts, and may be applicable to responses other than the accumulation of cyclic AMP resulting from the activation of adenylyl cyclase.

2041 HISTAMINE: RECEPTORS AND NEURONAL DISTRIBUTION IN MAMALIAN CENTRAL NERVOUS SYSTEM. Vinh T. Tran, Raymond S.L. Chang and Solomon H. Snyder, Dept. Pharmacol., Sch. Med., Johns Hopkins Univ., Baltimore, MD 21205

Histamine H_1-receptors have been successfully labeled in mammalian CNS with [^{3}H]mepyramine (Tran et al., PNAS 75, 6290, 1979). The ability to label the receptor biochemically allows us to study the potential sites of action of histamine. The receptors have wide spread distribution in mammalian peripheral organs. For examples, there are abundant histamine receptor sites in the bronchial tubing and the adrenal medulla. Histamine is a potent mediator of bronchial constriction and releases epinephrine from the adrenal medualla. We have found an heterogeneity of histamine H_1-receptors. Drug specificities differ significantly at H_1-receptors in varying organs and different animal species. Regional variations of H_1-receptors differ in several species and correlate poorly with endogenous histamine levels. To visualize histamine neurons we have purified histidine decarboxylase to apparent homogeneity, and inoculated rabbits and guinea pigs for antibody preparation and immunohistochemical studies. (Supported by USPHS grants MH-18501 and DA-00266 as grants of The John A. Hartford and McKnight Foundations).

2042 DRUG-INDUCED ALTERATIONS IN PLASMA CONCENTRATIONS OF DOPAMINE AND ITS METABOLITES. Glen R. Van Loon, Nathan Appel* Chul Kim* and Doris Ho*. Department of Medicine and Physiology, University of Toronto, Toronto, Ontario, Canada.

The source and significance of dopamine (DA) in plasma remain unknown. Furthermore, the sources of circulating dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA), the major metabolites of DA, are also unknown. Although circulating DA and its metabolites may come from peripheral nerve endings, it has been suggested that experimentally-induced alterations in brain DA metabolism may be parallelled by similar changes in plasma concentrations of DA and HVA. In order to investigate this problem further, we examined in 8 fasted (18 hrs.) male dogs the plasma DA, DOPAC and HVA responses to several drugs known to alter DA metabolism. An indwelling cannula for drug administration and blood withdrawal was inserted in a forelimb vein 90 min. prior to drug administration. After each sampling (7 x 3 ml over 3 hrs.), blood was replaced by an equal volume of saline. The dogs lay quietly throughout the experiments. DA was assayed by a radioenzymatic method and DOPAC and HVA by a gas chromatographic method. Basal concentrations of plasma DA, DOPAC and HVA in dogs are 36 ± 2 pg/ml, 9.6 ± 0.6 ng/ml and 9.0 ± 0.5 ng/ml respectively. The following table summarizes the plasma DA, DOPAC and HVA responses to administration of drugs thought to alter transmission in DA neurons. The drugs examined included haloperidol, a DA receptor antagonist; pimozide, another putative DA receptor antagonist, administered in a much smaller dose but which blocked the emetic effect of bromocriptine; bromocriptine, a putative DA receptor agonist.

Drug and Dosage (mg/kg)	DA	DOPAC	HVA
Haloperidol (0.5)	NC	NC	↑
Pimozide (0.025)	NC	↓	NC
Bromocriptine (0.015, then 0.03)	↓	↓	↑then↓
Pimozide (0.025) after bromocriptine (0.015)	NC	↓	↓
Bromocriptine (0.015) after pimozide (0.025)	NC	↑	NC

NC = No change ↑ = Increase ↓ = Decrease

These data are consistent with actions of pimozide and bromocriptine as mixed agonist-antagonists at DA receptors. Clearly, plasma measurements of DA, DOPAC and HVA may be used to monitor the effects of such drugs on DA metabolism. However, precise sites and mechanisms of action of these drugs in altering plasma DA, DOPAC and HVA remain undefined.

(Supported by grants MA-5183 and MA-7000 from MRC of Canada)

2043 DEVELOPMENT OF GABAnergic FUNCTION IN HIPPOCAMPAL CELL CULTURES. Charles R. Walker* and John H. Peacock (SPON: K. A. Kelts). Dept. of Neurology, Stanford Univ. Med. Sch., Stanford, CA 94305.

Inhibitory synaptic function is mediated by γ-aminobutyric acid (GABA) in the intact hippocampus. Similarly, it is very likely that GABA mediates the abundant inhibitory synaptic activity recorded in hippocampal cell cultures. Thus we have undertaken to determine when GABAnergic function occurs in mouse hippocampal cultures and to examine that function during the first 2 weeks in culture (equivalent postnatal animal age, 2-14 days).

Intracellularly recorded responses to GABA iontophoresis (0.5-1 M, pH 5) occur as early as 2 days after plating and most cells respond to GABA between days 6-14. Although responses can be elicited from distal processes, the response amplitude from processes is smaller than that recorded from the soma and proximal primary trunks. In older cultures, GABA application to the soma has been found to reversibly silence ongoing spontaneous activity.

Rapid desensitization to GABA occurs in some neurons and can mask the true magnitude of the response which ranges between 20-300 mV per nanocoulomb at a membrane potential hyperpolarized to about -100 mV. Desensitization occurred in 19/33 cells when tested with long GABA currents maintained for seconds to minutes.

GABA responses are usually positive at resting potentials of -70 mV but occasionally negative responses occur. Reversal potentials to GABA can be demonstrated with both pulse and steady iontophoresis at membrane potentials between -30 to -55 mV. During steady GABA application, membrane conductance to test electrical pulses increases 50-60% over a -20 to -100 mV membrane potential range.

The hippocampal cultures have Na^+ dependent ^{3}H-GABA uptake that is neuronally specific as shown by autoradiography and by use of the inhibitors DABA and β-alanine. The presence of Na^+ independent ligand binding has been found in culture with intact cells using both ^{3}H-GABA and ^{3}H-muscimol. The K_D for muscimol binding is approximately 2 nM but the kinetics for ^{3}H-GABA have been difficult to determine because of rapid dissociation of GABA from the receptor.

In sum, GABA receptors are present and functional at early times in culture. The diversity of GABA responses in terms of geographical distribution, polarity, and desensitization may reflect differences in cell type or differentiated function in these young cultures and pose questions for further study. (Supported by NIH grants NS 12151 and NS 07012).

2044 GABA INDUCED POTENTIATION OF NOREPINEPHRINE-STIMULATED CYCLIC GMP ACCUMULATION IN RAT PINEAL GLANDS. Robert A. Waniewski and Amin Suria. Dept. of Pharmacology, George Washington Univ. Medical Center, Washington, D.C. 20037.

Endogenous levels of GABA in the rat pineal gland are about 2 x 10^{-5}M and can be elevated to 4 x 10^{-4}M by inhibition of GABA-transaminase with amino-oxy acetic acid. Autoradiographic localization and uptake studies have demonstrated that GABA is found entirely within glial cells in the rat pineal gland. To determine the functional role of GABA in this tissue, the effect of GABA on pineal cyclic nucleotides was examined. Adenylate cyclase (AC) activity was measured in pineal gland homogenates. GABA at 10^{-4} M had no effect on basal or isoproterenol (2 x 10^{-5} M) stimulated AC activity. Rat pineal glands were made supersensitive by bilateral superior cervical ganglionectomy. Basal and isoproterenol-stimulated AC activity was measured in the pineals from these rats after 4 weeks. Again, GABA had no effect on AC activity in these supersensitive pineals.

Cyclic AMP and cyclic GMP levels were measured in intact pineals incubated in Kreb's bicarbonate buffer containing a phosphodiesterase inhibitor, isobutyl methylxanthine (IBMX) for 30 minutes. GABA from 10^{-6} to 10^{-3} had no effect on cyclic GMP levels. Similarly, no change in cyclic AMP levels after 10^{-4} M GABA was observed. However, GABA potentiated the increase in cyclic GMP produced by 10^{-5}M norepinephrine (NE) in a dose-related fashion between 10^{-6} and 10^{-4}M. At 10^{-4} M, GABA significantly increased cyclic GMP levels from 170.1 ± 55.8 picomoles /mg protein with NE alone to 477.0 ± 126.4 picomoles/mg protein in the presence of 10^{-5}NE. GABA produced no effect on NE-stimulated cyclic AMP levels in these same pineals. The potentiation of NE-induced accumulation of cyclic GMP by GABA was also dependent upon the concentration of NE used. GABA evoked a potentiation of cyclic GMP accumulation only in the presence of NE concentrations producing submaximal stimulation (2 x 10^{-6} and 10^{-5}M). These results suggest that endogenous levels of GABA in the pineal gland, presumably of glial origin, may enhance the increase in cyclic GMP elicited by NE. Thus, GABA possibly may play a role in the regulation of NE release from the sympathetic nerve terminals in the rat pineal gland. Interestingly, ascorbic acid (1%) prevented the rise in cyclic GMP produced by 10^{-5} NE. (Supported by NIMH grant #MH 30024-03)

2045 INHIBITION OF [^{3}H]-SPIROPERIDOL BINDING TO RAT STRIATAL MEMBRANES BY S-(+)-APOMORPHINE - COMPARISON WITH R-(-)-APOMORPHINE, (+)-BUTACLAMOL, AND (-)-BUTACLAMOL. R.E. Wilcox, M.E. Goldman*, J.A. Anderson*, P.J. Davis*, S. Seyhan*, R.V. Smith*, and W.H. Riffee* College of Pharmacy, University of Texas, Austin, TX 78712

R-(-)-Apomorphine (-APO) is the focus of much current interest because of its potential use in ameloriating the symptoms of tardive dyskinesia, Huntington's disease, Gilles de la Tourette's syndrome, and schizophrenia as well as its documented value in the treatment of Parkinsonism. These effects appear to be associated with the specific binding of -APO to dopamine receptors of the central nervous system.

Recently, we have prepared S-(+)-apomorphine (+APO), verified to be both > 99% enantiomerically pure and 99% chemically pure (Davis et al., submitted) and have now determined its percent inhibition (IC_{50}) of specific [^{3}H]-spiroperidol ([^{3}H]-SPIRO) binding to rat striatal membranes using the basic procedure of Creese (Creese et al., 1977). IC_{50} values were also established in the same tissue for inhibition of 0.15 nM [^{3}H]-SPIRO by -APO, (+)-butaclamol (+BUT), and (-)-butaclamol (-BUT) as controls since these have been documented in the literature (cf. Fields et al., 1977). In accord with the literature, IC_{50} values were determined to be 10^{-6}M for -APO, 10^{-9}M for +BUT, and 10^{-5}M for -BUT. The IC_{50} value for +APO was found to be 10^{-6}M, suggesting that +APO and -APO are equipotent in inhibiting [^{3}H]-SPIRO binding. Relative potencies of +APO vs. -APO are being further explored via inhibition of [^{3}H]-APO binding and by behavioral studies to account for this apparent lack of stereoselectivity. [Supported by grants NS-06114 (REW) and NS-12259 (RVS) from the National Institute of Neurological and Communicative Disorders and Stroke.]

2046 EFFECTS OF LITHIUM ON EXCITATORY RESPONSES TO SEROTONIN AND DOPAMINE IN APLYSIA. A. M. Williamson*, T. C. Pellmar, and D. O. Carpenter. Neurobiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Aplysia californica neurons can exhibit similar ionic conductance increases to several neurotransmitters. That has led to the suggestion that there are common ionophores for each class of ionic response (Swann and Carpenter, Nature 236: 751, 1973). If the ionophores mediating the fast sodium conductance increases in response to serotonin and dopamine are identical, then these ionophores should respond similarly to sodium substitutes. Since a different ionophore probably underlies the slow sodium conductance increase to serotonin, A' response of Gerschenfeld and Paupardin-Tritsch (J. Physiol. 243: 427, 1974), sodium substitutes might act differently on this response.

We tested the effects of substituting for 50% and 100% of the sodium in artificial seawater with lithium (Li-seawater) on the excitatory responses to iontophoretically applied serotonin and dopamine. Preliminary results suggest that the slow excitatory response to serotonin is reduced in amplitude and prolonged by 50% Li-seawater. There is a further reduction of amplitude in 100% Li-seawater, but the response was not completely abolished. The reduction in amplitude was partially reversible. The fast conductance increases due to serotonin and dopamine were also reduced in amplitude at both lithium concentrations. Those responses were not prolonged by lithium. Normal seawater partially reversed the reduction in amplitude of the responses to both neurotransmitters.

The observation that lithium affects the fast excitatory responses to dopamine and serotonin in a similar manner supports the hypothesis that they are mediated by the same ionophore. Since lithium acts differently on the slow excitatory response to serotonin, a different ionophore may be involved.

2047 RESPONSES OF MORPHOLOGICALLY IDENTIFIED MAMMALIAN, NEOCORTICAL NEURONS TO ACETYLCHOLINE (ACh), ACECLIDINE (ACec), AND CYCLIC GMP (cGMP). C. Woody, H. Sakai*, B. Swartz*, M. Sakai* and E. Gruen*. Departments of Anatomy & Psychiatry, Brain Research Institute, Mental Retardation Research Center, UCLA Med. Center, Los Angeles, CA 90024.

Effects of extracellular application of ACh (2M, 40-400nA, 30 sec), and ACec (1M, 40-50nA, 30 sec) and intracellular application of cGMP (5μm-5mM, 60-80 psi, 0.5-2 sec) were studied in a total of 34 units recorded from the coronal-pericruciate cortex in 26 cats. Unit activity and input resistance were evaluated for periods from 30 sec to 22 min after drug application (for technical details, see Woody et al. Br. Res. 158: 373-395, 1978). 4% HRP was injected intracellularly, coincidental with application of cGMP and at the conclusion of the experiments in which ACh and ACec were applied. (See Sakai et al. Exp. Neurol. 58: 138-144, 1978).

Of 9 cells given ACh or ACec, 6 showed increases in resistance and 3 did not. Of 22 cells given cGMP, 12 showed increases in resistance and 10 did not. Of 3 cells given ACh or ACec and cGMP, 1 showed increases in resistance to both agents and 2 showed no response to either agent. 11 cells responding to ACh, ACec, or cGMP with an increased resistance were identified morphologically as pyramidal shaped cells in layers V (n=6) and VI (n=5). Two additional responsive cells had dendrites in layer V and were antidromically activated by PT stimulation. The other responsive cells had only dendrites stained by HRP. The magnitude of increase in resistance in the responsive cells averaged more than twice their initial mean input resistance. The resting potentials of all cells averaged 45 mV. Their action potentials averaged 36 mV. These and initial values of input resistance did not differ significantly between responsive and unresponsive cells.

Results of further studies in which HRP alone or HRP plus 0.1mM cyclic AMP were injected indicate that the increases in resistance described above were not attributable to mechanical effects of pressure injection. Earlier studies of iontophoretic application of ACh, cGMP and 5' GMP indicate that the effects are attributable to the pharmacologic action of these agents when applied to cells of the mammalian sensorimotor cortex. (Supp. by HD 05958 and AFOSR 76-3074.)

2048 BICUCULLINE DISPLACES ^{3}H-MUSCIMOL AND NA-INDEPENDENT ^{3}H-GABA BINDING IN CULTURED MAMMALIAN SPINAL CORD AND FOREBRAIN NEURONS. A.B. Young and R.L. Macdonald. Department of Neurology, University of Michigan Medical Center, Ann Arbor, MI 48109.

The neutral amino acid γ-aminobutyric acid (GABA) is a major inhibitory neurotransmitter in the central nervous system and has a wide distribution in brain as well as in spinal cord. Electrophysiological and neuropharmacological studies using varied in vivo and in vitro preparations have suggested that many convulsant and anticonvulsant drugs interact with GABAergic systems to produce their pharmacological effects. Of particular interest is the relationship between convulsant-induced paroxysmal activity and antagonism of GABA-mediated inhibition. To approach the mechanism of action of these agents, we have used primary dissociated neuronal cultures derived from fetal mouse forebrain and spinal cord to investigate the acton of convulsant and anticonvulsant drugs on the uptake, release and binding of putative amino acid neurotransmitters. Such studies permit direct comparison of neurochemical and electrophysiological data using the same mammalian preparation. We report here that the convulsant alkaloid bicuculline displaced sodium independent GABA-binding in both brain and spinal cord cultures but that the ED_{50} for GABA-displacement was substantially different in the two culture systems.

Spinal cords and forebrains were removed from 13-14 or 14.5-15.5 day old fetal mice respectively, mechanically triturated and plated in 35 mm collagen-coated culture dishes. Spinal cords were plated at 1/2 cord/dish while forebrains were plated at 1/3 hemisphere/dish. At three to eight weeks, the cultures were suspended in 50 mm tris-citrate buffer at room temperature. Following addition of triton, homogenization and incubation for 30 min at 37°, the membranes were centrifuged at 48,000g for 20 minutes. The membranes were then twice resuspended in buffer, homogenized and centrifuged. GABA receptors were measured by ^{3}H-muscimol binding or Na-independent ^{3}H-GABA binding. Binding was displacable with GABA, imidazole acetic acid and muscimol but not by glycine or 2,4 diaminobutyric acid (a GABA uptake inhibitor). Bicuculline displacement of GABA-binding had an ED_{50} of 5-7μM in brain cultures. In spinal cord, the ED_{50} for bicuculline was more variable but appeared to be between 20 and 100μM. To confirm these data, we performed similar experiments on tritonized adult rat brain and spinal cord membranes and report that the ED_{50} for bicuculline displacement of GABA-binding was 5 and 40μM respectively. Thus these studies demonstrate that the convulsant alkaloid bicuculline has different effects on brain and spinal cord receptors both in vitro and in vivo. These differences determined biochemically in vitro have been compared to electrophysiological studies of bicuculline-induced paroxysmal discharges using the same preparation (see abstract of Macdonald, Young and Nowak).

2049 LIGHT MICROSCOPIC AUTORADIOGRAPHIC LOCALIZATION OF BENZODIAZEPINE RECEPTORS IN MAMMALIAN BRAIN. W. Scott Young, III, Mary K. Conrad*, and Michael J. Kuhar. Dept. Pharmacol., Johns Hopkins Univ. Sch. Med., Balt., Md. 21205.

We have recently described a novel technique for demonstrating, autoradiographically at the light microscopic level, receptors for diffusable drugs and neurotransmitters. We have used this method to map the distribution of ^{3}H-flunitrazepam (FLU) receptors in the rat and human central nervous system.

Binding of ^{3}H-FLU in 4-10μ slide-mounted cryostat sections at 2°C reaches equilibrium by 40 min and exhibits a half-time of dissociation of 19 min. The binding is saturable (K_D=2.79nM, B_{max}=210 fmoles/mg tissue), is inhibited by benzodiazepines (BZ), and shows appropriate stereospecificity. The binding of ^{3}H-FLU is stimulated by GABA and chloride ion. This method is quantitative as the autoradiography is linear with time of exposure and tissue radioactivity.

Autoradiography of ^{3}H-FLU (1nM for 40 min at 2°C with 10 min wash in Tris-HCl, pH 7.4) reveals striking variations in BZ densities in the rat brain. Highest levels of BZ receptors are found in the frontal cortex (especially the frontal poles), lamina molecularis bulbi olfactorii, insulae Calleja, medial forebrain bundle, nucleus entopeduncularis, nuclei amygdaloideus medialis and lateralis (pars posterior), parts of the hippocampus and basal hypothalamus, caudal zona incerta, nucleus subthalamicus, nucleus ventralis rostralis lemnisci lateralis, substantia nigra (dorso-lateral pars reticulata), molecular layer of the cerebellum, inferior colliculus, nuclei tegmenti dorsalis and ventralis of Gudden, and the substantia gelatinosa of nuclei trigemini and of the dorsal horn of the spinal cord. Other areas show lower levels of receptors. White matter areas display negligible binding of ^{3}H-FLU. Heterogeneity of receptor distribution was also seen in human tissue. Sections incubated in the presence of 1μM clonazepam or diazepam had no binding.

This procedure offers high resolution and should provide greater understanding of the action of BZ's. Similar studies are currently in progress on a number of receptors, including those for α-adrenergic, serotonergic, opioid and neurotensin drugs.

2050 GTP AND CATION EFFECTS ON RAT STRIATAL DOPAMINERGIC AND MUSCARINIC CHOLINERGIC RECEPTORS. Nancy R. Zahniser and Perry B. Molinoff. Dept. of Pharmacol., Univ. of Colo. Med. Ctr., Denver, CO 80262

Guanine nucleotides and monovalent cations decrease the apparent affinities of agonists for striatal dopamine receptors. In the presence of GTP both the amount of ^{3}H-apomorphine bound as well as the potency of agonists measured by inhibition of ^{3}H-spiroperidol binding to rat striatal membranes were decreased. These GTP dependent decreases in the apparent affinities of agonists for the dopamine receptor are due to an increase in the rate of dissociation of agonists from the receptor. At 15°C the half-time of dissociation of the partial agonist ^{3}H-apomorphine from dopamine receptors in rat striatal membranes was approximately 25 minutes. The addition of 0.3 mM GTP to the incubation medium caused a 3-4 fold increase in the rate of ^{3}H-apomorphine dissociation. At 37°C the half time of dissociation was 2 minutes in control membranes. Thus, in the presence of GTP little specific ^{3}H-apomorphine binding was measurable at 37°C. The presence of monovalent cations (30-150 mM) caused a 2-fold decrease in the ability of agonists or partial agonists to inhibit ^{3}H-spiroperidol binding. The mechanism by which monovalent cations produce their effects has not yet been established. It is interesting to note that the agonist-specific effects of GTP were observed either in the presence or absence of Na^+. Similar effects of monovalent cations were seen in studies of agonist inhibition of ^{3}H-QNB binding to muscarinic cholinergic receptors in rat caudate. GTP, in the presence or absence of monovalent cations, however, had no effect on either the affinity of ^{3}H-QNB or the inhibition of ^{3}H-QNB binding by muscarinic agonists or antagonists. Neither purine nucleotides nor monovalent cations had any effect on the binding properties of dopaminergic or muscarinic cholinergic receptor antagonists. On the other hand, divalent cations increased the affinities of agonists and decreased the affinities of antagonists for both dopaminergic and muscarinic cholinergic receptors. The results of this study together with those from other laboratories support the hypothesis that GTP affects agonist binding to receptors which are linked to adenylate cyclase. Since monovalent cation effects are seen with receptors that are and are not sensitive to GTP, these results suggest that the mechanism by which GTP and monovalent cations produce agonist-specific effects is not the same.

PAIN

2051 DEAFFERENTATION: EFFECTS OF TOOTH PULP EXTIRPATION ON TRIGEMINAL BRAINSTEM NEURONS. G.J. Ball, J.O. Dostrovsky, J.W. Hu and B.J. Sessle. Fac. of Dentistry, Univ. of Toronto, Canada, M5G 1G6.

Recent studies have shown that deafferentation can lead to marked structural and physiological changes in central neuronal organization that have been related to neurological disorders associated with sensory loss. Since it has recently been reported that partial tooth pulp extirpation results in transneuronally induced changes in neurons of the trigeminal (V) brainstem sensory nuclear complex, we wished to determine if the functional properties of V brainstem neurons change accordingly. The tooth pulp also offers an added incentive for such a study since it is predominantly, if not completely, associated with sensory experiences related to pain, and so the central changes induced by removal of an almost exclusive nociceptive sensory input could be explored.

We have initially investigated the effect of aseptic removal of the coronal pulp of the ipsilateral mandibular canine, premolar and molar teeth on the functional properties of single neurons recorded in the V spinal tract nucleus 13-28 days following the pulp extirpation. These recordings were made in adult chloralose-anaesthetized cats and were primarily, although not exclusively, directed at neurons in subnucleus oralis. Neuronal properties in the ipsilateral nucleus were compared with those examined in the contralateral nucleus of the same animal and in the nucleus of other animals which were not subjected to pulp extirpation. These properties included adequate stimulus, receptive field size, von Frey hair threshold, somatotopic pattern, spontaneous activity, inhibitory influences from afferent or nucleus raphe magnus sources, and short-latency excitatory inputs resulting from bilateral electrical stimulation of the remaining canine and premolar pulps, infraorbital and superior laryngeal nerves, and facial skin. Some of these functional properties were modified in neurons ipsilateral to the pulp extirpation. The most obvious changes included an increase in spontaneous activity that often had an erratic bursting character, an increase in receptive field size and number of excitatory inputs, and a partial disruption of the normal "inverted-face" somatotopic pattern of the nucleus; no obvious difference was noted in the inhibitory influences studied, or in the properties of V primary afferents in the nucleus. Most of these changes occurred in neurons located in the dorsal one- to two-thirds of the nucleus, and indicate that considerable functional changes may occur in V brainstem neurons as a result of a partial loss of sensory input from the tooth pulp.

2052 MORPHINE TOLERANCE DECREASES ANALGESIA PRODUCED BY INJECTION OF GLUTAMATE INTO THE PERIAQUEDUCTAL GRAY OF THE RAT. Michael M. Behbehani. Dept. Physiol., Coll. Med. U. Cincinnati, Cincinnati, Ohio 45267

The analgesic action of morphine is in part mediated through the activation of a descending pathway. Major components of this pathway include the periaqueductal gray (PAG) and the nucleus raphe magnus (NRM). It has been shown that injection of glutamate into the PAG increases the firing rate of these cells, leads to an increase in the firing rate of cells in the NRM and produces analgesia (Behbehani & Fields, Brain Res. 1979). To determine the effect of chronic morphine treatment on the analgesia produced by injection of glutamate into the PAG, rats were made dependent on morphine by implanting them with two pellets, each containing 75 mg of morphine. After 72 hours, the animals were anesthetized with urethane and single cells were recorded from the NRM. Glutamate (1µl,50mM) was injected into the PAG with a microsyringe. The analgesic effect of glutamate was measured by recording the EMG from the flexor muscle of a hind leg illicited by noxious heat. The result shows that glutamate injected into the PAG of morphine tolerant animals does not produce analgesia. However, if the animal is pretreated with naloxone and then glutamate is injected into the PAG, it does produce analgesia. In morphine tolerant animals, injection of glutamate into the PAG produces a slight increase in the firing rate of cells in the NRM. When naloxone is iontophoresed near the site of recording in the NRM, it causes a slight increase in the firing rate of these cells. However, after this treatment, injection of glutamate into the PAG produces a significant increase in the firing rate of the NRM cells. In order to determine the effect of glutamate in unanesthetized animals, animals were implanted with an indwelling cannula and after recovery, tail flick latency was measured before and after injection of the glutamate (1µl 50mM). Glutamate injection caused a significant increase in tail flick latency. After this measurement, the animal was implanted with two morphine pellets. 72 hours later, glutamate injection did not produce analgesia but 10 min. after naloxone injection (0.08mg/kg i.p.) glutamate produced significant analgesia. These results suggest that chronic morphine treatment decreases the stimulus induced release of neurotransmitter involved in the interaction between the PAG and the NRM.

2053 ASCENDING AND DESCENDING PROJECTIONS TO THE PERIAQUEDUCTAL GRAY OF THE RAT. Alvin J. Beitz. Dept. Anat., Univ. of South Carolina, Sch. Med., Columbia, SC 29208.

The afferent connections to the midbrain periaqueductal gray region (PAG) in the rat were examined utilizing the technique of retrograde transport of horseradish peroxidase (HRP). Iontophoretic injections of HRP (Sigma Type VI or IX) were made into the PAG of 14 adult rats utilizing a current of 1.9µA over a period of 10-25 minutes. Following the initial fixation with 2% glutaraldehyde-0.5% paraformaldehyde and subsequent perfusion with phosphate buffer, the brains were cut, and alternate sections were reacted with tetramethylbenzidine and diaminobenzidine, respectively. All sections were then carefully scanned and the location of retrogradely labeled cells charted. The predominant descending projections to the PAG were found to arise from the ipsilateral nucleus cuneiformis, the zona incerta, the ventromedial hypothalamic nucleus, and the anterior and lateral hypothalamic areas. A substantial number of labeled cells were also observed in the ipsilateral dorsal premamillary nucleus, the pretectal area, the posterior hypothalamic area, the periventricular gray and the contralateral nucleus cuneiformis. The major ascending projections to the PAG originate from the ipsilateral dorsal parabrachial nucleus, the nucleus reticularis pontis oralis and caudalis, the nucleus reticularis pontis caudalis pars α, the subnucleus reticularis ventralis medulla oblongata, and from the contralateral nucleus prepositus and cerebellum. HRP-labeled neurons were also found in the raphe magnus, the raphe pontis, the pedunculopontine nucleus, the nucleus reticularis gigantocellularis, the substantia nigra and the trigeminal complex. The results of this study indicate that the PAG receives its most predominant input from the hypothalamus and the zona incerta. These two structures may thus, influence the lower brain stem and spinal cord directly or indirectly by way of the central gray. The PAG has been implicated both as a central site of morphine's antinociceptive action and a central locus important to nociception per se. Further study is necessary to determine if the ascending input to the PAG from the reticular formation, the raphe nuclei and the trigeminal complex are involved in this aspect of PAG function.

2054 NEONATAL HYPOTHALAMIC DEFICITS REDUCE ANALGESIA INDUCED BY STRESS AND OPIATES. Richard J. Bodnar, Earl A. Zimmerman, Gary M. Abrams*, Alfred Mansour*, Lucy W. Thomas* and Murray Glusman. New York State Psychiatric Institute and Columbia University College of Physicians and Surgeons, New York N.Y. 10032.

Pain threshold elevations in rats occur following acute exposure to a wide range of severe envionmental stressors. The anti-nociceptive effects of several stressors appear to act independently of the endogenous opioid pain-inhibitory system, but can be altered by deficits in hypothalamic and pituitary function. The present study examined the role of discrete hypothalamic mechanisms in mediating stress-induced analgesia by through the use of selective, non-invassive techniques. In the first experiment, six rats were exposed neonatally to monosodium glutamate (MSG-2mg/g) while six littermate controls received placebo. One hundred and five days later, both groups were tested for basal reactivity to foot shock as well as their analgesic responses to cold-water swims, morphine, food-deprivation and 2-deoxy-D-glucose. MSG treatment altered shock detection but not basal nociceptive thresholds, while producing selective analgesic deficits. The MSG rats failed to display cold-water swim analgesia and exhibited an attenuated analgesic response to morphine. Yet normal analgesic responses were observed following food deprivation and 2-deoxy-D-glucose. In addition to the known deficits in arcuate dopamine and choline acetyltransferase, subsequent immunocytochemistry revealed that there was a marked, loss of arcuate cells containing ACTH and B-lipotropin in MSG rats. In the second experiment, homozygous Brattleboro rats which exhibit diabetes insipidus caused by an absence of vasopressin were examined for basal reactivity to foot shock. In addition the analgesic responsiveness to cold-water swims, morphine and food-deprivation was ascertained. The Brattleboro rats displayed hypersensitive basal nociception and were not analgesic following cold-water swims. Normal analgesic responses were observed following morphine and food deprivation. While peripheral administration of the vasopressin analogue DDAVP reversed the diabetes insipidus and increased basal nociception, it failed to alter the deficit in cold-water swim analgesia. Also, DDAVP did not alter morphine or food deprivation analgesia. These data indicate that the integrity of hypothalamic systems are essential for the full expression of both opiate and non-opiate analgesia. (Supported by NIH Grants #NS 14449, AM 20337 and N.Y.S. Health Research Council Grants #922 and 1518.

2055 PROLONGED ANALGESIA IN RATS AFTER ZINC TANNATE SALTS OF HEROIN, HYDROMORPHONE OR LAAM. B. Brands*, J.C. Baskerville*, M. Hirst and C.W. Gowdey*. Depts. of Pharmacology and Mathematics, Univ. Western Ont., London, Canada, N6A 5C1.

Studies in our laboratory have shown that a single injection of a narcotic agonist given as the zinc tannate will attenuate the severe abstinence syndrome normally seen when rats are withdrawn from repeated codeine administration. It was of interest to test the duration of analgesia induced by these compounds. The zinc tannate salts of heroin (HZT), hydromorphone (DZT) and ℓ-α-acetylmethadol (LZT) were synthesized (method of Gray and Robinson, 1974) and injected in a slow-release vehicle (Collier, 1972), subcutaneously, in adult male Sprague-Dawley rats. The aversive threshold of each rat was determined each day by means of electrical foot stimulation on a titration schedule. Only those rats which had consistent thresholds after saline injections were chosen to continue the experiments; each treatment group consisted of at least 6 rats. The aversive thresholds and body weights were measured every 24 hr after a single injection of either of 2 doses of HZT, DZT, LZT or the vehicle (SRV) alone. Analysis of variance shows that the aversive threshold was significantly increased ($\alpha = 0.05$) over that of SRV group 24 hr after the injection in all groups except low-dose HZT. Significant elevations in threshold persisted for 5 days after high-dose LZT and for 3 days after the low dose. With both doses of DZT significant increases in aversive threshold occurred for 4 successive days. Analysis of body weight changes revealed that whereas HZT rats gained as did SRV, significant decreases occurred in LZT and DZT groups, the greatest decreases occurring 2 days after administration of DZT and 3 days after LZT. These results demonstrate long-lasting analgesia after a single injection of 3 narcotic zinc tannate preparations.

2056 PERIAQUEDUCTAL GRAY LESIONS AND NON-NARCOTIC ANTI-NOCICEPTION. Martin Brutus, Dennis D. Kelly, Murray Glusman and Richard J. Bodnar. N.Y.S. Psychiatric Inst. and Columbia University, New York, N.Y. 10032.

The ventrolateral periaqueductal gray (PAG) has been implicated in the mediation of opiate and stimulation-produced analgesia. The present study examined whether this region also subserves the antinociceptive properties of stress and select non-narcotic psychotropic drugs. Alterations in pain thresholds were determined both by an operant liminal escape procedure which reflects both an animal's evaluation of the relative aversiveness of a given stimulus and its motivation to terminate its presence, and by a reflex tail-flick test measuring reactive latency to radiant heat. In Experiment 1, twenty-one rats were tested for baseline escape thresholds and then were exposed both before and after PAG lesions to the following variables, each of which had been previously shown to induce dose- or intensity-dependent elevations in escape thresholds: chlordiazepoxide (CDP: 15 mg/kg, ip, 30 min pre-test), haloperidol (HAL: .16 mg/kg, ip, 20 min pre-test), cold-water swims (CWS: 2°c for 3.5 min, 30 min pre-test) and 2-deoxy-D-glucose (2-DG: 600 mg/kg, ip, 60 min pre-test). Appropriate placebo and control tests preceded each determination. Rostral PAG lesions (n=9) decreased significantly the escape threshold elevations induced by HAL, CWS and 2-DG without affecting either basal escape thresholds or the CDP threshold elevations. By contrast, caudal PAG lesions (n=12), which have been shown to eliminate opiate and stimulation-produced analgesia, failed to alter either basal escape thresholds or threshold elevations induced by any of these drugs or stressors. In Experiment 2, stable baseline tail-flick latencies were determined for 26 naive rats which were then subdivided into three matched lesion groups: rostral PAG, caudal PAG and sham. Following surgery, each group was retested for post-operative tail-flick latencies and for sensitivity to CDP, HAL, CWS and 2-DG. First, the anti-nociceptive effects of HAL noted on the liminal escape test were not apparent on the tail-flick test, even in sham controls. Second, rostral PAG lesions (n=6) produced similar time-dependent increases in latency as shams (n=7) following CWS, prolonged latencies following 2-DG and decreased latency elevations following CDP. Third, as with escape thresholds, caudal PAG lesions (n=12) showed normal anti-nociceptive responses to CDP, 2-DG and CWS. These data indicate that the caudal PAG, while apparently important for both opiate and stimulation-produced analgesia, plays no role in the anti-nociceptive properties of stress or psychotropic drugs.

2057 PATTERNING OF NEURONAL INTERSPIKE INTERVALS IN THE THALAMUS OF THE CAT FOLLOWING MORPHINE. L.L. Burns* and T.J. Marczynski, Dept. Med. Pharmacol., Univ. of Ill. Med. Center, Chicago, Ill. 60612.

Single unit activity was recorded chronically in the centro-median-parafascicular (CM-Pf) complex of the feline thalamus using fine wire semimicroelectrode bundles. Animals were awake and freely moving.

Morphine was injected (1.0 mg/kg IM) and produced the classic signs of feline morphine mania including desynchronized electrocorticogram, widely dilated pupils and hyperreactivity to environmental stimuli. Analysis of neuronal interspike intervals was performed with an inequality testing pattern detection technique which made statements about consecutive interspike intervals; an interval was either longer (-) or shorter (+) than the previous interval. Occurrences of patterns composed of 3 through 6 signs were tabulated and empirical frequency distributions constructed. Empirical distributions of patterns were compared with those expected from a theoretical model based on independence of sequential signs, using the chi-square test (see Brudno and Marczynski Brain Res. 125: 65, 1977; Marczynski and Burns Neurosci. Abst., 1978). Neurons showed an increase in patterning throughout the course of action of morphine (3½-4 hours). ensembles of patterns developed which were invariant during the morphine effect. In the same neurons during other behavioral states such as slow wave sleep, quiet wakefulness and bar pressing for milk, different patterns developed usually with greater variability than those observed following morphine. The onset of the patterns occurred gradually during the first 40-60 min following the injection, remained stable for 1½-2 hours, thenslowly declined. Naloxone (0.015 mg/kg) was injected 60 min after morphine in two animals. Within 5 min, the patterns so prevalent with morphine either decreased or disappeared entirely, along with the signs of morphine mania. They were absent for 15-20 min, then the same pattern ensembles reappeared in concert with the signs of morphine mania and persisted for another 1½-2 hours. All cells recorded also showed dramatic increases in their firing rates during the action of morphine. Injections of fentanyl (0.0125 mg/kg) gave similar results, but with a much shorter duration of action (30-45 min). Smaller doses of morphine (0.3 mg/kg) and fentanyl (0.00375 mg/kg) did not show these effects.

It is suggested that if the CM-Pf is an integrating area for pain, entrainment of the firing patterns of neurons by morphine may preclude transmission of impulses encoding painful stimuli and thus inhibit the integration of such stimuli. The appearance of invariant patterns may be related to morphine mania or the euphorogenic properties of the drug.

2058 LATERAL HYPOTHALAMIC GATING OF THE AVERSION PRODUCED BY STIMULATION OF NUCLEUS RETICULARIS GIGANTOCELLULARIS. Kenneth D. Carr and Edgar E. Coons*. Dept. of Psychology, New York University, New York, N.Y. 10003.

Rats were implanted with two monopolar stimulating electrodes. One was aimed at the lateral hypothalamus (LH) and the other at medullary nucleus reticularis gigantocellularis (NGC). These rats were found to leverpress for 3-second trains of LH stimulation during continuous, aversive, stimulation of NGC. Because the LH-currents used in this experiment were too low to support self-stimulation in the absence of continuous NGC stimulation, we concluded that pressing was being reinforced by LH-mediated reduction of the NGC-aversion. However, in order to control for the alternative explanation that the LH-trains had been made rewarding by summation with some component of the continuous NGC stimulation, another test was conducted. By using raised currents, rates of pressing for LH-trains in the absence of NGC stimulation were equated with those obtained by using the previous, lower, currents in the presence of continuous NGC stimulation. It was found that gastric-loading depressed responding for LH-trains in the absence but not in the presence of continuous NGC stimulation. Thus, it would seem that leverpressing for LH-trains during NGC stimulation is maintained by aversion-ameliorating effects of LH stimulation which are not identical with the reward effect.

Rates of leverpressing for LH-trains during continuous NGC stimulation are greatest when the two trains are phased so that each pulse in the 25 pps NGC train is preceded by a pulse to LH at an interval of .1-.5 or 10-15 msecs. These two peaks of inhibition in the leverpressing function suggest that this aversion-ameliorating effect represents a specific interaction between outputs of the two stimulated brain regions.

A second experiment was conducted in which the reverse of the above experimental procedure was followed. That is, rats leverpressed for 3-second periods of escape from NGC stimulation during continuous stimulation of LH. The continuous LH stimulation reduced rates of NGC-escape. Most interestingly, escape reduction was greatest when each pulse in the 25 pps NGC train was preceded by a pulse to LH at an interval of .1-.5 or 10-15 msecs.

That the same bimodal function emerged in both experiments suggests that LH-mediated reduction of NGC-escape and working for LH-trains during NGC stimulation are two behavioral reflections of the operation of a common integrative mechanism. The dissociation of LH-responding from LH-reward in the first experiment, complemented by the LH-mediated reduction of escape in the second experiment, suggests that this integrative mechanism mediates a gating of aversion.

Pharmacological analyses of this bimodal gating will be discussed. (Supported by NIMH predoctoral fellowship #5F31 MH07302)

2059 PHARMACOLOGICALLY DISTINCT SYSTEMS IN MEDIAL AND LATERAL MIDBRAIN MEDIATING DESCENDING INHIBITION OF SPINAL NOCICEPTIVE TRANSMISSION IN THE CAT. E. Carstens and M. Zimmermann. II. Physiol. Inst., Univ. Heidelberg, D-69 Heidelberg, Im Neuenheimer Feld 326 (GFR).

Electrical stimulation of both the midbrain periaqueductal gray (PAG) and lateral reticular formation (LRF) strongly inhibits spinal dorsal horn neuronal responses to noxious skin heating. The mechanisms of inhibition from these two midbrain areas appear to be functionally separate (Pflügers Arch. 377:R52, 1978). To determine if these inhibitory mechanisms are also pharmacologically distinct, we tested whether manipulations of two putative transmitter/modulator systems-endogenous opiates and serotonin- have differential effects on spinal neuronal inhibition from PAG and LRF.

Lumbar dorsal horn neurons with A- and C-fiber input from hindlimb cutaneous nerves were recorded in anesthetized cats. Units responded to noxious radiant heat stimuli (50°C, 10 sec) applied at 3 min intervals either without or during stimulation of PAG or LRF (30 Hz). Inhibition was expressed as the ratio: heat-evoked discharge during midbrain stimulation/discharge in the absence of midbrain stimulation.

If descending inhibition is mediated by endogenous opiates, blockade of opiate receptors with the opiate antagonist naloxone should reduce inhibition. Naloxone (1-3 mg/kg i.v.) has no effect on inhibition of spinal neuronal heat-evoked responses by PAG stimulation (Neurosci. Lett. 11:323, 1979). However, naloxone partially reduced inhibition by LRF stimulation in 4 of 8 units studied to date. Inhibition was never completely blocked by naloxone.

Blockade of serotonin receptors by the serotonin antagonist methysergide (0.5 mg i.v.) greatly reduced or abolished inhibition from PAG in each of 5 units. Higher doses only partially reduced inhibition from LRF in 2 of 4 units. In cats pretreated with the serotonin synthesis inhibitor para-chlorophenylalanine (PCPA, 500 mg/kg), inhibition from PAG was significantly reduced while inhibition from LRF was enhanced.

These results indicate that serotonin mediates inhibition from PAG but not LRF. Endogenous opiates may play a modulatory role in descending inhibition from LRF which, however, is mediated by some other neurotransmitter. The role of catecholamines in descending inhibition from midbrain is currently under study.

2060 NUCLEUS RETICULARIS GIGANTOCELLULARIS: A COMMON NEURAL SUBSTRATE FOR MORPHINE AND STIMULATION PRODUCED SUPPRESSION OF DENTAL PULP EVOKED TRIGEMINAL RESPONSES IN THE CAT. Samuel H.H. Chan, Dept. of Life Sci., Indiana State University, Terre Haute, IN 47809.

A parallelism has been revealed in recent years between morphine-induced and stimulation-produced analgesia. Areas along the periventricular-periaqueductal axis are generally accepted to be critically involved in these analgesic processes. The present study attempts to demonstrate that the nucleus reticularis gigantocellularis (NRGC) in the medulla is also intimately related to opiate and stimulation induced antinociceptive actions, using dental pulp evoked trigeminal responses as experimental indices.

Experiments were performed on adult cats that were either lightly anesthetized with pentobarbital sodium (30 mg/kg, i.p.) or precollicularly decerebrated. Intradental stimulation was delivered via a pair of nichrome electrodes implanted into the left upper canine. The resultant evoked field potential was recorded from the ipsilateral subnucleus oralis (oralis potential) and the jaw-opening reflex (JOR) as EMG signals from the left digastric muscle. Microinjection of drugs (at a volume of 1 µl) to the NRGC was delivered by means of a 27-gauge syringe needle which is connected to a microinjection device. Electrical activation of NRGC was induced via a stereotaxically placed bipolar concentric electrode.

Bilateral microinjection of morphine to NRGC, at a dose of 6.5 µg/kg, elicited a small, though insignificant depression of the JOR. Significant inhibition of the evoked JOR, however, resulted when a dose of morphine at 10 µg/kg was introduced, sustaining for 30-60 min. Such suppression was reversed by naloxone, either administered systemically (1 mg/kg) or microinjected bilaterally into the NRGC (1 µg/kg).

The effect of NRGC stimulation on dental pulp evoked trigeminal responses was studied using the conditioning-testing technique. NRGC activation invariably elicited almost 100% suppression of the intradentally evoked oralis potential in all animals within 5-10 msec after the beginning of the reticular activation. This was followed by gradual and varying degree of decline in inhibition. Complete restoration of the control amplitude in most cases did not take place until 500-800 msec following the reticular activation. Similar temporal effect has been observed on JOR.

The present study thus demonstrated that the NRGC is a common neural substrate for morphine and focal stimulation suppression of dentalgia. Parallel investigations in this laboratory suggest that upon activation by the opiate or electrically, neurons in NRGC may prevent the transmission of nociceptive signals from the dental pulp by promoting a depolarization of the pulpal afferents, in a process that may also involve the opiate receptors and enkephalins.

2061 REVERSAL OF AUTOANALGESIA BY YOHIMBINE. William T. Chance and Martin D. Schechter. Prog. Pharmacol., N.E. Ohio Univs. Col. Med., Rootstown, Ohio 44272.

Recent research has delineated the existence of intrinsic pain inhibitory mechanisms which may be activated by acute stress, lesion-induced hyperemotionality or intense fear. These analgesic states have been termed autoanalgesia in that the antinociception is behaviorally-induced and therefore must result from the incipient neuronal activity of endogenously-synthesized molecules. Although initial observations suggested that autoanalgesia may result from activation of an endorphin system within the CNS, additional investigations have de-emphasized endorphin modulation by demonstrating the ineffectiveness of naloxone in reversing the analgesia as well as an absence of cross tolerance between morphine and autoanalgesia. The involvement of centrifugal inhibitory pathways in autoanalgesia has been demonstrated by its obviation upon spinal cord transection, however, no pharmacological treatment has successfully antagonized autoanalgesia, as assessed by tail-flick tests. Since recent research (Koss et al., Neuropharmacology 18: 295, 1979) has indicated that yohimbine may block tonic descending inhibition, we investigated the efficacy of this drug in antagonizing autoanalgesia and morphine analgesia.

Antinociception was assessed using the rat tail-flick procedure with basal latencies of 2-3 sec. and a cut-off criterion of 8 sec. being maintained. In the first experiment (n=20), the effects of yohimbine HCl (5 mg/kg; i.p.) on basal tail-flick latencies was assessed. In the second experiment (n=26), the effect of the drug (5 mg/kg) on analgesia acutely-elicited by footshock (1.0 ma; 15 sec.) or by the classical conditioning of fear to the tail-flick procedure (Chance et al., Brain Res. 141:371, 1978) was investigated. The last experiment (n=27) examined the effect of yohimbine (5 mg/kg) on analgesia elicited by morphine (8 mg/kg; s.c.). Yohimbine decreased basal tail-flick latencies by 47% 15 min after injection, with this hyperalgesic response lasting for at least 3 hr. Analgesia elicited by acute footshock was reduced to control levels following administration of the drug. As in previous research, classical fear conditioning elicited analgesia which incremented to an asymptote by day 5 (6.2 vs 2.6 sec). Yohimbine dramatically reversed this autoanalgesic effect to 1.7 sec on day 6. Morphine analgesia was also reduced 52% by yohimbine, 15 min after administration of the opiate. This reduction, however, declined to 32% at the time of maximum opiate analgesia (60 min). These observations demonstrate effective antagonism of autoanalgesia and suggest that this antagonism is due to removal of inhibitory influences descending to the spinal cord. This suggestion is supported by the drug's hyperalgesic effect and its partial antagonism of morphine analgesia. NIAAA Grant: 5 RO1 AA03157-02.

2062 PROTECTION OF ENDORPHIN DEGRADATION CAUSES ANALGESIA AND ENHANCES ELECTROACUPUNCTURE EFFECTS IN MICE. Richard S.S. Cheng* and Bruce H. Pomeranz. Dept. Zoology, University of Toronto, Toronto, Ontario M5S 1A1.

Recent evidence shows that systematic treatment with antipeptidases (D-leucine and D-phenylalanine) induces hypalgesia (pain reduction) in man and mice and also causes no addiction. These antipeptidases are postulated to act by protecting endorphins from peptidase destruction, since the hypalgesia they produced was naloxone-reversible. To further test the antipeptidase-endorphinergic hypothesis we compared antipeptidase effects in three related strains of mice. One strain (CXBK) is low in opiate receptors and exhibits poor electroacupuncture and morphine analgesia; another strain (Ob/Ob) has abnormally high levels of pituitary B-endorphin. A third strain $B6AF_{1/J}$ is used as control as it exhibits 'normal' electroacupuncture hypalgesia. The results show that Ob/Ob mice exhibit a higher baseline pain threshold level than B6AF, and CXBK, while the antipeptidases show hypalgesia in the order of Ob/Ob > $B6AF_{1/J}$ > CXBK. This correlates with the differences in endorphinergic systems in these 3 strains of mice. In addition, these antipeptidases increase electroacupuncture hypalgesia in $B6AF_{1/J}$ mice. The combination of antipeptidase and electroacupuncture may provide a non-addictive method for clinical pain treatment.

2063 STRESS AND ANTAGONIST POTENTIATION OF OPIATE ANALGESIA. J.E. Comaty, R.L. Borison, H.S. Havdala* and B.I. Diamond. Mount Sinai Hospital, Dept. of Anesthesia, Chicago, Il. 60608.

The endorphins produce morphine-like actions on pain systems, and these actions are blocked by the specific narcotic antagonists naloxone and naltrexone. Although the endorphin systems are well characterized, few practical attempts have been made to manipulate this system, so as to produce analgesia. We were intrigued by the potential analogy between endorphin and other neurotransmitter systems, where chronic administration of the antagonist results in a paradoxical potentiation of the agonist's actions. We have now tested the effects of chronic naltrexone on morphine-induced analgesia. Subjects were either white male Swiss mice or white male Sprague-Dawley rats. Analgesia was measured either by the hot plate test or the tail-flick test. We found in mice that with daily saline treatment and analgesia testing there was a gradual increase in their latency to demonstrate pain, going from a baseline of 4s to an average of 17s prior to withdrawal of treatment. In contrast, animals receiving naltrexone (20 mg/kg) failed to show this increase in latency. On the tenth day of pretreatment withdrawal, animals were challenged with morphine (5 mg/kg), which produces an analgesic response of 13s in naive mice. In saline pretreated mice, latency to response was 14s, however, in animals previously treated with naltrexone, the latency to response was 20s, and at 13 days after withdrawal the time was further increased to 27s. Similarly, in the tail-flick test, we found that one week after withdrawal of chronic pretreatment, the median latency to response to morphine (10 mg/kg) in saline pretreated animals was increased almost two-fold over baseline, whereas the response of animals pretreated with naltrexone was almost four-fold greater than baseline. This apparent hypersensitive response was reversed by two weeks after withdrawal. Our data shows that animals chronically treated with saline and tested for analgesia develop an apparent analgesia over time. This effect is most likely related to a stress-induced analgesia in response to the thermal stimulus used in testing. In contrast, animals receiving naltrexone under similar conditions failed to develop analgesia. This data would suggest that the stress-induced analgesia is most likely mediated via endorphin systems as would be consistent with its reversability by the specific narcotic antagonist naltrexone. The data also demonstrate that chronic naltrexone produces a marked potentiation of morphine-induced analgesia. This phenomenon may be explained by supposing either that naltrexone has produced a sensitization of opiate receptors, either by increasing their numbers or affinity, or by altering morphine's pharmacokinetics. Thus prior treatment of patients with specific narcotic antagonists may lead to an increased efficacy, and thus a decreased dosage of opiates used in clinical situations.

2064 ADRENERGIC AND 5-HYDROXYTRYPTAMINERGIC INFLUENCES ON MORPHINE ANALGESIA: ASSESSMENT BY THREE PAIN TESTS. S.G. Dennis and R. Melzack*. Dept. Psychol., McGill University, Montreal, Quebec, Canada H3A 1B1

The influences of adrenergic and 5-hydroxytryptaminergic (5HT) systems on morphine analgesia (MA) have been explored in many psychopharmacological studies (cf. Takemori, Ann NY Acad Sci., 281: 262, 1976). Unfortunately, the results are highly variable, and a consensus on 5HT and adrenergic mechanisms has been difficult to reach. An important factor in this variability appears to be the pain test. We have been systematically examining the effects of adrenergic and tryptaminergic agents on pain and MA as measured in rats by three pain tests--Tail-Flick, Hot-Plate, and Formalin. These tests differ in the type of noxious stimulation and in the behavioral responses from which pain is inferred. Each test reveals a unique pharmacological profile of analgesia.

In the Tail-Flick test, analgesia was produced and MA enhanced by L-tryptophan (>200 mg/kg), a 5HT precursor. MA was reduced by the β-blocker propranolol at low (1 mg/kg) but not high (>4 mg/kg) doses. In this test, α-adrenergic agents had no measurable effects at the doses used. In the Hot-Plate test, the α-blocker yohimbine (>1 mg/kg) was strongly analgesic and added to MA. Propranolol at 1 and 8 mg/kg, but not at 4 mg/kg, antagonized MA. Propranolol's antagonism was not manifested when methysergide (a 5HT receptor blocker) or yohimbine were present. Adrenergic agonists and L-tryptophan had little or no effect in this test. In the Formalin test, the α-agonist clonidine (>0.03 mg/kg) and the β-agonist isoproterenol (>0.5 mg/kg) were analgesic and synergized MA. Yohimbine and propranolol (both >1 mg/kg) were somewhat analgesic alone and appeared to add to MA. When combined, yohimbine (1 mg/kg) and propranolol (1 mg/kg) occasionally reversed MA. Methysergide (>2 mg/kg), L-tryptophan (>200 mg/kg), p-chloroamphetamine (PCA, 10 mg/kg), and p-chlorophenylalanine (PCPA, 150 mg/kg) enhanced MA, while PCA (20 mg/kg) and PCPA (300 mg/kg) antagonized MA in this test. PCA and PCPA deplete 5HT.

It appears that different pain tests reveal different underlying neural substrates of analgesia, thus making a single pain test insufficient to characterize pain in general. Both the type of noxious stimulation--heat or subcutaneous formalin--and the response required--elevation and licking of the paws or lashing of the tail--contribute to the observed variability. There appear to be multiple adrenergic and tryptaminergic systems--some cooperative and some competitive--that influence pain and analgesia.

2065 ELECTROPHYSIOLOGICAL EVIDENCE FOR A DIRECT PROJECTION FROM THE PERIAQUEDUCTAL GRAY TO NUCLEUS RAPHE MAGNUS IN THE CAT AND RAT. Jonathan O. Dostrovsky and Yasmin Shah*, Department of Physiology, University of Toronto, Toronto, Ontario, Canada M5S 1A8.

It is widely accepted that stimulation of the periaqueductal gray matter (PAG) can result in analgesia. At least part of this effect is thought to be due to the activation of a descending pathway projecting from the PAG to the nucleus raphe magnus (NRM) which in turn activates a descending inhibitory projection from the NRM to the spinal cord. There is anatomical evidence for a projection from the PAG to NRM and a recent electrophysiological study (Fields and Anderson, Pain, 5: 333, 1978) has demonstrated that PAG stimulation elicits a weak excitation of NRM neurons. This effect may be mediated by a polysynaptic pathway. The present study describes electrophysiological evidence for a direct projection from the PAG to the NRM and adjacent reticular formation obtained by antidromic stimulation.

Experiments were carried out on urethane or chloralose anesthetized cats and urethane anesthetized rats. A concentric bipolar stimulating electrode was stereotaxically placed in NRM. Single unit activity was recorded in the PAG using glass coated tungsten microelectrodes. Antidromic responses were identified by their constant latency and ability to follow two stimuli at intervals shorter than 3 ms. Most of the units could be activated by NRM stimuli of 40-200 μA, 0.1 ms duration. Eighty-four antidromically excited neurons within the PAG were recorded in 5 cats. Conduction velocities calculated from the response latency and stereotaxically estimated inter-electrode distance rangedfrom 0.5 to 23 m/s, with a mean of 6.9 m/s. In 4 rats, conduction velocities of 21 PAG neurons excited from NRM ranged from 0.9 to 10.4 m/s with a mean of 3.3 m/s. Most of the neurons had conduction velocities greater than 2 m/s implying that the PAG to NRM projection is mainly composed of small myelinated fibers. Antidromically activated units were encountered throughout the PAG region but were more numerous in ventral areas. Some neurons outside the PAG could also be antidromically excited. A few neurons were encountered which could be excited orthodromically from NRM.

2066 INFLUENCE OF ATTENTIONAL PROCESSES ON THE ACTIVITY OF NOCICEPTIVE NEURONS IN THE DORSAL HORN OF THE MEDULLA (TRIGEMINAL NUCLEUS CAUDALIS) OF AWAKE MONKEY. R. Dubner, R.L. Hayes* and D.S. Hoffman* (SPON: S. Gobel). Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

Rhesus monkeys were trained to release a panel when they detected the termination of warming stimuli (37° to 43°C) or the onset of noxious thermal stimuli (45°-49°C) applied to the face. In a second task, the same monkeys released the panel when they detected the onset of a light stimulus while behaviorally non-relevant thermal stimuli were presented. Nociceptive neurons exhibited maximum discharges and monotonic stimulus-response functions to noxious stimuli presented during both tasks. Neural activity also could be correlated with panel press and panel release in both tasks. Movements under the thermode were monitored by EMG recordings from the lip musculature. In many nociceptive neurons, an increase (1/10 to 1/3 peak frequency on 49°C trials) in neural activity was associated with panel release. Similar to the burst response of "attentional" neurons in the dorsal horn of the medulla (Hoffman et al, this volume), this increase in activity occurred when the monkey detected the relevant cue (temperature termination or light onset) that reliably predicted reinforcement. The burst discharge in some nociceptive neurons occurred only during the thermal task. During the inter-trial interval (ITI, 15 sec), in both tasks, there sometimes was a decrease in the level of background activity as the next trial approached. Neural activity during the ITI often was greater in the thermal task than in the light task. The activity of most nociceptive neurons was suppressed immediately preceding panel press. In many neurons this suppression was followed by a phasic or tonic increase in discharge at panel press that sometimes was greater in the thermal task. These changes in neural activity occurred in the absence of thermal stimuli and without mechanical displacement produced by lip movements. Often, the press response was enhanced in early trials of a sequence and was suppressed by preceding noxious thermal trials. These findings demonstrate that neurons, previously studied in anesthetized monkeys, and whose maximum discharge occurs in response to noxious thermal stimuli, exhibit dynamic changes in neural activity related to other events occurring during behavioral tasks. We conclude that attentional mechanisms, most evident in a task using oral-facial stimuli as relevant cues, influence the activity of second order sensory trigeminal neurons participating in the sequence of neural events related to goal-directed behaviors.

2067 APPARENT SAFETY OF HIGH ELECTROANALGESIA CURRENT APPLIED TO INTACT TEETH. R. Wayne Fields, Patrick J. Reynolds, Robert P. O'Donnell* and Richard B. Tacke*. School of Dentistry, University of Oregon Health Sciences Center, Portland, Oregon 97201.

We have demonstrated the effectiveness of electric current, applied to teeth of cats, in lessening the magnitude of trigeminal field potentials (Fields, et al., Exp. Neurol. 47:229-239, 1975) or responsiveness of identified primary afferents (Fields, et al., Exp. Neurol., 53:386-398, 1976) to electrical test stimuli applied to the pulps of those teeth. The presumably analgesic currents have been administered using a remote cathode with the anode applied to the exposed dentin of the tooth in question.

Direct current is theoretically harmful to vital elements of tooth pulp (Fields, et al., Oral Surg. 34:694-703, 1972). We have shown that pulsatile currents with peak levels as low as 70μA can be used as effectively as direct current to lower afferent excitability (Fields, et al., Arch. Oral Biol. in press). When much higher currents, to 1000μA, are used, long lasting hypoexcitability follows administration of direct current, while the effects of pulsatile current appear to be reversible (Fields, et al., Abstr. Soc. Neurosci. 4:459, 1978). In order to establish the clinical safety of electroanalgesia (EA) current we felt it was essential to examine tooth pulps histologically at intervals following administration of current. Such observation requires that the teeth remain intact to insure that pulpal changes are not secondary to invasion of the dentin.

We utilized both dc and ac (rectangular pulses at 1000Hz, 10% duty cycle, capacitively coupled) at peak levels spanning the range known to be effective in lowering afferent excitability and including the potentially damaging value of 1000μA. The anode was a saline soaked cotton wick in contact with a platinum wire, all encased in a length of silastic tubing pushed firmly onto the crown of the intact tooth and sealed in place with wax. The return electrode was an electrocautery grounding pad on a hindlimb. Acute current administration was done under Ethrane anesthesia, and teeth were harvested on days 2, 8, 21 and 60.

In no case, either with direct current or alternating current as high as 1000μA was any histologically recognizable sign of pulp damage apparent. The lack of expected damage with high direct current may be related to diffusion of the current by the highly resistant intact enamel. Unpublished single unit recordings, however, demonstrate that even at low levels, current applied to intact enamel effectively lowers excitability.

2068 MECHANISM OF ACTION OF DRUGS IN TRIGEMINAL NEURALGIA. Gerhard H. Fromm, Jay D. Glass, Amrik S. Chattha* and Christopher F. Terrence* Dept. Neurol., Sch. Med., Univ. Pittsburgh, Pittsburgh, PA 15261.

One approach to the investigation of trigeminal neuralgia is to examine the mechanism of action of drugs effective against it. Elucidating the effect of these drugs on the trigeminal nucleus should increase our understanding of the pathophysiology of the paroxysms of pain that these drugs can prevent, and also provide us with laboratory tests for predicting the potential usefulness of new drugs. We have therefore studied three drugs in order to compare their effects on the spinal trigeminal nucleus. Two of these drugs relieve trigeminal neuralgia and one does not.

We have previously reported that carbamazepine (CBZ), an anticonvulsant which is currently the drug of choice for the treatment of trigeminal neuralgia, depresses the response of spinal trigeminal neurons to maxillary nerve stimulation. CBZ increases the neurons' latency of response and decreases the number of spikes in response to each stimulus. We have now also found that CBZ facilitates afferent inhibition in the spinal trigeminal nucleus. The afferent inhibition was elicited by delivering a conditioning stimulus to the maxillary nerve prior to the test stimulus.

Phenobarbital (PB), an anticonvulsant which is not effective against trigeminal neuralgia, produced only a small depression of the response to the unconditioned maxillary nerve stimulus. In addition, PB decreased, rather than increased, afferent inhibition in the spinal trigeminal nucleus.

Baclofen (BCL) resembled CBZ both in its ability to relieve trigeminal neuralgia, and in its ability to facilitate afferent inhibition of some neurons in the spinal trigeminal nucleus. BCL depressed the response to the unconditioned maxillary nerve stimulus less than CBZ, but slightly more than PB.

Our results indicate that the two drugs that do relieve trigeminal neuralgia facilitate inhibitory mechanisms in the spinal trigeminal nucleus. This seems to be at least as critical as their ability to depress excitatory mechanisms in this nucleus.

2069 ATTENUATION OF STRESS-INDUCED ANALGESIA BY ANTERIOR HYPOPHYSECTOMY IN THE RAT. Murray Glusman, Richard J. Bodnar, Dennis D. Kelly, Carl Sirio*, Jordan Stern* and Earl Z. Zimmerman. Depts. of Psychiatry and Neurology Columbia Univ., College of Physicians & Surgeons and N.Y. State Psychiatric Inst., New York, NY 10032.

Naive rats subjected to any one of a number of different stressors display temporary analgesia which may last as long as 2 hours after termination of the stress. We reported recently that this phenomenon, generally called stress-induced analgesia (SA), is greatly attenuated by hypophysectomy (Bodnar, R.J. et al, Pain Abstracts, 1:262, 1978; Physiol. Behav. 23: 1979). Similar results, in agreement with ours, have been obtained by others (Pert, A., 10th Annual Winter Conference on Brain Research, 1978; Amir,S. & Amit, Z., Life Sci. 24:439, 1979). We now report that SA is dependent largely on the integrity of the anterior lobe of the pituitary. We studied 40 rats divided into 4 groups of 10 animals each. Group I consisted of rats in which the whole pituitary had been surgically removed; Group II had the anterior pituitary removed; Group III the posterior pituitary removed; and Group IV consisted of sham operated controls. For a period of 2 weeks post-operatively and throughout the experimental test period, Groups I, II and III - the totally and partially hypophysectomized animals - were given daily endocrine supplements of corticosterone (0.2 mg) and thyroxin (2 μg) to enhance their probability of survival in the laboratory environment and under the experimental stress conditions. Baseline nociceptive thresholds, measured by a modification of the Evans flinch-jump procedure, were determined repeatedly for all animals until stable levels were obtained. The rats were then subjected to a single, forced, cold-water swim (2°C for 3.5 min), followed 30 min later by a threshold retest. Prior to the cold-water swim the animals in all groups showed similar thresholds. The stress procedure, however, elicited striking differences among the 4 groups in post-stress thresholds. The Group IV sham operated controls and the Group III animals (posterior pituitary removed, anterior intact), displayed substantial post-stress threshold elevations indicating well-developed SA responses. In contrast, the Group I animals (total hypophysectomy) and the Group II animals (anterior pituitary removed, posterior intact) failed to develop SA, showing no increase in post-stress thresholds over baseline levels. The post-stress thresholds in Groups III and IV were not significantly different from each other, but they were significantly greater than those of Groups I and II. Our results indicate that the anterior pituitary plays a major role in stress-induced analgesia, and a hitherto unrecognized role in the modulation of pain perception. (Supported by NIH Grants MH 15174 and NS 14449).

2070 THE EFFECT OF NALOXONE ON MULTIDIMENSIONAL SCALES OF POSTSURGICAL PAIN IN NONSEDATED PATIENTS. R.H. Gracely*, W.R. Deeter*, P.J. Wolskee*, B.L. Wear*, J.S. Sayer*, M.W. Heft*, J. Sweet*, D. Butler*, and R. Dubner. Neurobiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

The influence of the narcotic antagonist naloxone and placebo on the experience of postsurgical pain was examined in 36 patients following extraction of at least one mandibular third molar. Extractions were performed with a short duration local anesthetic (2% lidocaine without epinephrine) and without the use of intravenous or inhalation sedatives. Visual analog (VAS) and verbal descriptor (VDS) scaling procedures were used to assess responses related to the sensory intensity, unpleasantness and painfulness of postsurgical pain for 2 hrs beginning 1 hour after the initiation of local anesthesia. Two groups of 12 subjects received double-blind intravenous injections of either 10 mg naloxone or naloxone vehicle (placebo) 2 hrs after injection of local anesthesia. A third group received no treatment. Both the VAS and VDS scales showed increased responses following no treatment and decreased responses following placebo. These differences were statistically significant for both the VAS (order X drug interaction, $F(1,22) = 5.29$, $p<0.05$) and VDS (order X drug interaction, $F(1,22) = 6.38$, $p<0.05$) scales of unpleasantness. VAS and VDS scales of sensory intensity and painfulness showed no statistically significant effects. VAS scales did not significantly differentiate between naloxone and placebo on any dimension. The VDS scales, however, showed a significant elevation in unpleasantness responses after naloxone in comparison to placebo (order X drug interaction, $F(1,22) = 6.13$, $p<0.05$). This effect was not significant for VDS scales of sensory intensity or painfulness. This experiment documents a significant difference in the unpleasantness of postsurgical pain following administration of either naloxone or placebo that cannot be explained by reversal of sedative agents used during surgery. The results suggest that naloxone increases the unpleasantness associated with postsurgical pain by reducing the levels of endogenous opiate-like substances present after surgery or after the administration of a placebo. The superior sensitivity of the unpleasantness scales is consistent with previous evidence from factor analyses of verbal pain responses and further stresses the importance of multidimensional assessment of pain experience.

2071 ELECTROPHYSIOLOGICAL EXAMINATION OF PRIMATE SPINORETICULAR TRACT NEURONS. Lawrence H. Haber, Bart D. Moore* and William D. Willis. Marine Biomedical Institute and Depts. of Anatomy and Physiology and Biophysics, Univ. Texas Medical Branch, Galveston, TX 77550.

Various lines of evidence suggest that cells in the nucleus reticularis gigantocellularis (NGc) may serve as a bulbar relay in a spino-reticulo-thalamic nociceptive pathway. The present work was undertaken to elucidate the response properties of spinal neurons projecting to this area of the caudal brain stem.

Experiments were carried out on 11 anesthetized monkeys (Macaca fascicularis). Twenty-nine spinoreticular (SR) neurons in the lumbar (10 cells) and cervical (19 cells) enlargements were identified by antidromic activation from the region of the ipsilateral (9 cells) or contralateral (20 cells) NGc. Three of the cells could also be antidromically activated from the ventro-posterior lateral nucleus of the contralateral thalamus. The threshold stimulus strength to produce an antidromic response varied from 20-300 μA (less than 100 μA in a majority of cases). Conduction velocities of SR neurons ranged from 9-51 m/s (mean = 24.0 m/s ± 9.8). Fifteen of 29 SR neurons could be excited by natural stimulation of one or more limbs. Of these, 1 cell was activated by tactile stimulation, 3 cells were excited by tactile stimuli but their discharge was enhanced still more by noxious mechanical stimulation (i.e., these cells had a wide dynamic range), 9 cells responded only to noxious mechanical stimulation of the skin and 2 cells were excited exclusively by stimulation of the deep tissues. SR cells having peripheral receptive fields were situated in nearly all regions of the spinal gray matter, whereas SR neurons unresponsive to peripheral stimuli were located primarily in laminae VII and VIII. The discharge of SR cells could be facilitated or in fewer cases inhibited by brain stem stimulation.

The implication of these experiments is that spinal neurons which send their projections to (or possibly through) the region of the NGc may be important for the transmission of information necessary for some aspects of pain perception and response.

This work was supported by a research grant (NS 09743) and by a postdoctoral fellowship to L.H. Haber (NS 05087) from the National Institutes of Health.

2072 ANALGESIA FOLLOWING MICROINJECTION OF PHENTOLAMINE IN THE NUCLEUS RAPHE MAGNUS. Donna L. Hammond and Richard A. Levy, Dept. of Pharmacol., Univ. of Ill. at the Med. Cntr., Chicago, IL., 60612.

The nucleus raphe magnus (NRM) of the brain stem is a source of descending serotonergic fibers which terminate in the dorsal horn of the spinal cord. There is strong evidence that activation of these fibers results in analgesia. Biochemical and histofluorescence studies indicate that the NRM receives a noradrenergic (NA) input which is probably inhibitory, as iontophoretic application of norepinephrine depresses NRM cell firing. It is not known, however, if the NA input modulates the activity of those NRM cells associated with analgesia. In the present study, this input was blocked by microinjection of the NA antagonist phentolamine into the NRM. If the NA input influences those NRM cells which mediate analgesia, then activation (disinhibition) of the NRM by phentolamine would be expected to induce analgesia.

Female rats (220-280 grams) were stereotaxically implanted with a guide sheath positioned 2 mm above the NRM. Following recovery from surgery, 5 or 10 μg phentolamine (P) in 0.5 μl saline was microinjected in the NRM region through an injection cannula extending 2 mm beyond the guide sheath. Alterations in nociceptive threshold were assessed with the tail flick (TF) and hot plate (HP) tests prior to and at fixed intervals following microinjection.

The introduction of both 5 and 10 μg P at sites in the NRM produced a significant elevation in TF latency. The magnitude of the elevation caused by 10 μg P was not significantly greater than that produced by 5 μg P, although the elevation following 10 μg P was more prompt in onset. TF latency was not elevated following microinjection of either tetracaine (4.7 μg, equimolar to 5 μg P) or saline at these same sites, or of P at sites located outside yet close to the NRM. Microinjection of both doses of P into the NRM also increased the nociceptive threshold as assessed by the HP test. HP latency was elevated to a greater extent by 10 than by 5 μg P, although the time to onset of the elevation did not differ. Injection of tetracaine and saline at these same sites did not alter the HP latency. HP latency was elevated following injection of P at sites located close to but outside the NRM, but the onset of this effect was substantially longer than that observed after injection of P at sites in the NRM. Preliminary data indicates that elevation of both TF and HP latencies also occurs following microinjection in the NRM of another NA antagonist, azapetine.

These results suggest that the descending raphe-spinal pathway involved in setting the nociceptive threshold is under tonic inhibitory control by a NA input. (Supported by USPHS NS 12649).

2073 ℓ-BACLOFEN PREFERENTIALLY DEPRESSES NOCICEPTIVE INPUTS IN LUMBAR DORSAL HORN IN THE CAT. James L. Henry, Dept. of Research in Anaesthesia, McGill Univ., Montréal, PQ, Canada. H3G 1Y6

Baclofen, a derivative of GABA best known for its antispastic actions, has also been found to have antinociceptive properties. This latter finding prompted an electrophysiological study of the effects of the d- or ℓ-isomer on single sensory neurones in the L_5-L_7 dorsal horn of the cat (chloralose anaesthetized, n = 8, or unanaesthetized decerebrated, n = 4) spinalized at L_1 and paralysed with pancuronium. In each experiment one single unit was studied; its responsiveness to natural cutaneous stimulation was determined and then one or the other isomer was administered in graded doses via the jugular vein and the effects noted on the single unit. Both forms had depressant effects on dorsal horn units, the ℓ-isomer being approximately 100 x more potent than the d-isomer. The most sensitive modality to baclofen was nociception. Wide dynamic range (WDR) neurones, which responded to automatically controlled periodic applications of noxious radiant heat alternating with an air stream, showed a marked depression of the on-going discharge rate and also of the response to noxious heat with 0.1 mg/kg of ℓ-baclofen, without a change in the response to air. In some cases, where electrical stimulation of the cutaneous receptive field of WDR neurones provoked early and late discharges (conduction velocities corresponded to Aβ and Aδ fibres, respectively), ℓ-baclofen depressed the late discharge at lower doses than those which depressed the early discharge. In other cases nociceptive specific or WDR neurones were excited alternatively by periodic applications of noxious radiant heat and glutamate (applied locally to the neurone by iontophoresis); ℓ-baclofen, at doses which depressed the heat response, had little or no effect on the excitatory response to glutamate, suggesting a presynaptic action. The depressant effects of either isomer could be reversed by the i.v. administration of bicuculline methiodide (1-5 mg/kg) but not of strychnine sulphate (0.1-0.2 mg/kg). These results suggest that baclofen has a presynaptic effect preferentially on small diameter afferent fibres, and acts via a GABA-ergic mechanism.

Supported by the Canadian MRC and the Quebec MRC.

2074 EXAGGERATION OF REFLEX GROOMING AND ITS DOMINANCE OVER NOCIOCEPTIVE RESPONSES IN THE BILATERAL DECORTICATED CAT. S.J.Herdman*, V.Cerny, C.N.Liu, W.W.Chambers*, and J.Yu. Dept. of Anat. and Inst. of Neurol. Sci., Univ.of Penna.,Phila., Pa. 19104.

Normal grooming responses consist of licking, nibbling, wiping the face and ears with the forepaws and scratching the head, neck and shoulders with the hindpaws. These responses are transiently lost after bilateral neodecortication or after bilateral removal of the frontal poles including the primary and secondary somesthetic cortical areas. The grooming responses gradually reappear and by 30 to 50 days post-op have become markedly exaggerated demonstrating the effect of cortical release. This grooming may become so marked that the animal cannot stand nor walk being consumed by licking. The reflex zones for the grooming responses in the decorticate cat are essentially the same as in the normal animal. The grooming movements, however, have poor local sign and are frequently ineffective since they are often misdirected. The type of response elicited is also related to the intensity of the stimulus and to a lesser extent to the modality of the stimulus.

Nocioceptive responses such as the flexion reflex, flicking of a limb, tail lashing, growling, and spitting can be completely inhibited by eliciting the licking response. This inhibition persists from 15 seconds to 2 minutes after cessation of reflexly induced grooming. The longer inhibition is related to a longer period of induced grooming. The nocioceptive response then rebounds with even greater intensity but can be inhibited again by eliciting grooming. To determine if the inhibition of the nocioceptive responses by grooming was mediated by endogenous morphine-like substances, we treated the cat with Naloxone (0.4-4 mg/kg body weight) which blocks opiate receptors. This treatment did not alter the grooming nor its inhibition of the nocioceptive responses. We conclude that excessive grooming and the dominance of the grooming response over nocioceptive responses in the decorticate cat is not due to endogenous opiates. Possible mechanisms will be discussed. (Grants 5T32 EY07035-02 and USPHS NS 10464)

2075 PITUITARY-ADRENAL ACTIVITY ASSOCIATED WITH CENTRAL PAIN FOLLOWING COMPLETE FORELIMB DEAFFERENTATIONS IN RATS. J.P. Heybach,* M. Levitt and A. Brodish.* Dept. of Physiol. and Pharm., Bowman Gray Sch. Med., Wake Forest Univ., Winston-Salem, NC 27103.

Adult male rats (SD; 270-350g) underwent bilateral dorsal rhizotomies at C5-T2, inclusive. Postoperatively, withdrawal responses to forepaw pinch and pinprick were absent. Within 17 days following surgery 7 rats with complete forelimb deafferentations displayed a behavioral syndrome characterized by abnormal chewing of the forelimbs. This behavior has been described in the monkey (Levitt, Fed. Proc. 1977, 36, 538) and in the rat and the hypothesis advanced that it represents the response to disturbing or painful sensations referred to the deafferented regions (Basbaum, Exp. Neurol. 1974, 42, 490). In the present study this behavioral syndrome was found to be variable in onset, severity and duration, and was associated with piloerection, squealing when gently handled and hyperreactivity to air puffs directed at lumbar body dermatomes. Control rats were not self-mutilating and consisted of: 2 rats with extensive dorsal rhizotomies; 1 rat with 2 dorsal roots cut bilaterally; and 1 rat with laminectomy and dural incision, but no rhizotomies. Deafferented self-mutilating rats were compared to the control rats with regard to basal plasma corticosterone (B) levels, as an index of pituitary-adrenal activity. Blood samples were taken (0800-1000h) by jugular venapuncture under ether at various pre- and postoperative intervals. Dramatic elevations in plasma B levels corresponded to the day of onset of self-mutilation and remained elevated compared to both pre-mutilation and control group levels while the syndrome persisted. Work in progress is aimed at determining if these elevated plasma B levels are simply a response to peripheral somatic tissue damage or are causally related to the CNS deafferentation which gives rise to the presumed central pain. In support of the latter it was noted that the elevated B levels in self-mutilating rats did not correlate with the degree of tissue damage.

These endocrine changes, which parallel those reported in human cases of phantom limb pain (Pozidaeva, Ortp. Travm. Protez. 1976, 10, 43 [in Russian]), and the associated behavioral changes suggest that this preparation merits further study as a potential model of stressful deafferentation pains.

Supported in part by NIH grant NS-11921 (M. Levitt).

2076 NEURAL ACTIVITY RELATED TO ATTENTIONAL PROCESSES IN THE DORSAL HORN OF THE MEDULLA (TRIGEMINAL NUCLEUS CAUDALIS) OF AWAKE MONKEY. D.S. Hoffman*, R.L. Hayes*, and R. Dubner (SPON: J.E. Albano). Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

Unit activity was recorded in the dorsal horn of the medulla (DHM) of rhesus monkeys trained in two reaction time tasks to release a panel when they: (1) detected the termination of a warming (37^{o}-43^{o}C) stimulus or the onset of a noxious (45^{o}-49^{o}C) stimulus applied to the face; (2) detected the onset of a light stimulus while behaviorally non-relevant thermal stimuli were applied to the face. Neural activity could be correlated with the following behavioral events: (1) panel press, which initiated the onset of thermal stimuli in the first task; (2) presentation of the cue for panel release-i.e., termination of thermal stimuli in the first task or onset of light stimuli in the second task; (3) panel release. A subset of neurons located deep in DHM had receptive field response properties that were similar to those of thermal nociceptive neurons in this nucleus. In contrast to the nociceptive neurons, these neurons exhibited peak activity at panel release. A burst of neural activity occurred just prior to panel release in warming, noxious and light trials and therefore was independent of the intensity or modality of the relevant cue. The burst was absent if the monkey failed to detect the cue and released the panel inappropriately. The neural discharge occurred following experimenter-presented trials, when monkey hand movements were not present at panel release. The neural activity also could be temporally separated from the lip perch in preparation for reinforcement intake. The latter was monitored by EMG recordings from the lip musculature. Thus, the burst of neural activity was temporally related to panel release, but it was not reliably correlated with any of the motor behaviors accompanying panel release. Finally, the burst of discharges was reduced in amplitude and eventually disappeared when reinforcement was withheld during experimenter-presented trials. These findings indicate that some neurons in DHM exhibit maximum neural activity when the monkey detects the relevant cues that reliably predict reinforcement. The neural response is the same irrespective of stimulus modality or stimulus intensity and occurs in the absence of appropriate motor responses. We conclude that neural activity at an early stage of central nervous system processing may be associated with attentional processes involved in organizing goal-directed behaviors.

2077 NOCICEPTIVE AND NON-NOCICEPTIVE TRIGEMINAL NEURONS: BRAINSTEM INTRANUCLEAR PROJECTIONS AND MODULATION BY PERIAQUEDUCTAL GRAY AND NUCLEUS RAPHE MAGNUS. J.W. Hu and B.J. Sessle. Fac. of Dentistry, Univ. of Toronto, Canada M5G 1G6.

In addition to its role as a major nociceptive relay site in the brainstem, trigeminal nucleus caudalis has also been implicated in ascending tonic modulatory influences on sensory transmission through neurons in more rostral trigeminal brainstem nuclei (e.g. nucleus oralis). Such a projection from caudalis has in fact been indicated in anatomical studies, but direct physiological evidence of the projection is lacking and no evidence is available of the functional properties of the caudalis neurons involved in the projection. We have tested for such a projection in nucleus caudalis and examined the functional properties of projection neurons.

In anesthetized adult cats, the activity of single caudalis neurons was recorded and their orthodromic responsiveness noted to noxious or innocuous orofacial stimuli. A neuron projecting to the ipsilateral oralis and/or contralateral posterior thalamus was identified by its antidromic responses to stimulation at these sites. Effects of conditioning stimulation of PGM and NRM were tested on both orthodromically evoked and antidromically evoked activity. A decrease in orthodromic responsiveness reflected inhibition of the caudalis neuron;an increase in antidromic excitability was an indirect measure of presynaptic depolarization of the axonal endings in oralis of the caudalis neuron.

Of 83 caudalis neurons tested, 45 could be antidromically excited from oralis; 3 of these 45 neurons also had a contralateral thalamic projection. Both non-nociceptive and nociceptive caudalis neurons located in marginal and deeper layers of nucleus caudalis were found to project to oralis, and the axonal conduction velocity of the former (mean 5.7 m/sec) was significantly faster than that of the nociceptive neurons (mean 1.7 m/sec); both values are significantly slower than trigeminothalamic velocities. Conditioning stimulation of PGM and NRM produced inhibition of the orthodromically evoked responses of both types of caudalis neurons. Moreover, conditioning stimulation also induced presynaptic depolarization lasting more than 400 msec in the axonal endings in oralis of both nociceptive and non-nociceptive neurons.

These studies have provided direct physiological evidence of an axonal projection from nucleus caudalis to more rostral trigeminal nuclei. Both nociceptive and non-nociceptive caudalis neurons are involved in the projection, and PGM and NRM exert inhibitory influences within caudalis as well as presynaptic modulatory influences on the axonal endings within oralis of both types of caudalis neurons.

2078 RELEASE OF SUBSTANCE P AND SOMATOSTATIN, IN VIVO, FROM PRIMARY AFFERENT TERMINALS IN MAMMALIAN SPINAL CORD. T.M.Jessell, A.W.Mudge*, S.E.Leeman and T.L.Yaksh. Depts. of Pharmacology and Physiology, Harvard Medical School, Boston, Mass. and Dept. of Neurologic Surgery, The Mayo Clinic, Rochester, Minn.

Substance P and somatostatin are contained within small diameter primary sensory neurons which terminate in the dorsal horn of the spinal cord and are associated with the transmission of noxious peripheral stimuli. However there is no direct evidence for the release of either peptide after activation of nociceptive afferents. By superfusing the mammalian spinal cord we have demonstrated the release of substance P and somatostatin in vivo following chemical and physiological stimulation of sensory afferents involved in pain transmission.

Rats and cats were anesthetized and a polyethylene (PE-10) cannula inserted into the sub-arachnoid space to the caudal margin of the lumbar spinal cord. Outflow was collected from a cannula in the cisterna magna (rats) or by a concentric cannula opening at the level of T-12 (cats). The spinal cord was then superfused with CSF containing serum albumin and bacitracin at a rate of 0.1 ml/min and samples were collected every 10 min (rat) or 30 min (cat) and divided for measurement of released peptide by radioimmunoassay. In rats, the release of substance P detectable in control periods was 1-2 fmol/min and release of somatostatin was 4-5 fmol/min. Superfusion of the rat spinal cord with CSF containing 40 mM potassium for 10 min evoked a 4-fold increase in the release of substance P, a 2.8-fold increase in somatostatin release and a 1.8-fold increase in neurotensin release. Chronic administration of capsaicin to rats has been shown to deplete substance P from sensory neurons. In the present experiments, superfusion of the rat spinal cord with capsaicin ($3x10^{-4}$M) produced a 9-fold increase in substance P release and a 4-fold increase in somatostatin release. The release of neurotensin,a peptide found in substantia gelatinosa interneurons but not in sensory neurons,was not increased by superfusion with capsaicin. Release of substance P evoked by potassium and capsaicin was greatly reduced by superfusion of the spinal cord with 2 mM cobalt.

In cats, bilateral stimulation of the sciatic nerve at intensities sufficient to activate only rapidly conducting, low threshold afferents did not increase the release of substance P. Increasing the stimulus intensity to recruit A delta and C fibre afferents produced a 2.6-fold increase in the release of substance P. In preliminary experiments, the release of substance P by high intensity sciatic nerve stimulation was reduced by the systemic administration of morphine (2mg/kg) and restored by systemic naloxone (1mg/kg).

2079 SUCCESSFUL PREDICTION BY THE AFFECT CODE OF UNIT RESPONSES TO REWARDING MEDIAL FOREBRAIN BUNDLE STIMULATION. James J. Keene. Dept. Physiol., Sch. Med., Univ. Puerto Rico, San Juan, PR 00936.

This report deals with verification of the proposed affect code (see Fed. Proc., 37: 2246-2250) which describes how certain anatomically localized neurons may represent information pertaining to an affective dimension (reward-pain) in their firing rates. Such "affect coding" neurons have been found in the medial thalamus where decreased and increased firing rates are associated with reward and pain respectively.

If the affect code is correct, one should be able to predict how an arbitrary input A with reward value would interact at the unit level with an aversive input, on the basis of knowledge of how reward input B interacts with the aversive input.

Four chronically implanted cats were trained to self-stimulate for medial forebrain bundle stimulation (MFB) (reward input A), and to escape from midbrain reticular (RET) stimulation (0.5 sec, 50 Hz trains). During these behavioral tests, 335 units were recorded from medial thalamus and overlaying cortex, with stereotaxically guided, moveable tungsten microelectrodes. Each unit was also tested with random presentations of the MFB and RET trains and of both simultaneously so that interaction of the effects could be examined. Separate tones distinguished self-stimulation and escape periods. The animal's enclosure was suspended so that a tension transducer provided continuous data on gross movements (slight turning of the head, positioning, etc.). Unit, movement, and bar pressing data were tabulated over real time by a PDP 11/20 computer system.

In the above model, escape was considered to be "reward input B". Since the RET stimulation was demonstrated to be aversive, and the majority of the units showed increasing excitation up to the bar press which initiated a 10 sec escape period, it was reasoned that decreased firing may code for reward in a unit (Type I) if it's activity in the escape period was less than the typical excitation after a randomly given RET train in a comparable post-stimulus period. In Type II units, post-escape activity was greater than that following a single RET train (temporal summation of pre-escape RET trains). If inhibition codes reward in Type I units, then MFB trains would be predicted, according to the affect code, to decrease unit activity and/or block RET-elicited excitation, as was found. On the other hand, MFB trains did not have this effect on Type II units. Indeed, they summated with the excitatory RET effects on Type II units producing an arousal coding pattern (see ref.) characterized by similar responses to the motivationally opposite MFB and RET stimuli.

These results showthat the affect code can be used to predict unit responses to motivational stimuli. NIH Grant RR-08102

2080 RESPONSES OF VPL_c NEURONS IN THE PRIMATE THALAMUS TO NOXIOUS THERMAL STIMULI. D.R. Kenshalo, Jr., G.J. Giesler, Jr., R.B. Leonard and W.D. Willis. Marine Biomed. Inst., and Depts. of Anat. and of Phys. & Biophys., UTMB, Galveston, TX 77550.

The primate spinothalamic tract terminates in several thalamic nuclei, including the caudal part of the ventral posterior lateral nucleus (VPL_c). To study the possibility that neurons in this nucleus are capable of transmitting nociceptive information, we have recorded from single thalamic units in monkeys (Macaca fascicularis). The animals were anesthetized with α-chloralose and an infusion of sodium pentobarbital (4 mg/kg/hr). Recordings were made with tungsten microelectrodes, and the position of units marked with electrolytic lesions. Noxious stimuli applied to the cutaneous receptive fields included intense mechanical stimuli and graded noxious heat pulses from 35°C adapting temperature to 43°, 45°, 47° and 50°C. Innocuous stimuli included hair movement, touch, rotation of joints, tapping and vibration. Many of the thalamic units were activated antidromically from the SI cortex using either a platinum ball electrode for surface stimulation or a steel microelectrode for stimulation within the cortex.

To date we have recorded from 94 thalamic neurons. Of these, 41 were excited by noxious heat pulses. The remaining neurons responded best to innocuous stimuli, and, of the five tested, none responded to noxious heat pulses. Reconstructions from electrolytic lesions indicated the cells responsive to noxious stimuli were somatotopically organized, those from the hindlimb being placed more laterally and those from the forelimb more medially in VPL_c. An ascending series of noxious heat pulses produced stimulus-response functions similar to those of spinothalamic tract neurons. In two experiments, lesions of the dorsolateral fasciculus on the side of the receptive field produced no observable changes in the responses of thalamic cells to noxious heat pulses, whereas in one case a lesion of the contralateral ventrolateral quadrant completely abolished the response.

We were able to activate antidromically 25 thalamic cells that responded to noxious heat pulses by surface stimulation of the SI cortex. Of these 13 were also antidromically activated by microstimulation within or subjacent to the SI cortex.

Based on these findings, we speculate that neurons located in the VPL_c nucleus of the primate receive input from the spinothalamic tract and transmit nociceptive information to the somatosensory cortex.

(Supported by research grant NS 09743 and postdoctoral fellowships NS 05698 and NS 06071 from the National Institutes of Health).

2081 PAIN ADAPTATION AND HYPERALGESIA DURING THERMAL STIMULATION OF HUMAN SKIN. R.H. LaMotte, C.J. Robinson and J.G. Thalhammer*. Dept. of Anesthesiology, Yale University, New Haven, Conn. 06510.

In these studies we measured the time course of changes in human sensitivity to pain during and following intense heating of the skin. Human subjects, each of whom gave informed consent to an approved protocol, made continuous category judgments of the magnitude of warmth and pain during constant-temperature, localized heating of the hand or forearm with stimuli of 38 to 47°C (10 min duration) or 50° (1 min). Stimuli greater than 45° were perceived as painful throughout the presentation, with ratings of magnitude remaining constant or increasing slightly. Pain evoked by stimuli of less than 45° was transient and adapted (disappeared) within 1 min. In some experiments, the capacity to detect and to rate brief (3-5s) increments in temperature (0.05-1.6°) superimposed on these sustained temperatures was also determined. Thresholds near the beginning and the end of each stimulation were not appreciably different regardless of base temperature.

In other experiments we obtained magnitude ratings for test stimuli (0.1-8.0° above a base of 38°) delivered before and at varying intervals of time following a conditioning stimulus (CS) of 50°. Durations of the CS varied from 5 to 100s. For a CS of less than 30s, magnitude ratings of warmth and pain were typically lower (suppression) by an amount equivalent to 3-6° immediately following the CS and recovered to normal over the next 30 min. For a CS of greater than 30s, suppression also occurred; but within 5 min after the CS, pain threshold was lower than normal and magnitude ratings of all stimuli were 2-6° elevated over those obtained for the same stimuli prior to the CS (hyperalgesia). Ratings remained elevated for 2 or more hours. Also present during this time was a mildly unpleasant sensation evoked by lightly rubbing the skin with gauze (dysesthesia). The development of suppression and hyperalgesia following a CS of 50° for 60s corresponded, in time and in magnitude, to the sequence of fatigue and sensitization observed in C-fiber mechanoheat nociceptive afferents (CMHs) in the monkey (Thalhammer and LaMotte, this vol.). The adaptation of pain during sustained stimulations at lower temperatures may be accounted for by fatigue of CMHs while the failure to adapt at higher temperatures may result, in part, from a combined input from CMHs and an increasingly active population of sensitized A-fiber nociceptive afferents.

2082 QUANTAL OPIATE ANALGESIA IN POST-OP PAIN. Jon D. Levine*, Newton C. Gordon*, Richard Smith* and Howard L. Fields. Dept. Neurol., Physiol., & Oral Surgery, UCSF, San Francisco, CA 94143.

The change in response to increasing drug dose may be discrete (quantal) or continuous (graded). Most researchers have assumed that opiate analgesia is a graded process. However, D'Amour and Smith (J. Pharmacol., 1941, 72, 74) and others, using the rat, have demonstrated a quantal suppression of tail flick by opiates. We present evidence that morphine analgesia in humans with clinical pain may also be quantal.

Twenty-one female and 18 male patients between the ages of 18 and 34 were studied. All patients underwent extraction of impacted third molars, without narcotics. Details of the procedure have been published (Levine et al, Lancet, 1978, ii, 654). At two hours following surgery all patients received a placebo (an equal volume of intravenous saline) and at three hours either a placebo again or a hidden intravenous injection of 4, 6, or 8 mg. of morphine. Pain was evaluated using a visual analog scale (10 cm. blank line; ibid.).

Blind administration of morphine produced a dose response curve which was monotonic over the range studied. However, individual patient's pain reports 50 minutes following morphine injection were clustered around two separate mean levels. The mean pain level of one of these clusters was above and the other below the pre-treatment mean. These clusters were defined as morphine responders and non-responders, respectively.

The mean pain level for responders (and non-responders) is independent of morphine dose. We found that for increasing dose, the decrease in mean pain is due to a larger percentage of morphine responders. Thus morphine analgesia is quantal. We have observed a similar division into two groups following placebo administration (Levine et al, PNAS in press). The mean pain level for morphine responders and consistent placebo responders (and non-responders) are not significantly different.

We conclude that opiate analgesia is a quantal process and that it may share a common neural circuit with placebo analgesia.

2083 EFFECT OF MORPHINE, PIMOZIDE AND NALOXONE ON RESPONDING BY RATS IN A SIGNAL DECISION PARADIGM: 23 DAY EFFECT OF PIMOZIDE. V. A. Lewis and I. Cathy Liles*, Department of Pharmacology, Dental Branch, University of Texas, Houston, 77025.

Signal detection theory has been employed in the evaluation of human response to noxious stimulation to differentiate the sensory components from the decision making or psychological components of the response. In this study, a signal decision paradigm has been adapted to evaluate the effect of analgesic and antipsychotic drugs on a foot shock escape response in rats. Four groups of 10 male Sprague-Dawley rats were trained to escape a 1.2 ma. foot shock by climbing onto a platform (15 x 9 x 3 cm.) After training, the effect of the narcotic-analgesic morphine (1,3,10 mg/kg); the selective dopamine-antagonist pimozide (.08,.20,.64 mg/kg); the narcotic-antagonist naloxone (1,3,10 mg/kg) and vehicle control were assessed on escape from tone and shock (HIT) and tone and no shock (False alarm, FA) contingencies. The frequency of escape and latency to escape were recorded for HITs and FAs. During any session only one drug and one shock probability was presented and 5 day rests were scheduled between sessions to minimize residual drug effects and tolerance. Sessions of 20 escape trials (7 s. trial and 15 s. ITI) with shock presented on 45% or 75% of the trials were run. The order of shock presentations, drug treatments and shock probabilities were randomized. Analysis of variance revealed significant effects for morphine and pimozide but not for naloxone, vehicle control or the different probabilities of shock. Morphine at 3 and 10 mg/kg significantly reduced responding to both HITS and FAs and increased the latency for response to shock. Morphine primarily increased the withdrawal criterion. Pimozide significantly lowered HIT and FA probabilities and prolonged escape latencies when compared to the vehicle control group, but not when compared to its within group vehicle control. These data suggested that pimozide had a prolonged behavioral effect lasting longer than 5 days. A pimozide time course study (0.64 mg/kg S.C in .1N acetic acid) demonstrated that pimozide maximally depresses responding between 8-24 hours post injection. HIT rates returned to control by day 5 but FAs were significantly depressed for 23 days and returned to control levels after 36 days. These studies demonstrate that for noxious stimuli, the response to HITs and FAs can be modified by pharmacologically distinct mechanisms and that dopamine is important in the generation of FAs. In addition, it has been shown pimozide may be a suitable agent for studying the long term effects of dopamine receptor blockade.

2084 STIMULUS-DEPENDENT CHANGES IN FOOTSHOCK SENSITIVITY FOLLOWING MEDIAL FOREBRAIN BUNDLE LESIONS IN THE RAT. Carlton E. Lints, Leonard H. Nenja*, and John F. Miller*. Dept. of Psychol., No. Illinois Univ., DeKalb, IL 60115.

Forebrain serotonin (5-HT) depletion has been reported to produce an increased sensitivity to footshock in rats, whereas forebrain norepinephrine (NE) depletion produces hyperalgesia as measured by the hot-plate technique. Thus, there appears to be stimulus specificity with respect to the type of hyperalgesia produced by forebrain monoamine depletion (e.g., Simansky & Harvey, ASFN, 1978, 4, 283). Medial forebrain bundle (MFB) lesions deplete the forebrain levels of both of these amines and have been reported to produce both types of hyperalgesia. However, difficulty in replicating the effects of MFB lesions on footshock sensitivity in this laboratory suggested that there might be considerable shock stimulus specificity within the forebrain 5-HT system mediating this effect. To test this possibility normal (N), sham-operated (SHM) and MFB-lesioned rats (N=8/gp.) were tested for sensitivity to footshock using the flinch-jump technique and two different constant current shockers that differed in terms of the nature of the current delivered to the grid floor of the test chambers (ac or dc). The animals were then retested with the ac shocker using three different shock durations (.05, .1 and .2 sec) with each of two different shock series (REG & Half). The REG series was the same series of shocks used in the initial tests and the Half series used current intensity increments 50% smaller than those of the REG series. The animals were always retested in the same chamber. Following behavioral testing the forebrains were assayed for 5-HT and NE levels and the brainstems were used for histological verification of the locus and extent of the lesions.

The lesions were well localized and produced 47% and 40% depletions of forebrain 5-HT and NE respectively. Jump thresholds of the MFB group were significantly lower than those of the SHM group with both shockers using the REG series, and there were no significant effects of the lesion on flinch thresholds. With the dc shocker the jump thresholds of the MFB group were also significantly lower than those of the N group, but this was not the case for the ac shocker. With both series on the ac shocker the jump threshold of all three groups decreased significantly as shock duration increased. However, only the .1 sec shocks in the REG series produced a significant lowering of the MFB jump threshold. Jump thresholds of the MFB rats were never significantly lower than those of the control groups with the Half series. Flinch thresholds of the lesioned rats were significantly lowered by the .05 and .1 sec shocks in the Half series and by the .05 sec shocks in the REG series.

2085 SENSATIONS AND MASSETERIC INHIBITORY PERIODS PRODUCED BY ELECTRICAL TOOTH PULP STIMULATION. Patricia A. McGrath*, Yair Sharav*, Richard H. Gracely* and Ronald Dubner (SPON: W.M. Falls). Neurobiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

Electrical tooth pulp stimulation in humans evokes inhibitory periods in the ongoing masseteric activity, that are usually regarded as indices of pain sensation. This study investigates both the sensations produced and the masseteric inhibitory periods evoked by electrical tooth pulp stimulation in 30 subjects. Stimuli consisted of a train of 30 monophasic, monopolar, 1 msec duration, cathodal pulses delivered at 2 sec intervals. EMG masseter activity, from surface electrodes, was rectified and averaged for the 30 pulses at each stimulus intensity. Three configurations of inhibitory periods were produced: Single, (S), a single inhibitory period with a latency of 10-15 msec and a duration of 10-20 msec; Double, (D), two inhibitory periods separated by a burst of muscle activity, the first having a latency and duration similar to S and the second having a latency of 40-50 msec and a duration of 10-20 msec; and Merged, (M), an elongated period in which the inhibitory periods of D seemed to merge. These inhibitory periods were correlated with stimulus strength, not magnitude of sensation; S and D periods were evoked at low and moderate stimulus intensities while M periods were evoked at high intensities. Non-pain and pain sensations were dissociated from inhibitory periods by the administration of a narcotic, fentanyl (.08 mg/45 kg body weight), in 15 subjects. Fentanyl significantly increased non-pain and pain thresholds and significantly reduced the magnitude of sensations in all subjects, but there were no changes in the latency, duration or configuration of the inhibitory periods. Non-pain and pain sensations were also dissociated from inhibitory periods by the application of an electrical conditioning stimulus (CS) to the central incisor in 15 subjects. CS, a 30 pulse train at a high stimulus intensity (70 uA ± 25), produced a significant elevation in non-pain and pain thresholds and a significant reduction in magnitude of sensation in the adjacent incisor, but produced no change in the masseteric inhibitory periods. The administration of an opiate antagonist, naloxone, 10 mg, partially reversed the suppression of sensation in 5 subjects tested. These data suggest that: 1) the masseteric inhibitory periods can occur independent of any detectable tooth pulp sensation; 2) narcotic manipulations reduce tooth pulp pain sensation, but do not affect the inhibitory periods; 3) the inhibitory periods involves trigeminal brain stem pathways distinct from those that mediate pain sensations; and 4) the suppression of tooth pulp non-pain and pain sensations by conditioning stimulation may be mediated in part by endogenous opiate pathways.

2086 PAG MORPHINE AND STIMULATION AND MORPHINE MICROIONTOPHORESIS EFFECTS ON BRAIN STEM NEURONS IN THE RAT. J. Scott Mohrland* and G. F. Gebhart, Dept. of Pharmacol., Univ. of Iowa, Iowa City, IA 52242.

Focal electrical stimulation or microinjection of morphine into the periaqueductal gray region (PAG) of the mesencephalon is known to produce analgesia. The purpose of the present investigation was to evaluate the involvement of neurons of the brain stem nucleus reticularis gigantocellularis (NGC), nucleus reticularis paragigantocellularis (NPGC), and nucleus raphe magnus (NRM) in the analgesia produced by these manipulations in PAG. Cannula electrode assemblies were implanted (chronically) into the PAG of 54 rats. Hot plate and tail flick tests were used to establish analgetic efficacy after either PAG stimulation or morphine administration (17.5 nmoles in 0.5 µl). Single unit activity in NGC, NPGC and NRM was recorded employing standard methods and the effects of PAG morphine and stimulation on both spontaneous and noxious stimulation evoked activity was examined in these brain stem areas. Multibarrel micropipettes were employed to locally apply morphine at the recording locus and compare effects to morphine applied at a distant, analgesia-producing locus (i.e., PAG). Stimulation of the PAG produced both excitation and inhibition of spontaneous activity in NGC and NPGC whereas only inhibition was observed in NRM. PAG stimulation inhibited the noxious evoked activity in greater than 80% of the cells in all three brain stem nuclei. Microinjection of morphine into the PAG produced an increase in spontaneous activity in 53%, 45% and 38% of the neurons in NGC, NPGC and NRM, respectively. Microiontophoresis of morphine at the recording site also produced excitation in these nuclei (42% in NGC, 54% in NPGC, and 20% in NRM) which could be reversed by microiontophoretic naloxone. Morphine administration in PAG inhibited noxious evoked activity in a high percentage of neurons in each of the three nuclei; inhibition of noxious evoked activity was rarely observed after morphine administered microiontophoretically. Morphine or stimulation at PAG cannula/electrode placements which were not analgesia-producing were without effect on noxious evoked activity in NGC, NPGC or NRM. Supported by NIH grants NS 12114, NS 06043 and GM 22026.

2087 RESPONSES OF SQUIRREL MONKEYS TO NOXIOUS AND INNOCUOUS THERMAL STIMULI. Thomas J. Morrow and Kenneth L. Casey. Depts. of Physiol. & Neurol., Univ. of Mich., Ann Arbor, MI 48109.

Pain assessment in animals is typically carried out using qualitative tests (pinch, pin prick, etc.), however, more quantitative measures would often provide more useful information. In response to this need, we have developed a humane, quantitative method of measuring the unlearned responses of squirrel monkeys to controlled natural stimuli. Subjects are trained to pull and hold one of two heated response levers (thermodes) to receive a liquid banana reward. Food availability is signaled by a light turning on over the respective thermode. Thermal pulse stimuli of 43, 47, 52 and 55°C (7 sec duration, 18°C/sec rise from a 38°C baseline) are delivered either to the hands or shaved tail during feeding or to the tail between feedings. The appropriate responses (thermode release or tail movement) terminate food delivery and/or the thermal pulse. A minicomputer controls the feeding schedule, stimulus parameters, timing and acquisition of response data. Each monkey has received an average of 309 ± 158 trials at each stimulus intensity.

When food availability is signaled (light on), the monkeys show a marked reduction in spontaneous movement, resulting in a lower number of responses to blank (38°C) trials as compared with the number of blank trial responses emitted between feedings. Consequently, all 3 monkeys show significant (χ^2 $p << .01$) responses to stimuli of 47°C delivered during feeding (prob. = 0.16),but show significant responses only to stimuli of 52°C or higher (prob. > 0.5ϕ) delivered between feedings. These differences are attributable to the smaller number of blank trial responses during feeding. Response latencies average 2.47 ± 0.55 (s.e.m) seconds from stimulus onset and are nearly the same during and between feedings; no changes in latency were noted as stimulus intensities increased. These data provide the necessary background for future neurophysiological and behavioral studies of pain mechanisms in this species and emphasize the importance of behavioral control (behavior clamping) during tests of responses to noxious stimuli.

2088 INHIBITION OF SPINAL NEURONES BY STIMULATION OF RAPHÉ MAGNUS IN THE RAT. J.A. Pearson, M.C. Green* and Carolyn Watson*. Dept. of Physiology, Univ. of British Columbia, Vancouver, B.C., Canada, V6T 1W5

Stimulation of the mesencephalic periaqueductal grey (PAG) results in an elevation of pain threshold which is dependent upon the integrity of serotonin-containing neurones. In view of the fact that PAG stimulation causes inhibition of spinal interneurones it is possible that stimulation-produced analgesia might be a consequence of the activation of descending inhibitory systems. The axons of serotonin-containing neurones of the raphé magnus (RM), unlike those located within the mesencephalic dorsal raphé, project to the spinal cord. Stimulation of the RM has been shown to cause analgesia in the rat and cat. The RM might therefore be an essential relay mediating the inhibitory influence of PAG stimulation upon spinal neurones.

Experiments were carried out to determine the effect of RM stimulation upon the activity of spinal neurones in urethane-anaesthetized rats. Two populations of cells were studied: a) spinothalamic tract neurones, identified by antidromic activation by stimuli applied to the contralateral ventral thalamus, and b) unidentified spinal neurones. Most of these cells responded to cutaneous stimulation. They could be activated by both weak, tactile stimuli and by intense, noxious inputs. The response pattern to electrical cutaneous stimulation consists of a short latency (5-10 msec) burst of action potentials to weak stimuli and a late (>50 msec) discharge to high stimulus intensities. Trains of stimuli applied to RM (20-200μA; 200Hz; 0.2 msec; train duration 45 msec, starting 50 msec prior to the cutaneous stimulus) inhibited the responses to weak cutaneous stimuli in 86% of cells tested and those to intense stimuli in 67% of neurones. The mean, threshold, RM stimulus intensities required to inhibit responses to "non-noxious" and "noxious" inputs were 102 ± SE 11.0μA and 153 ± SE 16.0μA respectively. The difference between these values is significant ($p<0.02$; t-test). In contrast to the findings obtained from experiments in monkey and cat, RM stimulation was more effective in inhibiting responses to weak cutaneous stimuli than those to more intense inputs. RM stimulation was shown to block the antidromically evoked action potential in 53% of the spinothalamic tract cells. This implies that the inhibitory effect of RM upon responses to cutaneous inputs may be a consequence of a direct post-synaptic influence on these cells.

2089 SYNAPTIC ACTIVATION AND INHIBITION OF NUCLEUS RAPHE MAGNUS (NRM) NEURONS FOLLOWING ELECTRICAL STIMULATION OF PERIAQUEDUCTAL GRAY (PAG) IN THE RAT. Scott Pomeroy and Michael M. Behbehani, Dept. Physiol., Coll. Med. U. of Cincinnati, Cincinnati, Ohio 45267.

Recent evidence has shown that electrical stimulation of PAG can produce analgesia by activating a system that projects to the spinal cord via the dorsolateral funiculus (DLF) to inhibit pain-transmitting neurons. Since PAG has no substantial projection to the spinal cord via the DLF, nuclei with direct spinal projections have been examined to determine whether they contribute to this analgesic system. It is now evident that the NRM has a critical role in the production of analgesia by PAG stimulation.

To examine the interaction of PAG and NRM, post-stimulus time histograms were recorded of NRM unit activity while electrically stimulating PAG. Single barreled glass electrodes filled with 2% pontamine sky blue in .5 M sodium acetate were made suitable for extracellular recording of single units and were stereotaxically positioned in NRM. Bipolar tungsten stimulating electrodes were positioned into ventrolateral PAG. Stimulus parameters: frequency = 1 Hz, duration = 30-50 microsec., amplitude = .5-2 ma. In approximately one-half of the experiments, NRM neurons were tested for spinal projection by electrically stimulating the lumbar DLF. NRM neurons were designated as raphe-spinal if DLF stimulation produced antidromic responses which were abolished by collision with orthodromic spikes. A total of 67 neurons were studied in all experiments. The distribution of responses was found to be: 54% facilitation, 15% inhibition, 12% facilitation and inhibition, and 19% no response. The mean latency to onset of facilitated response was 12.0 ± 1.6 ms (mean ± S.E.M.) and the mean latency to onset of inhibition was 2.8 ± .3 ms. Of 34 neurons tested, 26% were shown to have spinal projections (mean conduction velocity was calculated to be 14.6 m/s). No overt differences were seen in comparing distribution or latency of facilitated response between raphe-spinal and non-raphe-spinal neurons. For seven cells, the extent of current spread at the stimulating electrode was measured by systematically moving the PAG electrode 1,2, or 3mm dorsally or ventrally and recording additional post-stimulus time histograms. In all cases, moving the electrode 2mm dorsally abolished the response. Three neurons showed an attenuated response at 2mm ventral to reference but no response at 3mm ventral to reference.

On the whole, these data show that electrical stimulation of PAG most often leads to synaptic activation of NRM neurons. This lends further support to the hypothesis that activation of raphe-spinal neurons mediates spinal anti-nociceptive responses to PAG stimulation.

2090 EVIDENCE FOR SITE SPECIFICITY IN NALOXONE'S ANTAGONISM OF STIMULATION-PRODUCED ANALGESIA IN THE RAT. G. J. Prieto*, G. J. Giesler, Jr., and J. T. Cannon (SPON: J. C. Liebeskind). Dept. Psychol., UCLA, Los Angeles, CA 90024.

The phenomenon of stimulation-produced analgesia (SPA) has been characterized by inter-subject variability both in post-stimulation duration of SPA and in naloxone's ability to block it. We sought to determine if some of this variability could be due to differences in stimulation loci. Rats were implanted with bipolar stimulating electrodes along the midline of caudal periaqueductal gray (PAG) and the median raphe n. Stimulation consisted of constant current, biphasic pulse pairs (20/sec). Each member of the pair was 50 μsec in duration, with a 100 μsec separation. Analgesia was assessed with the tail-flick test using a modified ascending method of limits to determine currents necessary to inhibit this reflex (cut-off latency = 7 sec). In each session, separate determinations were made for thresholds of "during-stimulation" analgesia (DSA) and "post-stimulation" analgesia (PSA). Stimulation was delivered either for 10 sec before and continuing throughout tail-flick testing (DSA) or for 15 sec immediately prior to tail-flick testing (PSA). After DSA and PSA threshold determinations on the second and third test days, rats were injected with either naloxone (10 mg/kg, s.c.) or saline according to a counterbalanced order, and thresholds were reassessed. Most animals later received lesions of the n. raphe magnus (NRM) and were tested again at least 1 week after surgery.

Several differences of interest were found between placements in or below dorsal raphe n. versus those in PAG above this structure. For more dorsal placements, currents necessary to produce DSA (mean = 2.3 ma) and PSA (mean = 5.1 ma) were highly correlated ($r = .91$, $p < .01$). For deeper placements, however, this correlation was weaker ($r = .52$, n.s.), and significantly higher currents were required for PSA (mean = 10.8 ma) than was true for the dorsal placement group ($p < .01$). DSA thresholds for deeper electrode placements (mean = 2.7 ma) did not significantly differ from those of the dorsal group. Several animals with ventral placements were exceptional in that they failed to exhibit PSA within the current limitation of the stimulator (18 ma), even though their DSA thresholds were in the normal range. Whereas naloxone failed to antagonize SPA in any of the 16 animals with dorsal placements, SPA thresholds were elevated by this drug in 6 of 12 animals with ventral placements. To date, NRM lesions have not been seen to cause reliable changes in SPA thresholds even when adjacent reticular structures were invaded.

2091 EFFECTS OF MEDULLARY RAPHE LESIONS ON MORPHINE-INDUCED ANALGESIA AND NOCICEPTIVE THRESHOLD: DEPENDENCE ON THE POST-LESION TEST INTERVAL. Herbert K. Proudfit, Dept. of Pharmacol., Univ. of Ill. at the Med. Ctr., Chicago, IL., 60612.

Electrolytic lesions of the nucleus raphe magnus (NRM) result in hyperalgesia and attenuation of morphine-induced analgesia (MIA) when tested between ten days and two weeks following surgery (Proudfit and Anderson, 1975). However, in subsequent studies animals tested at seven days or less following the placement of lesions, showed no alteration in MIA. Therefore, we examined the time-course of lesion effects on both nociceptive threshold and MIA. Following electrolytic lesions of either the NRM or raphe pallidus, rats were tested at seven day intervals for 35 days using the tail flick test. Unoperated control rats were similarly tested. Seven days after lesioning the nociceptive threshold was reduced by 33%, and by 14 days by 42% of control. However, testing at subsequent seven day intervals showed a gradual recovery and return to control values by day 35. By contrast, the effect of lesions on MIA (5 mg/kg) was quite different. No effect was seen at seven days, but testing at subsequent seven day intervals revealed a gradually increasing attenuation of MIA throughout the 35 days of testing.

The effect of reversible lesions of the NRM produced by the microinjection of the local anesthetic tetracaine (TET; 5 ug in 0.5 ul of saline) was also examined. Rats were implanted with chronic indwelling microinjection guide tubes (25 ga) and seven days after surgery the nociceptive threshold was determined and morphine sulfate (5 mg/kg, sc) was injected. At the peak of MIA (30 min) TET was slowly infused through a 28 ga injection cannula into the NRM. Tail flick latencies determined 5, 10, 15, 25 and 45 minutes after TET injection were not significantly different from those determined before TET. However, when TET was injected locally in the absence of morphine pretreatment, the animals exhibited hyper-reactivity. This effect was evident immediately after the injection, but declined to near normal reactivity by 45 minutes.

These results suggest that raphe lesion-induced attenuation of MIA and hyperalgesia are mediated by the destruction of separate neuronal systems. In addition, the failure of acute raphe lesions or TET-induced inhibition of the NRM to alter MIA indicates that the NRM is not involved in mediating the anti-nociceptive actions of opiates. It is likely that an effect secondary to destruction of the NRM is responsible for the attenuation of MIA observed following chronic NRM lesions.

2092 INTRACEREBRAL SUBSTANCE P IN MICE: BEHAVIORAL EFFECTS AND NARCOTIC AGENTS. Anita Rackham and Norman N. Share*. Dept. Pharmacol., Merck Frosst Laboratories, Kirkland, Quebec, Canada.

In preliminary studies with mice, acute intracerebral injection of substance P was found to induce a unique behavioral phenomenon characterized by reciprocal hindlimb scratching movements. In mice weighing 18 to 22g, an injection site approximately midline at the level of the external auditory meatus, using a 27 gauge hypodermic needle of 3.5 mm in length, yielded the most dramatic and consistent responses. Dye marker experiments indicated injection directly into the IIIrd ventricle with the solution (2 µl) spreading to all cerebral ventricles.

Acute intracerebral injections of substance P induced distinctive behavioral changes whose intensity appeared dose-related. Within 60 to 90 seconds, the mice seemed agitated, preened excessively, and engaged in reciprocal hindlimb scratching movements directed toward the sides of the upper body and jaw areas. These latter responses were paroxysmal, being interspersed with periods of exaggerated preening and biting at the abdomen and hindquarters. The substance P-induced reciprocal hindlimb scratching response was the most consistent and reproducible of the behavioral responses observed, generally occurring within 2 minutes and always within 5 minutes after intracerebral injection. Considering a single reciprocal hindlimb scratching episode observed within 5 minutes after intracerebral injection as a positive response, the ED_{50} was for substance P ≃ 0.06 µg/mouse. Similar intracerebral dose-responses were obtained by the related undecapeptides physalaemin (ED_{50} ≃ 0.025 µg/mouse) and eledoisin (0.004 µg/mouse), but not by several unrelated peptides (TRH, neurotensin, bradykinin, somatostatin).

Analgesic narcotic agents with predominant agonist activity administered intraperitoneally prevented the reciprocal hindlimb scratching response induced by intracerebral substance P (0.625 µg/mouse = ED_{95}). In this in vivo assay their order of potency (etorphine > etonitazine > phenazocine = levorphanol > dihydromorphine ≥ methadone ≥ morphine > meperidine ≥ d-propoxyphene ≥ codeine) was similar to that reported for binding to rat opiate receptors in vitro. Narcotic agents with predominant antagonist activity (nalorphine, pentazocine) were inactive while the narcotic antagonist naloxone completely reversed the action of morphine.

Evidence suggests that the undecapeptide substance P may serve as an important transmitter or modulator of sensory processes, and its action may be associated with algesia or analgesia. (Fredrickson et al, Science, 199: 1359, 1978). The above findings suggest that acute intracerebral substance P-induced reciprocal hindlimb scratching responses in mice involves algesic systems within the central nervous system.

2093 COMPARISON OF ALTERNATING VERSUS DIRECT CURRENT ELECTROANALGESIA APPLIED THROUGH INTACT TOOTH ENAMEL. Patrick J. Reynolds, Ann Kloka*, Richard B. Tacke* and R. Wayne Fields. School of Dentistry, University of Oregon Health Sciences Center, Portland, Oregon 97201.

We have shown that trains of rectangular pulses, of 10% duty cycle at 1000Hz, capacitively coupled to effect alternating polarity, can block afferent activity from cat tooth pulp when applied to exposed dentin at levels of 70-100µA as effectively as direct anodal current of similar strength (Fields et al., Abstr. Soc. Neurosci. 4-459, 1978). For clinical use for electroanalgesia (EA), low duty cycle alternating pulse trains are conceptually superior to direct current (Fields et al., Oral Surg. 34:694-703, 1972) because of lower power dissipation (small duty cycle) and reduced monodirectional iontophoresis (alternating polarity). In unpublished observations, we have also found that neither alternating nor direct currents ranging to 1000µA cause histologically detectable pulpal aberrations when applied to intact teeth (through the enamel). Such current application simulates a practical clinical EA protocol, but it is not known if it truly induces afferent unit hypoexcitability.

This question was addressed in the present studies in which excitability of single pulp-driven units in cat Gasserian ganglion was observed during and following application of 0-100µA ac (1000Hz, 10% duty cycle rectangular pulses, capacitively coupled) and dc EA current to intact maxillary canine teeth. The excitability index was in terms of threshold to electrical stimulation via a pair of dentinal electrodes (e.g., Fields, et al., Exp. Neurol. 53:386-398, 1976). For both ac and dc waveforms a progressive rise in pulp-driven unit threshold, compared to pre-EA control, was seen with increasing current over the 0-100µA range. Threshold elevation of at least 500% was seen for both waveforms at 100µA after as little as 1 minute duration. Recovery to control threshold following 1 minute of dc at 100µA required as much as 10 minutes; for the majority of units examined, recovery periods following ac were shorter than following dc of similar intensity.

These results demonstrate that a) both ac and dc EA currents applied to intact enamel of cat maxillary canine teeth are capable of attenuating activity of pulp-driven units in the Gasserian ganglion, and b) the ac EA employed exhibited adequate efficacy but superior recovery characteristics when compared to dc of similar intensity.

2094 PROFOUND POTENTIATION OF MORPHINE'S ANALGETIC POTENCY BY CONCURRENT INTRATHECAL AND INTRAVENTRICULAR ADMINISTRATION. Thomas A. Rudy and Joseph C. Yeung*. School of Pharmacy, Univ. of Wisconsin, Madison, WI 53706.

To examine the mode of interaction between the spinal and supraspinal narcotic-sensitive structures in the mediation of analgesia, we have measured the antinociceptive effect [hotplate (HP) and tailflick (TF) methods] produced by concurrent intrathecal (i.t.) and intraventricular (i.vt.) injections of morphine sulfate. Rats in which the fourth ventricular exits had been acutely occluded received an i.t. injection of morphine (lumbar spinal subarachnoid space; 0-10 ug in 4 ul) followed immediately by an i.vt. injection (ventral third ventricle; 0-50 ug in 5 ul). Each rat was used in only one experiment. That there was no significant transfer of morphine between the spinal and supraspinal compartments at the time of peak analgesia was shown in diffusion studies using radiolabeled morphine.

It was found that the analgetic potency of morphine injected i.vt. was profoundly potentiated by concurrent administration of morphine i.t., and vice-versa. Dose-response curves (minimum of 50 rats/curve) for i.vt. morphine were shifted progressively to the left as the spinal dose of morphine was increased. At the optimal balance of spinal and supraspinal dosage, the ED50's for i.vt. morphine for the HP and TF tests were reduced by factors of 45 and 33, respectively. A similar, but less profound, shifting of the i.t. dose-response curves was seen when the i.vt. dosage was progressively increased. Isobolographic analysis of the data revealed that the isobols were hyperboloids having extreme negative curvature at all effect levels. Inspection of the isobols indicated that, at all ratios of spinal to supraspinal agonism which could conceivably be obtained when morphine is given systemically, the spinal-supraspinal interaction is purely multiplicative. In a multiplicative interaction, removal of either input reduces output to zero. Thus, it seems likely that narcotic agonism at both the spinal and supraspinal morphine-sensitive structures is essential to the production of analgesia by systemically administered morphine and that neither action locus can be considered the "primary" site of action.

2095 MODULATION OF SENSORY EXCITABILITY IN THE CAT TOOTH BY EXTRACELLULAR POTASSIUM AND SODIUM. Donald Scott, Jr. and W.I.R. Davies* Dept. Physiol. University of Penna. Phila.,Penn.19174

The effect of thermal, mechanical and other forms of tooth stimulation encountered by normal mammals have been extensively studied and shown to evoke characteristic impulse frequency patterns which can be recorded by electrodes in dentinal cavities. Whereas the response to cold stimulation was similar to that observed when cooling an axon, the effect of heat showed marked differences which could be attributed to the specialized receptor. Davies (1969) examined the excitability of dentinal receptors in the cat tooth in response to heat and found an increase of excitability when extracellular potassium was decreased and an inhibition when it was increased. These observations have been confirmed and extended. However, increases in extracellular sodium concentration have only resulted in comparable increases in excitability. Since the sensory response to heat is only slightly affected by topical application of tetrodotoxin (TTX), sodium may not be a major contributor to the transducer process. This finds support in the report by Rockert (19) that intracellular potassium in the odontoblast process may be significantly above the level in dentinal fluid. A scheme for transducer function consistant with these observations is proposed.

2096 ENDOGENOUS OPIATE-RELATED INFLUENCES FROM PERIAQUEDUCTAL GRAY AND NUCLEUS RAPHE MAGNUS ON SOLITARY TRACT NEURONS AND RESPIRATORY-RELATED FUNCTIONS. B.J. Sessle, G.J. Ball and G.E. Lucier (SPON: A.T. Storey). Fac. of Dentistry, Univ. of Toronto, Toronto, Canada, M5G 1G6.

Much emphasis has recently been placed on the role of the periaqueductal gray matter (PGM) and nucleus raphe magnus (NRM) in endogenous opiate-related mechanisms of analgesia. Little consideration has been given to possible influences from these two sites on functions other than those involved in pain and its control. Yet projections from one or both these sites, as well as opiate receptors, have been found concentrated in central regions concerned with functions other than nociception, e.g. the solitary tract nucleus (STN), the site of respiratory reflex interneurons and respiratory neurons. We wished to determine if the activity of such STN neurons, and respiration and related reflex functions, are influenced by PGM and NRM stimulation and if any observed influences could be reversed by the administration of the opiate antagonist naloxone.

In anesthetized cats, we first determined if some of the functions that are subserved by STN neurons (respiration, swallowing, coughing) could be influenced by PGM and NRM stimulation. Only a transient depression of respiration was observed with PGM and NRM stimuli, but a marked decrease occurred in the incidence of coughing and swallowing elicited by stimulation of the superior laryngeal nerve or upper respiratory tract; naloxone (0.4 mg/Kg, I.V.) could reverse these PGM and NRM induced depressive effects. The effects were reflected in changes in the activity of functionally identified single neurons recorded during microelectrode penetrations of STN. These neurons were characterized by their rhythmic respiratory-related activity, or their short-latency reflex responsiveness to low-threshold superior laryngeal or vagal nerve stimuli. The rhythmic activity of respiratory neurons was generally retained during PGM and NRM stimulation, although a decrease in the peak firing frequency of each rhythmic burst was regularly observed. In contrast, the reflex responses of STN neurons could be powerfully suppressed by PGM and NRM stimulation, and the suppression could be reversed by naloxone.

These studies indicate that respiration and in particularly the associated reflex activities of coughing and swallowing are depressed by endogenous opiate-related influences derived from PGM and NRM. Such effects may be associated with the depression of respiration and coughing that can result from opiate overdose. The depressive effects appear to be reflections of the susceptibility of STN neurons that are involved in respiration and associated reflex activities to inhibitory influences from PGM and NRM, and indicate that PGM and NRM may be involved in functions other than analgesia. (Supported by NIH).

2097 LOCAL BRAIN GLUCOSE UTILIZATION EVOKED BY DENTAL PULP STIMULATION IN THE RAT AND THE CAT: A COMPARATIVE STUDY. Andrew G. Shetter and Carol Kreinick.* Neurosurgical Research Laboratory, Barrow Neurological Institute, Phoenix, AZ 85013

The pattern of local brain glucose uptake produced by dental pulp stimulation in cats and rats was investigated using the 2-deoxyglucose method of Sokoloff. Bipolar electrodes were inserted into the pulp cavity of either a mandibular or a maxillary incisor tooth under pentobarbital anesthesia. Constant current 10Hz electrical pulses were delivered at an intensity sufficient to produce a visible jaw jerk reflex. An intravenous injection of ^{14}C-2-deoxyglucose (10μCi/100gm) was given and continuous stimulation was performed for 45 minutes. Autoradiographs were prepared from unfixed sections of the brainstem and upper cervical spinal cord, and the resultant optical density patterns were analyzed with the aid of a microdensitometer. Control groups included animals who had electrodes implanted but not stimulated, and those in whom maximal stimulation was performed after surgical exoneration of the pulp cavity.

Stimulus-related increases in glucose uptake were seen throughout the entire trigeminal sensory system in both species, extending from nucleus caudalis at C1-2 to nucleus oralis - main sensory nucleus in the rostral midbrain. Enhanced glucose metabolism was less pronounced in nucleus interpolaris, and no changes were apparent in the trigeminal mesencephalic nucleus or the motor nucleus. The increases in metabolic activity produced by dental pulp activation in the rat were exclusively ipsilateral to the site of stimulation. Alterations in the cat were present bilaterally but were maximal on the ipsilateral side. Afferent input from mandibular pulp stimulation evoked increased glucose utilization in the most dorsal portions of the trigeminal sensory nuclei. Maxillary pulp input was represented more ventrally and covered a larger area. This somatopic distribution was apparent in both species, but was more discrete in the rat than in the cat. No alterations in glucose uptake were detected in extra-lemniseal or reticular pathways for any of the animals studied. The 2-deoxyglucose technique appears to be a useful means of investigating trigeminal nociceptive systems.

2098 TRIGEMINAL PRIMARY AFFERENT DEPOLARIZATION AND REFLEX INHIBITION PRODUCED BY PERIAQUEDUCTAL GRAY AND RAPHE MAGNUS STIMULI: INFLUENCE OF NUCLEUS CAUDALIS AND EFFECTIVENESS OF OTHER BRAINSTEM STIMULATION SITES. R. Sumino, J.W. Hu, J.O. Dostrovsky and B.J. Sessle. Fac. of Dentistry and Dept. of Physiology (J.O.D.), Univ. of Toronto, Canada M5G 1G6.

We have recently found that electrical stimulation of the periaqueductal gray matter (PAG) or nucleus raphe magnus (NRM) can cause a powerful suppression of the digastric (jaw-opening) reflex and primary afferent depolarization (PAD) of tooth pulp afferent endings in trigeminal (V) brainstem nuclei oralis or caudalis. Many recent studies have implicated nucleus caudalis in the relay of orofacial pain, and PAG and NRM in endogenous opiate-related mechanisms of analgesia. Moreover, caudalis receives a direct projection from NRM and is also a major site of opiate receptors. Thus it might be expected that the reflex inhibition and PAD in oralis induced by PAG and NRM stimulation would be abolished by procedures that disrupt nucleus caudalis. Accordingly, we have examined the effects of such procedures on these PAG and NRM induced effects. We have also tested to see if the reflex inhibition and PAD effects are specifically induced from PAG and NRM or whether they can be produced by stimuli delivered to brainstem regions outside PAG and NRM.

Utilizing methods previously described (Brain Res. 117: 211, 1976; Nature 276: 283, 1978), we verified in anesthetized or decerebrate cats that PAG or NRM stimulation could induce suppression of the digastric reflex evoked by pulp or low-intensity infraorbital nerve stimuli, and PAD of pulp afferent endings in oralis. A V tractotomy procedure or cold block of synaptic transmission in nucleus caudalis was then used to assess the influence of caudalis in these effects. The cold block procedure was used most often since it has the advantage that it is reversible and tests could be repeated numerous times in the same animal. Although tractotomy or cold block abolished synaptic transmission in caudalis, we consistently found no change in the threshold inhibition of the digastric reflex evoked by pulp or low-intensity infraorbital nerve stimuli or in the PAD of pulp afferent endings in oralis. This indicates that these effects of PAG and NRM are not dependent on relays through nucleus caudalis for their production. Furthermore, brainstem regions other than PAG and NRM may be similarly involved in the reflex inhibition and PAD in view of results obtained by carefully mapping the effects of stimuli applied in a series of electrode penetrations within and outside PAG and NRM in 6 cats. Reflex inhibition and PAD could be induced from reticular formation areas outside PAG and NRM at stimulation intensities that were comparable to those effective within PAG and NRM.

2099 FATIGUE AND SENSITIZATION OF NOCICEPTIVE AFFERENTS IN THE MONKEY. J.G.Thalhammer* and R.H. LaMotte. Dept. ofAnesthesiology Yale University, New Haven, Conn. 06510. (SPON.:J.G.Collins)

In these studies we measured the time course of changes in responsiveness of nociceptive afferents in monkeys during and following intense local heating of the skin. Twenty-three C-fibers (CMHs) and 25 A-fibers (AMHs) were classified as sensitive to noxious mechanical and noxious heat stimuli. Initial heat thresholds of all AMHs were greater than 48°C while those of CMHs averaged 45°. A conditioning stimulus (CS) of 50° (60s duration) was delivered to the receptive fields of 14 CMHs and 17 AMHs and 9 warm (C) fibers innervating the hand or foot. During the CS, CMHs responded with a relatively high rate of discharge at onset of the stimulus and then adapted,while most AMHs (n = 12) responded only after a long latency with a rate of discharge that increased gradually. The warm fibers responded only during the first few seconds of the stimulus. After termination of the CS, brief stimuli of 39-47° or 39-51° were delivered over a period of 0.5-30 min. Initially, CMHs were fatigued and their thresholds increased to 2-8° above corresponding values obtained prior to the CS; but, by 5-10 min after the CS,the thresholds were 2-6° below prior values and their responses to suprathreshold stimuli greater than normal (sensitized) and remained so up to the end of testing. At this time, some CMHs had decreased thresholds to mechanical stimuli and some could be activated by lightly rubbing the skin with gauze.

All the warm fibers were suppressed without sensitization following the CS. Six of those 12 AMHs responsive to the CS became sensitized within 10 min after the CS. Neither AMHs nor CMHs developed spontaneous activity. Many of those AMHs that did not become sensitized following the 50° CS did so following multiple stimulations of higher temperatures (e.g. 53°, 5-20s) and some of these developed spontaneous activity as well as lowered mechanical thresholds and a sensitivity to rubbing the skin with gauze.

Fatigue and sensitization of CMHs following a stimulus of 50° for 60s may account, in part, for the sensory phenomena of suppression and hyperalgesia (LaMotte et.al., this vol.). The sensitization of AMHs is likely to contribute to the hyperalgesia induced by stimuli of higher intensities or longer durations.

2100 A NEUROANATOMICAL STUDY OF ANALGESIA AND CATATONIA INDUCED BY ETORPHINE IN THE RAT. B. E. Thorn, R. A. Levitt, J. T. Hill and K. Ward. Dept. Psychol. and Sch. Med., Southern Ill. Univ., Carbondale, IL 62901; Dept. Psychol., Univ. of Ala. in Birmingham, Birmingham, AL 35294.

Etorphine hydrochloride is a fast-acting narcotic analgesic, several thousand times more potent than morphine. We studied the analgesic and catatonic properties of etorphine when microinjected into one of 11 neuroanatomical sites: periaqueductal gray; midbrain reticular formation, cerebral aqueduct; cerebellum; caudate putamen; basolateral amygdala; cortico-medial amygdala, globus pallidus, medial thalamus, hippocampus. Each site was represented by a minimum of 6 subjects.

The flinch-jump technique was used to assess pain sensitivity and the bar test was used to study catatonia. Etorphine was administered in a 1 µg dose. Each animal was used only once in one experiment and was administered etorphine only one time. The animals received a baseline bar test followed by a flinch-jump test followed by a second bar test (taking 10 min). They were then injected with drug (either water or etorphine in a 1 µl solution) into one neuroanatomical location. All animals received both water and etorphine, presented in a counterbalanced order and separated by a four-day interval.

Neuroanatomical location ranged from AP+3.0 to AP-9.0. Significant analgesia and catatonia was elicited with 1 µg injections of etorphine into the periaqueductal gray (PAG), the midbrain reticular formation (MRF) and the cerebral aqueduct (AQ). Degree of analgesia or catatonia was not significantly different between these three sites. Injection of 1 µg etorphine into the medial thalamus (MT) resulted in analgesia and catatonia that approached significance. Injections into the cerebellum (CB), basolateral amygdala (BLA), cortico-medial amygdala (CMA), caudate putamen (CPU), globus pallidus (GP) or hippocampus (HP) failed to elicit significant elevation of the nociceptive threshold, although catatonia was elicited in the CMA and GP.

Although in most cases a high correlation was found between analgesia and catatonia, this and previous studies (Thorn and Levitt, 1978) suggest that at some sites these behavioral effects may be separable. Interesting differences between results of this and other studies will be discussed. Results suggest a possibility for separate neurological substrates for analgesia and catatonia. Additionally, results show at least some site-specificity for analgesia and catatonia after etorphine injection, suggesting that the effect is not just a result of gross diffusion following microinjection of a lipophilic substance in the brain.

2101 EFFECTS OF 6-HYDROXYDOPAMINE AND 5,7-DIHYDROXYTRYPTAMINE BRAINSTEM LESIONS ON MORPHINE ANALGESIA. Yousef Tizabi, V. John Massari, Thomas L. O'Donohue*, David M. Jacobowitz and Agu Pert. Dept. Pharmacol., Howard Univ., Washington DC 20059 and Lab. Clin. Sci. and Biol. Psychiat. Br., NIMH, Bethesda, MD 20205

Opiate analgesia, at least in part, appears to be determined by the activation of descending pathways from the brainstem to the spinal cord. Considerable evidence has been presented to implicate both descending serotonergic (5-HT) pathways originating from the nuclei raphe magnus, pallidus and obscurus and noradrenergic (NE) pathways originating from the A-1, A-2 and A-6 catecholamine nuclei in morphine analgesia. To decide which pathways are predominantly involved, morphine analgesia was assessed in rats that had been lesioned in the brainstem raphe nuclei with 9 µg of 5,7-dihydroxytryptamine or in the A-1 catecholamine nuclei with 6 µg of 6-hydroxydopamine injected bilaterally. At the termination of the study, the spinal cord was removed and sectioned into 500 µm slices. The dorsal and ventral horns were microdissected from these slices, and monoamines were assayed using sensitive radioenzymatic methods. The lesions were confirmed by measuring the monoamines at the injected sites. Destruction of the raphe nuclei resulted in a 50% depletion of 5-HT in the dorsal horn. NE in the ventral horn was unaffected. Destruction of the A-1 catecholamine nuclei resulted in a 64% depletion of NE in the dorsal horn. Analgesia was assessed 30 min after injections of either 5 or 10 mg/kg of morphine in the tail-flick, hot-plate and finch-jump tests. The effects of the lesions were relatively subtle and varied in modifying morphine analgesia across the various tests. Raphe lesions had little effect in the tail-flick test, whereas morphine analgesia in the hot-plate and flinch-jump tests was slightly attenuated. A-1 lesions appeared to attenuate morphine analgesia in the hot-plate tests and at 5 mg/kg in the tail-flick test. Combined lesions of A-1 and raphe nuclei were not significantly more effective in attentuating morphine analgesia. Thus, neither system appears to be critical for mediating systemically induced opiate analgesia. This suggests either the presence of other descending systems that are activated by morphine, the ability of the remaining descending catecholamine pathways to mediate opiate analgesia or the predominance of spinal actions. Studies are underway to ascertain whether these monoaminergic lesions would be more effective in attenuating morphine analgesia induced by direct injections either into the periaqueductal gray matter or the n. gigantocellularis. Additional studies are directed at ascertaining the importance of other catecholaminergic brainstem nuclei (e.g., A-2, A-5 and A-6) in morphine analgesia following either single or combined lesions.

2102 ECTOPIC GENERATION OF IMPULSES IN PERIPHERAL SENSORY NERVE FIBRES IN MAN. Erik Torebjörk* and José Ochoa. University Hospital, Uppsala, Sweden, and Dartmouth Medical School, Hanover, NH, USA.

Although much is known about pathological peripheral nerve fibres as abnormal conductors of impulses, little is known about them as abnormal generators. There are some insights into abnormal spontaneous activity of motor nerve fibres, but knowledge about similar activity in sensory nerve fibres in man is virtually nonexistent. This paper reports abnormal activity in single peripheral sensory fibres and correlates such activity with abnormal sensation, in volunteers experiencing a variety of paresthesiae.

Methods: Paresthesiae were induced after release of a sphygmomanometer cuff inflated above systolic blood pressure round the arm for about 30 minutes. Single unit impulses were recorded from sensory nerve fibres in the median and ulnar nerves, proximal and distal to the cuff, using the microneurographic technique of Vallbo and Hagbarth (1969).

Results: "Buzzing" paresthesiae of high frequency, referred predominantly to finger tips, peaked during the first 90 seconds after deflation of the cuff. High frequency unitary discharges (up to 220 impulses/sec) lasting for 1-7 seconds were prominent during this stage of paresthesiae. "Buzzing" was progressively substituted by sharp painless "pins and needles" and intermitent "tingling"; now the neural bursts recorded were shorter and often appeared in a rhythmical fashion.

Conclusions: Post-ischemic paresthesiae in man are due to abnormal impulse generation within the sensory unit. Recognizable changes in perception of paresthesiae follow modulations of frequency, duration, and rhythm of the abnormal discharges. It is possible, but not yet proven,that a simple change in the rhythm of discharge might determine a fundamental change in the quality of sensation under these abnormal circumstances.

Although the contribution to paresthesiae from different fibre types has not yet been investigated, the sustained, very high frequency of discharge recorded in some fibres endorses participation of myelinated fibres.

2103 INTRACARDIAC BRADYKININ INJECTIONS AND THEIR EFFECT ON SPINAL NEURONS HAVING VISCEROSOMATIC CONVERGENCE. R. Neal Weber* and Robert D. Foreman, Dept. Physiology & Biophysics, Univ. of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma 73190.

Previous studies from this laboratory have shown that the neural discharge rate of spinal neurons either increased or decreased during occlusion of the left coronary artery or the pulmonary artery. The purpose of this study was to determine whether an algesic substance such as bradykinin would influence the discharge rate of these cells when the substance was injected into the heart. The activity of single cells was recorded extracellularly from the left gray matter of the T_2 and T_3 spinal cord segments in 12 chloralose anesthetized cats. All the cells responded both to mechanical manipulation of the somatic receptive field and to electrical stimulation of the left T_2 to T_3 sympathetic chain. These cells responded to noxious pinch when it was applied to the receptive field of the left forelimb and chest. After the cells were tested for viscerosomatic convergence, bradykinin was injected into the chamber of either the left atrial appendage or left ventricle. The injected concentration of bradykinin varied between 100 µg/ml and 1 mg/ml in doses of .2 to .3 ml giving a total of 20 to 300 µg per injection. A total of 31 cells responded to both somatic manipulation and sympathetic stimulation. Fourteen of the 31 cells responded to the chemical injection while the remainder showed no change in their discharge pattern. Of the 14 cells, 13 were excited and one was inhibited following the chemical injections. The latency from the injection to onset of the response ranged from 4 to 20 seconds and had an average latency of 11 $\pm$ 0.4 (S.E.)s. Following the intracardiac injections, the same volumes and concentrations of bradykinin were injected into the femoral artery. Five of the 11 cells tested were responsive but they had a lesser increase in discharge rate and the onset of the response averaged 20 s. In two cells the excitatory responses to bradykinin were reduced or abolished following transection of the left sympathetic chain. These results lead to the suggestion that injections of bradykinin caused the excitation of cardiac receptors whose afferents made synaptic connections with cells of the thoracic spinal cord. Since these cells received input from nociceptors located in somatic receptive fields and from visceral receptors activated by algesic chemicals, they may be involved in transmitting information that is important for referred pain. Supported by NIH Grant 22732 and the Oklahoma Affiliate of the American Heart Association.

2104 LONG TERM THERMAL ANALGESIA AND SPINAL SUBSTANCE P (sP) DEPLETION BY INTRATHECAL CAPSAICIN (C). T.L. Yaksh, D.H. Farb, S.E. Leeman, G.M. Tyce*and T.M. Jessell. Mayo Fdn., Rochester, MN 55901; Dept. of Pharmacology, Harvard Med. Sch., Boston, MA 02115.

Following the rationale that sP may be a nociceptive transmitter in primary afferents, its depletion in the spinal cord might result in analgesia. C given systemically can deplete sP in the cord. We therefore sought to examine the effect of this drug administered intrathecally on the nociceptive threshold and sP levels in the rat. To carry out these experiments, rats were chronically implanted with intrathecal catheters inserted through the cisterna magna into the lumbar subarachnoid space. Following a 7 day recovery, animals received C (3 or 30 µg/15 µl of 50% saline-dimethysulfoxide vehicle) or vehicle. The injection of C, but not vehicle produced a 2-phased dose-dependent response: the first, lasting 1-3 min was characterized by muscular contractures; in the second phase the animal regained voluntary control and exhibited intense gnawing and scratching of the caudal regions of the body (15-30 min). After these phases the animals displayed no unusual motor signs and exhibited normal reflex function. Subsequent nociceptive testing revealed that 60-70% of the animals receiving 30 µg C showed no response to otherwise noxious thermal stimuli as measured with the 55°C hot plate or tail flick. These animals showing significant blockade continued to show no response for periods up to 3 months after C treatment (until natural death or sacrifice). The aversive behavior produced by subcutaneous injections of formalin (0.1 ml/2%) was substantially reduced but not blocked in C-treated animals as compared to non-treated controls. In contrast to the elevated thermal and chemical threshold, these C-treated rats displayed a normal response to mechanical pinch applied to the paws. Intrathecal C produced a dose-dependent depletion up to 50% in the spinal but not hind brain levels of sP. Comparison of degree of thermal analgesia with degree of depletion of sP indicated a highly significant correlation. I.V. administration of 30 µg of C produced no change in either sP levels or in the nociceptive threshold. Intrathecal 5,6-dihydroxytryptamine (20 µg in 15 µl ascorbic acid vehicle) produces a 70-90% decline in spinal 5-HT and a 40% decline in spinal sP. This neurotoxin in contrast to C, produced a significant reduction in the nociceptive threshold. These results suggest that there are two populations of sP containing spinal terminals, a portion is associated with the descending serotonergic system and a second portion is located in primary afferent terminals, the latter of which is depleted intrathecally. With regard to nociceptive transmission this data suggests that sP may be associated with primary afferents which carry information related to heat and peripherally applied algesic chemicals. This work supported by NINCDS 14629.

2105 TAIL-FLICK NEURONS OF THE NUCLEUS RAPHE MAGNUS. M.D. Zaretsky, J.D. Levine* and H.L. Fields. Depts. of Neurology and Physiology, Univ. of California, San Francisco, CA 94143.

We have recorded from individual neurons of the nucleus raphe magnus (NRM) in rats performing tail-flicks in response to noxious heating of the tail. The tail-flick test has been used to demonstrate both stimulus-produced (Mayer. D.J. et al, SCIENCE 174: 1351, 1971) and opiate (Akil, H. et al, SCIENCE 191:961, 1976) analgesia. Histological studies and electrical stimulation of the NRM suggest that the NRM is a significant region of a descending analgesia pathway (Basbaum, A.J. et al, PNAS 73:4685, 1977). We now report that the NRM contains two classes of neurons with discharge patterns that are strongly correlated with tail-flicks in response to noxious heating. In the first class of neurons, tail-flick triggers, strong excitation occurs when noxious heating results in a tail-flick. Excitation of these units does not occur when noxious heating fails to produce a tail-flick. Increase of the firing rate of these neurons begins just prior to the onset of the tail-flick. Sone neurons of this class discharge briefly, others continue to discharge after the tail-flick occurs. The second class of NRM neurons, off-units, firing spontaneously at a moderated rate, are inhibited from firing by noxious heating of the tail.

PLASTICITY

2106 UPTAKE AND RETENTION OF ^{45}Ca IN HIPPOCAMPAL PYRAMIDAL NEURONES DURING LONG TERM POTENTIATION. K.G. Baimbridge* & J.J. Miller (SPON: T.W. Calvert). Dept. Physiology, Univ. British Columbia, Vancouver, Canada V6T 1W5.

Previous studies have demonstrated that the presence of extracellular Ca during tetanic stimulation of hippocampal afferents is necessary for the development of long term potentiation (LTP) of synaptically evoked responses in this region. Inasmuch as Ca plays a significant role in transmitter release, and an augmented transmitter output may underly the phenomenon of LTP, the present experiments were undertaken to determine whether there is a significant uptake and retention of Ca following brief tetanic stimulation of the Schaeffer-collateral input to Ca_1 pyramidal neurones which induces LTP. Transverse slices of the rat hippocampus were prepared for electrophysiological recording and incubated in a modified Ringer's solution containing ^{45}Ca for 2 hrs prior to stimulation. Paired control and tetanized (50-100 Hz, 2-5 sec.) slices were removed at 5 and 30 min. following stimulation and washed in Tris-buffer (pH 7.4) containing 10 mM $LaCl_3$ in order to remove surface bound ^{45}Ca and to prevent release of intracellular Ca. Slices were freeze dried and the soluble protein dissolved in buffer and aliquots taken for total protein determination and ^{45}Ca content. In all pairs and at both time intervals, tetanic stimulation resulted in an increased ^{45}Ca content compared to controls. No loss of ^{45}Ca was observed 30 min. after tetanization compared to 5 min. post-tetany. The large influx of Ca which occurs as a result of tetanic stimulation and the fact that this Ca is retained for at least 30 min. suggests that an augmented transmitter release, dependent in part upon uptake and retention of intracellular Ca, may underly the phenomenon of LTP.

2107 EFFECTS OF UNILATERAL HORIZONTAL SEMICIRCULAR CANAL PLUGS AND THE INTRAVENOUS ADMINISTRATION OF DIAZEPAM ON THE DEVELOPMENT AND COMPENSATION OF ASYMMETRY OF THE HORIZONTAL VESTIBULO-OCULAR REFLEX OF THE RABBIT. Neal H. Barmack and Vito E. Pettorossi*. Department of Ophthalmology, Neurological Sciences Institute, Good Samaritan Hosp. & Med. Cntr., Portland, OR.

The activity originating from the ampulla of a horizontal semicircular canal (HSC) is increased by ipsilateral angular acceleration of the head and decreased by contralateral angular acceleration. This activity directly excites the ipsilateral medial vestibular nucleus (MVN) and indirectly inhibits the contralateral MVN via a GABA-ergic commissural pathway. This reciprocal organization can be altered by plugging one HSC. The postplug activity of the MVN contralateral to the plugged HSC would be modulated only by an excitatory signal originating from the intact HSC. The activity of the MVN ipsilateral to the plug would be modulated only by an inhibitory signal relayed through the commissural pathway. We have studied the effects of unilateral plugs of the HSC on the horizontal vestibuloocular reflex (HVOR) of the rabbit, and examined the influence of intravenously administered diazepam (0.4mg/kg), a GABA agonist, on the HVOR following unilateral plugs of the HSC. An HSC was plugged by inserting a small silver spindle into the bony canal. The HVOR was evoked by sinusoidal oscillation of rabbits on a rate table (0.01-0.8Hz ±10 degrees) and measured with an infrared technique. Immediately following a unilateral HSC plug, the gain (eye velocity/head velocity) of the HVOR is reduced. If "postplug" vestibular stimulation is maintained, an asymmetry in the HVOR slowly develops (3-15hr). This asymmetry reflects a relative increase in the gain of the HVOR when the eyes move toward the side of the plugged canal. Maximum asymmetry occurs in 24-48hr. The onset of the asymmetry can be delayed by postponing the initiation of postoperative vestibular stimulation. Although the average gain never recovers, the relative asymmetry of the HVOR is gradually compensated in a frequency-dependent manner. After 5-10 days this compensation is even reversed, causing a relatively higher gain of the HVOR when the eyes move toward the intact side. Intravenous injections of diazepam in normal rabbits reduce the gain of the HVOR. Diazepam injections after unilateral HSC plugs greatly increase the asymmetry of the HVOR. The time course of this diazepam-induced effect corresponds to that of the development and compensation of the asymmetry. The efficacy of the diazepam might be attributed to the relatively increased postsynaptic sensitivity of the MVN on the plugged side to GABA-ergic agents. This increased sensitivity may be stimulated by the near-exclusive modulation of the MVN on the plugged side by the GABA-ergic commissural system. (Supported by PHS Grant EY-00848 and The Oregon Lions Sight & Hearing Foundation.)

2108 THE CRITICAL PERIOD FOR STRABISMUS-INDUCED LOSS OF BINOCULARITY IN CAT VISUAL CORTEX. Nancy Berman and E. Hazel Murphy. Departments of Physiology/Biochemistry and Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

We produced a surgically induced strabismus in 11 kittens by cutting the right medial or lateral rectus muscle at different ages. Following at least one year of visual experience, we recorded from single neurons from area 17, and for each unit we determined the eye dominance group, receptive field type (simple or complex), receptive field size and position in the visual field.

We found a gradual increase in the percentage of binocularly driven units with age at surgery. In kittens made strabismic between postnatal days 10 and 18, only 10% of the units could be driven by both eyes. Surgery performed on days 26, 36-38, and 60 gave percentages of binocular cells of 25%, 30% and 50% respectively. Following surgery on day 80, the percentage of binocularly activated units was not significantly different from that found in normal adult cats. We found no abrupt change which might signify the end of the critical period.

In kittens operated before day 43, a high proportion of those cells which were binocularly driven had complex receptive fields, which is in agreement with observations that complex cells are more resistant than simple cells to other manipulations which reduce binocularity (Payne et al. 1979).

We found some cells with abnormal receptive field properties in these kittens. In the earlier operates, we commonly found visually unresponsive cells at the borders between the eye dominance columns. In the later operates, we found binocularly driven cells with abnormally large receptive fields (up to 11x15°).

The critical period for changes in binocularity resulting from surgically induced strabismus differs somewhat for the critical period for the effects of monocular suture. Following monocular suture, all units will be driven only by the experienced eye even if the deprivation is begun as late as day 30 (Hubel and Wiesel, 1970) whereas kittens made strabismic on day 26 retain 25% binocularly driven units. Our findings suggest: (i) some complex cells can retain their input from both eyes despite a severe eye misalignment; (ii) abnormal receptive fields can be produced in kittens without deprivation of visual experience of form or movement; (iii) the critical period for squint ends earlier and more gradually than the critical period for monocular deprivation.

2109 CYCLIC DENDRITIC DEGENERATION AND REGENERATION OF RAT MOTONEURONS AFTER VENTRAL ROOT SECTION. Jerald J. Bernstein and Nancy Standler.* Dept. Neurosci. Univ. Fla. Coll. Med., Gainesville, Fla. 32610.

Somatic bouton rejection and dendritic branch loss can be induced by axotomy. The following experiment studies the dendritic profile of rat motoneurons in the segment under the T_1-T_2 vertebrae after ventral root section (Normals, 14, 30, 60, 90 days postoperative). Six animals per group were utilized and the segment of spinal cord of the crushed root impregnated by the tungstate modificating the Golgi technique. Neurons were selected by size and location. Six independent samples were generated per postoperative day. Dendrites were analyzed for total number of branches, branches that were terminal and serpentine length (total length of entire dendrite). (Statistics: ANOVA a priori; Neuman-Keuls a posteriori). There was a significant, cyclic, loss and gain of numbers of dendritic branches (Low, 14 and 60 days, high 30 and 90 days) and numbers of branches that were terminal (Low, 14 and 60 days, high 30 and 90 days). The serpentine length of the dendrites showed the same significant cycle. These data show that following axotomy motoneurons show cyclic growth and branching.

2110 SPROUTING OF PERIPHERAL SYMPATHETIC NEURONS IN THE ABSENCE OF AFFERENT NEURONAL INPUT. Leslie Brothers*, Keith A. Crutcher and James N. Davis. (Spon: E. W. Busse), VA Medical Center and Duke University Medical Center, Durham, N. C.

Although it is well established that neuronal rearrangements occur after brain injury, relatively little is known of the factors that regulate such plasticity. One particular rearrangement, the appearance of peripheral noradrenergic neurons in the dentate gyrus several weeks after medial septal lesions, provides a useful model for the study of the regulation of reactive synaptogenesis or sprouting.

We took advantage of the accessibility of the superior cervical ganglion to surgical manipulation and cut the preganglionic input to the ganglion (decentralization) in some animals, removed the ganglion in others and carried out a sham neck operation on the remainder. The decentralized and sham-operated controls had a bilateral medial septal lesion placed the day following neck surgery and were sacrificed four weeks later. The ganglionectomized animals were also sacrificed four weeks after septal lesioning, but their superior cervical ganglia were removed 3 weeks after lesioning (one week before sacrifice). All decentralized animals developed an ipsilateral Horner's syndrome which could be reversed by parahydroxyamphetamine eye drops. Furthermore peripheral noradrenergic fibers in the pineal and on pial blood vessels appeared unaffected by the decentralization. The septal region was sectioned and examined histologically to verify lesion placements in each animal. The hippocampal formations were studied with a glyoxylic acid method for visualizing catecholamine fibers.

All sham-operated controls demonstrated obvious bilateral noradrenergic sprouting identical to non-operated animals. Ganglionectomized animals had no peripheral noradrenergic fibers ipsilateral to the removed ganglion, but sprouting in the contralateral hippocampal formation appeared similar to controls. Decentralization did not prevent sprouting, since all but one decentralized animal had peripheral noradrenergic fibers in the hippocampal formation ipsilateral to the decentralization.

Our data show that afferent input and neuronal activity is not necessary for peripheral noradrenergic neurons to sprout. These data further show that some factor in the target tissue initiates the sprouting response. The attenuation of sprouting in the decentralized animals is harder to interpret. It may be that, like the developing animal, nerve impulse flow plays an important role in the extention or maintenance of sprouted fibers.

2111 NEURONAL CONNECTIVITY IN ISOLATED GANGLIA OF ADULT HELISOMA: STABILITY AND LABILITY DURING CULTURE. Andrew G. M. Bulloch, A. Don Murphy and Stanley B. Kater. Dept. Zoo., Univ. of Iowa, Iowa City, Iowa 52242.

Previously we described a system for study of neuronal regeneration in the snail Helisoma trivolvis which involves culture, in the hemocoel of host snails, of the buccal mass with attached buccal ganglia and salivary glands (Murphy and Kater, Brain Res, 156, 322-328, 1978). Under these conditions synaptic connections remain stable for many months. Recently we have cultured isolated, i.e. completely axotomised ganglia, and in contrast to ganglia with intact target organs, found both physiological and morphological changes. Of particular interest are apparent changes in connectivity, indicated by the diminished efficacy of certain chemical synapses, whereas electrical synapses remain stable.

To date we have concentrated on the Protractor Motoneurons (PMN's), a group of cells that receive IPSP's from a coupled network of premotor neurons, the Cyberchrons. In ganglia cultured for one week, spontaneous IPSP's are no longer apparent in most PMN's and have been replaced by EPSP's. In one pair of PMN's the IPSP is present, but is diminished both in amplitude and duration.

In normal ganglia the IPSP may be assayed by Esophageal Trunk (ET) stimulation, owing to the presence of Cyberchron axons in this nerve. On blocking chemical synapses with high Mg^{2+} 0 Ca^{2+} saline, ET stimulation evokes a barrage of electrical EPSP's in PMN's. These are normally shunted by the chemical IPSP.

ET stimulation of ganglia cultured for one week produces an EPSP barrage in PMN's. These EPSP's are voltage insensitive, are not accompanied by any apparent change of membrane conductance, and are therefore thought to be electrical in origin. High Mg^{2+} 0 Ca^{2+} saline causes the amplitude of the EPSP's to increase, presumably by removal of a shunt due to remaining IPSP's.

After two or more weeks of in vivo culture the IPSP of some PMN's was apparently restored to normal. However, such ganglia often become wrapped in a dense neuroma which makes intracellular recording progressively more difficult.

The temporary loss of efficacy at some chemical synapses is presumably a response to axotomy, while the neuritic growth and apparent restoration of normal connectivity indicate a considerable degree of regulative ability in the adult buccal ganglia.

2112 INFLUENCE OF EARLY MONOCULAR DEPRIVATION ON [^{14}C]-2-DEOXYGLUCOSE LABELING PATTERN IN PIGEON VISUAL STRUCTURES. Andreas Burkhalter* and Peter Streit* (SPON: Michel Cuénod). Brain Research Institute, CH-8029 Zurich.

The visual behavior of pigeons, monocularly deprived for the first 8-11 months, was found to be deficient in respect to pattern discrimination and interocular transfer. Since the [^{14}C]-2-deoxyglucose method provides an instrument to visualize functional activity of cerebral structures, this method was used to study patterns of glucose consumption after long-term deprivation in the pigeon.

Six pigeons were raised for 244 to 341 days with one eye occluded by an opaque plastic cap from the day of hatching. At the end of the deprivation period 50µCi [^{14}C]-2-deoxyglucose were injected i.v. in 3 groups of 2 awake animals: During 45 min, both eyes were free (DBE) or one eye was covered, either the deprived one (DDE) or the nondeprived one (DEE). The autoradiographic labeling pattern of (DBE), (DDE) and (DEE) was compared with the pattern of normal adult binocularly (BE) and monocularly (ME) exposed animals. During the experiment the animals were freely moving in an aviary.

In groups DDE, DEE and ME labeling of all known visual structures was asymmetrical and heavier on the side contralateral to the open eye. However the asymmetry, predominantly in the hyperstriatal areas IHA and HA, was most pronounced in DDE. In DBE, with both eyes free an asymmetry was observed only in IHA and HA where the labeling was stronger on the side contralateral to the deprived eye. After binocular exposure of normal adult animals (BE) however the hyperstriatum, receiving input from both eyes, was always symmetrically labeled.

Present results suggest, that the asymmetry of hyperstriatal labeling in experiments with both eyes free (DBE), seems to be more closely related to the system having its origin in the contralateral, deprived eye.

2113 EFFECT OF EARLY GUSTATORY NEOCORTICAL LESIONS ON TASTE AVERSION LEARNING IN RATS. Rebecca J. Cabral, Stephen W. Kiefer and John Garcia*. Dept. Psychol., Mental Retardation Research Center, UCLA, Los Angeles, CA 90024.

In adult rats, lesions of the gustatory neocortex severely disrupt the ability to associate a taste with illness. However, quite often cortical lesions produced before maturity result in less detrimental effects on some learning tasks.

To investigate plasticity in taste aversion learning rats received bilateral gustatory neocortical lesions (GNC) as neonates (10 days), weanlings (20 days) or adults (70 days). They were allowed to recover and were tested on acquisition and extinction of a saccharin aversion at 120 days of age. For training, the rats were habituated to a drinking schedule in the home cage. They received a preexposure to a 0.1% saccharin solution (day 117), three saccharin-lithium chloride (0.15M, 2% bwt., i.p.) acquisition trials (days 120, 123, 126) and five saccharin extinction trials (days 129, 132, 135, 138, 141). After testing, histological verification of the lesions was performed.

The results showed that rats receiving GNC lesions as neonates (n=10), weanlings (n=17) or adults (n=10) demonstrated significant deficits in acquisition and extinction when compared with control-lesioned, sham-operated or normal control rats. After three acquisition trials GNC rats, regardless of age at lesion, reduced saccharin consumption to 50% of water baseline compared to 100% reduction by control rats.

Thus, sparing of taste aversion learning does not occur when GNC lesions are sustained as early as ten days of age. These results contrast with other reports of recovery of function after early cortical lesions.

2114 RAPID KINDLING INDUCED BY LOW-FREQUENCY STIMULATION OF THE AMYGDALA. Donald P. Cain and Michael E. Corcoran, Dept. Psychology, U. Western Ont., London, Canada N6A 5C2 and Dept. Psychology, U. Victoria, Victoria, Canada V8W 2V2.

Previous research in kindling has suggested that low-frequency stimulation (below approximately 5.0 Hz) is ineffective in kindling amygdaloid seizures. The present experiment reassessed this question using biphasic square wave pulses of 1.0 msec duration delivered at 2.0 or 3.0 Hz through bipolar electrodes chronically implanted into the amygdala of 24 male hooded rats. Animals were stimulated once daily with a 60-sec train of pulses. All animals developed fully generalized seizures after a mean of 3.1 evoked afterdischarges. A number of animals displayed a generalized seizure upon the first application of the stimulation. Rekindling with a conventional 60 Hz 1-sec train of pulses confirmed that all animals were fully kindled. The threshold current intensity necessary was approximately 300 μA (peak pulse intensity measured baseline-to-peak). Intensities much below this were completely ineffective even when administered repeatedly. Pulses of 0.1 msec duration were also completely ineffective. Frequencies of 2.0 and 3.0 Hz were about equally effective in kindling seizures. The results indicate that amygdaloid kindling can proceed very rapidly using low-frequency pulses providing the peak pulse intensity exceeds a certain threshold level. This suggests that it is necessary to activate a 'critical mass' of neurons for kindling to proceed, and that low-frequency activation is more effective than activation with conventional 60 Hz currents in kindling.

2115 VERY LONG AND SHORT-TERM CHANGES IN EXCITABILITY OF RAPHE-EVOKED THALAMIC POTENTIALS. K. L. Casey and T. J. Morrow. Depts. of Physiol. & Neurol., Med.Sch., Univ. Mich., Ann Arbor, MI 48109.

Electrical stimulation within the nucleus centralis superior (nCS) evokes two different field potentials in the thalamus of awake squirrel monkey and cat. A 2 msec peak latency potential is recorded bilaterally from the pulvinar-posterior nucleus complex of the posterolateral thalamus (P-PO). Repetitive nCS stimulation (1 Hz for 10 min or 10 Hz for 30 sec) produces a 2 to 4 fold enhancement (to nearly 800 μV) of response amplitude which gradually decays over a period of at least 2 hours. Stimulation of adjacent pontine reticular formation is ineffective. During the course of 8 experimental sessions over a 3 week period in one monkey, the duration of this enhancement was extended to at least 5 days. Once enhanced, the P-PO potential is not affected by general anesthesia with ketamine, thiamylal or fluothane, but the effect of repetitive stimulation is reduced. Morphine (1 mg/kg I.M.) markedly reduces the amplitude of an enhanced P-PO potential, reduces the enhancing effect of repetitive stimulation, and accelerates the decay of enhancement to about 30 min. Naloxone (0.1 mg/kg I.M.) reverses the effect of morphine and unmasks the stimulus-induced enhancement blocked by morphine.

A 4 msec peak latency potential is recorded bilaterally with maximum amplitude in the centre-median parafascicular complex (CM-Pf) of the medial thalamus. This potential is unaffected by repetitive stimulation but shows a second to second variation in amplitude (from 100 μV to 2000 μV) in the awake animal. Repeated testing and observation show that maximum response amplitude is not simply related to "arousal" for continuous tail pinch is ineffective. Rather, the excitability of this nCS-elicited response appears greatest when the animal is actively exploring and attending to environmental events. The CM-Pf potential is eliminated by general anesthesia with fluothane or chloralose and markedly reduced by morphine (1 mg/kg I.M.). The effect of morphine is reversed by naloxone (0.1 mg/kg I.M.).

These findings demonstrate the existence of opiate and anesthetic-sensitive raphe-mediated influences which differentially affect different thalamic regions and are likely to play an important role in the selective acquisition and storage of information. The results further emphasize the importance of using unanesthetized animals in neurophysiological investigations of reticulo-thalamic systems.

2116 ANALYSIS OF CORTICOPONTINE SPROUTING AFTER CORTICAL LESIONS IN NEWBORN RATS. Anthony J. Castro. Dept. Anat., Stritch Sch. Med., Loyola University, Maywood, Il 60153

A somatotopic organization of corticopontine projections has been described in several animals. In general terms, although more specific details are available, fronto- and occipitopontine fibers demonstrate a medial to lateral projection pattern within the basilar pontine gray. The present study was undertaken in search of alterations of these projection patterns that might ocurr in response to neonatal cortical lesions.

Under hypothermic anesthesia, newborn (2-3 day old) Long-Evans black-hooded rats sustained unilateral frontal or occipital cortex ablations. At maturity, animals with neonatal frontal cortex lesions sustained ablations under sodium pentobarbital anesthesia of either the contralateral frontal cortex or of the occipital cortex ipsilateral to the neonatal lesions; and animals with neonatal occipital cortex lesions sustained ablations of either the contralateral occipital cortex or of the frontal cortex ipsilateral to the neonatal lesion. Animals were sacrificed by anesthetic overdose and vascular perfusion 4-7 days after adult lesions. Corticopontine projections were examined using the Fink-Heimer method and were compared to control animals that only received adult frontal or occipital cortex lesions.

Control frontopontine projections are mostly ipsilateral but with a small crossed projection to the opposite medial pontine gray. After neonatal frontal cortex lesions, an increase of the crossed frontopontine projection from the neonatally unablated hemisphere was observed. Anatomical remodelling of corticopontine projections was not observed in any of the other experimental groups.

The observed apparent specificity of corticopontine plasticity is attributed to two possible factors: (1) the small normally occurring crossed frontopontine projections would seemingly provide a substrate of fibers capable of sprouting to innervate cells deafferented by the neonatal lesions, and (2) the ultrastructural differences between fronto- and occipitopontine terminals (Mihailoff, 1978, Neurosci. Let. 8:219) suggest a compatibility for homotypic (frontal-frontal) remodelling but not heterotypic (frontal-occipital) remodelling.

2117 QUANTITATIVE STUDY OF SYNAPTIC REMODELING IN THE COCHLEAR NUCLEUS FOLLOWING DEAFFERENTATION. Stephen D. Collins and Robert L. Gulley Dept. of Anatomy, Case Western Reserve Univ., Cleveland,OH 44106, and Univ.of Texas Health Science Cntr. San Antonio, Tx 78284.

Reorganization of non-primary neuronal input following removal of primary afferents has been quantitatively studied in a discrete neuronal population of defined morphology. The rostral pole of the guinea pig anteroventral cochlear nucleus is homogeneously composed of large spherical cells,each receiving a single large primary terminal from a spiral ganglion cell in the cochlea. This calyceal terminal covers about 46% of the spherical cell perimeter. The terminals of the spiral ganglion cells degenerate after cochlear ablation, thus removing all primary sensory innervation to the large spherical cells. Three morphological types of boutons (O-boutons,F-boutons,and SR-boutons) are apposed to approximately 13,5, and 4% of the normal spherical cell perimeter (Schwartz & Gulley,1978). All primary terminals have degenerated by four days after cochlear ablation. Up to six days after cochlear ablation, significant remodeling of non-primary inputs to the spherical cell has not occurred (Wenthold and Gulley,1977). In the present study, perimeters from 250 spherical cells from 15 animals were examined at 7,14,21,28 and 180 days following cochlear ablation. Following bouton identification,cell perimeter and bouton appositional length were measured on a digital plotter in conjunction with a PDP-11/45 computer. At day 7,the amount of spherical cell perimeter covered by O-boutons increases from 13% to approximately 33%, an increase of 250%. By day 7, the amount of F-bouton apposition has nearly quintupled,now covering aproximately 25% of the spherical cell. The SR-boutons remain nearly the same in their appositional length. The O and F-bouton appositional length remains increased throughout the time period studied. In the external membrane leaflet of the spherical cell following deafferentation,three responses are observed in freeze-fracture studies (Gulley et al, 77): Non-aggregate particles increased seven fold; perisynaptic aggregates are removed from the membrane and the number of particles in junctional aggregates remains the same. In the present study 7 days following cochlear ablation the increase in non-aggregate particles reverses towards normal levels, perisynaptic aggregates return to the membrane and the number of particles in junctional aggregates decrease.

2118 CEREBRAL PROTECTION IN SHRSP RAT. Peter Coyle. Dept. Anat., Univ. Mich. Med. Sch., Ann Arbor, MI 48109.

Occlusion or transection of the middle cerebral artery (MCA) in the Wistar rat is followed by expansion of the collateral arteriole supply vessels and MCA field tissue survival (Neurosci. Abstr. 4: 469, 1978). In contrast, for spontaneously hypertensive stroke-prone rat (SHRSP) the procedure results in tight endothelial cell junctions opening, Evans blue-albumin extravasation, reduced arteriole filling, tissue necrosis and atrophy extending from the occlusion site to the anastomotic zone (Anat. Rec. 193: 740, 1979). Objectives were to evaluate the response in SHRSP following ipsilateral carotid artery occlusions and/or cervical sympathectomies. Twenty-one SHRSPs ranging in age from 33 to 330 days and of either sex were anesthetized intramuscularly with ketamine hydrochloride, 125-200 mg/kg body wt. In 6 animals the right superior cervical ganglion was excised or the cervical sympathetic trunk was transected 6 to 20 days prior to the MCA experiment. In the remaining rats, the nerves were carefully dissected from the common carotid artery then the artery and its external ramus were each double ligated and cut 0-15 days prior to transection of the right MCA just dorsal to the rhinal fissure. To mark opened endothelial cell tight junctions and tissue necrosis, 1 ml of 2% Evans blue in physiologic saline was injected intraperitoneally immediately after the MCA operation. Six rats died 3-5 days later, 8 had Horner's Syndrome. Lesion size was graded 1-4 with 4 extending from the transection site to the zone of anastomoses. Young (33-46 day old) and old (268-330 day) rats showed grade 3 and 4 lesions whereas 6 intermediate age SHRSPs (66-86 day) had lesions graded 1 or 2. Lesion grade was not related to the sympathectomy. MCA vessels in rats with grade 1-2 lesions were filled more extensively with Vultex or Rockland liquid photographic emulsion than those in grade 3-4 rats. The data indicate carotid occlusions 5-6 days prior to the MCA experiment facilitate cerebral collateral expansions, possibly due to a lowered blood pressure.

Supported by a grant from the Michigan Heart Association.

2119 THE EFFECTS OF BILATERAL SERIATIM VERSUS SINGLE-STAGE HIPPOCAMPECTOMY ON THE ACQUISITION OF DRL 20 IN JUVENILE, ADULT AND AGED RATS. S.D. Curtis* and A.J. Nonneman. Dept. Psychology, Univ. of Kentucky, Lexington, KY 40506

Previous research has shown that performance on a low rate operant schedule (DRL 20) after prior high rate operant experience (CRF) is severely impaired after bilateral single-stage lesions of the hippocampus in adult rats. In contrast, DRL 20 performance is much more efficient if the hippocampus is removed in two stages separated by interoperative DRL training. This study attempted to determine whether this serial lesion effect would also occur in juvenile or aged rats.

Rats from each of 3 age groups (35, 160, or 570 days) received training on CRF prior to either single-stage hippocampectomy, sham operative treatment, no surgical treatment or bilateral lesion of of either anterodorsal or posteroventral hippocampus. After forty days of DRL 20 training, the seriatim groups received bilateral lesions of remaining hippocampus. All animals then received thirty final days of DRL training. Relative to the single-stage hippocampal operates, serially lesioned animals of all ages demonstrated substantial recovery of DRL 20.

Also addressed in this study were 1) the nature of the "recovered" behavior and 2) the generality of the "recovery" across tasks. The former was examined by periodic mapping of the movements of each animal while performing DRL and the latter by a final shift back to CRF. Both of these measures indicated that the serially lesioned "recovered" animals were still very much like the single-stage operates (i.e. they tesnded to show less variety of operant box movements than controls and they shifted to CRF more slowly than controls).

The facts that 1) all three ages of serially lesioned animals demonstrated similar DRL capacities and 2) the "recovery" was apparently task spedific, both serve to predict a recovery mechanism that does not involve substantial rearrangement of brain connectivity (a capacity that is apparently age dependent). Rather a learning mechanism is proposed that is in essence an application of Kamin's multiple cue blocking theory. Specifically, it is proposed that during a serial lesion sequence, the subtotal disruption of a neural system that exists during the interoperative period allows only subasymptotic performance and thereby forces a recognition and recruitment of redundant, normally nonprefered cues. Following the second lesion these now 'primed', nonprefered cues serve to mediate the behavior.

2120 STUDIES OF THE MODIFIABILITY OF THE VISUAL CALLOSAL PATHWAY IN RATS. C. Cusick* and R. D. Lund. Depts. Biol. Struct. and Neurosurg., Univ. Wash. Sch. Med., Seattle, WA 98195.

The configuration of callosal degeneration in the occipital region following total section of callosal fibers has been described previously for normal adult albino and pigmented rats (Cusick, 1978, Neurosci. Abstr.). We have examined the consequences of the following experimental manipulations on the developing visual callosal pathway: 1) dark rearing, 2) unilateral enucleation, 3) bilateral enucleation and 4) unilateral section of an optic tract.

Animals were reared in the dark from birth or were operated on the day of birth. At 4-8 weeks of age the fibers of the corpus callosum were sectioned by a paramedian approach. Lesions were performed ipsilateral to unilateral enucleation and contralateral to the tract lesions. After a 2-4-day survival, the animals were perfused and the brains processed by the Fink-Heimer method. Brains were sectioned coronally, or the unlesioned hemisphere was flattened during fixation, sectioned tangentially and prepared by a bleached Fink-Heimer technique.

Dark rearing and unilateral enucleation have little appreciable effect on the configuration of the callosal projection, its density, or the breadth of its distribution. However, bilateral enucleation and optic tract section produce very pronounced changes. After bilateral enucleation, the normal callosal pattern is recognizable, but additional bands and rings of callosal input lie within normally acallosal regions of areas 17 and 18a. The spread of degeneration into area 17 is prominent laterally and posteriorly. Anteriorly, it virtually fills in area 17. In contrast, the callosal projection to the 17/18a border in the hemisphere ipsilateral to the neonatal tract lesion is severely decreased in width relative to normal. This effect is specific to the visual callosal pathway, since the callosal input to nonvisual areas of the same brains appears normal in distribution and density.

Comparison of the results from albino and pigmented rats and the findings in dark reared and unilaterally enucleated animals shows that in cases in which an intact but abnormal visual input is present, the callosal pathway appears normal. This contrasts with the results from similar experiments in cats. However, after neonatal bilateral enucleation, optic tract section, or thalamectomy (Cusick, 1978, Neurosci. Abstr.), cases in which the cortext is totally deprived of a retinal input via the ipsilateral lateral geniculate nucleus, the callosal pathway is abnormal. (Supported by USPHS Grants EY-00596 and GM-07108 from the National Institutes of Health.)

2121 *RECOVERY FROM UNILATERAL NEGLECT: BEHAVIORAL AND FUNCTIONAL ANATOMIC CORRELATIONS IN MONKEY.* *Ruthmary K. Deuel, Robert C. Collins, Nancy Dunlop* and Torris V. Caston*. Departments of Pediatrics & Neurology, Washington University, St. Louis MO 63110.*

Unilateral damage to frontal cortex in the periarcuate region (FPC) in monkeys results in a syndrome of contralateral visual and tactile neglect and an absolute preference for the ipsilateral hand. Spontaneous, complete recovery occurs by unknown mechanisms. We have used the ^{14}C-deoxyglucose autoradiographic technique (DG) to study functional cerebral anatomy (glucose utilization) during three phases of recovery. Five adolescent Macaca fascicularis were tested with a standard neurological exam and taught a conditional motor response to criterion before operation. FPC was removed by subpial resection from the right hemisphere, testing was repeated postoperatively, and animals were sacrificed following DG infusion at 4, 14 or 23 days. Brains were perfused with formalin, frozen in freon at -50° C, then cut at -30° C. Four adjacent 30 µm sections were taken at 600 µm intervals through the entire brain (three for densitometric analysis, the other for histologic study).

Animals examined within two weeks after injury showed severe contralateral neglect, including hemianopsia and absolute preference for the hand ipsilateral to the lesion, and no retention of the conditional motor response. DG studies showed a 10-40% depression of DG uptake in ipsilateral (Right) subcortical structures, primarily thalamus and basal ganglia. Compared to contralateral (Left) homotopic sites, the greatest depression of DG uptake occurred in n. medialis dorsalis (Right = 58% of Left), n. reticularis (R = 70% L), n. ventralis anterior (R = 74% L), n. X of Olszewski (R = 75% L), caudate (R = 75% L), putamen (R = 77% L), and pulvinar (R = 80% L). Animals showed substantial recovery from neglect by four weeks. DG studies at the time revealed only a slight depression of glucose uptake (<10%) in ipsilateral subcortical sites, principally in caudate (R = 93% L) and putamen (R = 92% L). In none of these three phases was depression of ipsilateral cortical DG marked.

The findings lead us to postulate that the multimodal neglect is related to a widespread metabolic dysfunction in subcortical grey masses. The monkeys' recovery from neglect occurs in parallel with reappearance of symmetrical metabolic activity in these structures.

2122 GOLGI ARCHITECTONICS OF A REGION INVOLVED IN SONG PRODUCTION IN THE CANARY. T. J. DeVoogd and F. Nottebohm. Rockefeller University, New York, N. Y. 10021.

Nucleus robustus archistriatalis (RA) is a large telencephalic nucleus in the canary. When RA is lesioned in singing male canaries, song is disrupted (Nottebohm et al., J. Comp. Neur., 165:457, 1976). This effect is much more pronounced on the left side than on the right: song production appears lateralized to the left side. RA is substantially smaller in female canaries which do not normally sing. RA has been shown to receive input from hyperstriatum ventrale, pars caudale (HVc) another song integration center. However, the cell types and connectivity pattern within RA have not yet been described.

In the present experiment, six pairs of one year old male and female canaries were sacrificed when in full reproductive condition. Brains were stained with several rapid Golgi variants. All sections were retained, allowing reconstruction of nuclei and of the total dendritic fields of the cells observed. RA was clearly delineated in the Golgi stained tissue. The nucleus was 39% as large in the females as in the males, in accord with previous Nissl studies. Input from HVc was observed to course to RA in large fiber bundles which arborized in a dense fiber band at the dorsal surface of RA. Fiber bundles exited RA caudally and medially. Four distinct cell types common to both males and females were associated with RA. The first, with a large soma (13-17u) and fine, highly branched, spiny dendrites, is embedded in the initial arborizations of incoming axons just dorsal to RA proper. The second is a small aspinous cell (8-12u) with a highly branched compact dendritic field. The third has a large cell body (15-20u) and many fine, sparsely spined dendrites. The fourth cell type was the most frequently observed. These have a large soma (18-23u) and have thick, extremely spiny dendrites. Four or five primary dendrites give rise to a dendritic tree covering a radius of about 100u. The axons project anteriorly and send out a complex network of local collaterals. Camera lucida tracings were made of a sample of these cells. Preliminary Sholl and branch segment analyses indicate that male and female cells do not differ in number of primary branches or in the amount of dendrite arising from each primary. However, they do appear to differ in the distribution of that dendritic material. Male cells have 20% less dendrite than females within 50u of the soma but have 32% more dendrite beyond 50u. No consistent left-right differences were seen in these measures.

2123 LONG-LASTING POTENTIATION IN THE PERFORANT PATHWAY TO CA1 NEURONS IN THE HIPPOCAMPUS, IN VITRO. Herbert J. Doller* and Forrest F. Weight (SPON: J. Y. Summy-Long). Laboratory of Preclinical Studies, National Institute on Alcohol Abuse & Alcoholism, Rockville, MD. 20852.

In the hippocampus several pathways have been shown to exhibit a long-lasting potentiation following a brief tetanic stimulation of the pathway investigated. This potentiation of evoked responses lasts for minutes to hours in in vitro preparations (Brain Res. 89:107, 1975) and has been reported to last for days in whole animal preparations (J. Physiol. 232:357, 1973). Anatomically, the perforant pathway terminates, in part, on the apical dendrites of the CA1 pyrmidal neurons. We recently reported electrophysiological evidence for this pathway in the hippocampal slice preparation (Soc. Neurosci. Abst. #679, 1978). We report here a long-lasting potentiation of this perforant to CA1 pathway in the hippocampal slice.

Male Hartley guinea pigs weighing 300 to 400 gm were sacrificed. The hippocampus was quickly removed and placed in ice cooled medium. Thin (350 to 400 um) tranverse sections of the hippocampus were cut using a Sorvall tissue sectioner. Using small knives, a section (1 to 2 mm wide) in the CA1 region of the slice was removed. This section started at the ventricular surface and included regions down to but not including perforant pathway. Removal of this section insured that CA1 activation was not the result of stimulating other layers of the CA1 region. Slices of the hippocampus were then placed in a trough-like chamber and superfused at rate of 5 ml/min with medium saturated with 95% O2 & 5% CO2. The medium contained 124 mM NaCl, 5 mM KCl, 2.4 mM CaCl2, 1.3 mM MgSO4, 1.24 mM NaH2PO4, 10 mM glucose, and 26 mM NaH2CO2. A bipolar stimulating electrode was placed in the perforant pathway on the entorhinal side of the removed CA1 section. The pathway was stimulated at a frequency of 1/min with pluses of 0.02 msec duration and amplitudes of 10 - 100 V. To produce potentiation, a tetanus of 15 Hz for 15 sec was used. A glass recording microelectrode (filled with 3 N NaCl) was placed in the region of CA1 cell bodies on the CA3 side of the removed CA1 section. The electrode resistances were 2 - 8 megohms. The amplitude of the field potential was determined by measuring from the maximum negative peak of the population spike to the peak of the positive wave following the population peak. Following a tetanus, the amplitude of the field potential increased 150% to 300% and remained elevated for at least 15 min. These data indicate that CA1 neurons exhibit long-lasting potentiation in response to perforant pathway stimulation.

2124 PERMEABLE AND IMPERMEABLE TECTAL BARRIERS IN GOLDFISH: DIFFERENT EFFECTS ON ROSTRAL COMPRESSION AND CAUDAL ESCAPE BY OPTIC FIBERS. M. A. Edwards* and M. Jacobson. Depts. of Physiology & Anatomy, Univ. of Utah School of Medicine, Salt Lake City, UT 84108.

Electrophysiological mapping and anatomical methods were used to evaluate changes in the retinotectal projection of goldfish 20-200 days after insertion of various barriers into an incision which bisected the tectum into rostral and caudal halves. Yoon's report (Exp. Neur. 35: 565, 1972) that Gelfilm barriers (300 Å m thick) induce an orderly, near-complete compression of the visual representation in rostral tectum was replicated. The time course of decrease in the rostrocaudal retinotectal magnification factor (MF) was similar to that seen in half-tectal control fish, both reaching about 60% of normal control values 2-3 mos postoperatively. Barriers constructed of Nucleopore filter material with no holes (10 Å m thick) caused a similar, but slower, compression, whereas equivalent barriers with either .1 Å m or 8 Å m holes did not cause significant compression.

Surprisingly, the caudal tectum became reinnervated among all groups, such that the visual representation was exclusively partitioned on the two sides of the barriers. In contrast to the normal projection usually reformed behind permeable barriers, the regenerated projection caudal to Gelfilm and no-hole Nucleopore barriers consisted of an expanded representation of about 20° of the extreme temporal visual field. Rostral and caudal MF's were inversely related. Reinnervation was well in progress by 1 mo postoperatively, which was in advance of the onset of compression. Escape took the form of huge fiber bundles that dived under the barriers no matter how deeply they were placed, according to H^3-proline autoradiography and the orthograde horseradish peroxidase technique (cut nerve application; DAB; 30-50 hrs). The former method was more effective in revealing the optic fibers in caudal tectum indicated by the mapping data. Regeneration under the barriers was not merely a mechanical response to obstruction, for when interrupted Gelfilm barriers were implanted, optic fibers funnelled through the gap staying within their appropriate layers.

The evidence suggests that diffusible factors released from the deafferented caudal tectum and passing through the pores of permeable barriers, somehow facilitate successful regenerative escape by optic fibers; impermeable Nucleopore and Gelfilm barriers block these signals more effectively, reducing the amount of escape, and the disconnected fibers are forced to take an aberrant accommodation in front of the barrier, displacing the intact projection rostrally in the process. The possibility of a regulative respecification of the tectum appears unlikely.

2125 SPECIFICITY OF REINNERVATION OF FROG SYMPATHETIC GANGLIA. Daniel H. Feldman* (SPON: K.T. Brown). Dept. Physiology, Sch. Med. UCSF, San Francisco, CA 94143

In frog lumbar sympathetic ganglia, B-cells and C-cells can be distinguished by the propagation rate of antidromic spikes elicited in the postganglionic nerve trunk. The two types of ganglion cells are selectively innervated by separate populations of preganglionic axons; B-fibers innervate B-cells, and enter the sympathetic trunk at levels anterior to the sixth segmental ganglion, while C-fibers innervate C-cells and enter the trunk at the seventh and eighth segmental levels. Thus, fast excitatory synaptic inputs to B-cell or C-cell populations may be driven separately by stimulating the appropriate preganglionic nerve roots. This simple anatomical arrangement of selective inputs to two cell populations allows examination of the specificity of innervation of both normal and reinnervated ganglia using intracellular recording techniques.

In normal ganglia of Rana pipiens, C-fiber input to B-cells (n=59) has never been observed, and B-fiber input has been observed in approximately 4% of C-cells (n=48). When examined 6-22 weeks after crush of both B- and C-fibers, most ganglion cells were reinnervated. From a total of 188 B-cells examined, only 2 were reinnervated by C-fibers, while most were appropriately reinnervated by B-fibers. Approximately 16% of reinnervated C-cells, or 12% of the total C-cell population (n=146), were driven by B-fibers, while most were appropriately reinnervated by C-fibers. Thus, while regenerating preganglionic fibers occasionally form synapses with inappropriate target cells, reinnervation is on the whole highly specific when assessed at relatively long times after denervation. Preliminary observations 1½-6 weeks postoperatively suggest that during early reinnervation, there is a higher incidence of inappropriate connections: 75% of reinnervated C-cells (46% of all C-cells) in 4 preparations had been reinnervated by B-fibers. No B-cells innervated by C-fibers were observed.

These results indicate that the selective innervation of B- and C-cells which exists in normal adult frogs is restored upon reinnervation. This selectivity appears to be generated by a combination of accuracy in restoration of contacts and elimination of inappropriate connections which do arise.

2126 TWO FORMS OF SPROUTING ARE PRESENT IN THE NEONATALLY DEAFFERENTED DENTATE GYRUS OF THE RAT. Christine Gall and Gary Lynch. Dept. of Psychobiology, UCI, Irvine, Ca. 92717.

The commissural afferents of the dentate gyrus of the rat, normally restricted to the inner one third of the dendritic field, sprout into the more distal region following deafferentation of that territory by removal of the ipsilateral entorhinal cortex. Previous autoradiographic and electron microscopic studies have demonstrated that following such lesion placement in the 14 day old rat the commissural projections rapidly expand to occupy the full depth of the dendritic field and ultimately establish an even density of synapses throughout. In the present study this sprouting response was reexamined using Holmes stain for normal fibers.

In those pups sacrificed 4 days after the lesion, the dentate's inner molecular layer fiber plexus (known in the adult rat to correspond with the commissural and associational afferent systems) was not found to be expanded; a surprising observation in light of autoradiographic data demonstrating that the commissural system has in fact sprouted by this postlesion interval. However, by 8 days postlesion the plexus was enlarged to approximately the same extent as seen after entorhinal lesions in the adult. With longer postlesion survival this plexus expands no further relative to controls leaving the most distal aspects of the deafferented dendritic field remarkable fiber-poor. In addition to this delayed and limited plexus expansion the appearance of a few unusually large caliber axons in the most distal deafferented field was noted, being particularly evident at the longer survival intervals.

The present data, considered in light of the previous autoradiographic and electron microscopic work on sprouting of these afferents, suggest that two forms of sprouting are present in the neonatal hippocampus: one being rapid and extensive as described by the autoradiographic and electron microscopic data and the second being more limited and exhibiting a several day postlesion delay to onset. This latter form observes the same spatial and temporal parameters exhibited by the commissural sprouting induced by entorhinal cortex removal in the adult rat. It is proposed that the former more extensive form of growth is exhibited by only the more immature axons in the field and that this form of sprouting is lost to unmask with development the more limited pattern of adjustment. This second more restricted form of sprouting is then retained in the adult.

2127 VISUAL FIELD DEFICITS IN CATS WITH ONE EYE ROTATED. Barbara Gordon, Jeffrey Moran* and Joelle Presson. Dept of Psychology, University of Oregon, Eugene, OR 97403.

We have performed visual perimetry on cats reared with one eye rotated in order to determine (1) whether the animals can localize objects accurately using the rotated eye and (2) whether the rotated eye has a normal visual field. Four groups of animals were used: (1) right eye intorted 67-90°; (2) right eye intorted about 65-75°, left eye sutured; (3) right eye extorted about 90°; (4) right eye, all extraocular muscles cut, eye in normal position (muscle cut control). When the animals were about 4 months of age or older, they were trained on a modification of the visual perimetry task described by Sprague and Meikle and by Sherman. For the normal eye, the horizontal visual field extended from about 80° in the nasal retina to about 30-45° in the temporal retina. The vertical visual field extended from about 45° in the inferior retina to about 30° in the superior retina. Perimetry with the rotated eye showed that the cats are quite good at localizing visual stimuli with the rotated eye. Only 5% of the responses were to an incorrect location. For the normal eye the comparable figure is 1%. The rotated eye did, however, have a considerably smaller visual field than the normal eye. The visual field deficits appear to depend upon the orbital position occupied by each portion of the retina. The retina that occupied the temporal position appeared virtually blind, whether that retina was anatomic inferior retina (animals with right eye intorted) or anatomic superior retina (animals with right eye extorted). The retina that occupied the nasal position showed no detectable deficit. The retina that occupied the superior position had a reduced field regardless of whether that retina was anatomic temporal retina or anatomic nasal retina. The retina that occupied the inferior position had little or no deficit.

These results are specific to rotation and do not result from mere ocular immobility; the muscle cut control animals had normal visual fields. The deficits do not result from damage to the optic nerve during surgical rotation; the animals with their right eye intorted and their left eye sutured had a normal visual field using their intorted eye. We conclude that the visual field deficits result from changes in the central nervous system that depend on the animal's failure to use visual information from the rotated eye.

2128 ACOUSTIC EXPERIENCE MODIFIES DENDRITIC FORM IN NUCLEUS LAMINARIS Lincoln Gray*, Daniel J. Smith and Edwin W Rubel, Department of Otolaryngology, University of Virginia Medical Center, Charlottesville, Virginia 22908

The brain stem auditory system of chickens provides an opportunity to predict specific cellular changes in central neurons that may result from differences in sensory experience. The dorsal and ventral dendritic arborizations of nucleus laminaris (NL), a third-order brain stem auditory nucleus, receive segregated excitatory inputs from the ipsilateral and contralateral auditory nerves respectively, through one intervening excitatory synapse in nucleus magnocellularis (NM). Neuronal activity in the 8th nerve, NM and NL monotonically increases with increasing acoustic stimulation.

Silicone plastic ear plugs that provide a 40 db broadband conductive hearing loss were placed in one ear of embryonic chickens before they entered the air space of their eggs (day E 18) and were maintained in place for 28 days thereafter. At 25 days post-hatch, the brains were coded and then impregnated by a Golgi-Kopsch method. Six to ten clearly impregnated NL cells from each side of each brain were paired by position in the nucleus and drawn under camera-lucida. Blind procedures were used to prevent observer bias. The number of primary dendrites and the total projected length of the dendrites were measured on the dorsal and ventral side of every cell that had been drawn. In each bilateral pairing of cells, the dorsal and ventral dendrites that received input from the normal ear were compared with the dorsal and ventral dendrites from those same cells that received input from the deprived ear.

Analysis revealed a statistically reliable decrease ($p < .01$) in the number of primary dendrites on the sides of the NL cells receiving input from the deprived ear. An average loss of 14% of the primary dendrites on the deprived sides of the cells was observed. A small decrease in the projected length of the deprived dendrites, that was not statistically significant, was also observed.

In conclusion, a unilateral change in sensory experience differentially affected the form of specific dendritic surfaces of central neurons. This change was predictable from the structure and pattern of innervation of those neurons. These results are consistent with the hypothesis that local synaptic activity can influence the form of postsynaptic elements. 2129 THE EFFECTS OF EXTENDED PERIODS IN A COMPLEX OR ISOLATED ENVIRONMENT ON DENDRITIC BRANCHING IN THE VISUAL CORTEX OF ADULT RATS. William T. Greenough, Janice M. Juraska, Cynthia Elliot*, Richard Berkowitz* and Kenneth Mack*. Dept. Psychol. and Neural & Behav. Biol. Prog., Univ. of Ill., Champaign, IL 61820.

Placing adult rats in complex environments in adulthood results in heavier and thicker visual cortices (Riege, Dev. Psychobiol. 4:151,1971; Rosenzweig et al., Macromolecules and Behavior, J. Gaito (ed.), 1972) and longer terminal basilar branches in occipital layer III pyamidal cells (Uylings et al., Exper. Neurol. 62:658, 1978) than are seen in littermate controls in standard laboratory cages. These effects are not as pronounced as those following differential housing imposed immediately after weaning. Also, we have reported that after daily Hebb-Williams maze training adult rats exhibit more oblique branches in the upper apical dendrite of layer IV and V pyramidal neurons in occipital cortex, compared to handled controls (Greenough et al., Beh. Neural Biol., in press). In the present experiment male hooded rats were housed in social littermate groups from weaning to 145 days of age. They were then placed in either a complex environment (EC) with other rats and toys changed daily or in isolated, standard laboratory cages (IC) for 12 weeks, a more prolonged period of exposure than in the post-weaning studies. At approximately 230 days of age the rats were sacrificed and their brains Golgi-Cox stained. One hundred micron coronal sections were taken from the occipital cortex. Fifteen layer III pyramidal neurons per animal were traced with the aid of a camera lucida from six littermate pairs. Each neuron was scored for number and length of basilar dendritic branches at each order. There were no significant changes in the number of branches at any order. However, neurons from EC rats exhibited greater overall dendritic length ($p < .005$) greater length of terminal branches ($p < .05$) and fifth order branches ($p < .05$). This is a pattern of change in the length of distal basilar dendrites similar to that found by Uylings et al. after only 30 days of environmental exposure. We are further analyzing this cell population, as well as extending the results to other neuron populations in the visual cortex.

2130 CHARACTERIZATION OF IDENTIFIED NEURONS OF HELISOMA MAINTAINED IN IN VITRO ORGAN CULTURE FOR THE STUDY OF REGENERATION. Robert D. Hadley and Stanley B. Kater. Dept. Zoology, Univ. Iowa, Iowa City, IA 52242.

Previous studies using an in vivo organ culture have shown that identified neurons of the snail Helisoma can functionally regenerate and specifically reinnervate postsynaptic target organs subsequent to axon interruption (Murphy and Kater, 1978). We are developing an in vitro organ culture method for Helisoma tissues using media based on commercial M199 (GIBCO) medium with salts adjusted to Helisoma hemolymph values.

Rhythmic, coordinated muscular contractions characteristic of feeding behavior in vivo are observed for at least two weeks in culture. Intracellular recording and staining techniques show that the physiology and morphology of identified neurons differ little from normal preparations. Overshooting action potentials and synaptic inputs to specific neurons in vitro have the same characteristics as neurons in non-cultured preparations.

Earlier studies have shown (with in vivo culture) that, following a nerve crush, axons of salivary secretoeffector neurons extend many sprouts through the crush site and reach the salivary glands in less than one week. Present in vitro studies show that these neurons, when axotomized, extend sprouts beyond the crush site in a similar length of time, though the exact time course of growth is variable. Furthermore, sprouting in vitro occurs by exactly the same mechanism as regeneration. That is, growth occurs by the extension of numerous small sprouts from the injured axon and these sprouts extend through and beyond the site of nerve trunk injury. Finally, in agreement with previous findings, the presence of a viable postsynaptic target organ is not necessary for initiation of sprouting.

Additionally, we have found that sprouting of neurons in the buccal ganglia is not dependent on trophic influences from other nervous tissue such as the central ganglionic ring. Sprouting of injured neurons can occur in vitro in a preparation consisting of only the buccal ganglia and buccal musculature. Observations on growing neurons in vitro are quite comparable to regeneration in vivo and allow us to employ in vitro organ culture as a higher resolution approach to questions of neuronal pathfinding.

2131 TWO-DIMENSIONAL MAPPING OF PROTEINS FROM RAT SYMPATHETIC GANGLIA FOLLOWING AXOTOMY AND NERVE GROWTH FACTOR TREATMENT. Michael E. Hall and David L. Wilson. Dept. Physiology and Biophysics, Sch. Med., Univ. Miami, Miami, FL 33101.

Axotomy induces a number of changes in the sympathetic ganglion, including neuronal chromatolysis, cessation of ganglionic transmission due to synaptic disjunction, and changes in the two-dimensional pattern of newly-synthesized proteins (Hall, et al, 1978). It has recently been shown that, when axotomy is followed by administration of nerve growth factor (NGF), chromatolysis and the synaptic disjunction characteristic of axotomized neurons are at least partially prevented (West and Bunge, 1976; Nja and Purves, 1976). We have now examined the pattern of newly-synthesized proteins in rat superior cervical sympathetic ganglia (SCSG) following axotomy and NGF administration. The postganglionic axons exiting the SCSG in the internal carotid nerve were sectioned, under ether anesthesia, and small cubes of gelfoam containing approx. 100 µg of NGF (Mobley, Schenker, and Shooter, 1976) in a buffered salt solution, or gelfoam cubes containing only the salt solution, were implanted adjacent to the severed nerve ending. Other rats were implanted with NGF-containing gelfoam cubes without prior axotomy. Upon recovery from anesthesia, the presence of ptosis was used to confirm that the postganglionic nerve had been severed. Three days later, all SCSG were removed and the extent of ganglionic synaptic transmission (an index of synaptic disjunction) was assessed electrophysiologically. Suction electrodes were used to stimulate the preganglionic fibers and to record population spikes from the postganglionic nerve stump. Following this brief electrophysiological examination all ganglia were incubated for 1 hr in media containing ^{14}C-leucine, then homogenized and subjected to two-dimensional gel electrophoresis as previously described (Wilson, et al, 1977). The proteins were thereby separated according to both isoelectric point and molecular weight. Results indicated that, while NGF at least partially maintained ganglionic transmission, as previously reported, it did not consistently prevent the qualitative changes in the pattern of newly synthesized proteins typically induced by axotomy. NGF treatment did selectively enhance the relative rates of synthesis of some protein species. Quantitative analysis of changes in the pattern of newly-synthesized proteins following axotomy and NGF treatment will be presented.

2132 NEURONS IN HOST RAT BRAINS WHICH PROJECT TO TECTAL TRANSPLANTS. A. R. Harvey* and R. D. Lund. Dept. Biol. Struct., Univ. Wash. Sch. Med., Seattle, WA 98195.

It has been shown previously that tectal tissue transplanted from fetal to newborn rat brains not only survives but receives afferents from the host retina and visual cortex (Lund et al., Science 193 [1976]). More recently we have used horseradish peroxidase (HRP) and ^{3}(H) proline to examine in more detail both the afferent and efferent connections of tectal transplants. The work presented here is confined to a description of the host cells projecting into the transplants.

Whole or half tectae from 15- or 16-day fetal rats were transplanted onto the dorsal surface of the superior colliculus of newborn rats. After 4 to 6 weeks the skull of the host animal was opened and the transplant injected with HRP dissolved in ^{3}(H) proline. After 24 hours the animals were sacrificed and the brains processed with either tetramethyl benzidine or diaminobenzidine as well as for autoradiography. The majority of transplants in this series were found to lie over the inferior colliculus and rostral part of the cerebellum. They were usually connected unilaterally with the host superior colliculus by one or more fiber trunks.

The most consistent input to tectal transplants arises from pyramidal cells in lamina V of the cortex ipsilateral to the side with which the transplant connects. These cells are often located in area 17 and adjacent visual areas but are also frequently found in other regions including auditory and sensorimotor cortex. Some cells have been found in cortex contralateral to the transplant. Labelled cells have also been identified in the ipsilateral and contralateral superior colliculus and occasionally in some visual and nonvisual tegmental nuclei.

The density of the host cortical projection to tectal transplants stands in contrast to that found for cortical transplants, even though the two types of tissue are commonly placed in the same region of the host brain. Experiments are currently in progress to examine the development of afferent connections to the superior colliculus in normal rats in order to compare these projections with those found to tectal transplants.

2133 NEONATAL RATS: EFFECTS OF SUBSTANTIA NIGRA DESTRUCTION AND THE ONTOGENY OF SENSORIMOTOR AND REGULATORY BEHAVIORS. Mark Henault* and C. Robert Almli. (SPON: M. M. Patterson). Psychol. Dept., Ohio Univ., Athens, Ohio 45701.

Newborn albino rats (males and females) sustained bilateral electrolytic lesions of the substantia nigra-ventral tegmental area (SN) at one day of age (24 ± 12 hours postpartum). From one through 35 days of age, the SN and sham-operated control rats were subjected to a sensorimotor testing battery which included evaluation of orientation to multimodal sensory stimulation (e.g., vision, olfaction, somatic sensation) and simple and complex motor reflexes, as well as observations of reactivity level, activity level, posture and gait. After 40 days of age, the SN and control rats were tested for feeding and drinking behaviors under a variety of conditions, e.g., hypertonic saline injections, food deprivation, amphetamine injections. Body weight was measured daily from one to 35 days of age, and every fifth day through 100 days of age.

Following SN destruction the rats displayed attenuated growth as evidenced by reduced body weight. The tests of feeding and drinking behaviors revealed that the SN rats responded at control levels on most tests (e.g., hypertonic saline injection, amphetamine injection); however, the SN rats differed from control rats on tests involving taste and preference. For example, in a simultaneous choice situation (.05% quinine hydrochloride, demineralized water, .01% saccharine), the SN rats differed from control rats by displaying a reduction in the amount of saccharine solution consumed.

Evaluation of sensorimotor behaviors revealed an essentially normal ontogenetic development of orientation to multimodal sensory stimulation and performance of simple and complex motor reflexes. However, the SN rats tended to be hyperreactive to tactile stimulation.

The present results for SN destruction in newborn rats are in strict contrast to the severe and persistent sensorimotor and regulatory deficits which occur following SN destruction and/or catecholamine depletion in older infants and adult rats. For example, destruction of the SN in rats at 10 days of age produces widespread sensorimotor deficits, and the rats die unless maintained by hand and/or tube feeding. However, damage to this system only nine days earlier in life results in remarkable sparing or escape from sensorimotor or regulatory deficits. These results suggest that this neural system is undergoing significant maturation during the first week of life in rats.

2134 QUANTIFICATION OF SYNAPSES AND BOUTON SIZES IN CENTRAL NOREPINEPHRINE FIBERS DURING POST-NEUROTOXIN REMODELLING. B.-H. Hwang*, J. Jew and T. H. Williams. Dept. Anat., Univ. of Iowa, Iowa City, Iowa 52242

This is part of a quantitative study of turnover of central catecholaminergic (CA) elements under experimental conditions. The tendency of boutons to reaccumulate within the paraventricular hypothalamic nucleus (PAR) subsequent to neurotoxin lesions is noteworthy and has been demonstrated by fluorescence microscopy and electronmicroscopy. CA terminals in the PAR are further characterized by a high proportion of synaptic contacts. The paraventricular nucleus therefore provides an opportunity to assess the impact and limits of the sprouting responses, the presumption being that the synapses are in a functional state. Data about bouton sizes and numbers of synapses will be dealt with separately.

Young adult male rats were perfused and the hypothalamus processed for fluorescence microscopic (FM) and electron microscopic (EM) examination at 4, 21, 56 and 180 day intervals after administration of 200 µg 6-OH-DA into the right lateral cerebral ventricle. CA varicosities in the PAR were counted. Norepinephrine is the major catecholamine present in this nucleus.

FM data showed CA varicosities at 45% of control numbers 4 days after 6-OH-DA, with partial restoration to 79% of controls by 180 days. EM data for CA terminals (identified by the marker 5-OH-DA) showed a more severe reduction (to 12% of control numbers) after 4 days, with partial restoration to 54% by 180 days. Average bouton diameter (for terminals identified as CA by EM marker) was strikingly similar (1.0 µ) for controls and all survival intervals, although boutons larger than 2.3 µ in diameter were encountered with greater frequency in all experimental groups than in controls.

Specializations that meet accepted criteria for synapses were counted around the contours of CA terminals. Synapses were recognized around profiles of 33% of CA terminals in control preparations. Synapses were evident around 31% of boutons 4 days after 6-OH-DA; 42% of boutons 21 and 56 days after treatment; and 36% of boutons 180 days after the neurotoxin. These results suggest that the new CA sprouts (seen 21, 56 and 180 days post-lesion) are associated with synaptic specialization. (HL21914 to JJ; NS11650 to THW).

2135 IS SENSORY NERVE ACTIVITY NECESSARY FOR COLLATERAL SPROUTING IN THE SKIN OF ADULT RATS? Patrick C. Jackson and Jack Diamond. Dept. Neurosciences, McMaster Univ. Med. Ctr., Hamilton, Ontario, Canada L8S 4J9.

We found previously in rats that intact low-threshold mechanosensory nerves appeared to sprout into adjacent denervated skin only prior to about 20 days of age; in older animals this "denervation sprouting" did not occur (Jackson and Diamond, Abstr. 1515, Soc. Neurosci.; 1978). We have new evidence that high-threshold mechanosensory nerves can be induced to sprout in denervated adult rat skin. In these experiments the presence of high-threshold innervation is defined behaviourally in quiet unanaesthetized rats, by the ability of brief forceps-pinches of back skin to elicit a reflex contraction of the underlying cutaneous trunci muscle. In three groups of adult animals clearly defined areas of back skin lacking sensibility were produced by section of selected dorsal cutaneous nerves. The first group was behaviourally mapped one day after operation. The second group was mapped 24 days after operation. The animals of the third group were lightly anaesthetized at 4 day intervals, and pinches (somewhat stronger than those used for the behavioural testing) were applied to both innervated and denervated skin regions; at 24 days after the denervation behavioural mapping was done.

The results from the first two groups showed that in the 24 days following the denervation there was no significant shrinkage of the insensitive regions (675 $\pm$ 140 (mean $\pm$ S.D.) mm^2, and 625 $\pm$ 150 mm^2 respectively); i.e. there was no evidence of high-threshold nerve sprouting. In the third group however the insensitive skin regions shrank (to 215 $\pm$ 150 mm^2). It would appear then that stimuli normally adequate to excite high-threshold endings provoked nerve sprouting into denervated skin in the adult animal; in the absence of such stimulation sprouting did not occur. Significantly, the post-operative pinching did not cause an extension of the low-threshold "touch" fields, suggesting that regeneration after damage to nerve endings may not have been responsible for the decrease of the insensitive area. Among the possibilities we are now examining is that the combination of nerve-free target tissue plus activity in remaining nerves causes collateral sprouting in the adult animal.

2136 CONNECTIONS BETWEEN CEREBRAL CORTEX TRANSPLANTS AND RAT HOST BRAIN. Christine B. Jaeger and Raymond D. Lund. Depts. Biol. Struct. and Neurosurg., Univ. Wash. Sch. Med., Seattle, WA 98195.

Cerebral cortex from rat embryos survives and matures after transplantation to newborn rat brains. We studied the question whether transplants form connections with the host brain, and if so, whether these connections were specific for the type of brain region transplanted or whether they were influenced by implant position within the host brain.

Cerebral cortex from rat embryos of gestational age 16 to 17 days was transplanted to the tectal region of newborn rats and allowed to mature for periods of 4 to 7 weeks. Subsequently, efferent fibers were demonstrated using anterograde transport of tritiated amino acids and the Fink-Heimer degeneration technique. Afferent fibers to the transplant could be shown by retrograde transport of horseradish peroxidase. Animals with transplants that were either embedded in the host tectum or connected to it by a recognizable fiber trunk were selected for this study.

Small bundles of efferent fibers could be demonstrated most often in the central gray and superior colliculus of the host. In some cases distribution of transplant efferents was noted in the pretectum and midbrain tegmentum.

Afferent connections to cortex transplants were identified from layer V pyramids in various regions of the host cortex, pretectal neurons, and occasional neurons from deep layers of the host superior colliculus. The afferent fibers to cortex transplants are relatively sparse compared to afferent connections that are formed if embryonic tectum is transplanted to the same region, as shown in other experiments. In no case tested could retinal afferents be demonstrated within the cortex transplant.

The results show that cortex transplants develop fiber connections with the host brain. Except for the lack of retinal afferents the pattern of connections formed more closely resemble those expected of superior colliculus rather than cerebral cortex. This suggests that location is a significant factor in determining fiber connections which form between the transplant and host. However, qualitative and quantitative differences in transplant-host fiber connections could be observed in cortex transplants, compared to tectal or retinal transplants placed in a similar position of the host brain. Consequently, the influence of neuron specific qualities on pathway formation cannot be disregarded. (Supported by USPHS Grant EY-01950 from the NIH.)

2137 EFFECTS OF DIFFERENTIAL POSTWEANING ENVIRONMENTS ON DENDRITIC FIELDS OF MALE AND FEMALE RATS. Janice M. Juraska and William T. Greenough. Dept. Psychol. and Neural & Behav. Biol. Prog., Univ. of Ill., Champaign, IL 61820.

There is behavioral evidence that females are less susceptible to the effects of the environment during development than males (e.g., Sackett, Sex Differences in Behavior, R. C. Friedman et al. (eds.), 1974). There is also neuroanatomical evidence that female rats, when exposed to a complex environment from 60 to 116 days of age, show a smaller change in visual cortex thickness than do male rats (Diamond et al., Intern. J. Neurosci. 2:171,1971). In the present experiment dendritic fields were examined after male and female rats had been exposed to differential environments at weaning. Twelve littermate sets of two male and two female hooded rats were assigned to either a complex environment (EC) with other same sex rats and daily toy changes or to an isolated standard laboratory cage (IC) at weaning (23-25 days of age). After 30 days of environmental exposure, the brains of all animals were stained with the Golgi-Cox method and 100 nm coronal sections were taken from the visual cortex area. Fifteen layer IV stellate neurons were traced with the aid of a camera lucida from each member of seven littermate sets. Each neuron was scored for number and length of dendritic branches and the number of intersections of branches with a overlay of concentric rings at 20 micron intervals. Although there were no differences in the number of dendritic branches, the concentric ring analysis revealed that the EC animals had significantly more intersections in the middle rings in both sexes. In the outermost rings there were significant environment by sex interactions where male EC rats had more outer dendritic material than female EC rats while there were no differences between male and female IC rats. Dendritic length measures followed the same pattern of greater length for EC and male rats. Another cell population is currently being collected. The results thus far show that the dendritic processes of both sexes may respond to differential environments but that the male response is somewhat greater.

2138 REDIRECTION OF PYRAMIDAL TRACT AXONS IN NEONATAL HAMSTERS: SOME MECHANISMS OF AXONAL GUIDANCE DURING DEVELOPMENT.
K. Kalil and T. Reh. Dept. of Anatomy and Neurosciences Training Program, Univ. of Wis., Madison, WI 53706.

In previous experiments we have shown that when pyramidal tract axons are cut in infant hamsters there is massive regrowth of the severed axons via a new brainstem pathway which decussates in an aberrant position, descends through the brainstem in an abnormal course, but nevertheless terminates appropriately in the dorsal column nuclei and spinal cord on the correct side of the brain (Kalil and Reh, '78). Regrowth of the cut fibers is maximal in animals 4-8 days of age.

In the present experiments, animals younger than 48 hours received a unilateral lesion of the medullary pyramid several mm rostral to the decussation of the tract. At this age a substantial portion of the fibers are still growing into the medullary pyramid. Thus when (H^3) proline was injected into the ipsilateral sensorimotor cortex of animals surviving to adulthood, we observed not only labeled regrowing fibers as previously described, but also many apparently later arriving fibers which were redirected rather than damaged by the lesion. Many of the fibers were deflected across the midline and descended through the intact contralateral pyramid. Surprisingly, when these fibers reached the decussation they recrossed to the "wrong" side of the brain. Other fibers which were deflected completely away from both pyramids descended through the brainstem to form a completely anomalous pathway in the lateral margin of the spinal cord. These findings suggest that (1) Growing axons deflected across the midline to the opposite side of the brain appear to be pulled along to the incorrect side by the decussating normal fibers from the intact pyramid, (2) Axons deflected far from the decussation continue on that side of the brain rather than crossing, (3) Growing axons appear able to descend through channels or pathways which under normal circumstances they never follow. These results indicate that mechanical factors in the substrate rather than intrinsic factors in the axon itself may play a more important role in determining specifically how axons cross and more generally how they are guided to their destinations in the developing brain.

2139 **NEUROGENESIS IN THE ADULT RAT VISUAL CORTEX**
Michael S. Kaplan* (SPON. J.W. HINDS). Dept. Anatomy, Boston University School of Medicine, Boston, MA. 02118

The existence of newly formed neurons in the adult mammalian neocortex has been reported by several investigators using the light microscope. Unfortunately, none of these studies could confirm that the cells labeled with H^3-thymidine were indeed neurons because in light micrographs labeled neurons cannot be distinguished with certainty from neuroglial cells. In the present study it has been confirmed that new neurons are indeed forming the adult visual cortex, substantiated by a method that allows serial thin sectioning of 1μm, plastic embedded sections previously prepared for light microscopic radioautography.

Four normal male rats (Charles River) were injected once at 90 days of age with H^3-thymidine (4.3 μc/gm body weight), and after a 30 day survival the animals were perfused. Very rarely, labeled cells were found in 1 μm plastic sections that resembled small neurons. Analysis of electron micrographs of selected examples of these labeled cells clearly demonstrated stellate neurons in layer IV with synapses along their cell bodies and dendrites. In order to quantify the relative frequency of labeled neurons, the number of heavily labeled cells seen in 1μm sections was expressed as a percentage of the total number of neurons identified in sections through the entire visual cortical thickness; the percentage was 0.0037%.

The labeled neurons are not considered to result from polyploidy since several recent investigations discredit earlier reports of polyploid DNA in large neurons, and small neurons have never been observed to be greater than the diploid amount. Furthermore, all of the labeled stellate neurons have been found in layer IV, which makes the possibility that the labeling results from non-specific DNA repair unlikely. The results of the present study are in agreement with evidence of neurogenesis of granular type neurons in the adult rat olfactory bulb and dentate gyrus (Kaplan & Hinds 1977). Thus it has now been confirmed that relatively small neurons and their synapses are found in at least 3 brain regions (olfactory bulb, dentate gyrus and visual cortex) in a normal adult mammal.

2140 SPREAD OF CATECHOLAMINES PERFUSED INTO VISUAL CORTEX: EFFECTIVE CONCENTRATION FOR MODIFICATION OF CORTICAL PLASTICITY.
Takuji Kasamatsu, Toru Itakura*, and Gösta Jonsson*. Div. Biology, Calif. Inst. Tech., Pasadena CA 91125, and Dept. Histology, Karolinska Institute, Stockholm, Sweden.

We have been studying the role of catecholamine (CA)-containing terminals in the modulation of synaptic plasticity in kitten visual cortex. In the previous physiological assay, 4 mM 6-hydroxydopamine (6-OHDA) seemed to reach a region about 6 mm away from the perfusion site after a week-long, continuous microperfusion (Kasamatsu et al., J. Comp. Neur. 185, 1979). In the present study, we have further examined the extent of intracortical diffusion 6-OHDA and norepinephrine (NE) delivered through the continuous perfusion technique. Three methods have been used.

1) CA histofluorescence

The kitten visual cortex was perfused locally with 4 mM 6-OHDA for a week, and then prepared for CA histofluorescence using a modified glyoxylic acid-cryostat method. We found an area close to the perfusion site in which no greenish fluorescent fibers and terminals remained. The radius of this primary lesion area was 4-5 mm from the center of perfusion.

2) Endogenous CA

An electrochemical assay was performed for NE and dopamine (DA) (Keller et al., Life Sci. 19, 1976) in kitten visual cortex after the microperfusion of 6-OHDA. Endogenous NE was less than 10% of the control 3-4 mm away from the perfusion site, and then it increased to 80-90% of the control at 7-8 mm. The DA content was less affected by 6-OHDA treatment.

3) Intracortical distribution of tritiated NE

The spatial distribution of tritium in the neocortex was studied following 1, 3, or 7 days of continuous perfusion with 50 μM nonradioactive NE mixed with a tracer quantity of tritiated NE. As reported previously, counts were maximal at the site of perfusion and decreased exponentially in the neighboring area (Kasamatsu et al., J. Comp. Neur. 185, 1979). This distribution pattern was attained as early as 1 day after the start of perfusion. Although the radioactivity at a given site in the cortex increased with time, its maximum detectable extent was about the same (10 mm) for the three different perfusion methods.

Combined with the dose-response relation obtained in other physiological experiments, the above information has enabled us to estimate that the threshold concentration for NE's effect on synaptic plasticity is around 10^{-7} M.

2141 FAILURE TO FIND SPARING OF SPECIES TYPICAL BEHAVIORS FOLLOWING NEONATAL PREFRONTAL CORTEX LESIONS.
Bryan Kolb and Ian Q. Whishaw. Dept. of Psych., U. of Lethbridge, Canada.

Rats with lesions of the prefrontal cortex (PFC) in infancy exhibit remarkable sparing of function compared to adults with similar removals. Lesions of the medial frontal (MF) cortex in infancy fail to produce deficits on tests of cognitive behavior such as spatial reversals, delayed response and active avoidance which are seriously disrupted by MF lesions in adulthood. Further, unlike adult lesions these early lesions fail to produce the degeneration in the dorsomedial nucleus of the thalamus that typically accompanies adult lesions. (Kolb & Nonneman, Br. Res., 1978, 151, 135).

The findings that early lesions can spare certain functions led to two questions that we addressed in the current project. 1) Was the sparing of function being mediated by other frontal cortical zones? This was tested by removing the entire frontal lobe at 7, 25 or 100 days of age. 2) Would there be sparing on such tests of natural behaviors as food hoarding or maternal behavior? This was studied by observing the same animals on tests of spatial reversals, active avoidance, hoarding, and maternal behavior as well as by videotaping each rat's home cage behavior for 24 h.

The results showed that sparing following PFC lesions is task specific as species typical behavior shows little sparing as compared to tests of cognitive behavior. Removal of the PFC at 7 or 25 days of age allowed normal performance on spatial reversals and active avoidance but abolished hoarding and maternal behavior. In the 24 hour home cage study the 7 day Ss were virtually identical to controls whereas the 25 and 100 day Ss had difficulties in drinking from a water spout and were excessively active.

Anatomically, the lesions in 7 day operates were smaller to visual inspection but the brains of these animals were significantly smaller overall than those of older animals, weighing about 85% of the 25 and 100 day Ss even though there was no difference in body weight. We again failed to find degeneration in the dorsomedial nucleus of the thalamus of the 7 day Ss as compared to the 25 and 100 day animals.

These results imply that species typical behaviors are more sensitive to neonatal brain injury than are tests of cognitive behavior. It is likely that other regions of the brain can assume general functions required for acquiring problems such as spatial reversals but the coordination of the details of complex praxic behaviors such as are observed in many species-typical behaviors can only be performed by the prefrontal cortex.

2142 PLASTICITY OF A SOMATOSENSORY CORTICAL COLUMN: A COMPARISON OF THE EFFECTS OF NEONATAL AND ADULT RECEPTOR ABLATIONS IN THE RAT USING THE (^{14}C)-2-DEOXYGLUCOSE TECHNIQUE. M. Kossut*, P. Hand, J. Greenberg*, A. Sylvestro*, C. Goochee*, and M. Reivich. Departments of Animal Biology and Neurology, Schools of Veterinary Medicine and Medicine and Institute of Neurological Sciences, University of Pennsylvania, Philadelphia, Pennsylvania 19104; Department of Neurophysiology, Nencki Institute of Experimental Biology, Warsaw, Poland; and Laboratory of Cerebral Metabolism, NIMH, Bethesda, Maryland, 20014.

Plasticity of cortical representation of mystacial vibrissae of rats (barrel columns in SI cortex) after receptor ablation was studied by the (^{14}C)-2-deoxyglucose (2DG) method in unanesthetized, restrained rats. The local cerebral metabolic rate of glucose (LCMRG) of layers I-VI of the SI barrel column responding to stimulation of C3 vibrissa was determined. The stimulation was brush stroking for 45 minutes preceeded by an intravenous injection of 50 uCi of 2DG as described by Hand et al. (Neurosci. Abst., 3,4:1977,78). They demonstrated that stimulation of one whisker increases the LCMRG of one cortical column, which extends from layer I to VI in a candle-pin shape. Columnar plasticity was investigated 3 months after unilateral ablation of all but the C3 vibrissal follicle, done either in adulthood or 2 to 4 days postnatally. With adult receptor damage the appearance of the column related to single vibrissa stimulation resembles the control, being easily discernable in all layers. However, LCMRG of layer IV of the column is decreased by 7%, while that of the lower part of lamina V is higher (18%) than in the control column. The diameter of layer IV activation is 20% larger than on the control side, which is in agreement with the barrel measurements on thionin sections. In addition, the activated region surrounding the columnar profile is more extensive in layers I-IV. With neonatal follicle ablations, the cortical area labeled by single whisker stimulation is enlarged and, with the exception of layer IV, the typical columnar profile is lost. The diffuse label within SI cortex is patchy, especially in supragranular layers, unlike the normal column in which the pericolumnar activity gradually diminishes. The LCMRG in layer IV is reduced by 15%, but is elevated in supragranular layers. The tangential spread of pericolumnar activity is much greater in rats with neonatal damage. In conclusion, these results are in agreement with the findings of electrophysiological alterations observed after neonatal vibrissal removals (Killackey et al., Neurosci. Abst., 3, 1977) and stress the role of supragranular and to a lesser extent, infragranular layers in cortical plasticity. (Supported by grants NS-06716 of USPHS and 76-10-9 of Sloan Foundation).

2143 GROWTH OF AXONAL PROCESSES FROM IN VIVO TRANSPLANTS OF RAT LOCUS COERULEUS. Richard M. Kostrzewa and Hideki Fukushima*. Dept. of Pharmacology, College of Medicine, East Tennessee State University, Johnson City, Tennessee 37601.

As a means of determining mechanisms associated with neuronal growth and development, we have transplanted a discrete central noradrenergic nucleus of newborn rats to other neonatal rat brains. Sterile technique was used to remove the locus coeruleus which was then immediately (< 2min) placed into a number of different recipient brain sites. Using a glyoxylic acid staining procedure we were able to observe fluorescent cell bodies of the coeruleus, when the latter was placed either within the cerebellum or neocortex. Cell bodies of the transplant retained their fluorescence, and axonal processes began to emerge from the transplant into recipient brain tissue within 2 days. Using a trihydroxyindole fluorimetric assay, we have also found that the norepinephrine content of the cerebellum is elevated at 2 months after transplantation into this region. These studies indicate that selective noradrenergic cell nuclei remain viable after transplantation, and that such nuclei can innervate recipient brain tissue. (This study was supported by NEUA grant no. NS-14797).

2144 ULTRASTRUCTURAL CHANGE IN THE HIPPOCAMPAL SLICE FOLLOWING REPETITIVE ACTIVATION. Kevin S. Lee, Mike Oliver*, Frank Schottler* Bob Creager* and Gary Lynch. Dept. of Psychobiology, Univ. of Calif.,Irvine, Irvine, Calif.,92717

Recently we reported that changes in synaptic structure occur in conjunction with the induction of long-term potentiation (Anat.Rec.193,3:601,1979). Specifically, an increased incidence of synapses onto dendritic shafts was observed in the stratum radiatum of CA-1 in the rat hippocampus following high frequency stimulation of the combined Schaffer collateral and commissural afferents. In the present study we sought to replicate this finding utilizing the in vitro hippocampal slice preparation. This technique has been extensively employed for electrophysiological and biochemical studies, however, little information exists as to its utility for anatomical investigations. Initially parametric analyses were performed to optimize the preservation of neuronal elements. Once conditions for achieving replicable tissue quality were ascertained, experiments were undertaken to examine the effects of repetitive afferent activation on neuronal ultrastructure. Evoked potentials recorded in the stratum radiatum were tested prior to and following either high (200 sec^{-1}) or low frequency (0.2 sec^{-1}) repetitive stimulation of the Schaffer collateral and commissural axons. High frequency stimulation consistently resulted in a non-decremental (over 15 min) increase in the size of the evoked response while low frequency stimulation had little or no effect on the potential. Ultrastructural analyses of the synaptic region which was activated showed no difference between the high and low frequency stimulated slices in the following measures: 1)the incidence of synapses onto dendritic spines, 2)the number of multiple synaptic boutons, 3)spine area, 4)spine stalk width, 5)psd length for synapses onto dendritic spines and 6)psd length for synapses onto dendritic shafts. However, in the potentiated slices, the incidence of synapses onto dendritic shafts was increased by 50% ($p < 0.01$, on a two-tailed test). These results are consistent with our previous study in which the only structural modification observed was an increase in the number of dendritic shaft synapses. The primary difference between this and the previous study, aside from the in vitro versus in vivo preparations, was the time interval allowed between afferent stimulation and tissue fixation. The slices were tested for only 15 minutes following stimulation, after which time they were immediately immersed in fixative. It thus appears that the structural change observed can occur at a very rapid rate.

2145 UNUSUAL REORGANIZATION OF THE INTACT MOUSE OLFACTORY BULB AFTER LONG-TERM SURVIVAL OF NEONATAL UNILATERAL BULBECTOMY. Richard R. Levine* and Pasquale P. C. Graziadei (SPON: Karen K. Glendenning). Dept. Biol. Sci., Unit I, Florida St. Univ., Tallahassee, FLA 32306.

In previous work we have shown that by 30 days following unilateral bulbectomy in neonatal mice, olfactory fibers regenerate and penetrate various regions of the ipsilateral telencephalon. Here they form glomerular structures and synapse with neurons within the host forebrain.

Recently, however, we have encountered a number of preparations with long-term survivals displaying a heretofore unobserved degree of neuronal reorganization. Each of these animals was bulbectomized at 5 days postnatally, sacrificed 180-365 days later, and prepared routinely for light microscopy. Our histological results, in general, indicate the typical regenerative phenomena previously noted, i.e., innervation of the ipsilateral telencephalon and glomerular formation in the forebrain by the reconstituted olfactory axon terminals. However, in some animals, we have also observed a medial expansion of the intact, unoperated bulb into the space vacated by the operated bulb. Furthermore, many of the regenerated axons on the operated side could be seen entering the fiber plexus innervating the intact bulb. This outgrowth of the intact olfactory bulb may be characteristic of all its cellular components, although it is most strikingly displayed by the granule cells. In one case, the expansion and reorganization of the intact bulb was rather extensive, so that the bulb appeared to be continuous with both the ipsilateral and contralateral telencephalic hemispheres. The role of possible injury to the intact bulb and/or neighboring bone and the pattern of bulbar reorganization is presently under study.

Both the observed bulbar outgrowth and the subsequent innervation of regenerated fibers may result in non-specific connections within the olfactory system and illustrate a potential capacity for neuronal plasticity after surgical insult to this system. Supported by NIH Grants 5/T/32 NS07010 (R.R.L.) and NS 08943 (P.P.C.G.) and NSF Grant BNS 77/16737 (P.P.C.G.).

2146 CORTICAL ORGANIZATION IN PRENATAL ENCEPHALOCLASTIC PORENCEPHALY. A GOLGI STUDY. M. Marin-Padilla and M.T. Marin-Padilla*. Dept. Pathology, Dartmouth Medical School, N.H. 03755.

Prenatal encephaloclastic porencephalies are characterized by focal destruction of the cerebral wall which may be reduced to a thin membrane composed of ependymal and arachnoidal elements, by hydrocephalus and by glial and vascular scar formation. It is belived that this type of congenital malformation is caused by an accident of undetermine nature (vascular,ischemic or infeccious) which resulted in cortical destruction, secondary hydrocephalus and eventual formation of porencephalic cysts. The fundamental plan of neuronal migration and cortical organization are considered to be primarily unaltered in this disorder. Therefore, the cerebral cortex away from the cystic lesions may appear to be histologically 'normal' or without obvious cytoarchitectural abnormalities. On the other hand, areas closer to the defects depict glial and vascular scars, prominent cytologic anomalies and various degrees of cortical atrophy. Intermediate cortical areas depict, however, more subtle changes including: a tendency of neurons to form columnal aggregates in upper layers which alternate with cell-free spaces, arachnoidal glial and vascular scars and the presence of abnormaly large neurons in layer II and III.

Rapid Golgi preparations of the cerebral cortex of a premature infant with this type of disorder has permitted, for the first time, a morphological investigation of changes described above which has resulted in a better understanding of their nature. This study has also demonstrated that many of those changes could be the result of an active reorganization of cortical structures which has followed the prenatal injury and reflect the degree of fibrillar-neuronal plasticity still present. Of special interest is the bizarre dendritic morphology of the giant neurons of the upper cortical layers. Detailed morphological analysis of the features of these giant abnormal neurons and of the development of the glial and vascular scars will be presented. The case illustrates the capacity and degree of the human cerebral cortex to undergo structural reorganization following a prenatal injury. It should be pointed out, that infants with this disorder may survive and become mentally retarder and epileptics. the interrelationships between a prenatal injury, the degree of cortical reorganization and the subsequent appearance of epilepsy should be explored in this type of congenital disorder.
(Supported by NICH-HD grant # 09274).

2147 CHRONIC INTRAVENTRICULAR ADMINISTRATION OF LSD AFFECTS THE SENSITIVITY OF CORTICAL CELLS TO MONOCULAR DEPRIVATION. Maureen A. McCall*, David G. Tieman*, and Helmut V.B. Hirsch. Neurobiology Research Center, State University of New York at Albany, Albany NY 12222.

In kittens, but not in adult cats, depriving one eye of vision (MD) for a week reduces the proportion of units in the visual cortex that can be activated by both eyes. The sensitivity of cortical units in adult cats to MD can be altered by changes in levels of monoamines in the brain (Kasamatsu, Pettigrew and Ary, 1979). Since LSD interacts with monoamines, we have examimed the effects of chronic administration of LSD on the sensitivity to MD of cortical cells in adult cats. Cats were assigned randomly to one of four conditions: MD/LSD; MD/no-LSD; no-MD/LSD; no-MD/no-LSD. An osmotic minipump (Alza Corp) was placed subcutaneously, and attached to a cannula made from a 25-gauge needle which was implanted in one lateral ventricle. The pump delivered either LSD tartate (0.88 µg/kg/hr dissolved in normal saline at pH 5.5) or the vehicle solution alone for a period of one week. In addition, at the time of implantation, the lids of one eye of the MD animals were sutured shut. The behavior of the animals was observed during administration of the drug, but no obvious anomalies were detected. One week after the implantation of the cannula/minipump assembly the response properties of single units in area 17 of the visual cortex were studied. The experimenters did not know the contents of the individual minipumps during the course of the recordings.

With the exception of ocular dominance, the response properties of units recorded in all animals did not differ from those of cells present in normal cats. In the three control conditions (MD/no-LSD, no-MD/LSD, no-MD/no-LSD) the proportion of monocular cells was less than 20%. This percentage does not differ from that observed for normal adult cats. However, if LSD was administered during the period of monocular deprivation, some 40% of the cells were monocular. Comparable results were obtained from three animals given LSD during MD in a pilot study. Our results suggest that chronic intraventricular administration of LSD affects either directly or indirectly the sensitivity of cortical neurons to monocular deprivation (supported by USPHS Grant RO1DA01684 and by Alfred P. Sloan Foundation Fellowship BR1677).

2148 DEVELOPMENT OF RETINA TRANSPLANTED TO THE TECTUM OF NEONATAL RATS. Steven C. McLoon and Raymond D. Lund. Dept. Biol. Struct., Univ. Wash. Sch. Med., Seattle, WA 98195.

We have attempted to dissociate some of the developmental patterns which are innate to the developing retina from those imposed upon the tissue by the context in which it develops. Retinas were excised from rat embryos and injected adjacent to the left superior colliculus of neonatal rats from which the right eye was removed. Four weeks later lesions were made in the transplanted retinas. After an appropriate survival time they were perfused with paraformaldehyde and sections of the brains were processed with neurofibrillar, degeneration and Nissl stains.

Embryonic retina transplanted to the superior colliculus survived and frequently fused with the host tissue. Large retinal transplants were often embedded in the tectum. Histological examinations revealed the retinal transplants to be well differentiated. They developed the three cell layers characteristic of normal retina. Frequently, these layers were arranged in rosettes with the photoreceptor cells towards the center. The photoreceptor cells did not have outer segments, but they did show a ciliated border. The ganglion cell layer was sparsely populated with large well differentiated neurons, presumably ganglion cells.

The neurofibrillar stain revealed fibers coursing between the transplants and the host brains. The greatest number of fibers appeared to run between the ganglion cell layer and the superficial layers of the host's tectum. It was common for transplants to be embedded in the anterior cerebellum with grossly discernible tracts connecting it with the tectum. This facilitated lesioning the transplant without damaging the tectum. Degeneration analysis after these lesions showed projections only to visual nuclei. The heaviest projection was to the superficial layers of the tectum, the stratum opticum and stratum griseum superficialis. There were also projections to the pretectum, dorsal terminal nucleus and the dorsal lateral geniculate nucleus. The discrete efferent projections of retinal transplants contrast with the broader distribution of connections from cortex and tectum transplanted to the same region.

These results suggest that retinal efferents may have a special affinity for denervated visual nuclei; furthermore, this appears to be a useful preparation for studies on neuronal specificity. (Supported by USPHS Grant EY-01950 from the NIH.)

2149 COOPERATIVITY IN THE GENERATION OF POST-TETANIC SYNAPTIC ENHANCEMENT APPEARS TO REQUIRE NEAR SIMULTANEITY OF AFFERENT INPUT. B. L. McNaughton and C. A. Barnes. Dept. Psych., Dalhousie Univ., Halifax, Nova Scotia, CANADA, B3H 4J1.

Following brief episodes of high frequency activity, synapses of the perforant pathway may undergo a prolonged enhancement of their efficacy (Bliss & Lømo, J. Physiol., 1973, 232, 331-356). This enhancement has been shown to involve a cooperativity among coactive afferent fibres (McNaughton, Douglas, & Goddard, Brain Res., 1978, 157, 277-293). In particular, synapses of the medial and lateral components of the perforant path exhibited considerably more enhancement when activated concurrently than when activated independently with the same stimulus parameters. It was of interest to determine whether such cooperativity requires simultaneity of afferent input, or whether there might still be some cooperation observed when temporal delays between the bursts of activity on the two input pathways are introduced. This question is of interest not only because of its reation to the mechanism of enhancement, but also because it relates to models of associative memory which postulate enhancement as an underlying mechanism.

Methods for extracellular recording synaptic responses of the medial and lateral perforant pathways were as described by McNaughton et al. (1978). The experimental paradigm was also essentially identical except for the stimulation parameters. In one hemisphere, 10 stimulus trains of 40 msec at 250 Hz were delivered at alternate six second intervals to each pathway. In the other hemisphere, each 40 msec train to the lateral pathway began 10 msec following the end of the equivalent train to the medial pathway. Eighteen animals were used, with the two hemispheres serving as matched samples as described previously.

There were no statistically significant differences within either pathway (paired t medial = 1.44, d.f. = 17; paired t lateral = -1.07, d.f. = 17) in the amount of enhancement produced by the two stimulus conditions. As in the previous study, however, the lateral pathway showed significantly more enhancement than the medial.

Given the magnitude and reliability of the cooperative effect observed in the previous study with simultaneous activation (e.g. in 15 animals, there were none in which the simultaneous condition gave less enhancement than the independent (six second) condition), we are inclined to accept the null hypothesis in this case and conclude that the cooperative effect requires very nearly simultaneous input from both pathways. For models of associative memory, this conclusion implies that there must be simultaneously active internal representations of two events in order for an association to be formed between them.

2150 LESION-INDUCED CHANGES OF COMPLEX CARBOHYDRATES IN THE RAT DENTATE GYRUS. E.E. Mena* and C.W. Cotman (SPON: H.C. Agrawal) Dept. of Psychobiol., Univ. of California, Irvine, CA 92707.

Glycoproteins and glycolipids have often been suggested to play a role in synapse formation. The hippocampus is a suitable system to examine the distribution of glycocomponents in a well-defined laminated system. By using lectins coupled to horseradish peroxidase, we have investigated both the normal distribution of glycocomponents in the rat hippocampal formation (HF) and also the rearrangement of these groups in response to lesions of the entorhinal cortex.

Con A (100 µg/ml) receptors in the HF are concentrated on the cell bodies of the pyramidal and granule cells. Con A binds in greater quantity to the inner third of the molecular layer of the dentate gyrus than any other dendritic zone of the HF. Very little reaction product is found in the stratum radiatum or stratum lacunosum-moleculare. At higher Con A concentrations (250 µg/ml) reaction product is homogeneously distributed throughout the molecular layer and stratum radiatum. However, Con A still fails to react with the stratum lacunosum-moleculare. Fucose binding protein (FBP) (200 µg/ml) also reacts with the granular and pyramidal cell layers. In addition, there is a band of intensified staining at the interface between the first and second thirds of the molecular layer. Otherwise the reaction product appears homogeneous throughout the remainder of the molecular layer and stratum radiatum.

Ricinus communis agglutinin (RCA) (200 µg/ml) also shows homogeneous staining throughout the stratum radiatum and outer two-thirds of the molecular layer. Like Con A and FBP, there is intensified staining in the first third of the molecular layer. Also, the stratum lacunosum-moleculare contains the lowest amount of RCA binding in the hippocampal formation. This is also the case for Con A binding.

The hippocampus was studied at 3 or 30 days after a unilateral entorhinal lesion. At 3 days post-lesion no changes were found in Con A binding. However, at 30 days post-lesion an alteration of these lectin receptors patterns was seen. The amount of Con A (100 µg/ml) binding increased greatly in the entire molecular layer and the stratum lacunosum-moleculare. FBP and RCA binding also increase throughout the entire molecular layer. The increase in binding of FBP extends past the fissure but does not appear to occupy the entire stratum lacunosum-moleculare. However, in contrast to Con A and FBP, the increase of RCA binding is largely restricted to the dentate molecular layer. These data demonstrate a plasticity of glycocomponents during active synaptic growth in the mature brain. (Supported by Grants NS08597 and MH19691)

2151 COLLATERAL-SPECIFIC LONG TERM POTENTIATION (LTP) OF HIPPOCAMPAL FIELD CA_3 OUTPUT IN THE RAT. J.J. Miller & N. McNaughton*. Dept. Physiology, Univ. British Columbia, Vancouver, Canada V6T 1W5.

Brief, high frequency stimulation of hippocampal afferents has previously been shown to result in LTP of the synaptically evoked potentials to subsequent single pulse stimulation of these inputs. While the mechanisms involved remain unclear, it has been demonstrated that the response is input specific and not a property of the target cell, implying that alterations in presynaptic or immediate postsynaptic regions may account for LTP. If a presynaptic change was involved (e.g. augmented transmitter release) then it might be expected to occur in all terminal projections of a particular neurone. To test this possibility, the characteristics of frequency potentiation and LTP of CA_3 projections to the CA_1 pyramidal and the lateral septal neurones (LS) was investigated in the urethane-anaesthetised rat.

Stimulation in the region of hippocampal field CA_3 evoked CA_1 and LS responses which exhibited similar threshold profile, strength-duration and frequency following characteristics suggesting that the same population of CA_3 neurones was being activated in both cases. CA_3 neurones were also antidromically driven from both LS/fimbria and CA_1/Schaeffer collateral stimulation sites. During low frequency (10-15 Hz) stimulation of CA_3, the CA_1 population spike exhibited potentiation while the LS response was depressed. Tetanic stimulation (100 Hz) resulted in LTP of the subsequent CA_1 population spike (400%) but no consistent change in the LS evoked field.

The collateral-specific properties of LTP demonstrated in this study, together with data indicating input-specificity suggest that changes in the immediate postsynaptic membrane are necessary to induce LTP or that presynaptic changes must be terminal specific.

2152 NEURONAL PATHWAY SELECTION: DIFFERENTIAL ABILITY OF REGENERATING IDENTIFIED NEURONS TO DISCRIMINATE BETWEEN "CORRECT" AND "INCORRECT" PATHS. A.D. Murphy and S.B. Kater. Lab. Molecular Biol., Univ. of Wisconsin, Madison, WI. 53706 and Dept. Zool., Univ. of Iowa, Iowa City. IA. 52242.

The mechanisms which guide the paths of growing neurites are fundamental to the formation of specific neuronal connections and the establishment of functional neuronal circuitry. We addressed the problem of neuronal pathfinding in the context of a regenerating system by taking advantage of a well-known feature of gastropod mollusks, i.e. large identifiable neurons that can be reliably relocated within different individuals of a given species. We employed the snail, Helisoma trivolvis, for these studies and have centered our studies around two pair of large identified neurons in the buccal ganglia, neurons 4 (R&L) which innervate the salivary glands, and neurons 5 (R&L) which innervate the gut. Standard intracellular recording and staining procedures were used throughout. Neurons 4 and 5 normally have axons in the esophageal trunk (ET). The ET trifurcates to form the gastric nerve (GN) to the gut, the salivary nerve (SN) to the acinar portion of the salivary gland, and the dorsobuccal nerve (DBN) which courses along the duct of the gland and enters the buccal mass. Neuron 4 normally has an axon branch in the SN and DBN but "avoids" the GN. Neuron 5 normally has a large axon in the GN, a smaller branch in the DBN and no axon in the SN. During regeneration following crush of the ET proximal to the first branch point, neuron 4 neurites select their paths indiscriminately. Several of these neurites typically traverse each of the nerve branches including the "incorrect" GN. In only 2 of 14 cases did neuron 4 avoid the GN and in one instance neuron 4 sent all of its neurites down the incorrect GN. In contrast, neuron 5 tends to traverse its normal pathways during regeneration. In each of 13 cases neuron 5 always sent most of its neurites out the GN with a smaller number out the DBN. In only 6 of the 13 cases were any neurites seen in the incorrect SN and never more than 2 very fine neurites were seen in the SN as compared to as many as 60 which could be seen in the correct GN and DBN. While it is extremely difficult to extrapolate from regeneration paradigms to ontogeny, this study shows that processes fundamental both to ontogeny and regeneration, i.e. neurite outgrowth, can be differentially and specifically encoded in different neurons of the same nervous system and that the fidelity of regenerating neurons for selecting nerves normally containing their axons differs for different identified neurons. (Supported by PHS grants 1 RO1 NS09696 and 1 RO1 AM19858.)

2153 NON-NEURAL (HUMOURAL?) MECHANISMS ELEVATE EPSP AMPLITUDES FOLLOWING SPINAL CORD TRANSECTION. S.G. Nelson, T.C. Collatos and L.M. Mendell. Duke Med. Ctr., Durham, N.C. 27710.

Spinal cord transection at T13 or L5 elevates the amplitude of medial gastrocnemius (MG) Ia fiber-motoneuron EPSPs beginning a few hours after transection (Nelson et al, J. Neurophysiol. 41, 1979). The present experiments were undertaken to test whether this increase requires interruption of descending input which is in mono- or multisynaptic contact with the motoneurons. Cats chronically transected at T13 (9 to 13 weeks before) were subject to a second transection at T11 several hours before individual EPSPs were recorded in MG motoneurons (at L7-S1) using spike triggered averaging. Chronic transection at T13 yields EPSPs similar to those in intact preparations although a few unusually large EPSPs (400-650 µV) are observed in slow motoneurons (Nelson and Mendell, J. Neurophysiol. 41, 1979). The mean EPSP in double transected preparations was significantly larger than after chronic transection alone (201±22 µV, N=69 vs 114±8 µV, N=161, $p<0.01$). Furthermore, the mean EPSP in each of these preparations was larger than the largest mean EPSP in any single transected one. The percentage of EPSPs smaller than 100 µV was reduced whereas those larger than 400 µV became more frequent with EPSPs as large as 1150 µV being observed. However, these large EPSPs were restricted to small motoneurons and tended to have long rise times unlike EPSPs after acute transection alone which exhibited very brief rise times and which were observed in motoneurons of all conduction velocities. These features of the EPSP enlargement seen following acute transection alone seem to require interruption of fibers in synaptic contact with the test motoneurons. However, indirect, non-neural (humoural?) mechanisms affecting Ia-EPSP amplitude must also exist. The normal blood pressure in these preparations indicates this factor is not crucial. Furthermore, increases in EPSP amplitude do not require elevation of motoneuron input resistance since these were within normal limits. Control experiments revealed that these increases do not occur immediately after acute transection nor do they occur if the 2nd transection is very close (T12) to the chronic one. We speculate that this increase is triggered by neural activity which influences the recording site indirectly and that the number of functional fibers cut at T12 is too small to initiate these changes. (Supported by NIH).

2154 AGE AND HORMONES INFLUENCE GROWTH OF VOCAL CONTROL STATIONS OF THE CANARY BRAIN. F. Nottebohm. Rockefeller University, New York, N.Y. 10021.

Vocal control pathways of the canary brain include two discrete telencephalic nuclei, hyperstriatum ventrale, pars caudale (HVc) and nucleus robustus archistriatalis (RA). These two stations show gross sexual dimorphism, presumably related to the fact that males, but not females, sing complex, learned songs (Nottebohm and Arnold, Science 194 211 '76). In the first experiment described here, male canaries were sacrificed in groups of 4 at ages 15, 30, 45, 60, 75, 90 and 120 days after hatching. Their brains were weighed, fixed in formalin, embedded in gelatin albumen, sectioned at 50 u intervals and stained with cresyl violet. All age groups had adult brain volumes. The volume of HVc and RA was reconstructed as described in lit. HVc is first recognizable on day 30 after hatching. At this age RA and HVc volumes are 30% and 25%, respectively, as large as those of 1-year-old males in full reproductive condition. HVc and RA grow by a factor of 2.5 between the 30th and 60th post-hatching day. Adult volume is reached, respectively, by the end of the third and fourth month. The 30th to 60th day period of rapid growth coincides with the subsong stage of song development, a time when auditory-motor vocal experience may be integrated into HVc and RA patterns of growth and connectivity.

In a separate experiment, 10 male and 10 female canaries were gonadectomized 5-19 days after hatching. Half of the ovariectomized females received silastic cholesterol (Ch) implants, the other half received silastic testosterone (T) implants at 11 months. Both groups of gonadectomized females, 6 intact females of the same age, the castrate males and 10 intact male siblings of the latter were sacrificed at 12 months of age. Attempts were made to record song from all these birds. All intact males developed adult song. The castrate males produced subsong and plastic song, but fell silent at approximately 8 months, when their intact siblings were coming into stable adult song as well as into reproductive condition. Of the females, only the T-treated group produced male-like song. HVc and RA volumes were reconstructed for all these birds. HVc and RA were 90% and 53% larger, respectively, in the T-treated than in the Ch-treated females. HVc and RA were 45% and 54% smaller in the castrate than in the intact males. The ratio of male/female HVc and RA was comparable in intact and gonadectomized individuals, suggesting that events preceding gonadectomy had already biased development of these structures in the two sexes.

The canary HVc and RA seem to be unusual in the extent to which gross neural plasticity normally associated with early development can be induced in adulthood at the time a new behavior is acquired. (Supported by MH18343 and RF70095).

2155 **THE EFFECT OF EYE ROTATION ON VISUOMOTOR PERFORMANCE.** **Joelle Presson, Jeffrey Moran* and Barbara Gordon. Dept. of Psychology, University of Oregon, Eugene, OR 97403.**

To assess the effect of an abnormal relationship between the retina and the visual world on visuomotor behavior we have studied visually guided jumping in kittens who had one eye intorted about the time of natural eye opening. In 3 groups of animals the right eye was rotated and the left eye was either: (1) normal; (2) sutured; or (3) normal, but the animal reared with alternating occlusion. A control group had all the muscles of the right eye cut (no rotation) and a normal left eye. Starting at about 5-8 weeks of age, each animal's jumping ability was tested (under monocular control) twice a week for about 11 weeks. The kitten was required to jump from a tower of variable height onto a square platform in a pan of water without getting its feet wet. If the kitten jumped successfully 4 out of 5 times, the height was increased. Because jumping ability varied somewhat from kitten to kitten, we compared performance using the operated eye with the same kitten's performance using the normal eye, whenever possible. The muscle cut control animals performed equally well with both eyes. The rotated eye cats showed clear deficits when using the rotated eye. By 8 weeks of age they could jump from 45 cm using the normal eye, but they never attained this height using the rotated eye. The eye rotation, alternating occlusion animals showed deficits when using the rotated eye at 7 weeks, but by 13 weeks of age were jumping equally well with both eyes. The eye rotation, left eye sutured cats also did poorly (compared to other cats using their normal eye) at 7 weeks, but jumped normally by 13 weeks.

To determine whether the jumping deficits were due to an acuity deficit, the eye rotation, left eye normal, animals were trained in a two-choice acuity task. The animals were trained to choose a door with horizontal black and white stripes over a door with vertical black and white stripes. The size of the stripes was decreased until the animals performed no better than chance. When using the normal eye the cats could see, on the average, stripes as small as 11' of arc. With the rotated eye the animals could only resolve stripes as small as 21' of arc. The acuity deficit cannot account for the jumping stand deficit because the angle subtended by the platform at its highest was 12°. We conclude that rotation of the visual world following eye rotation causes a visuomotor deficit that is independent of acuity. The deficit is ameliorated if the animal is forced to use the rotated eye.

2156 RECOVERY OF ALTERNATION PERFORMANCE FOLLOWING ENTORHINAL CORTEX LESIONS. J. J. Ramirez* (SPON: D. G. Stein). Psych. Dept., Clark Univ., Worcester, MA 01610, and Dept. Neur., U. Mass. Med. Sch., Worcester, MA 01605.

Sprouting is thought to be correlated with behavioral recovery. For example, rats with unilateral entorhinal cortex (EC) damage previously were shown to be a model preparation for analysis of the relationship between collateral sprouting and recovery of alternation performance. The present study was conducted to confirm that recovery of alternation performance co-occurs with sprouting (Loesche and Steward, 1977). Thirty-six food-deprived male rats were trained to alternate for food reward in a Y-maze. Rats subsequently received unilateral or bilateral lesions and were tested for retention of the alternation task. Alternation performance was spared in rats with unilateral damage, whereas alternation performance was disrupted by perseverative responding in rats with bilateral damage. Disruption of alternation performance in rats with bilateral damage depended upon re-test paradigm: namely, massed trials (i.e. daily training) resulted in transient deficits (mean=32 days), whereas distributed trials (after Loesche and Steward, 1977) resulted in persistent deficits (58 days). Histological analysis verified that EC was damaged almost entirely in both groups of subjects.

Fink-Heimer analysis was conducted to reveal patterns of degeneration resulting from unilateral EC damage. Preliminary results indicate that there is anomalous growth into the outer molecular layer of dentate gyrus originating in intact EC. These preliminary findings corroborate those of other investigators who provided evidence for lesion-induced reorganization of entorhinal-hippocampal circuitry.

The present investigation demonstrates that impaired alternation performance is not a necessary consequent of unilateral EC damage. In addition, the preliminary histological results suggest that sprouting might be correlated with spared alternation performance following unilateral damage. Finally, the results obtained from animals with bilateral lesions indicate that variables in addition to sprouting (e.g. extensive postoperative training) may influence the recovery of alternation performance. (Supported by NIA grant 5RO1 AG 00295-03.)

2157 ELECTRON MICROSCOPIC EVIDENCE FOR ESTABLISHMENT OF SYNAPTIC CONNECTIONS BY REGROWING PYRAMIDAL TRACT AXONS IN THE INFANT HAMSTER. T. Reh and K. Kalil. Neurosciences Training Program and Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706.

In a previous report (Kalil and Reh, '78) we presented light microscopic autoradiographic evidence demonstrating that pyramidal tract axons severed in the medulla of infant hamsters are capable of regrowing over long distances to innervate their normal targets in the medulla and spinal cord, albeit by an abnormal route. We now present electron microscopic evidence that the regrowing fibers form synaptic connections in at least two of these terminal regions, the dorsal column nuclei (DCN) and the dorsal horn of the cervical spinal cord.

Hamsters ranging in age from 4-8 days received a unilateral lesion of the pyramidal tract at the level of the inferior olive and were allowed to survive to adulthood. The sensorimotor cortex ipsilateral to the lesion was then removed and the animals sacrificed 2-8 days after the cortical lesion. The tissue was processed for electron microscopy and thin sections through the DCN and cervical spinal cord examined for degenerating axons and terminals. Sections taken from identical areas of normal animals with similar cortical lesions served as control material.

The results obtained for experimental and control animals were qualitatively similar. The fibers of both the normal and regrowing pyramidal tract showed similar rates of degeneration. After 8 days survival, myelinated axons exhibited various stages of degeneration. Some contained degenerating mitochondria and dense bodies, but their microtubules and microfilaments appeared normal. Other axons in a more advanced state of degeneration were completely filled with a dense granular matrix. Degenerating axons were similar in appearance but far less numerous at 2 days than at 8 days.

Synaptic terminals in the DCN and cervical spinal cord contained an accumulation of dense bodies and darkened cytoplasm similar to that observed in degenerating axons. At earlier stages of degeneration, synapses retained their postsynaptic contacts, while at more advanced stages glial processes frequently engulfed the terminals.

These results demonstrate that regrowing pyramidal tract fibers form synaptic terminals in their appropriate target areas. This suggests a mechanism for possible recovery of function.

2158 FUNCTIONAL AND ANATOMICAL REORGANIZATION OF THE SOMATOSENSORY INPUT TO THE HAMSTER'S SUPERIOR COLLICULUS FOLLOWING NEONATAL ENUCLEATION. Robert W. Rhoades, Dept. of Anat., Coll. of Med. and Dent. of New Jersey, NJSOM, Piscataway, N.J. 08854.

Superior collicular neurons responsive to tactile stimuli are encountered only in the laminae ventral to the stratum opticum in normal hamsters. In the posterior part of the colliculus the vast majority of these cells can be activated both by electrical shocks delivered to the spinal cord (at the second cervical segment) and also by similar stimulation of the ipsilateral sensorimotor cortex. These data coincide well with the results of both autoradiographic and degeneration experiments which have indicated that the spinal input to the tectum in this species terminates for the most part in the stratum album intermedium and to a lesser extent in the stratum griseum intermediale in the caudal portion of the structure. Sensorimotor cortical injections of tritiated amino acids in normal animals revealed further that the projection from this cortical region to the tectum was also restricted to the laminae ventral to the stratum opticum.

In animals which have had one eye removed on the day of birth this functional and anatomical organization is clearly altered. In the posterior half of the colliculus ipsilateral to the remaining eye neurons responsive to somatosensory stimuli are encountered in all tectal layers and electrical stimulation of the type described above revealed that most of these cells received convergent input from the cord and sensorimotor cortex. The latency distributions for responses to shocks delivered at these two loci were essentially identical in the normals and the neonatal enucleates and for a given collicular cell the response latency for stimulation at the second cervical segment was invariably shorter than the latency of the discharge obtained with cortical shocks. Degeneration and autoradiographic experiments carried out in neonatally enucleated hamsters indicated that a probable anatomical substrate for the observed functional changes was a dorsal expansion of the terminal distributions of both the spinal and somatosensory cortical projections to the partially denervated colliculus. 2159 SI CORTEX IN MOUSE: INCREASED, RANDOM DISPARITY BETWEEN THE AREAS OF BARREL FIELDS IPSILATERAL AND CONTRALATERAL TO FOLLICL ABLATIONS. F.L. Rice, D. Jeanmonod*, and H. Van der Loos*. Institut d'Anatomie, Lausanne, Switzerland CH1011.

Unilateral vibrissal follicle ablations on the muzzles of mice have been shown to produce deformations only in the contra lateral barrel field of SI cortex and only when the ablations were made between the day of birth (P-0) and P-4. The deformation is specifically located (e.g. row C follicle ablation lea to contralateral row C barrel deformations) and its form varies with the age the ablation occurs (Woolsey and Wann; JCN, 170: 53). The barrel field ipsilateral to the lesion appears normal A quantitative analysis of the tangential area occupied by the posteromedial barrel subfield (PMBSF) reveals that unilateral follicle lesions also produce a more generalized, interhemispheric abnormality. 37 experimental Swiss-Webster mice had the left row C of follicles ablated on either P-0, P-1..., or P-5 and 20 control mice had no ablations; all were sacrificed on P-12. The tangential area occupied by the PMBSF in each hemisphere was measured from reconstructions of 40 μ thick, Nissl-stained serial sections (usually a maximum of 3) cut tangential to the PMBSF. The PMBSF areas of the left hemispheres were com pared (T-test and F-test) to those of the right and no significant difference (0.05 level) was found for either the ex perimental or control population. Thus, the follicle lesions produced no consistent increase or decrease in the size of the contralateral PMBSF's relative to the ipsilateral or vice versa Next, a measure of the disparity between the left PMBSF area (L and the right (R) was derived for each animal: $(L-R) \div 0.5 (L + R) \times 100\%$. Positive percentages indicate a larger left PMBSF; negative a larger right. The disparities within both the experimental and the control populations followed a normal distribution with a mean value (-0.9% and 0.8% respectively) nearly equal to 0. However, the range of disparity was significantly greater (0.001 level) for the experimental population (range: 19% to -27%; SD = ± 10.7) than for the controls (range: 11% to -12%; SD = ± 5.8). Ablations at all ages (P-0 to P-5) produced increased disparities with no obvious age related trend. These results demonstrate that, in addition to specific contralateral effects, unilateral follicle ablations produce an increase in the range of interhemispheric disparity of PMBSF area that is unrelated to the side where or age when the ablation occurred. Perhaps a loss of peripheral symmetry results in a decrease in some kind of interdependence that may exist between the two hemispheres during development. Supported by grants 3.1350 and 3.776 from the Swiss National Science Foundation to HVdL.

2160 EFFECTS OF FIELD AND LABORATORY ENVIRONMENTS ON DEVELOPMENT OF BRAIN IN GROUND SQUIRRELS: EVOLUTION OF BRAIN PLASTICITY. Mark R. Rosenzweig, Edward L. Bennett, Paul W. Sherman*. Dept. Psych. & Lawrence Berkeley Lab., Univ. of Calif., Berkeley 94720.

We compared brain development in Belding's ground squirrels (Spermophilus beldingi) in 2 laboratory environments--enriched (EC) and impoverished (IC)--and that of feral (F) conspecifics. Laboratory young were born from pregnant females live-trapped near Tioga Pass, Calif.; they were weaned and assigned to differential environments at about 30 days of age and kept in conditions for 40 days. Just before sacrifice, feral juveniles of the same age were live-trapped near Tioga Pass; they were sacrificed together with the laboratory squirrels. There were 20 animals in each condition, half of each sex. In weights of cerebral cortex, (EC≈F)>IC; EC>IC, $p<.01$. In skeletal development (hindfoot length), F>EC>IC; F>IC, $p<.01$. In total RNA of occipital cortex, (EC≈F)>IC; EC>IC, $p<.05$. In total DNA of occipital cortex, F>(EC≈IC); F>IC, $p<.05$; this indicates a greater number of cortical cells in feral as compared to laboratory-born animals. Differences between EC and IC ground squirrels conformed in most respects to those found earlier between EC and IC laboratory rats, mice, and gerbils. Comparisons with feral animals showed EC ground squirrels to be close to the natural baseline in most cerebral and behavioral measures that we made.

Further research is under way with 2 species of ground squirrels to test the following hypotheses about evolution of brain plasticity: 1) Other things being equal, a species that has evolved in a varied and less predictable environment will show more plasticity in response to environmental demands than will a related species from a simpler and stabler environment. 2) In view of the metabolic costs of a large brain, there is survival value in reducing brain size at times in the individual's life when a low level of demand is placed on it; conversely, the brain must be large enough to meet sudden demands and plastic enough to increase its capacity when increased demand occurs. A preliminary test was made of hypothesis 2 by placing 4 juvenile ground squirrels in a cold room at 5°C where they hibernated Nov.-April while 4 others maintained normal activity at 20°C. Growth of body and brain continued at 20°C whereas the hibernators showed cessation of brain growth and even a slight loss of brain weight.

2161 AXON SPROUTING AND SITE OF SYNAPSE FORMATION IN INNERVATED MUSCLES. Shlomo Rotshenker* and Fanny Reichert. Dept. Anat. Embryol. HU - Hadassah Med. Sch. Jerusalem, Israel.

Multiple end plate potentials (e.p.p.s.) can be recorded in single muscle fibers innervated by several motor neurons when the whole motor nerve is stimulated by successive impulses of increasing intensity. Such multiple e.p.p.s. were recorded in 16% of muscle fibers comprising cutaneous-pectoris muscles of normal frogs. The number of muscle fibers in which multiple e.p.p.s. were recorded increased in intact right muscles after injuring the motor nerve to left muscles. Is this increase in the incidence of polyneuronal innervation attained by the formation of new synapses and if so where do new axon terminals arise from and where on muscle fiber surfaces do they terminate?

Motor axon terminals stained by a mixture of zinc iodide and osmium are visible in light and electron microscopy. In normal frogs, myelinated motor axons give rise to several terminal branches that end abruptly upon the muscle fiber they innervate In contrast, in intact right muscles of experimental frogs some axons and nerve endings gave rise to sprouts that gained contact with muscle fibers apparently not innervated by their parent axons. The number of axons comprising the motor nerve to right intact muscles and left denervated muscles was similar (counts made proximal to site of injury).

In normal frogs, muscle fibers comprising cutaneous-pectoris muscles are innervated at a single end plate region that can be marked histochemically by staining for the enzyme cholinesteras which is confined to the synaptic site only. The average end plate size in right muscles is within ± 10% of that of left muscles. However, after cutting the motor nerve on the left side there was an increase in the average end plate size in right intact muscles over that in left muscles. In the same right muscles there was also an increase in the incidence of polyneuronal innervation (determined electrophysiologically). Also, electron microscopical examination of randomly chosen neuromuscular junctions revealed only a 10% incidence of neuromuscular junctions where 2 axonal profiles were identified in a single gutter.

Supported in part by the Dysautonomia Foundation and the Muscular Dystrophy Association.

2162 ELECTROPHYSIOLOGICAL MAPPING OF ABERRANT AND NORMAL RETINAL PROJECTIONS TO THE SAME SUPERIOR COLLICULUS IN HAMSTERS. George M. Sachs* and Gerald E. Schneider. Department of Psychology, M.I.T., Cambridge, MA 02139

After ablation of the superficial layers of the right superior colliculus (SC) in newborn hamsters, optic tract fibers from the left retina recross the midline at the tectum and terminate in a medial portion of the intact left SC. Neuroanatomical studies have shown that this aberrant projection displaces terminals from the normal contralateral retinotectal projection. Twelve weeks to one year after early right tectum ablation, 12 hamsters underwent acute removal of visual cortex, and visually evoked multi- and single-unit responses were recorded from the left SC. Five hamsters also received injections of ^{3}H-leucine in the left eye 4 days before recording.

Electrophysiological results indicated that the tectal projections from the two eyes exhibited varying degrees of overlap. For some cases, tectal units recorded medially were driven exclusively by the left eye and there was an abrupt transition to units activated only by the right eye as more lateral regions were sampled. Autoradiography showed a dense aberrant projection with a sharp lateral border. In cases where the aberrant projection appeared less dense as seen with autoradiography, there was electrophysiological evidence for overlap of the two retinal projections. From some sites two groups of units, each driven by a different eye, could be recorded simultaneously. These sites were encountered in a region that always included the lateral part of the aberrant projection and sometimes extended to the medial edge of the left SC. The normal projection showed little compression in the mediolateral tectal axis so that, particularly in cases with segregated projections, the lowest portions of the right retina were not represented in the left SC. The aberrant projection arose primarily from the lower half of the left retina and exhibited the same polarity as the normal projection (lower retina projected medially, nasal retina projected caudally). This polarity failed for only a few pairs of recording sites, at which reversals in the mediolateral tectal axis were noted. Binocularly driven single units were encountered only rarely. Inputs to such binocular units often, but not invariably came from homologous (mirror image) regions in the visual fields of the two eyes. Although the aberrant projection to the left SC never represented the entire left retina, it did show some compression. As a result of this compression, homologous points in the two retinae were represented in two different topographic maps within the same SC.

Supported primarily by NIH grant EY00126

2163 SPARING AND RECOVERY OF FUNCTION WITHIN THE 'PREFRONTAL SYSTEM' OF THE INFANT RAT. C. L. Sahley and A. J. Nonneman. Dept. of Psychology, Univ. of Kentucky, Lexington, Kentucky 40506.

In an attempt to distinguish between sparing and recovery of function within the 'prefrontal system' of the rat, 7-8 day-old infant rat pups were given medial frontal (MF), orbital frontal (OF), caudate nucleus (CN) and sham (SH) lesions allowed to recover and then tested at 14-days of age on a variety of tasks known to be sensitive to prefrontal dysfunction in the adult rat. These tasks include resistence to extinction of a learned approach response, passive avoidance, spatial discrimination and reversal and activity in the open-field. They were also tested on an odor-aversion task. Additional rat pups 10-14 -days old without lesion were tested on the same tasks to determine if there were any age-dependent differences in performance within this age range which might interact with the lesion-dependent changes in performance. The results indicated that MF lesions produced no deficits on any of the tasks employed. In addition, only the CN operates showed an increased resistance to extinction and an increased number of trials to passive avoidance as compared to SH pups. Both CN and OF operates, however, had difficulty learning the spatial reversal and demonstrated an increase in activity as compared to shams. All lesioned and SH pups learned the odor-aversion task similarly. No age-dependent differences in performance were observed in normal pups on any of the tasks.

The results suggest that there may be a sequential encephalization of function within the 'prefrontal system' of the rat from the CN to the cortical areas. Further, both sparing and recovery of function appear to be operative in the prefrontal system. The primary determinant of the degree of sparing or recovery appears to be the degree of functional maturity of the tissue at the time of the neural damage. Finally, it appears that the CN is capable of mediating behavioral functions of the 'prefrontal system' both in the infant rat before maturation of the cortical areas is complete and following damage to the cortiareas in the infant rat.

This reasearch was supported in part by a NIMH Grant #MH 27345 to A.J.N., a Sigma Xi Grant-in Aid to C.L.S. and the University of Kentucky Graduate School.

2164 MOVEMENT OF OPTIC TERMINALS IN GOLDFISH TECTUM AFTER LOCAL PRE- OR POSTSYNAPTIC BLOCKADE OF TRANSMISSION. John T. Schmidt. Dept.Anat.,Sch.of Med.,Vanderbilt University, Nashville, TN 37232.

Alpha-bungarotoxin(5nM) was found to be effective in blocking the synapses of all three classes of retinal fibers in goldfish tectum. It severly decrements the field potentials at all depths after either photic stimulation or electrical stimulation of the nerve. Current source-density further shows that it blocks the flow of synaptic currents into radially oriented tectal cells, although presynaptic activity remains largely unaffected. Microinjection from a pipette(10μm tip) produces a local blockade of a restricted area. One microliter blocks an area 0.6mm in diameter; two microliters increases this to 1mm. Outside this area normal size field potentials are recorded. Six to eight days later no optic terminals can be recorded within the toxin-treated area. However, construction of an extensive retinotectal map shows no corresponding scotoma in the visual field. Instead the terminals with receptive fields within the corresponding area can then be recorded from surrounding tectal areas. Usually these take the form of enlarged multiunit receptive fields from the surrounding areas overlapping into the area, so that all visual areas are still represented in the map. Apparently the optic terminals within the toxin-blocked area move outward to colonize neighboring normal areas, confirming Freeman's results in toad(Nature 269,218,1977). The time course of the exodus of terminals as well as their eventual reentry is now being determined.

Following similar local blockade by β-bungarotoxin, there is a corresponding scotoma in the visual field even after one week. Extensive mapping,however,shows complete coverage of all tectal areas including the toxin-treated area. Apparently neighboring healthy terminals move in to occupy sites vacated by toxin-damaged terminals. At the neuromuscular junction, it causes nerve terminals to degenerate. There remains to be determined whether the optic terminals also degenerate, whether they are the only terminals affected, and also whether they eventually regenerate to reclaim their usual tectal loci.

2165 DEVELOPMENTAL ALTERATIONS IN BINOCULAR COMPETITION AND VISUAL ACUITY IN VISUALLY-DEPRIVED CATS. Douglas C. Smith, Harris D. Schwark*& Deborah M. Beaudry*. Dept. of Psychology, Southern Illinois Univ.,Carbondale, Ill. 62901, and Neural & Behav. Biol. Prog., Univ. Illinois, Champaign, Ill. 61820.

Alterations in binocular competitive interactions during postnatal development produce marked effects on the physiological properties of single cells in striate cortex of the cat. For example, if a kitten is monocularly deprived (MD) during development, almost all of the cells in striate cortex respond exclusively to visual stimulation of the nondeprived eye. In contrast, in a kitten which is binocularly deprived (BD) via lid suture, neither eye has a decided advantage over the other and the electrophysiological effects are less severe than the effects of MD. If the deprived eye of an MD cat is placed at a competitive advantage during postnatal development by removing the other eye at the same age at which MD is initiated (MDE), binocular competitive interactions are absent and only the effects of deprivation per se are present. Consequently, the response properties of cells in area 17 are less severely affected than following BD, although deprivation effects are evident in MDE cats (Kratz and Spear, 1976).

The differences which exist in striate cortex of kittens in these developmental conditions are also evident in terms of behaviorally measured visual acuity. Using the Mitchell et al., (1976) jumping stand, visual acuity for MD, BD and MDE cats was determined following 4-12 months of deprivation. The stimuli were high contrast square-wave gratings (luminance 138 cd/m^2). Threshold visual acuity (70% correct) for 3 MD cats using the deprived eye was 0.87, 0.75, or 0.3 cycles/deg ($\bar{x}$= 0.64). For 3 BD cats using a single deprived eye, threshold visual acuity was 3.7, 3.25 or 2.55 cycles/deg ($\bar{x}$= 3.17). For 2 MDE cats visual acuity was 3.94 or 3.84 cycles/deg ($\bar{x}$= 3.89). A third MDE cat is being tested. These results indicate that the nature of competitive interactions between the eyes during development determines postdeprivation visual acuity. Further, comparisons between MD and MDE cats suggest that the acuity deficits associated with developmental monocular deprivation are primarily due to abnormal competitive interactions; however, threshold acuities for MDE cats are below those found for cats using a nondeprived eye and this finding attests to the effects of deprivation per se on visual acuity. Finally, the MDE cats studied provide additional support for the correlation between visual acuity and the responsivity and specificity of single cells in striate cortex of visually-deprived cats (Smith et al., 1978).

2166 REINNERVATION INDUCES PROLIFERATION OF A NOVEL FORM OF RADIAL GLIA IN THE OPTIC TECTUM OF GOLDFISH. James A. Stevenson, Dept. Psychology, Dalhousie Univ., Halifax, N.S., Canada.

Previously, we have described "periependymal" cell proliferation in the goldfish optic tectum. Labeling among these cells, whose nuclei are located between the ependyma and the neuronal stratum periventriculare (SPV), is seen when ^{3}H-thymidine injections are made 25-35 days after optic nerve section, the time at which functional reinnervation of the tectum occurs. Tecta denervated by eye enucleation do not show such proliferation (Stevenson and Yoon, '78, Brain Res., 153).

The present report describes the periependymal (PE) cells. In the light microscope these cells are easily recognized by their location and thymidine labeling properties. Unlabeled PE cells are distinguished from their neighbors by their deeply invaginated nuclei with eccentric nucleoli, moderately basophilic cytoplasm and large perikarya. Golgi preparations display a single peripherally directed process extending from such perikaryá. The process reaches the stratum opticum where it divides into several oblique branches which terminate at the tectal surface as subpial end feet. Along its course the process is covered in mossy branches, giving it the appearance of a spruce tree. Neither the Golgi rapid nor the Kopsch technique demonstrates an apical process connecting the PE cell perikaryon with the ventricle. Ultrastructurally, the PE cell perikaryon contains its invaginated nucleus, abundant Golgi apparatus, mitochondria which often contain single dark granules, rough and smooth endoplasmic reticulum, free ribosomes, and a great number of microtubules which funnel into the process where they run longitudinally.

The notable absence of fine filaments and an apical process connecting the perikaryon with the ventricle distinguish the PE cells from other radial glia in the goldfish tectum.

2167 CHANGES IN THE UPTAKE OF 3H-2-DEOXYGLUCOSE ACCOMPANYING DENERVATION AND REINNERVATION OF THE RAT'S DENTATE GYRUS. Oswald Steward and Lodi K. Smith*. Depts. of Neurological Surgery and Physiology, Univ. of Va. Sch. Med., Charlottesville, VA 22908.

Following the removal of the major excitatory projection to the rat dentate gyrus, which originates in the ipsilateral entorhinal cortex, the dentate granule cells are reinnervated as a result of the sprouting of several surviving afferent systems. The present study measured 2-deoxyglucose (2DG) uptake in the dentate gyrus to determine, a) if the removal of a major excitatory pathway would decrease 2DG uptake in the denervated dentate gyrus, and b) whether any decreases would be reversed as a consequence of the reinnervation. 2DG uptake was measured autoradiographically at 1,2,4,8,10, and 14 days post-lesion by injecting the animals intravenously with 3H-2DG 45 min. prior to sacrifice, and processing the tissue on emulsion-coated slides, permitting a quantitative evaluation of 2DG uptake through grain counting. For comparison, a few animals were also injected with 14C 2DG, and processed on x-ray film. 2DG uptake in the denervated dentate gyrus ipsilateral to the lesion was compared with that in a comparable region on the contralateral side. 2DG uptake was reduced in the denervated dentate gyrus during the early post-lesion intervals (1,2, and 4 days), although the extent of the decrease is surprisingly slight (approximately 10-20%) given the density of the entorhinal projection system. At 8-10 days post-lesion, 2DG uptake in the denervated zone was not only not decreased, but was actually somewhat increased relative to the contralateral control. This increased uptake was restricted to the outer portion of the dentate stratum moleculare. The enhanced uptake was not evident at the 14 days post-lesion. These results suggest that denervation results in decreases in 2DG uptake, while reinnervation (which occurs predominantly around 8-10 days post-lesion) is accompanied by a reversal of these decreases, and even a slight increase in uptake relative to a contralateral control during the period of active synaptogenesis. The question of whether this increase at 8-10 days post-lesion reflects a metabolic accompaniment of the active phase of sprouting, or simply a return of excitatory innervation will require a further analysis at longer post-lesion intervals, after the lesion-induced synaptogenesis has reached completion. Because the extent of the changes was so slight given the density of the entorhinal projection system, it is probable that most of the 2DG uptake in areas of neuropil in the hippocampus is associated with elements other than afferents and terminals. The results demonstrate the usefulness of the 3H-2DG method for quantitative studies.

2168 SENSITIVITY OF MYELINATED PATHWAYS TO ENVIRONMENTAL MANIPULATION. Frank Szeligo, Gerald F. McCarthy*, Jeannine Ewen*. Dept. Psyc., UNB, Fredericton, Canada E3B 5A3.

Comparison of the brains of rats raised for a month or more in a stimulating environment with those of siblings raised in a non-stimulating environment reveal a number of anatomical differences. In this way a variety of components of the neural microenvironment have been found to be susceptible to the differences between an enriched environment which contains a number of rats plus toys and an impoverished environment which houses rats in isolation. Axons were added to the list by an abstract in the Anat. Rec., 187: 726-727 (1977) which reported differences in the thickness of the myelinated pathway at the base of the occipital cortex, above the corpus callosum. This size difference was apparently the result of greater numbers of axons in enriched cortex. The generality of this finding is being investigated by studying the sensitivity to environmental manipulation of the size of other myelinated pathways. Pathways for which there presently are adequate samples include the cingulum, the fornix and the stria terminalis. The tissue was prepared by perfusion with mixed aldehydes and fixation in osmium and was then embedded in Epon. Semithin sections of the tissue were stained with toluidine blue. There is data available for the cingulum in 9 sibling pairs. The cingulum was sampled in the coronal plane at the level of the posterior edge of the midline corpus callosum. The dorsal-ventral extent was measured at .2 mm intervals over an .8 mm extent. Enriched rats had a thicker cingulum by 11% ($p<0.01$). The fornix was sampled in the cross sectional horizontal plane, at the level of the anterior commissure in 12 pairs of rats. The area of the entire fornix was determined. There were no significant differences. The stria terminalis was sampled in the same plane as the fornix. Again, area measurements were used. For 11 pairs of animals, there were no significant differences.

2169 INTERNEURONS AS POSSIBLE SOURCE FOR THE RETURN OF SUBSTANCE P (SP) AFTER LUMBOSACRAL DEAFFERENTATION. Alan Tessler,* Roman Artymyshyn,* Marion Murray and Michael Goldberger. The Medical College of Pennsylvania, Philadelphia, PA 19129.

Dorsal root afferents are the major known source of SP in the spinal cord. Using the unlabeled antibody (PAP) technique for demonstrating SP, we have shown that following lumbosacral deafferentation of the cat hindlimb by dorsal root section, the amount of SP reaction product in the dorsal horn of lumbar segments progressively decreases for the first 10-11 days after surgery. However, the SP never disappears altogether from the dorsal parts of the dorsal horn. The quantity of SP then increases and by 1 month has returned in substantial amounts. We have interpreted these changes to indicate sprouting by SP containing processes which remain in the deafferented dorsal horn. The reaction product which returns is different in appearance from that of control animals, being finer, more regular, and less intense. The source or sources of these sprouting terminals is unknown. Deafferentation combined with transection at the L1 level did not prevent SP reaction product from returning in amounts comparable to those seen after 1 month survival with deafferentation alone. This suggests that long descending tracts are not the sources of the SP which returns after deafferentation. Deafferentation combined with midlumbar (L4) transection did not prevent the return of SP reaction product to the dorsal horn of segments rostral to the transection. This suggests that ascending fibers are not a major source of sprouting SP axons. However, L4 transection abolished most or all SP staining from the dorsal horn on the chronically deafferented side. Thus, one origin of the sprouting fibers may be interneurons with descending collaterals. In fact, SP containing cell bodies are seen in the lumbar grey matter in normal control and operated animals. They are located in several laminae, including VII, VIII, and X, of lumbar segments both on the side of deafferentation and on the side with intact dorsal roots. The SP containing cell bodies do not constitute a specific nucleus since they lie scattered within several laminae. Moreover, the fact that they are also dispersed rostrocaudally while the return of SP is found in all deafferented lumbar segments, suggests that the SP cells maintain widespread projections which extend rostrocaudally for several segments. Sprouting by interneurons may provide one explanation for the hyperreflexia which occurs in chronic, deafferented animals.

2170 EVIDENCE FOR THE INVOLVEMENT OF THE RETROGRADE REACTION IN SUSTAINED COLLATERALS DURING RECOVERY OF FUNCTION FOLLOWING BRAIN DAMAGE. Roy G. Thompson* and Fred H. Gage. Chemistry of Behavior Program, Texas Christian University, Fort Worth, Tx 76129.

Present understanding of neural mechanisms subserving recovery of function following brain damage stress various means of compensating for the loss of neural input, e.g., collateral sprouting and receptor supersensitivity. Reversible consequences of nerve damage are poorly understood. Several lines of evidence have recently demonstrated that nerve terminals proximal to the site of damage exhibit a transient decrease in both their neurotransmitter content and biosynthetic enzymes. These data have been interpreted to reflect the occurrence of a functional denervation at the terminal sites of axon collaterals which remain structurally intact following axotomy. The purpose of the present experiment was to further investigate the consequences of axotomy on the functional integrity of sustained collaterals. The ability of hypothalamic nerve terminals to accumulate and retain their neurotransmitter was determined at various times following septal lesions and compared with changes in uptake occurring in nerve terminals exhibiting anterograde degeneration. Crude synaptosomes were prepared from hippocampal and hypothalamic tissue at 1, 5, 10 and 15 days following septal lesions and incubated in the presence of tritiated norepinephrine, serotonin or choline. The results show that uptake of all three transmitter substances is decreased by 20-30% on the first day after septal lesions in both hippocampus and hypothalamus. Maximal loss of uptake was observed by day 5. While loss of hippocampal uptake remains depressed at 10 and 15 day survival times, hypothalamic uptake returns to normal by day 15. The initial decrease in uptake observed in the hypothalamus lends support to the hypothesis of a disruption in the functional integrity of proximal nerve terminals following axotomy. Recovery of hypothalamic uptake can be interpreted to reflect one of two events; 1) collateral sprouting of intact axons in response to degenerating septo-hypothalamic projections, or 2) recovery of uptake within nerve terminals exhibiting the initial loss. A kinetic analysis of neurotransmitter uptake is currently being performed in order to further elucidate the neural events contributing to this recovery.

2171 AGE-RELATED COMMISSURAL SPROUTING IN THE DENTATE GYRUS DEMONSTRATED BY ANTEROGRADE TRANSPORT OF HORESRADISH PEROXIDASE. James R. West, Asa C. Black, Jr., and Terence H. Williams. Department of Anatomy, University of Iowa, College of Medicine, Iowa City, Iowa 52242.

Using a modification of the horseradish peroxidase technique (West and Black, Neuroscience Letters, in press), we studied post-lesion growth in the dentate gyrus.

In accord with Lynch and co-workers, we found moderate growth of the commissural terminal band into the outer molecular layer in rats receiving unilateral entorhinal lesions as adults (group A). In rats lesioned at 11 days of age and examined as adults (group B), we observed prolific growth throughout all but the most distal edge of the outer molecular layer.

The density and distribution of label in group A suggests that the sprouting probably results from direct expansion of fibers and terminals into the proximal portion of the lesion-induced deafferented zone. In group B, particularly in the dorsal leaf of the dentate gyrus, the label appeared as two dense bands (the proximal band corresponded to the normal commissural terminal field), separated by an area of lighter labeling. This disparity in patterns of re-innervation between groups A and B suggests that the mechanisms underlying the reorganization might not be the same.

We suggest that one of the following mechanisms is responsible for these results: (1) The commissural fibers grow into the normal zone and then sprout into the outer molecular layer. Their terminals are distributed to two different portions of the dendritic tree, creating the appearance of two separate bands. (2) There is a division of the commissural fibers as they grow into the altered dentate gyrus during development, creating two adjacent bands. (3) A combination of the above mechanisms is also possible, such that the two bands result from the division of the commissural fibers as they enter the dentate gyrus. The inner fiber plexus could then sprout; the sprouts occupying the space between the two bands. (Supported by NS 11650 to THW).

2172 INCREASE IN ^{3}H-GLUTAMATE ACCUMULATION FOLLOWING INDUCTION OF LONG-TERM SYNAPTIC POTENTIATION IN HIPPOCAMPAL SLICES. A. Wieraszko*[1], M. Baudry*, R. Creager*, R. Finn* and G. Lynch. Dept. of Psychobiology, Univ. of California, Irvine, CA 92717 and [1]Dept. of Biochemistry of Nervous System and Muscle, Nencki Inst. of Exp. Biology, Warsaw, Poland.

Long-term potentiation (LTP) in the hippocampus has been the subject of considerable interest in recent years as it represents a potential model of learning and memory. LTP is routinely produced in the hippocampal slice preparation by a brief repetitive electrical stimulation of the Schaffer collaterals and commissural fibers. However, the biochemical processes underlying this long-term change in synaptic efficacy are not yet understood.

The present study examined the possibility that LTP in the hippocampal slices is accompanied by changes in the accumulation of the excitatory amino acids glutamate and aspartate, which are possible neurotransmitters in the potentiated pathways.

Potentiated slices incubated with a low (50 nm) concentration of ^{3}H-glutamate accumulated more radioactivity (+20%) than did control non-stimulated slices. Further, this increase was still present 30 minutes after the stimulation. A similar increase in accumulation of radioactivity was exhibited in potentiated slices incubated with ^{3}H- or ^{14}C-aspartate. It is not likely that the increased accumulation found with the excitatory amino acids represents a non-specific effect since potentiated slices incubated with ^{14}C-tyrosine or ^{14}C-glucose showed no increase in the accumulation of radioactivity. In addition, the increased accumulation of ^{3}H-glutamate was more pronounced in the regio superior, the locus of the potentiated synapses, than in the dentate gyrus. Under the present conditions, the accumulation of ^{3}H-glutamate by slices is not likely to simply reflect uptake by presynaptic elements since, after commissural lesions, the accumulation by slices is not changed whereas the uptake in homogenate is decreased by 30%. Thus, the present results are consistent with the hypothesis that LTP induces an increased number of binding sites for glutamate.

2173 AUDITORY DEPRIVATION AFFECTS DENDRITIC SPINE DENSITY IN THE MONGOLIAN GERBIL CORTEX: A QUANTITATIVE GOLGI STUDY. Robert W. Williams*, Michael D. McGinn*, Richard G. Coss*, Albert Globus* (SPON: A. J. Sillman). Department of Psych., University of California, Davis, CA 95616.

We have assessed the effects of auditory deprivation in the cortex of the mongolian gerbil. Compared to littermate controls 32 day old experimental animals showed significantly lower spine densities along pyramidal cell apical dendrites. Ligation of the external meatuses at day 12 caused acoustic deprivation of more than 25 decibels. Groups of gerbils were sacrificed 12, 22 and 32 days after birth and cerebral blocks were processed for rapid Golgi. The auditory cortex was mapped in a parallel electrophysiological study using single unit and evoked response criteria. Electrolytic lesions in Nissl stained material provided a reference for Golgi quantification. This quantification was restricted to pyramidal cells of layer V in primary auditory cortex. Drawings of all well impregnated neurons were made at a magnification of 1000 X using a drawing tube and spine densities were determined from these drawings. A 50 µm long segment of the apical shaft beginning 150 µm above the soma was quantified. In 32 day old material spine densities were lower an average of 38% in experimentals ($p < .005$; n of cells: 14 control, 15 experimental). A comparison of the entire 200 µm segment also yielded significantly lower densities in experimentals ($p < .025$). An insufficient amount of 22 day old control material precluded a similar analysis at this age. However, a comparison between the 22 and 32 day old deprived groups showed significantly higher densities in the younger material. Additionally there is no significant difference between 22 day old deprived and 32 day old control material (mean per 10 µm is 12.1 and 10.7 spines respectively). These data suggest that the lower spine density seen in the month old gerbils is due to a reduction from a state of higher spine density rather than being the result of delayed maturation.

2174 CHANGES IN THE CORTICAL BARREL FIELDS SUBSEQUENT TO VIBRISSAL CAUTERIZATION IN THE NEONATAL AND ADULT MICE DEMONSTRABLE WITH CYTOCHROME OXIDASE HISTOCHEMISTRY. Margaret Wong-Riley and Carol Welt. Dept. Anat., Univ. Calif., San Francisco, CA 94143, and Central Wisconsin Center for the Developmentally Disabled, Madison, WI 53704.

Cytochrome oxidase histochemistry has been applied previously in the study of functional changes within the auditory and visual systems of cats (Wong-Riley, Merzenich & Leake, Brain Res. 141: 185-192, 1978; and Wong-Riley, Brain Res., in press). The present study examines the applicability of this technique in the somatosensory system of rodents. The barrels in layer IV of normal mouse SmI face cortex were found to have a high level of cytochrome oxidase activity. Surrounding each barrel was a clear zone of very low enzyme reaction. Preliminary electron microscopic examination indicated that most of the reactive mitochondria within the barrels reside in the neuropil, rather than in the cell bodies. Thus, the barrels normally have a higher level of oxidative metabolism, most likely reflecting a higher level of functional activity, than surrounding regions. In order to determine whether vibrissal damage induces any change in the oxidative activity of the neonate and adult animals, and whether the C.O. technique is sensitive enough to detect such functional changes in the somatosensory cortex, two groups of mice were tested. In the first group, selective row or rows of mystacial vibrissae were cauterized on postnatal day 1 (within hours after birth), and the animals allowed to survive for 2-3 months. In the second group, vibrissal cauterization was performed in adult animals, and they survived for 2-3 months post-operatively. The results indicated that neonatal removal of vibrissae caused severe shrinkage and often fusion of affected cortical barrels, with concomitant expansion of neighboring barrels (confirming previous reports by others), and the level of cytochrome oxidase activity of the shrunken barrels was lower than that of normal. Removal of vibrissae in the adult did not cause size changes of cortical barrels. However, there is a significant decrease in the level of oxidative enzymatic activity within these barrels. Thus, the removal of sensory input through the destruction of peripheral sensory organ causes distinct functional changes at the level of the cortex. Such changes are more severe in the neonate, where cortical fields actually shrink in size. Changes, however, can still be induced in the adult animal, where the levels of oxidative activity of cortical fields are demonstrably reduced. These functional changes are detectable morphologically with the cytochrome oxidase technique.

PSYCHO-PHARMACOLOGY

2175 EFFECTS OF APOMORPHINE ON ELICITED AND OPERANT PECKING IN PIGEONS. Joanne S. Abelson* (SPON: B.P.H. Poschel). Psychology Department, University of Michigan, Ann Arbor, MI. 48104.

Apomorphine (APO) elicits stereotyped behavior in a number of species, but its effects on operant behavior are less consistent. In general, APO causes decreases in rates of operant responding, but some subjects show paradoxical rate-increases. To account for such findings,it has been postulated that an occasional subject might redirect its stereotyped responding toward the operant manipulandum and thereby generate high operant rates. The relationship between the effects of APO on elicited (stereotyped) and operant behavior was studied by examining the effects of the drug on both behaviors in the same subjects.

Fifteen test- and drug-sophisticated pigeons were used as subjects in both experiments. In the pigeon, behavior induced by APO takes the form of persistent and continuous pecking. Examination of elicited pecking was conducted in the home cage during a 1 hr observation test. APO, in half-log unit doses from 0.032 to 32.0 m/k administered I.M. immediately prior to testing, caused dose-related increases in elicited behavior in all subjects, as has been observed previously. Pecking was first observed at 0.1 m/k and reached a maximum at 3.2 m/k. The stereotypy induced by APO was remarkably similar across subjects.

In contrast to the effects on stereotyped behavior, operant responding on a multiple FI-5, FR-30 schedule revealed individual differences in response to the drug. These differences were used to form descriptive groups based on the lowest dose which would eliminate operant responding. Doses of 0.32 m/k eliminated all operant responding in four subjects (Group 1); 3.2 m/k was needed in nine other subjects (Group 2); and two subjects required 32.0 m/k to eliminate responding (Group 3). Groups 1 and 2 showed similarities in overall drug effects and differed only in the sensitivity of operant behavior to disruption by APO. These groups showed dose-related decreases in operant responding with concomitant increases in elicited behavior. In contrast, data from group 3 showed increases in operant responding which were highly correlated with increasing stereotypy.

It is concluded that the effects of APO on operant behavior were dependent on induced stereotypy. Rate-decreasing effects appeared to be related to the disruption of ongoing operant behavior by elicited pecking aimed elsewhere in the chamber, while rate-increases seemed to be produced by the redirection of elicited pecking to the operant key. Further, since operant behavior showed individual differences in sensitivity to APO while elicited behavior did not, operant and elicited pecking may be differentially mediated by dopaminergic mechanisms. This separation of the key-peck response into two components may provide a model for the screening of neuroleptic drugs.

2176 EFFECT OF STRAIN DIFFERENCES IN TYROSINE HYDROXYLASE ON PHENCYCLIDINE-INDUCED LOCOMOTOR ACTIVITY

Perrie M. Adams, Dept. of Psychiatry and Behavioral Sciences and Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX 77550

Phencyclidine-induced locomotor activity was studied in three strains of albino rat that differ in the level of tyrosine hydroxylase (TOH) in the brain (Segal, et al, 1972). The strains included: F344 (high in TOH), Sprague-Dawley (moderate level of TOH), and BuF (low in TOH level). Activity level following 0.5-4.0 mg/kg phencyclidine (PCP) was recorded for a 30 minute period in a circular horizontal runway with each animal receiving a baseline session 24 hours prior to drug treatment. A control group for each strain received saline on the day of PCP treatment. There was a significant dose-response curve for each strain. Activity increased in a linear way with increasing dosage level. Further, there were significant differences between the strains in the amount of activity induced by PCP. Because of baseline differences in activity level across strains a transformation of the data was made and the treatment effects analyzed through analysis of variance methods. The F344 strain was significantly more responsive to PCP at 2.0 and 4.0 mg/kg. The BuF strain was the least responsive to the effects of PCP.

These results when interpreted in view of the TOH differences across these strains and the response of these strains to norepinephrine infusion as previously reported suggest that PCP does act like a sympathomimetic. It is consistent with this suggestion that strain differences in catecholamine receptor activity associated with the TOH differences would account for the observed distinction in responsiveness to PCP as measured in the present study.

2177 LOW LEVEL HYPERBARIC ETHANOL ANTAGONISM IN MICE. Ronald L. Alkana and Richard D. Malcolm. School of Pharmacy, University of Southern California, Los Angeles, CA 90033.

Recent studies in our laboratory demonstrated that exposure to hyperbaric oxygen-helium environments at 6 and 8 but not 10 atmospheres absolute (ATA) antagonized the narcosis in mice induced by 3.2 g/kg ethanol. The antagonism did not result from the direct effects of oxygen nor enhanced ethanol elimination. The present study further explored the mechanism and strength of the antagonism using the hypothesis that the increased heat loss induced by helium and/or hypoxia during compression may have obscurred demonstration of a pressure related antagonism. Drug naive, male C57 Bl/6j mice were injected i.p. with 3.2, 3.6 or 4.0 g/kg ethanol (20% w/v). Upon loss of their righting reflex, they were placed in a hyperbaric chamber. The atmospheric pressure was taken to 1 ATA air or 1, 4, 6, 8, 10 or 12 ATA oxygen-helium at the rate of 1 ATA/30 sec using procedures designed to keep the compression oxygen partial pressure between 0.2 and 0.7 ATA to avoid hypoxia. Oxygen partial pressure at the final testing pressure was 0.2 ATA. The chambers were immersed in a water bath and maintained at 33 ± 3°C using a pyrometer probe to reduce helium-induced hypothermia. A 20 µl tail vein blood sample taken at wake-up was used for gas chromatographic ethanol determination. Hyperbaric treatment significantly reduced sleep-times and increased wake-up blood ethanol concentrations at all doses tested ($p<0.05$, t-test). The degree of antagonism was pressure and dose related. The mean sleep-times and wake-up blood ethanol concentrations (BECs)±S.E. following 3.2 g/kg ethanol are shown below. The sleep-time reduction was greatest

Pressure (ATA)	Sleep-time (min)	BEC (mg/dl)	N
Air			
1	27.1 ± 3.8	368 ± 8	9
Oxygen-Helium			
1	22.2 ± 2.4	383 ± 5	9[A]
4	16.0 ± 3.6**	384 ± 5	9
6	15.1 ± 3.3**	391 ± 8*	9
8	18.5 ± 4.1	384 ± 5	10
10	13.6 ± 2.6**	398 ± 6****	9[A]
12	12.3 ± 2.6****	391 ± 6**	10

A - BEC N=8 *p<0.05; **p<0.025; ***p<0.01; ****p<0.005

at 12 ATA oxygen-helium. There was also a non-significant trend ($p<0.1$) toward reduced sleep-time in the 8 ATA treated mice. These findings indicate that the antagonism is not limited to a small range of hyperbaric pressures nor to low hypnotic ethanol doses. The implications of these results regarding the mechanisms of low and high pressure ethanol anesthesia antagonism are discussed.

2178 ONTOGENY OF STRAIN DIFFERENCES OF NIGROSTRIATAL TYROSINE HYDROXYLASE ACTIVITY AND SPONTANEOUS AND DRUG-INDUCED BEHAVIORS IN MICE. H. Baker, J.S. Fink, T.H. Joh, A. Swerdloff*, and D.J. Reis, Dept. Neurol., Cornell Univ. Med. College, New York, N.Y. 10021.

Adult mice of the BALB/cJ strain have more midbrain dopamine (DA) neurons and greater tyrosine hydroxylase (TH) activity in the substantia nigra-A10 (SN) region, caudate nucleus (CN), and mesolimbic brain areas than mice of the CBA/J strain (Nature 264:964, 1976). These differences correlate with greater spontaneous and amphetamine-induced locomotion and lesser sensitivity to stereotypy induced by apomorphine in BALB/cJ than CBA/J mice (Neurosci. Abst. 4:492, 1978). We sought to determine: (a) if the strain-dependent differences in TH activity in SN and a major terminal field, the CN, develop postnatally; and, (b) whether there is a temporal correlation between the ontogeny of the differences in TH and the behavioral differences in these two strains. In both strains, TH activity in SN increased rapidly, peaked at 125% of adult levels 15 days postnatally (P15) and decreased gradually to adult levels (P56) at P28. TH in the CN increased gradually, with TH activity at 65% of adult levels at P15 and 90% of adult levels at P21. Strain differences in TH activity (BALB>CBA) were not present before P7 but first appeared in the SN at P9 and in the CN at P11. Choline acetyltransferase (CAT) activity, an index of the maturity of intrinsic neurons of the CN, was 40% of adult levels at P15 and 70% of adult levels at P21. In early development (P8-P15), spontaneous and amphetamine-induced locomotion were less than, and apomorphine stereotypy greater than or equal to, the adult values. At this time, in contrast to adults, BALB/cJ mice were less active, less responsive to amphetamine, and more responsive to apomorphine than CBA/J mice. Between P15 and P21 spontaneous and amphetamine locomotion increased markedly in both strains. During this same period apomorphine stereotypy decreased in BALB/cJ mice and increased in CBA/J mice. By P21, then, evident strain differences in spontaneous and drug-induced behaviors which resembled the adult patterns were present. We conclude: (1) strain differences in TH activity in the nigrostriatal system and the adult pattern of DA-mediated behaviors first appear postnatally; and, (2) the development of strain-differences in TH activity in the nigrostriatal system precede the adult patterns of strain differences in DA-mediated behaviors. These data suggest that the phenotypic expression of DA-mediated behaviors is dependent not only on the level of TH activity in the nigrostriatal system, but may also depend on the maturation of its major afferent nucleus, the CN.

(Supported by NIH grants HL 18974, NS 03346 and MH 24285).

2179 BLOOD PLASMA OSMOLALITY AND MANIC-DEPRESSIVE ILLNESS
Claude F. Baxter, Ken Tachiki* and Lawrence F. Gosenfeld*. Neurochemistry Labs (151B2), VA Medical Center, Sepulveda, CA 91343, and Affective Disorders Clinic, Brentwood VA Medical Center, Los Angeles, CA 90073.

A variety of physiological, nutritional and pathological conditions are known to alter the osmolality of blood plasma. In turn, these changes in plasma osmolality can affect the biochemistry and biochemical composition of the Central Nervous System. In particular, changes can be produced in the cerebral levels of urea, carbohydrates, keto acids, amino acids and amines. The latter two categories include several putative neurotransmitters and neurotransmitter precursors.

A preliminary clinical study has been conducted with manic and depressed patients, most of whom were kept under well controlled conditions in a hospital ward. All patients were on lithium therapy with blood levels in the range of the "therapeutic window" 0.8 to 1.2 meq/liter. All blood samples were drawn before a meal, usually before breakfast on the day that the mood and condition of the patient was tested using the Research Diagnostic Criteria of Spitzer and Endicott. Blood plasma osmolality of normal volunteers and staff ranged from 285 to 295 mOs, whereas the range in patients extended from 270 to 310 mOs. Although the highest plasma mOs were found in some depressed patients and the lowest mOs in some manic patients, no absolute correlation between plasma osmolality and clinical condition could be demonstrated. However, clinical improvement of manic patients, as measured by research diagnostic criteria, was correlated in a highly significant manner with an increase in plasma osmolality. Similarly, clinical improvement of depressed patients was correlated in a highly significant manner with a decrease in plasma osmolality. The clinical improvement was not correlated with fluctuations within the "therapeutic window" of plasma lithium concentrations.

It is conceivable that the small changes in plasma osmolality observed in these patients can be translated into small but significant metabolic and compositional changes in brain tissue and, thus, influence mood and behavior. (Supported by the Medical Research Service of the Veterans Administration.)

2180 USE OF CONDITIONED SUPPRESSION AND EXTINCTION TO EVALUATE THE NATURE OF NEUROLEPTIC-INDUCED AVOIDANCE DEFECITS. Richard J. Beninger* (Spon: Anthony G. Phillips) Dept. Psychology, Univ. British Columbia, Vancouver, B.C., Canada V6T 1W5.

Numerous studies have shown that animals with brain catecholamines (CA) depleted are impaired in their ability to acquire a conditioned avoidance response (CAR) and the results of additional experiments indicate a critical role for dopamine (DA). To evaluate the nature of this CAR defecit, in Experiment 1 rats were injected with the neuroleptic pimozide (1.0 mg/kg) and received five sessions of CAR training in which a tone signalled shock on each trial (and were observed to fail to avoid). These same rats when in an undrugged state received food-reinforced lever-press training until responding stabilized. The tone that had signalled shock in CAR training was then presented. Significantly greater conditioned suppression to the tone was observed in the rats that had received CAR training while drugged, than in unshocked controls, indicating that the neuroleptic-treated rats had learned the tone-shock association in spite of their failure to avoid. Thus, neuroleptic-induced avoidance defecits were not related to an impairment in associative learning. To determine if the CAR deficit was related to an impairment in response learning, in Experiment 2 pimozide-injected rats received five sessions of CAR training and were then tested while undrugged. One group was tested in extinction (i.e., shocks were no longer presented) and another continued to receive shocks. Both groups showed gradual acquisition of the CAR indicating that they had failed to learn the appropriate response during training. The fact that the extinction group acquired the CAR indicated that they must have learned the significance of the tone while drugged; this observation was consistent with the results of Experiment 1. These data indicate that DA is not required for learning the association between stimuli. They further suggest that normal DA functioning is required for conditioned (i.e., shock-associated) stimuli to acquire the ability to elicit specific responses. (Supported by the Medical Research Council of Canada).

2181 EFFECTS OF ANTICHOLINERGICS ON VISUAL ACUITY OF MACACA MULATTA. C. T. Bennett*, G. D. Callin*, D. N. Farrer*, C. Link* and P. Garcia* (SPON: James King). USAF School of Aerospace Medicine/RZW, Brooks AFB, TX 78235.

Rhesus monkeys were trained to discriminate between left- and right-opening Landolt rings. The test apparatus presented stimuli at 1 meter in seven discrete sizes corresponding to Snellen acuities 20/200, 20/100, 20/50, 20/40, 20/30, 20/20 and 20/15; a titration paradigm was designed to elicit performance at maximum acuity. Upon establishment of stable baseline performance, the subjects were injected IM with the following drugs prior to testing: (1) benactyzine, 0.054 to 0.54 mg/kg; (2) atropine, 0.014 to 0.14 mg/kg; (3) TAB (a compound consisting of atropine, benactyzine, and the oxime TMB-4 in a ratio of 1:4:40), 0.64 to 6.4 mg/kg; and (4) a diluent control. Injection of active substances caused dose-related decreases of near visual acuity. Onset times and effect durations differed among drugs.

2182 INCREASED AMPHETAMINE POTENCY FOLLOWING CHRONIC NALTREXONE ADMINISTRATION IN RATS. Richard S. Blair*, Shimon Amir* and Zalman Amit. Department of Psychology, Concordia University, Montreal, Quebec, Canada.

There is evidence to suggest that enkephalins may modulate the normal functioning of the nigro-striatal dopamine system by interacting with opiate binding sites in the brain. Given this and the recent finding that chronic naloxone administration produces an increase in opiate receptor binding sites, we undertook to investigate the effect of chronic naltrexone pretreatment on the effects produced by the dopamine agonists, d-amphetamine and apomorphine.

Thirty male Wistar rats received a daily injection (subcutaneous) of saline (1ml/kg) or naltrexone (1mg/kg) for eight consecutive days. Forty-eight hours after the last naltrexone injection, animals then received an intraperitoneal injection (I.P.) of either d-amphetamine (1mg kg), apomorphine (1mg/kg) or saline (1ml/kg). Fifteen minutes after the I.P. injection, the animal's locomotor activity in an open field was measured by the number of photo-beams broken during the 30 minute testing session. The animals were retested seven and 14 days after the termination of the naltrexone pretreatment using the same experimental procedure.

An analysis of variance revealed a significant overall increase in the activity by naltrexone. Furthermore, a significant drug effect, as well as a significant overall decrease in activity over the three testing sessions were noted. Multiple t-tests revealed that amphetamine produced a greater activity in animals given naltrexone pretreatment than in animals that received saline pretreatment.

The increase in locomotor activity observed in rats chronically treated with naltrexone, as well as the marked potentiation of d-amphetamine's excitatory effect, suggests that prolonged blockade of the opiate receptor may lead to the development of a supersensitivity in the dopamine systems that mediate motor functions. If, as previously suggested, endogenous enkephalins excite striatal dopamine neurons, then an increase in the number of opiate binding sites produced by chronically administered naltrexone, may have potentiated the excitibility of the nigro-striatal dopamine system.

2183 INTRASTRIATAL AND INTRALIMBIC INFLUENCES OF DOPAMINE, PHENYLETHYLAMINE AND AMPHETAMINE. R.L. Borison, J.E. Comaty and B.I. Diamond. Mt Sinai Hosp & Ill St Psych Inst, Chicago, Il 60608 & 60612.

Stereotyped behavior in animals is believed to result from stimulation of striatal dopaminergic mechanisms, however, it is now widely held that this behavior can be modulated by limbic dopaminergic and noradrenergic influences. Stereotyped behavior in rodents elicited by d-amphetamine (dA) has been used as a pharmacological paradigm for schizophrenia because this behavior is blocked by neuroleptics, and amphetamine administration in man can result in a paranoid schizophreniform psychosis. We have shown that the administration of phenylethylamine (PEA), an endogenous biogenic amine, is also capable of producing stereotypy. Dopamine receptor blocking antipsychotics antagonize both dA and PEA elicited stereotypy, however thioridazine and clozapine, which are proposed to be more limbic than extrapyramidal system site specific, selectively antagonize PEA behavior. Moreover, upsetting the striatal dopamine-acetylcholine balance by administering an anticholinergic potentiates dA but not PEA stereotypy. Based on these data, we have suggested that PEA stereotypy may more specifically involve limbic mechanisms. To test this hypothesis we have studied the effects of intrastriatal and intralimbic injections of dopamine, dA and PEA. Subjects were white male Sprague-Dawley rats with bilateral stereotactically placed 0.8mm stainless steel cannula in the caudate-putamen nucleus and the nucleus accumbens. Animals were rated for stereotypy using a 5 point scale of ascending intensity of stereotypy. The administration of dopamine (100µg) into the striatum produced stereotyped sniffing, head-weaving and occassional gnawing resulting in a stereotypy score of 3.37 ± 0.12. In comparison, intrastriatal dA (100µg) elicited a stereotypy score of 4.25 ± 0.16 and increased locomotor activity. In contrast, PEA (100µg) administration resulted in a score of 2.00 ± 0.01 with animals exhibiting stereotyped grooming and sniffing lasting 20 min. We found that intralimbic dopamine produced increased locomotion, occassional gnawing, stereotyped grooming and sniffing. At a dose of dopamine of 100µg, the stereotypy score was 2.8 ± 0.12, whereas at 200µg the score reached 3.5 ± 0.14. The administration of dA (100µg) produced stereotyped sniffing, achieving a score of 2.62 ± 0.13. In contrast, intralimbic injection of PEA (100µg) resulted in a stereotypy score of 3.50 ± 0.11 with increased locomotion, and stereotyped grooming, sniffing and head-swaying. These results demonstrate that PEA, as compared with dA, exerts more potent effects on stereotyped behavior via the activation of mesolimbic mechanisms.

2184 EFFECT OF DIETARY LIPID COMPOSITION ON LOCOMOTOR ACTIVITY AND PSYCHOMOTOR STIMULANT RESPONSE. Douglas E. Brenneman* and Charles O. Rutledge. Dept. Pharmacol. and Toxicol., Sch. Pharm., Univ. Kansas, Lawrence, KS 66045.

Spontaneous locomotor activity was compared in rats fed semi-synthetic diets enriched in either polyunsaturated fat (sunflower oil) or saturated fat (coconut oil). Control animals were given Purina rodent chow. Neonatal rats received the dietary lipid through the maternal milk. After weaning, the pups were maintained on the same diet given to the dam. There were no significant differences in body weights among the dietary groups. Cumulative counts as measured in an Animex activity chamber were monitored every 6 min. for one hour. All experiments were performed on naive animals. Developmental studies revealed that animals fed sunflower oil had a 40-60% increase in locomotor activity as compared to animals given coconut oil. Significant differences were observed on days 20, 30, and 65. No changes in activity were found on day 10. The activities of rats given sunflower oil were also increased when compared to animals receiving the standard rodent chow.

Locomotor activity responses to i.p. administration of d-amphetamine, methylphenidate, and atropine were compared in day 30 animals fed the various regimens. Animals receiving sunflower oil had a decreased response to d-amphetamine in comparison to rats fed coconut oil. Maximal activity was observed at 3 mg/kg for the coconut oil fed group and at 10 mg/kg for those receiving sunflower oil. A dose-response study for methylphenidate revealed no differences in activity among the dietary groups. Atropine (2 mg/kg) decreased activity 40% below basal levels in rats fed sunflower oil. High doses of atropine (15 mg/kg) were necessary to achieve an increase in locomotor activity in this group. In contrast, coconut oil fed animals exhibited an increase in activity with 1 mg/kg atropine. Maximal response to atropine occurred at 15 mg/kg in both dietary groups but the activity of the sunflower oil fed group was 30% less than in rats fed coconut oil. Thus, the animals given sunflower oil had higher basal levels and responded to a lesser extent to d-amphetamine and atropine. These results indicate that sunflower oil can induce a hyperactive state in developing rats and that the response to psychomotor stimulant drugs are differentially affected by dietary fat composition. Supported by USPHS Grants NS 12760 and RR 5606.

2185 AN AMPHETAMINE-INDUCED DYSKINESIA IN MONKEYS MEDIATED BY PERIPHERAL SYMPATHETIC STIMULATION. P. J. Bushnell* and C. M. Baysinger* (SPON: W. T. McKinney). University of Wisconsin Primate Laboratory, Madison, Wisconsin 53706.

A highly characteristic behavioral response to d-amphetamine injections (0.3 or 0.6 mg/kg, SC) in infant rhesus monkeys was identified. This response consisted of bizarre, catatonic-like postures and dyskinesias in which the animals' hands and/or feet appeared to float for prolonged periods of time. This "floating limb" developed over the first 1 - 10 biweekly injections in monkeys tested beginning at 4 weeks of age, and over the first 2 - 4 semiweekly injections in monkeys one year of age. When fully developed, the response to drug occurred with an average frequency of 7/min., and occupied on the average 30% of the animals' total ongoing behavior. While floating limb was most dramatically induced by d-amphetamine, peripherally-acting sympathomimetics including hydroxyamphetamine (0.6 mg/kg) and epinephrine (25 ug/kg) also produced a qualitatively similar response. The increased intensity of the dyskinesia following d-amphetamine may have resulted from its central, attention-focusing action, added to its stimulation of the peripheral sympathetic nervous system. The peripheral mechanism(s) mediating floating limb are presently being explored with sympathomimetic drugs having specific alpha- and beta-receptor activities.

Since hydroxyamphetamine and other sympathomimetics lacking CNS activity have rarely been used as control substances in psychopharmacological research with amphetamine, these results call into question the assumption that the behavioral effects of amphetamine are mediated solely by its activity in the CNS.

2186 AN IMMOBILIZING STIMULUS SIGNIFICANTLY ATTENUATES BOTH AMPHETAMINE AND APOMORPHINE-INDUCED STEREOTYPIES. A.R. Caggiula and L.A. Chiodo. Psychobiology Program, Dept. of Psychology, Univ. of Pittsburgh, Pittsburgh, PA 15260.

We have recently suggested that the behavioral effects of activating and immobilizing stimuli depend, at least in part, on their reciprocal influence on the functioning of brain dopamine (DA)-containing systems. For example, an activating stimulus, such as tail pressure (TP), can induce a variety of appetitive behaviors and this effect is attenuated by pharmacological blockade of brain DA activity. Moreover, the same TP procedure dramatically alters the firing rate of DA neurons in the substantia nigra of anesthetized rats. Conversely, an immobilizing stimulus, such as cervical probing (CP), counteracts both the behavioral and electrophysiological effects of TP. Consistent with our view that CP can block the behavioral effects of DA activation, we now report that CP drastically attenuates stereotyped responses produced by two DA agonists, amphetamine and apomorphine.

Ovariectomized female rats received 50 µg/kg (s.c.) of estradiol benzoate 48 and 24 hours prior to testing. The test consisted of three 30 sec. bouts of CP which were preceeded and separated by one minute baseline observation periods. The tests were conducted 30 and 120 minutes after amphetamine and 30 minutes after apomorphine. CP, which was administered with a saline lubricated glass rod (3 mm diameter) inserted into the vagina and pressed firmly against the cervix, attenuated all aspects of stereotypy for 6, 12 and 18 mg/kg of amphetamine and 3 and 6 mg/kg of apomorphine. For example, 60 minutes after 12 mg/kg of amphetamine, 85% of the animals were sniffing and 70% licking prior to CP, whereas percentages were 15 and 18%, respectively, during CP, and 72 and 62% after. Similarly, the values for 6 mg/kg of apomorphine were 100% sniffing prior to CP, 5% during CP and 95% after (N=7 per group).

It therefore appears that an immobilizing stimulus, such as CP, is able to dramatically attenuate both drug and sensory-induced activated behaviors which are thought to be the result of increases in mesencephalic DA function.

2187 SELECTIVE ATTENTION DISRUPTED BY APOMORPHINE IN THE MONGOLIAN GERBIL. MaryLou Cheal. Neuropsychol. Lab., McLean Hospital, Dept. Psychiatry, Harvard Medical School, Belmont, MA 02178.

In previous research, selective attention was intact in gerbils following injections of amphetamine (Phys. Behav., 1978, 21, 299-305). Amphetamine-treated gerbils (2.0-3.0 mg/kg) selectively responded to objects that were novel even though the amphetamine-induced competing stereotypies resulted in an attenuation of the amount of active investigation of the object. Additionally, when a large dose (6.0 mg/kg) of d-amphetamine was administered, intense stereotypy occurred and very little active investigation was seen. However, "passive" attention could be inferred from data collected the next day when the acute effects of the drug had passed (Soc. Neurosci. Abst., 1978, 4, 487). Because habituation can be demonstrated in normal gerbils up to two weeks following a single 60 sec nonreinforced trial (J. Biol. Psychol., 1978, 20, 26-32), it was possible to test amphetamine-treated gerbils for habituation on the second day. The responses of these gerbils reflected habituation similar to habituation in controls that had actively investigated the object following injection. Thus, the stimulus-elicited investigation paradigm allows the separation of active investigation or alertness from selective attention.

Several lines of research implicate the action of amphetamine in increasing dopamine (DA) activity as the mechanism whereby amphetamine affects exploratory behaviors and motor activity. However, in the stimulus-elicited investigation paradigm, the DA receptor stimulant, apomorphine, produced results that differed from those of amphetamine. Selective attention was disrupted following doses as low as 1.0 mg/kg apomorphine. At this dose, the gerbils moved to the object as frequently as controls on the first trial, but subsequent trials did not reflect rapid habituation as seen in controls. Further, although "passive" attention was found following 0.3 mg/kg apomorphine, at higher doses (1.0, 3.0 or 10.0 mg/kg) the gerbils showed no evidence of earlier exposure to the object when retested the second day. It was also demonstrated that failure of habituation following apomorphine injections was not due to amnesia or retrieval problems. Additional gerbils were tested for habituation to the object prior to injections. Following subsequent apomorphine treatment, habituation levels of responding occurred indicating that once the memory was stored, it was not disrupted by apomorphine. The data indicate that apomorphine can disrupt selective attention at doses where active investigation, or alertness, can be exhibited. 2188 ESTROGEN MODULATION OF DA DEPENDENT BEHAVIORS L.A. Chiodo, A.R. Caggiula and C. F. Saller.* Psychobiology Program, Depts. of Psychology and Biological Sciences, Univ. of Pittsburgh, Pittsburgh, PA 15260.

We have previously shown that estrogen potentiates two behavioral consequences of drug-induced changes in DA activity. That is, ovariectomized (OVX) female rats treated with estradiol benzoate (EB; 100 µg/kg, s.c.) 48 h before testing showed significantly longer durations of spiperone-induced catalepsy (0.5 mg/kg) and more intense amphetamine-induced stereotypy (3 and 9 mg/kg) than OVX/oil controls (Chiodo and Caggiula, 1978). The present study demonstrates that OVX female rats receiving the same hormone treatment also show significantly more intense apomorphine-induced stereotypy (3 and 6 mg/kg) than OVX/oil controls. In all cases stereotypy was rated on a 7 point scale.

We also examined the effects of EB on the uptake of radioactively labelled spiperone, amphetamine and apomorphine in order to determine whether estrogen may have increased the behavioral effects of these drugs by altering their peripheral metabolism or uptake into the brain. We now report that an EB treatment which increased spiperone-induced catalepsy (0.5 mg/kg) also elevated levels of ^{3}H-spiperone in both blood and whole brain. EB increased whole brain tritium levels, relative to oil controls, at both three (129%) and six hours (129%). Tritium levels in blood were also elevated at these same times (125% and 146% respectively). Similar results were obtained after chromatography of brain and blood, indicating that most of the radioactivity was accounted for by ^{3}H-spiperone. These findings suggest that at least some of the increased catalepsy may have resulted from estrogen's ability to increase the levels of spiperone reaching the brain.

In the same manner, we examined the effects of EB on the uptake into the brain of tritiated amphetamine (3 mg/kg) and apomorphine (3 mg/kg) administered intraperitoneally. EB did not increase whole brain or blood levels of labelled apomorphine, amphetamine or its active metabolite, p-hydroxynorphedrine. Similar results were obtained with chromatography. In fact, there was a non-significant trend for OVX/EB animals to show lower tritium levels than controls. In contrast to the changes in peripheral metabolism of spiperone, increased uptake into the brain cannot account for EB's effects on amphetamine or apomorphine stereotypy.

In summary, both central and peripheral effects of estrogen must be considered when assessing its role in the behavioral and neurochemical consequences of drug-induced alterations in DA function.

2189 COCAINE-INDUCED STEREOTYPED BEHAVIOR; ONGOING RESPONSES DETERMINE DRUG EFFECTS. Jeremiah P. Collins and Henry Lesse. Department of Psychiatry and Brain Research Institute, School of Medicine, University of California, Los Angeles, CA 90024.

Stereotyped behaviors result following the administration of a number of different drugs, primarily the psychomotor stimulants. The stereotypies consist of responses occurring repetitively with little variation, have no apparent source of reinforcement, and are relatively insensitive to changes in ambient stimuli. Examples of these behaviors are repetitive orienting or arousal reactions such as head bobbing, rearing, sniffing, grooming, or in man, complex response chains including speech and cognition. Interactions of ongoing behaviors with the actions of psychomotor stimulants have also been reported. We investigate in the present study whether ongoing operant responses occurring at the time of cocaine administration become stereotyped. Cats were trained in a discrimination task in which each bar-press emitted when a tone (S+) was present resulted in milk reinforcement. When the tone was absent (S-) milk was not delivered. The duration of S+ and S- periods varied randomly from 1 to 5 mins and a 1-min DRL contingency was in effect during S-. Training continued until a high level of discrimination was achieved. Drug testing was then begun with injections of cocaine hydrochloride (1 mg/kg). The ongoing behavior was manipulated by scheduling either a 5-min S+ or S- period immediately following cocaine administration. When the S+ *period followed cocaine administration, stereotyped bar-*pressing developed, i.e. bar-pressing continued during subsequent S- periods despite the absence of reinforcement. When the S- period followed cocaine, marked suppression of bar-pressing resulted. This effect was reversible in the same subjects when stimulus conditions were later reversed. A similar study conducted with rats yielded similar results. Whatever the mechanism rezponsible for these drug-induced behaviors, it is clear that the stimuli and the behaviors occurring at the time of cocaine administration are powerful determinants of subsequent stereotyped behaviors.

(Supported in part by Grants NIDA DA-1351 and RR05756.)

2190 CENTRAL AMINERGIC NEURONAL SYSTEMS AND THE BEHAVIORAL EFFECTS OF HALLUCINOGENS. R. Commissaris*, W.H. Lyness, R.H. Rech and K.E. Moore. Dept. of Pharmacol. & Toxicol., Michigan State Univ., East Lansing, MI 48824.

The mechanisms by which a variety of drugs produce hallucinations are not well understood, but it has been suggested that these drugs interact with 5-hydroxytryptamine (5HT) and dopamine (DA) neuronal systems in the brain. The present study was designed to examine the role of 5HT and DA neurons in modulating the behavioral effects of two hallucinogens having different chemical structures: d-lysergic acid diethylamide (LSD), an indolealkylamine analog, and 2,5-dimethoxy-4-methylamphetamine (DOM), a phenylethylamine analog.

Male rats, maintained at 70-80% of their free-feeding weight, were trained to press a bar for food pellets on a fixed ratio-40 (FR-40) operant schedule. When trained, these rats respond at a constant, rapid rate (approximately 100 responses/min) during daily test sessions of 40 min duration. The rats continue to respond when central stimulant or depressant drugs are administered, but the rates of responding change. On the other hand, the administration of hallucinogens causes an abrupt cessation of responding followed sometime later by an equally abrupt reinstatement of responding. The duration of the "hallucinatory pause" was found to be dose-dependent for both LSD (25, 50, 100 and 200 µg/kg, i.p.) and DOM (0.25, 0.5, 1 and 2 mg/kg, i.p.). The same tests were repeated in rats that had previously received an intraventricular injection of 5,7-dihydroxytryptamine (5,7-DHT; 200 µg/10 µl). This neurotoxin destroyed 5HT neurons, as evidenced by the marked reduction in the uptake of ^{3}H-5HT by brain synaptosomes, but did not alter regional brain concentrations of DA or norepinephrine. In the 5,7-DHT-treated rats the dose-response curves for the "hallucinatory pause" induced by both LSD and DOM were shifted to the left. On the other hand, *the behavioral effects of LSD and DOM were not altered in rats* in which DA nerve terminals in nucleus accumbens were selectively destroyed by microinjections of 6-hydroxydopamine (8 µg/2 µl) into this nucleus; the locomotor stimulant effects of d-amphetamine are reduced in these animals.

In summary, the hallucinatory pause induced by both LSD and DOM is enhanced when 5HT neurons in the brain are destroyed, but not altered by destruction of DA nerve terminals in nucleus accumbens. (Supported by USPHS grant DA1836.)

2191 THE PRECLINICAL IDENTIFICATION OF PSYCHOTOMIMETIC BENZOMORPHAN ANALGESICS. A. Cowan, F.C. Tortella and M.W. Adler. Dept. Pharm., Temple University School of Medicine, Philadelphia, PA 19140.

A large number of benzomorphan narcotic antagonists possess clinically useful analgesic properties; unfortunately, many have been discarded because of their psychotomimetic side-effects. Reliable preclinical tests for identifying such activity are currently lacking. In the present study, we defined the profile of SKF 10,047 (N-allylnorphenazocine), the prototype (benzomorphan) σ receptor agonist, in terms of rat Y-maze behavior and EEG activity. The corresponding profiles of cyclazocine, ethylketocyclazocine (EK), morphine, 8-methoxycyclazocine (8-MC), and Win 42,156 (2'-hydroxy-2,5,9α-trimethyl-9β-(3-oxooctyl)-6,7-benzomorphan) were then compared.

Groups of 6-8 male, S.D. rats (100-120 g) were injected s.c. with vehicle or test compound and 30 min later were individually placed in a Y-maze for 3 min. Only the known hallucinogenic compounds, SKF 10,047 (2.5-40 mg/kg), cyclazocine (0.63-5 mg/kg), and 8-MC (2.5-10 mg/kg), caused the following dose-related and naloxone-insensitive "psychotomimetic" profile: increased locomotion, perseveration of exploratory behavior during the 3rd min, circling, absence of grooming, and side-to-side head swaying at the end of each runway.

Additional rats (150-200 g) were prepared with cerebrocortical electrodes for continuous recording of the EEG. Three to 5 days later, the rats were placed in individual glass chambers and allowed to acclimate and move freely for 3-4 hr during which time control EEG recordings were taken. Drugs were injected i.p., and EEG and behavior were monitored until the onset of slow-wave sleep. Morphine (2.5-10 mg/kg) induced biphasic EEG and behavioral effects characterized by an initial phase of high-voltage EEG slow-wave activity (slow bursts) and associated stupor followed by EEG activation and behavioral arousal. EK (0.63-10 mg/kg) caused similar effects. The profile with SKF 10,047 (10-40 mg/kg) was different. There was an initial "psychotomimetic" phase of EEG activation with increased locomotion and side-to-side head swaying lasting 20-50 min followed by intermittent periods of stupor (associated with EEG slow bursts) and behavioral arousal (and EEG activation). Cyclazocine (2.5-10 mg/kg) induced similar effects. 8-MC gave a morphine-like profile at 2.5 mg/kg and a SKF 10,047-like profile at 10 mg/kg. In all cases, pretreatment with naloxone (10 mg/kg, s.c. at -10 min) antagonized the morphine-like EEG slow bursts and stupor but it had no effect on the "psychotomimetic" component. Preliminary results indicate that the profile of Win 42,156 (2.5-40 mg/kg) is not like that of SKF 10,047 and allows us to predict that this interesting narcotic antagonist analgesic will not possess SKF 10,047-like subjective effects in man. (Supported by Grant DA00376 from NIDA.)

2192 EFFECTS OF PHENOBARBITAL ON THE ACTIVITY OF HYPERACTIVE AND NON-HYPERACTIVE ANIMALS. J.Diaz, K.Watanabe*, and J.Zagun*. Dept. of Psychology, Univ. of Washington, Seattle, WA 98115, Dept. of Psychiatry, NPI/MR, Los Angeles, CA 90024.

Studies show that stimulants may not only improve the attention span of children including hyperactive children, but may also reduce their activity. In addition, most central nervous system depressants will not sedate but rather agitate hyperactive children. The purpose of the present study is to examine the effects of a CNS depressant - phenobarbital - on the activity of a normally very active rodent - the Mongolian gerbil (Meriones Unguiculatus) and a considerably less active rodent - the rat.

Thirty-day old gerbils were assigned to either a phenobarbital group (n=20) or to a vehicle group (n=19) and were injected daily with phenobarbital (60 mg/kg,s.c.) or the vehicle for 4 months. After approximately 14 weeks of drug administration, the activity of the animals in a 5 minute open field test was recorded once a week at varying times after injection (1,2,4,6,8,16,24 hours). During this testing period blood was drawn from the drug animals to determine phenobarbital levels at the time of testing. Vehicle treated animals were subjected to the same proceedure to control for the stress of the bleeding. Thirty-day old male Wistar rats were also assigned to either a phenobarbital group (n=22) or to a vehicle group (n=17) and were given drugs and tested in the same way as the gerbils (after 1,2,4,6,8,24 hours).

The results indicate that the control gerbils and rats show a stable level of locomotor activity for all the time intervals after injections. Moreover, the activity scores for the control gerbils were more than double the activity scores for the control rats. Even though phenobarbital did not appreciably change the activity of rats, it did dramatically alter the activity of gerbils. Animals tested within a few hours after injections were sedated but the handling involved in moving them into the testing device seemed to rouse them. Once in the open field the activity of the phenobarbital treated gerbils was 3 times higher than that of control gerbils. This heightened level of activity remained for at least 8 hours, and by 16 hours after injection the drug group returned to activity levels which were similar to control gerbils. The phenobarbital plasma levels of the drug animals indicate that even though gerbils clear phenobarbital at a slightly faster rate, both rats and gerbils show peak plasma levels at one or two hours after injections.

There are striking similarities between the effects of CNS depressants on the behavior of hyperactive children and the behavior of gerbils. The data from this preliminary study suggest that the gerbil may be a useful model for hyperactivity.

2193 SENSITIZATION OF DRINKING DURING CHRONIC AMPHETAMINE ADMINISTRATION. A.J. Eichler*, S.M. Antelman* and P. Longstreet.* (SPON: G. Werner). Psychobiology Program, Dept. of Psychology, Univ. of Pittsburgh, Pittsburgh, PA 15260.

It is believed that the progressive enhancement (sensitization) of behaviors following repeated administration of stimulants such as amphetamine (AM) may mimic the development of AM psychosis in humans, a condition markedly similar to paranoid schizophrenia. The behaviors typically studied with regard to sensitization in animals have been locomotion and various motor stereotypies. We now report that chronic AM can induce a polydipsic response in rats which shows significant sensitization over time.

Rats were injected daily I.P. with saline, 2, 4, or 8 mg/kg of d-AM sulfate. Water intakes were measured for the 5 hrs immediately following drug administration on different days into the chronic regimen. No significant drinking occurred acutely. However, by day 6 animals were drinking significant amounts to all doses of AM (2 mg/kg: 5.4 ml; 4 mg/kg: 5.9 ml; 8 mg/kg: 4.7 ml; V = 1.0 ml) and by day 35, the response had risen to 15.7 (2 mg/kg), 21.8 (4) and 18.8 ml (8). AM also increased urine output during the same 5 hr period. However, this diuresis was dissociable from the polydipsia, since it showed no sensitization over time. The drinking response is unlikely to be due to conditioning or an accumulation of AM, since the polydipsia could also be seen following only 2 injections of AM spaced at a 20-day interval.

While we have yet to address directly the mechanisms underlying AM-induced drinking, we have observed a significant drinking response which sensitizes during chronic electrical stimulation of the medial frontal cortex, a terminal area of the mesocortical dopamine system. Since electrical stimulation of this region also produced a sensitization to AM stereotypy, it is possible that the medial frontal cortex may be involved in sensitization phenomena in general, as well as in the progressive polydipsia reported here.

We suggest that AM-induced drinking may serve as a suitable measure for studying AM sensitization. The simplicity of the procedure coupled with its objectivity offer distinct advantages over previously employed sensitization paradigms. Finally, it should be noted that the induction of drinking following repeated AM may be clinically relevant, since Bell (1973) has reported increased thirst in individuals manifesting AM psychosis.

2194 SEROTONIN INVOLVEMENT IN MURICIDE BLOCKADE BY IMIPRAMINE. Norman Eisenstein*, Donald Clody* and Louis C. Iorio*. (Spon: W. Gray). Department of Pharmacology, Schering-Plough Corporation, Bloomfield, New Jersey 07003.

The role of serotonin (5HT) in muricidal behavior has been well documented. Decreases in central 5-HT levels produced by p-chlorophenylalanine, fenfluramine or raphe lesions induces killing in non-killer rats; increasing 5-HT by reuptake inhibition (fluoxetine) and administration of precursors (l-tryptophan, 5-HTP) and 5-HT agonists (quipazine) blocks muricide in established spontaneous killers. It has been reported that imipramine and other tricyclic antidepressants block muricidal behavior. These drugs also increase 5-HT, norepinephrine (NE) and dopamine (DA) by inhibiting reuptake mechanisms. This study was done to test the hypothesis that imipramine and other antidepressants may produce their antimuricidal effects through alterations in 5-HT.

Groups of established killers with and without a tryptophan-free diet were tested with various doses of imipramine. The tryptophan-free diet, which decreased whole brain levels of 5-HT, produced a shift to the left of the dose-response function of the antimuricide activity of imipramine. This shift was also produced by treatment with p-chloroamphetamine, a specific 5-HT neurotoxin. L-5-hydroxytryptophan, at doses which did not reduce mouse-killing, potentiated the antimuricide activity of imipramine.

Therefore, it appears that the antimuricidal effect of imipramine is dependent, in part, on its ability to block reuptake of 5-HT. However, it is important to note that no antiserotonergic treatment completely blocked the imipramine effect, suggesting that other neurotransmitter systems may also be involved.

2195 FOLLOWING SEVERAL DAYS OF CONTINUOUS ADMINISTRATION D-AMPHETAMINE ACQUIRES HALLUCINOGEN-LIKE PROPERTIES. Gaylord Ellison, Erik B. Nielsen*, and Arlene Stark*. Dept. Psychology, UCLA, Los Angeles, CA 90024

Rats injected with LSD or mescaline show the behavioral syndrome which has been previously reported to be hallucinogen-specific in higher mammals: limb flicks and whole body shakes. Although these behaviors are decreased in a dose-dependent manner by acute injections of d-amphetamine, they are present 4-5 days after rats are implanted with slow-release silicone pellets producing continuous d-amphetamine administration. These behaviors can be elicited at a high frequency in rats which have been pretreated for 4 1/2 days with an amphetamine pellet, given a 12 hr. rest period, and then injected with a low dose of d-amphetamine. Such pellet-pretreated animals also groom their body surface excessively. We propose that this novel behavioral syndrome which follows continuous amphetamine administration can serve as a new animal model of amphetamine psychosis, since it is based on the same drug regimen which most reliably produces a model psychosis in humans. This behavioral syndrome is altered by concurrent injections of dopamine or serotonin antagonists.

2196 STABILIZATION OF BLOOD ETHANOL LEVELS BY SUBCUTANEOUS RELEASE OF ETHANOL IN RATS DRINKING PREFERRED LIQUID DIETS. Carlton K. Erickson, Kathe I. Koch* and Joseph E. Knipper*. Dept. Pharmacol. Coll. Pharmacy, Univ. Texas, Austin, TX 78712

Liquid diets containing ethanol are a popular method of producing long-term exposure, tolerance and physical dependence in rats and mice. The diets consist of formulations developed a) for weight reduction or nutritional supplementation in humans, or b) expressly for rodent nutrition. We have tested four human nutritional supplements (Nutrament chocolate and vanilla, Sustacal chocolate and vanilla) and two rodent formulations (Lieber-DeCarli, Bioserv; Shorey AIN, custom formula) during 5-day preference tests in female Sprague Dawley rats. Ethanol or (in controls) dextrin supplied 37% of calories in each diet. Animals were housed individually and liquid diets in sterile bottles equipped with Richter drinking tubes were the sole source of food and water. Fresh diet was provided daily. Rats in general preferred chocolate-flavored diets over vanilla-flavored diets, and dextrin-containing diets over ethanol-containing diets. The Lieber-DeCarli diet with dextrin was preferred over the Shorey AIN diet with dextrin, but when ethanol isocalorically replaced dextrin the preference was reversed. Severe withdrawal symptoms could not be evoked after the 5-day exposure. Blood ethanol levels (BEL) cycled during the diet drinking periods, as determined by gas chromatographic analysis of arteriovenous (tail) blood samples.

Stabilized BEL (less cycling compared to diet-induced BEL in the above study) were obtained by using diet in combination with subcutaneous silastic tubes (Sustained Ethanol Release Tubes, SERT; Pharmacologist 20: 159, 1978) which slowly released 95% v/v ethanol. These were refilled once a day. An initial intragastric dose of ethanol in liquid diet was used to "set" the desired BEL. The SERT sustained the BEL, while an available diet added supplemental ethanol and calories for maintenance of stable BEL and body weight. After 4 days of high BEL (above 300 mg/dl), severe withdrawal symptoms were seen upon removal of ethanol, indicating the development of physical dependence. This combination of two models is therefore useful for studying physical dependence in rats or for studying the effects of stable (vs. cycling) BEL in rats over short or long-term exposure to ethanol.

2197 EFFECTS OF d-AMPHETAMINE AND NALOXONE ON BRAIN-STIMULATION REWARD. Ralph U. Esposito, William Perry*, and Conan Kornetsky. Laboratory of Behavioral Pharmacology, Boston University School of Medicine, 80 E. Concord St., Boston, MA. 02118 and Hampshire College, Amherst, MA. 01002 - WP

Rats were stereotaxically implanted with bipolar electrodes aimed at either the medial forebrain bundle or the ventral tegmental area. Self-stimulation thresholds were determined by means of a modification of the psychophysical method of limits (Esposito, R., & Kornetsky, C., Science, 195:189, 1977). Reinforcement values were determined after the administration of d-amphetamine alone, naloxone alone and naloxone administered 2 minutes prior to the injection of d-amphetamine. d-Amphetamine yielded dose related decreases in the threshold (0.25 - 1.00 mg/kg, i.p.), while naloxone alone (2.0 - 16 mg/kg, i.p.) caused no consistent changes. For each animal, the dose of d-amphetamine that yielded the maximum threshold lowering effect was then selected to be administered with varying doses of naloxone. The results indicate that naloxone blocks the threshold lowering effect of d-amphetamine at doses as low as 2.0 or 4.0 mg/kg of naloxone. This finding suggests the possible involvement of an opiate receptor in the mediation of the reward enhancing action of d-amphetamine on brain-stimulation reward.

2198 BRAIN WEIGHT, COCAINE AND SEIZURE SUSCEPTIBILITY. R. J. Fanelli, P. J. Donovick, R. G. Burright*, B. A. Symchowicz*, and A. N. Ritz. Dept. Psych., SUNY Binghamton, Binghamton, N.Y. 13901.

From the Binghamton heterogeneous (HET) stock of mice, Fuller selected three lines on the basis of their brain weight (high, medium and low). These lines, stabilized for some time now, have been shown to differ in both the rate of development of brain weight and behavior as assessed by a variety of tasks. One overriding theme is that the brain weight lines may differ in sensitivity to their environment. We therefore examined the susceptibility of these lines to seizures and how it might be affected by a single administration of cocaine. While seizure susceptibility and its interaction with drug sensitivity is a diffuse measure, it may nonetheless indicate differential cortical excitability.

Male and female mice of the three brain weight lines and HET strain were weaned (ca. 21 days of age) and injected with either saline or 5 or 10 mg/kg cocaine hydrochloride. Litters were distributed across the three dosage groups. Fifteen minutes after the mouse was injected a 3 ma transcorneal electroconvulsive shock was applied for 0.5 sec. We recorded both duration and severity of seizures. All testing was conducted between 10 a.m. and noon.

In saline injected groups HETs and low brain weight mice were most susceptible to seizures and high brain weight mice least. Medium brain weight line mice lay approximately half way between these two groups. Surprisingly, cocaine appeared to provide some protection against seizure in the more susceptible lines of mice (HETs and low brain weight). That is the higher the dose the less frequent the seizure. In contrast neither of the less susceptible lines (medium brain weight and high brain weight) showed clear changes in seizure susceptibility following cocaine administration.

While repeated administration of cocaine has been shown to increase seizure susceptibility, our results indicate that this is not true following a single administration at 21 days of age. Further, seizure sensitivity was clearly affected by genotype and may be critically related to stage of development.

2199 ALTERATIONS IN STRIATAL NEUROTRANSMITTER RECEPTOR BINDING FOLLOWING CHRONIC ADMINISTRATION OF PSYCHO ACTIVE AGENTS. J.W. Ferkany* and S.J. Enna. Dept. Pharmacol and of Neurobiol. & Anat., Univ. Texas Med. Sch., Houston, Tx. 77025

Numerous studies have indicated that chronic activation or blockade of neurotransmitter receptors may lead to alterations in receptor sensitivity. In a previous study we have reported that the chronic administration of inhibitors of 2-oxyglutarate aminotransferase (GABA-T), the enzyme responsible for the metabolism of GABA in brain, causes an increase in ^{3}H-spiroperidol binding, a decrease in ^{3}H-muscimol binding but no change in cholinergic muscarinic receptor binding in homogenates of rat corpus striatum (Fed. Proc. 38:747, 1979). Kinetic analysis of ligand binding indicated that these changes were due to alterations in receptor number and not receptor affinity. The increase in dopamine receptors correlated with an increase in stereotypic behavior following an apomorphine challenge in mice treated chronically with a GABA-T inhibitor. In the present investigation, studies were undertaken to further study neurotransmitter receptor interactions in this brain region following chronic administration of drugs. Rats were administered either aminooxyacetic acid (AOAA) (10 mg/kg, i.p.), atropine (At)(1 mg/kg i.p.) or AOAA (10 mg/kg i.p.) and At (1 mg/kg, i.p.) for 15 days, and 24 hr following the last injection the brains were removed, dissected into regions and receptor binding assayed using ^{3}H-ligand binding procedures. In agreement with previous results, AOAA caused an increase in ^{3}H-spiroperidol binding in the corpus striatum of treated animals. However, in the At and At and AOAA treated animals, ^{3}H-spiroperidol binding was significantly decreased (38%) with respect to control animals. These findings suggest a cholinergic influence on dopaminergic activity in this brain area. In additional studies, animals were treated chronically with ethanolamine-O-sulfate (EOS) (500 mg/kg i.p.), a peripheral inhibitor of GABA-T, muscimol (Mus) (0.6 mg/kg, i.p.) a direct acting GABA receptor agonist, or EOS (500 mg/kg, i.p.) plus Mus (0.6 mg/kg, i.p.). At the doses studied, neither GABA nor dopamine receptor binding were significantly altered in the corpus striatum following any of these treatments. This finding suggests that, at this dose, systemically administered muscimol may not act as a GABA receptor agonist in brain. These results indicate that neurotransmitter receptor binding studies may be useful for investigating neurotransmitter interactions in brain and may provide information with regard to the therapeutic potential and side effect liability of pharmacological agents. 2200 GENETIC DIFFERENCES IN ^{3}H-SPIROPERIDOL BINDING IN CAUDATE NUCLEUS AND CATALEPTIC RESPONSE TO NEUROLEPTIC DRUGS IN INBRED MOUSE STRAINS WITH DIFFERENT NUMBERS OF MIDBRAIN DOPAMINE NEURONS J. Stephen Fink, Alissa Swerdloff, Tong H. Joh and Donald J. Reis. Laboratory of Neurobiology, Dept. Neurology, Cornell Univ. Medical College, New York, NY 10021.

Mice of the BALB/cJ strain have 25% more midbrain dopamine (DA) neurons than mice of the CBA/J strain. This difference is reflected in a correspondingly higher activity of tyrosine hydroxylase (TH), the rate-limiting enzyme for DA biosynthesis, in the caudate nucleus (CN) (Nature 264:654, 1976) and mesolimbic nuclei, and correlates with greater exploration and behavioral response to amphetamine (Neurosci. Abst. 4:492, 1978). We sought to determine whether these strains also differ in: (a) binding of a radiolabelled neuroleptic, ^{3}H-Spiroperidol (^{3}H-SPIRO), in the CN; and (b) the cataleptic response produced by neuroleptic drugs. ^{3}H-SPIRO binding was measured by the method of Creese and Snyder (Eur. J. Pharm. 49:201,1978) using 0.05-2.0 nM ^{3}H-SPIRO. In membrane preparations from CN the maximal number of ^{3}H-SPIRO binding sites determined by Scatchard analysis was 24% greater in BALB/cJ than in CBA/J mice (B_{max}: BALB/cJ=279 ± 4, CBA/J=224 ± 11 fmole/mg protein; n=15, $p<0.01$). There was no difference in K_d between the two strains (K_d: BALB/cJ=0.22 ± 0.05, CBA/J=0.22 ± 0.03 nM; n=15, $p>0.05$). Neuroleptic drugs of three chemical classes [butyrophenones (spiroperidol and haloperidol), phenothiazines (trifluoperazine) and diphenylbutylpiperidines (pimozide)] produced 3-20 times greater catalepsy in BALB/cJ than in CBA/J mice:

	Catalepsy Score (secs/300 min test)		
Drug	BALB/cJ (n=10)	CBA/J (n=10)	P
Spiroperidol (1 mg/kg)	849 ± 239	131 ± 85	<0.05
Haloperidol (4 mg/kg)	755 ± 292	39 ± 26	<0.05
Trifluoperazine (12 mg kg)	1139 ± 174	193 ± 65	<0.001
Pimozide (4 mg/kg)	881 ± 167	275 ± 166	<0.05

Time action curves for a given drug were similar between strains. A greater number of midbrain DA neurons and greater TH activity in CN correlates with a correspondingly greater number of ^{3}H-SPIRO binding sites and greater cataleptic response induced by several classes of neuroleptic drugs. Because ^{3}H-SPIRO binding probably labels a population of DA receptors, BALB/cJ mice may also have more DA receptors in CN. Genetically-determined differences in the number of midbrain DA neurons are associated with a greater number of neuroleptic receptors in the CN and may contribute to a greater cataleptic response to neuroleptic drugs. (Supported by NIH grants HL18974, MH24285, NS03346).

2201 COMPARISON OF CENTRAL BIOCHEMICAL AND BEHAVIORAL ACTION OF ETHANOL AND 1,3-BUTANEDIOL. G.D. Frye, R.A. Vogel, R.B. Mailman, M.G. Ondrusek, R.A. Mueller and G.R. Breese. University of North Carolina School of Medicine, Chapel Hill, North Carolina 27514.

The aliphatic alcohol, 1,3-butanediol (1,3-BD), like ethanol, has been reported to effectively suppress signs of ethanol withdrawal in the rat. Unlike ethanol, this action of 1,3-BD is reported to occur at doses which do not impair motor function in alcohol-naive animals (Majchrowicz et al., Science 194: 1181, 1976). The present studies were conducted to further evaluate the relative potencies of ethanol and 1,3-BD in several behavioral and biochemical tests sensitive to ethanol. During ethanol withdrawal, a dose of 1,3-BD as low as 1.0 g/kg reduced the severity of motor tremor and the frequency of audiogenically-induced seizures, while higher doses completely suppressed them. Impairment of the aerial righting reflex and decreases in cerebellar cyclic GMP were similar after doses of 1,3-BD and ethanol that were equivalent on a molar basis. In addition, 1,3-BD and ethanol both increased punished drinking in a conflict paradigm in which licking was suppressed in water deprived rats that received shock after every 20 licks. Whereas ethanol (1.0 - 2.0 g/kg) stimulated the locomotor activity of HA/ICR female mice, no stimulatory effect of 1,3-BD was seen over doses ranging from 1.0 - 10.0 g/kg. Withdrawal of 1,3-BD administered to rats for 12 days via a liquid diet vehicle (used to produce physical dependence on ethanol) resulted in severe motor tremor in all animals and susceptibility to audiogenically-induced seizures in 8 of 10 rats. Thus these studies indicate that 1,3-BD shares many pharmacological properties with ethanol, including the ability to induce an ethanol-like withdrawal syndrome. (Supported by USPHS Grants AA-02334 and AA-05047 and funds from the Alcohol Research Authority.)

2202 ALTERATION OF THE DISCRIMINATIVE STIMULUS PROPERTIES OF ETHANOL DURING CHRONIC ETHANOL TREATMENT. S. Gibbs* and H.L. Altshuler. TRIMS and Baylor College of Medicine, Texas Medical Center, Houston, TX 77030

This study evaluated the effects of chronic ethanol (ETOH) administration on the discriminative stimulus properties of ETOH in rats trained to perform a double lever operant drug discrimination task. Twenty-five male Sprague-Dawley rats ranging in weight from 240 to 260 gm were used in these studies. These were reduced to 80 per cent of free feeding weight and gradually shaped to perform operant responses for food reinforcements under a variety of schedules culminating in the performance of the double lever choice paradigm during a DRL-10 schedule of reinforcement. The animals were then shaped to preferentially respond on one of the levers when they had been pretreated with ETOH, 1.0 gm, Kg, IP, 15 min. prior to testing. Criteria for correct responding in this portion of the shaping schedule was that the group mean ETOH correct lever responses was at least 85% of total responses. Following the acquisition of this behavior at the ETOH training dose was gradually reduced from 1.0 gm/Kg, IP to 0.75 gm/Kg, IP during a 30 day period. Following acquisition of the 0.75 gm/Kg discrimination, a dose response curve was generated to establish the generalization of correct discriminations across a range of ETOH doses from 0.5 gm/Kg-1.5 gm/Kg. The animals were divided into three groups, Group A received saline chronically. Group B, ETOH, 2.5 gm/Kg. three times daily and Group C ETOH 5 gm/Kg, 3 times daily. Drug was administered by intragastric intubation, 7 days per week. The animals were tested every ten days to assess levels of correct responses after saline or ETOH (0.75 gm/Kg, IP) pretreatment. Chronic ETOH administration continued for sixty days and dose-response, generalization curves were established after 30 days and 60 days. These experiments demonstrated that chronic ETOH administration produced significant reductions in the discriminative stimulus properties of ETOH at all points in the dose response curve, producing a highly significant shift to the right of the curve. The differences between the two groups were significant. No significant changes in correct responding were noted in the saline control group. These data demonstrate that the chronic administration of ethanol to rats trained to perform a double lever operant task produced dose related alterations in the discriminative stimulus properties of ethanol, suggesting that the development of tolerance to ethanol is associated with reduction in the animal's perception of the drug's effects.

2203 THE SITE SPECIFIC EFFECTS OF NALOXONE ON INTRACRANIAL SELF-STIMULATION RATES IN THE RAT. F. Gimino* R. Farrell*, A. Tempel*, S.S. Steiner, and S.J. Ellman. Dept. Psych., City College, City University, N.Y. 10031.

Male sprague-Dawley rats were stereotaxically implanted with bipolar electrodes aimed at various self-stimulation sites. After recovery from surgery, all rats were shaped to respond for .1 msec. monophasic rectangular pulse-pairs of intracranial stimulation (ICS) at a variety of current levels (150-500 microamps). The first pulse in a pair (C-conditioning pulse) was followed by a second (T-test pulse) which was parametrically varied in time (.5-5.0 msec.). A condition in which the T-pulse was omitted was also randomly presented with these values in a latin square design.

All subjects were then tested until ICS response rates were stable. These animals were then entered into a drug paradigm of 3 days .9% saline followed by a fourth injection day of naloxone hydrochloride. The dosage of naloxone to be administered (1.0,10.0, or 40 mg./kg.) was determined by a counterbalanced design. This sequence of naloxone and saline was repeated until all animals completed three tests at each dose level. All subjects were then given three more days of saline followed by a fourth injection day of morphine at 1.25 mg./kg.

Naloxone was found to differentially affect ICS response rates. Most subjects demonstrated response suppression at the higher doses (10 mg.,40 mg) and at the middle range of C-T intervals (.5-2.5 msec) In other subjects,response rates were either enhanced or remained the same under naloxone. Thus far, subjects showing a response suppression have enhanced their response rates under morphine, while subjects showing no naloxone induced rate suppressions have evidenced no effect to morphine. The data also suggest some evidence for a reverse tolerance to naloxone (progressive sensitivity) from some sites.

2204 ORAL DYSKINESIA IN BRAIN-DAMAGED RATS WITHDRAWN FROM ANTIPSYCHOTIC DRUGS. Robert B. Glassman and Harriet N. Glassman*. Dept. Psychol., Lake Forest College, Lake Forest, IL 60045

Many schizophrenic patients who are maintained on antipsychotic medication (neuroleptics) eventually develop a syndrome called tardive dyskinesia, which consists primarily of active movements of lips, jaw, and tongue (Tarsy & Baldessarini, Biol. Psychiat., 1977). While the use of neuroleptics is widely considered indispensable, this iatrogenic disorder is recognized as a major problem. Animal models may help to understand it.

To date, schizophrenia has not been shown to be associated uniformly with a specific, gross brain pathology but some symptoms of schizophrenia resemble those of frontal cortical damage (Glassman, Behav. Sci., 1976). For this and other reasons based on known loci of action of neuroleptics, it was hypothesized that frontal damage would predispose an organism to drug-induced dyskinesia. Three groups of rats were maintained chronically on chlorpromazine (0.5 mg/ml in drinking water) for six weeks; (a) frontally damaged, (b) occipitally damaged controls, and (c) unoperated controls. Numbers of rats surviving in each group were 7, 4, and 5, respectively. Eight additional operated and unoperated rats were kept undrugged for an equal amount of time. Before and after withdrawal each rat was observed for 5-minute periods during which tabulations were made of occurrences of chewing and of other behaviors.

The frontally damaged, drugged rats showed more vacuous chewing on withdrawal than did any other group. The mean (and range) numbers of occurrences of chewing were: frontal 8.6 (1-23); occipital, 1.0 (0-2); unoperated 1.6 (0-3); undrugged, 0.3 (0-1). A t-test comparing frontals with the combined occipitals and unoperated drugged groups yielded $p < .05$. The same differences were obtained on retesting, by an observer who did not know to which group each animal belonged. Additional observations showed the dyskinesias to last for at least a month after withdrawal. The effect was not changed significantly by a subsequent reintroduction of chlorpromazine for six weeks, at the same dose, nor by a later six week course of treatment with haloperidol (0.02 mg/ml in the drinking water). Other behavioral measures (e.g., grooming, walking, rearing, shaking) did not show an effect of drug treatment.

The results suggest that oral dyskinesia is due to release of parts of the nervous system, that control certain fragments of behavior, from higher level organization. Frontal cortical damage and chronic neuroleptic treatment, which is thought to disrupt striatal function, combine to yield this effect.

Supported by the Illinois Department of Mental Health and Developmental Disabilities.

2205 EVALUATION OF FLUNITRAZEPAM, AMITRIPTYLINE, MAPROTILINE, CLOZAPINE AND PROPRANOLOL IN A SQUIRREL MONKEY CONFLICT PROCEDURE. Fred S. Grodsky* and Jerry Sepinwall. Dept. Pharmacol., Hoffmann-La Roche Inc., Nutley, New Jersey 07110

We have previously used a sensitive behavioral procedure to define the antipunishment (anticonflict) effects of benzodiazepine antianxiety agents (JPET 204: 88, 1978) and of barbiturates (Fed. Proc. 37: 617, 1978). In the present experiments, the benzodiazepine compound, flunitrazepam (FLNTZ), the antidepressant agents, amitriptyline (AMIT) and maprotiline (MAPR), and the antipsychotic agent, clozapine (CLOZ), were studied. In addition, the ß-adrenergic antagonist propranolol (PROP), which has been claimed to have some antianxiety activity clinically, was studied alone and in combination with diazepam (DIAZ) or chlordiazepoxide (CDAP).

Compounds were administered by intragastric tube (three to eight monkeys per dose level) 30 min. before a 90 min. test session to twenty-one squirrel monkeys working on a food-maintained two-lever concurrent VI 1.5' VI 6' schedule. Responses in the VI 1.5' component were also punished intermittently (VR 24) with footshock.

Like other benzodiazepines, FLNTZ increased responding in the punished component (Min. Effect. Dose = 0.04 mg/kg), but was 8 and 16 times more potent than DIAZ and CDAP, respectively; however, FLNTZ was effective over a narrower range of doses. In agreement with its clinical efficacy as an hypnotic agent, FLNTZ at 0.62 mg/kg appeared to induce sleep rapidly in 5 out of 6 monkeys. When retested 24 hrs. later, these animals had recovered to baseline levels of performance. CLOZ exhibited significant anticonflict activity of a low magnitude within a limited dose range (1.25 to 2.5 mg/kg). At 5 and 10 mg/kg, dose-related depression of both punished and unpunished responding was seen; in some monkeys these effects persisted for at least 24 hours.

Neither AMIT (0.62 to 10 mg/kg) nor MAPR (2.5 to 20 mg/kg) showed any anticonflict activity. At 10 mg/kg AMIT decreased both punished and unpunished responding although no overt symptoms of sedation were seen. At 20 mg/kg, MAPR decreased responding in some monkeys and produced copious salivation. Thus, neither antidepressant agent exhibited antianxiety-like activity in this test up to doses that produced side-effects.

PROP (1.25 to 40 mg/kg) showed no anticonflict activity; depressed responding and salivation were observed at 40 mg/kg. Nor did PROP (10 mg/kg) show any additive or potentiative effects when it was given in combination with either 2.5 mg/kg of DIAZ or CDAP. These results are consistent with previous animal experiments suggesting that the antianxiety effects of propranolol, if real, are of a different kind than those of benzodiazepines.

2206 GENERALIZATION OF MORPHINE AND PENTAZOCINE TO THE APOMORPHINE DISCRIMINATIVE STIMULUS COMPLEX: DOSE-RESPONSE CURVES. Linda L. Hernández, Alice M. Holohean* and James B. Appel. Behavioral Pharmacology Lab., Dept. of Psychology, U. of South Carolina, Columbia, SC, 29208, USA.

In rats trained to discriminate intraperitoneal doses of apomorphine (0.25 mg/kg) from saline in a two-lever bar-pressing task, both morphine (1.25-5.0 mg/kg, i.p.) and pentazocine (2.50-15.0 mg/kg, i.p.) produce dose-dependent responding on the lever associated with apomorphine. However, morphine is two to three times more potent than pentazocine (ED_{50}'s = 2.76 and 7.55 mg/kg, respectively), and the (log_{10}) dose-response curves for the two opiates differ in form. The dose-response curve for morphine is steep (slope = 132.1 percent per log dose), linear, and reaches 97% apomorphine-lever responding following a dose of 5.0 mg/kg of morphine. The dose-response curve for pentazocine is less steep than that for morphine (slope = 90.5), linear up to a dose of 10.0 mg/kg, but reaches a maximum of only 63% apomorphine-lever responding. Increasing the dose of pentazocine beyond 10.0 mg/kg produces no further increase in bar-pressing on the apomorphine-appropriate lever, but produces a decrease in the number of animals responding. The results replicate and extend our previous report of generalization of the morphine stimulus complex to the apomorphine cue (PB&B, 1978, 9: 459) and suggest that morphine and pentazocine differ with respect to the dopaminergic components of their stimulus complexes.

2207 EFFECTS OF PRENATAL AND/OR EARLY POSTNATAL EXPOSURE TO ETHANOL ON OFFSPRING OF RATS. Joan A. Holloway and Walter N. Tapp*. Dept. Psychiatry & Behav. Sci., Univ. Okla. Health Sci. Ctr., P.O. Box 26190, Oklahoma City, OK 73190.

Nutritionally matched pregnant female rats received ethanol or sucrose in liquid diets from the third or 15th day of gestation. Another group received ad lib lab chow and water. Litters were reduced to eight and cross-fostered on the third day after birth. Thus, there were groups whose mothers had ethanol diets during gestation and lactation, during gestation only, or during lactation only. Animals born to mothers receiving the ethanol diet or the sucrose diet were smaller and lighter than the offspring of the ad lib lab chow mothers. Developmental patterns of activity indicated all groups except the ad lib lab chow group showed abnormal development, and no increased activity in the experimental offspring was found. The weight and activity effects are explainable as malnutrition effects or as being due to the confounding of ethanol exposure and malnutrition. Offspring of animals receiving the ethanol diet showed an increased ethanol preference at 28 days of age, an effect not explainable by malnutrition effects. At 70 days of age all groups showed reduced ethanol preference, especially those whose mothers received ethanol diets. Additionally, males showed a greater reduction in ethanol preference than did females.

2208 REVERSIBILITY OF TARDIVE DYSKINESIA SYMPTOM. Chuong C. Huang. Department of Psychiatry and Mental Health Sciences, Medical College of Wisconsin, Milwaukee, WI. 53226

In a double blind controlled study of 30 Tardive Dyskinesia (T.D.) patients, alpha-methyldopa at doses of 750 to 1500 mg daily and Reserpine at doses of 0.75 to 1.5 mg daily provided statistical significant improvement of the symptomatology of T.D. in comparison to that of placebo. The results are compatible with the "postsynaptic receptor hypersensitivity" theory. It is therefore believed that the T.D. symptom is a functional disorder, not a structure change and should be eliminated completely by desensitization processes. To test this hypothesis, it is necessary to have a long term follow up study. The author had previously proposed a gradual desensitization method as the treatment of T.D. which includes reduction or discontinuation of neuroleptics, discontinuation of antiparkinson drugs and desensitization with reserpine. Six chronic T.D. patients (2 female and 4 male) who had had persistent, severe T.D. symptoms for 3 to 10 years were treated with this method. The treatment period lasted for 4 months to one year and 5 months. They had shown remarkable improvement of their symtoms--2 cases had complete recovery, 4 cases had minimal involuntary tongue movement remained. The tongue movement is always the intractable and last symptom to be eliminated. Four other subacute T.D. patients who had had T.D. symptoms for one month to 3 months had improved completely, simply by discontinuation of causative agents, neuroleptics and antiparkinson drugs. The treatment period lasted for one month to 12 months. In conclusion, the T.D. symtom is a functional disorder and is reversible. The results of this study are contrary to the general belief that T.D. symptoms become irreversible if they have lasted for more than six months. This study reaffirms the postsynaptic receptor hypersensitivity theory. However the remaining intractable minimal involuntary tongue movement could be due to a structure change. Further study is necessary to answer this question.

2209 COMPARISON OF BEHAVIORAL EFFECTS OF 6-HYDROXYDOPAMINE, RESERPINE, AND TETRABENAZINE. C. W. Hughes, S. H. Preskorn, B. K. Hartman, and P. Veit*. Depts. of Psychiatry, Washington Univ. School of Medicine, St. Louis, MO, and Dept. Psychology, Univ. Missouri - Rolla, MO 65401.

Motor deactivation has been postulated to occur as a result of norepinephrine depletion (e.g., Weiss, J. M., et al., Animal Models in Human Psychobiology, Plenum Press, 1974). To test this hypothesis, three different ways of depleting norepinephrine centrally were used. This approach also permits assessment for non-adrenergic effects. Adult rats were compared on a battery of behavioral tests following stereotaxic administration of 125 µg of six hydroxydopamine (6-OHDA) injected intraventricularly in 10 µl of artificial cerebrospinal fluid (csf) over a five minute period. Sham-treated animals received an equal volume of the artificial csf only. Additional behavioral comparisons included groups of rats that received intraperitoneal injections of tetrabenazine, reserpine (2.5 & 5.0 mg/kg), or saline. The behavioral effects of these latter two drugs are often related to their depletion of catecholamines; however, they also have other CNS effects.

If a behavioral effect is mediated by depletion of norepinephrine specifically, then the effect should be observed with all three treatments. Whereas behavioral measures of shuttle-avoidance, open field, and swimming performance were all severely impaired by tetrabenazine and reserpine, the only effect found for the 6-OHDA treated animals was a small decrease in the total amount of open field activity. Although immunohistochemistry indicated that our 6-OHDA treatment resulted in a fairly specific depletion of noradrenergic fibers with little damage, if any, to surrounding tissues or other fiber systems, our behavioral data and finding of no body weight differences in 6-OHDA treated and sham animals (measured over a 45 day period) bring into question the role of norepinephrine depletion in behavior. Previous studies of 6-OHDA-induced deficits in behavior may be due to the nonspecific cytotoxic effects of 6-OHDA on brain tissue. Similiarly, pharmacologic studies reporting motor deactivation due to norepinephrine depletion with agents such as tetrabenazine and reserpine may be a result of drug effects on other central systems.

2210 DISRUPTIONS IN THE SLEEP-WAKE CYCLE OF MICE CAUSED BY N,N-DIMETHYLTRYPTAMINE. P.R. Hyde*, L.J. Bearden, D.L. Weiler* and G.V. Pegram. Neurosciences Program, Univ. Ala. in Birmingham, Birmingham, Ala. 35294.

N,N-Dimethyltryptamine (DMT) is an endogenous compound which produces behavioral disruptions in animals, and hallucinations in humans. Most of the attention regarding the neural role of DMT has focused on the possibility that DMT might precipitate or accentuate various psychiatric disorders. Recent work indicates that there are specific recognition sites for DMT on synaptic plasma membranes (Rosengarten and Friedhoff, Neurosci. Abst. 4:519, 1978; Bearden, et al., Neurosci. Abst. 4:419, 1978), and that the conversion of DMT to inactive metabolites in vitro is accelerated by nicotinamide (Barker et al., in preparation), a compound which exerts benzodiazepine-like effects in vivo (Möhler, et al., Nature 278:563, 1979). These findings could be interpreted as additional evidence suggesting the involvement of DMT in behavioral disorders. To examine further the behavioral effects of DMT, we have studied the effects of this compound on the sleep-wake cycle of mice.

Mice were implanted with chronic cortical electrodes, and following recovery, were given either no treatment, saline (i.p.) DMT (10 or 20 mg/kg; i.p.), or 1,5-diazabicyclo (4.3.0)non-5-ene (DBN; 300 mg/kg, orally; an indoleamine-N-methyltransferase inhibitor). Fronto-parietal electrocorticograms were recorded for seven hour periods (900-1600 hrs.), and scored for awake, slow wave sleep (SWS) and rapid eye movement (REM) sleep. DMT given at either 10 or 20 mg/kg produced a transient increase in total awake time, and a decrease in both SWS time, and in REM sleep time as a percentage of total sleep time. These effects were dose dependent, and disappeared within three hours, with the sleep pattern returning simultaneously to that seen in controls. Inhibition of the synthesis of DMT by DBN produced no observable changes in the sleep-wake pattern of these animals. These results show that DMT administered i.p. produces a short-term disruption in the normal sleep-wake activity of mice. Other workers have observed that LSD, tryptamine and other tryptamine analogs exert similar effects on sleep-wake activity.

2211 MULTIPLE NALOXONE EFFECTS IN VIVO IN MICE. Yasuko F. Jacquet and Michael Jimenez*. Center for Neurochemistry, Rockland Research Institute, Ward's Island, New York City, NY 10035.

Swiss Webster male naive mice (n = 48) were randomly assigned to one of 4 groups and given intraperitoneal (i.p.) injections of either saline or naloxone hydrochloride (1-,10- or 100-mg/kg in a volume of 0.005 cc/gm body weight) twice daily for 4 days. Following each injection, the mice were placed, 4 cagemates together, in an unfamiliar glass jar (30.5 cm in diameter, 61 cm high) and their behavior observed for 30 min. The saline group showed an unexpectedly high incidence of hyperactivity and jumping behavior (mean jumps = 17.49 ± 2.91). Additional control groups of mice (n = 4 ea) given either i.p. needle puncture of no needle puncture prior to being placed in the glass jar also showed a high incidence of this hyperactivity and jumping behavior. This suggested that this behavioral syndrome was due to an "emotional" reaction to the unfamiliar environment.

Naloxone-treated mice showed a dose-dependent reduction in this behavior. At the highest dose (100-mg/kg), naloxone induced sleep in mice, the sleep occurring within 2-3 min, and lasting for the 30-min observation period. Otherwise, there were no detectable adverse effects on mice receiving this high dose of naloxone twice daily for this period. The inactive enantiomer, (+)-naloxone, at 100-mg/kg, resulted in behavior no different from the saline group.

Mice injected with morphine sulphate (25- or 50-mg/kg) or etorphine hydrochloride (0.5-mg/kg) showed a typical opiate syndrome characterized by Straub tail and compulsive, robot-like ambulation around the perimeter of the glass jar. These opiate-injected mice never showed jumping behavior. The opiate behavioral syndrome was fully reversed by naloxone at 1-mg/kg.

These results emphasize the strikingly different responses to opiates by different species (as noted previously by other workers).

The present results suggest that naloxone in vivo in mice have two distinct effects: (1) It antagonized the behavioral effects of opiates at low doses; (2) It inhibited behavior arising from the "emotional" effects of being placed in an unfamiliar environment. This latter suppression required higher doses of naloxone, being only partially effective at the low dose. At the highest dose (100-mg/kg), this "sedative" action of naloxone resulted in inducing sleep, an effect not previously reported for naloxone. Both actions of naloxone were stereospecific, occurring only with the (-)-enantiomer, and not with the (+)-enantiomer.

2212 REDUCED PHYSIOLOGICAL AND SUBJECTIVE EFFECTS AFTER REPEATED ADMINISTRATION OF COCAINE IN HUMANS. J. I. Javaid, M. W. Fischman*, J. M. Davis* and C. R. Schuster*. Illinois State Psychiatric Institute, IL 60612 and Department of Psychiatry, University of Chicago, IL 60637.

Cocaine is a potent central nervous system stimulant and local anesthetic. Although, it is believed that cocaine use produces psychological dependence, most studies suggest that there is no tolerence developed to any of cocaine effects. In fact, it has been suggested that repeated use of cocaine devlops supersensitivity to its behavioral and physiological effects.

In this study, cocaine HCl was administered intranasally followed by intravenous injection. Eight volunteers, who had given their informed consent, were included in the study. Each received, either 4 mg or 96 mg of cocaine HCl, intranasally. Sixty minutes later, either 16 mg, 32 mg or 48 mg of cocaine were given intravenously. Blood was withdrawn for cocaine determinations prior to the drug administration and at different times after drug administration. Physiological measures were monitered continuously and subjective effects of the drug were measured by the stimulant sections of the Addictive Research Center Inventory (ARCI) questionnaire and the Profile of Mood Scales (POMS).

The plasma concentrations of cocaine were always related to dose administered. This was not true for changes in heart rate and subjective effects. When intavenous cocaine was given after 96 mg intranasal administration the increase in heart rate was not as great as when an intravenous injection followed 4 mg inhalation. Comparable changes were obtained in subjective effects. The heart rate changes were plotted against plasma concentrations of cocaine in a scattered diagram. When an intravenous injection was given after high dose of intranasal cocaine the slope of the line fitted to the data was smaller than the slope obtained when an intravenous injection followed low dose inhalation. These results suggest that there is a decrease in physiological and subjective effects of cocaine when administered repeatedly in humans. (Supported in part by PHS grant DA01491)

2213 DECREASED LOCOMOTION IN THE OPEN FIELD AND AFTER AMPHETAMINE IN RATS WITH UNILATERAL DENERVATION OF DOPAMINERGIC MESOLIMBICO-CORTICAL TERMINAL FIELDS. D. Jeste* and G.P. Smith. Dept. Psychiatry, Cornell Univ. Med. College, New York and NIMH Lab. of Clin. Psychopharmacol., Saint Elizabeth's Hospital, Washington, D.C.

Severe bilateral denervation occurs in all dopaminergic (DA) mesolimbicocortical terminal fields after bilateral injections of 6-hydroxydopamine (6-OHDA) into the anterolateral hypothalamus (Fink, Greenfield and Smith, Neuroscience Abstract 660, 1976). Such denervation has been correlated with abolition of the locomotor response to amphetamine (Ervin et al, Brain Res. 132:507, 1977) and with decreased activity in the open field (Fink et al, 1976). To determine if bilateral denervation is necessary to produce these behavioral deficits, we injected 6-OHDA into right (n=4) or left (n=4) anterolateral hypothalamus (A7.0, L2.0, 8.0 mm down according to de Groot). Vehicle injections were also made into the right (n=4) or left (n=3) anterolateral hypothalamic site. 6-OHDA damage of ascending NE fibers was prevented by pretreatment with DMI. Behavioral testing began 15 days after surgery. Rats were tested in the open field (OF) for 5 min on 3 consecutive days. 6-OHDA rats traversed less than half the number of squares vehicle rats traversed on all 3 days ($p < .05$ on all 3 days). Right and left 6-OHDA injections produced the same results. After OF testing was completed, 6-OHDA and vehicle rats were injected with d-amphetamine (1.5 mg/kg) and the locomotor response was recorded by interruptions of photocell beams for 2 hours. The locomotor response of 6-OHDA rats was about 50% of the locomotor response of vehicle rats ($p \ll .05$). No circling was observed and right and left 6-OHDA injections produced the same results.

The significant decrease in activity in the OF and in response to amphetamine observed in unilateral 6-OHDA rats demonstrates that bilateral denervation of any one mesolimbicocortical DA terminal field is not required for significant decreases in response to novel stimuli of an OF and to a low dose of amphetamine. The fact that unilateral 6-OHDA rats responded significantly more to amphetamine than bilateral 6-OHDA rats suggests that the extent of mesolimbicocortical DA denervation correlates with the magnitude of the decrease of the amphetamine response. All the results are consistent with an arousal function of the mesolimbicocortical DA system for locomotor responses to a novel OF and to a low dose of amphetamine.

2214 EFFECTS OF NEONATAL LEAD EXPOSURE ON SPONTANEOUS ALTERNATION PERFORMANCE IN RATS.

Daniel L. Jones. Dept. of Microscopic Anatomy Baylor College of Dentistry, Dallas, TX 75246

One frequent consequence of subacute lead toxicity is hyperactivity, usually viewed as a result of diminished ability to inhibit responding and/or lack of habituation to environmental stimuli. Spontaneous alternation performance is a behavioral measure which could be used to assess this effect. Alternation performance is thought to be a result of habituation to the cues of the maze arm most recently visited, leading to exploration of the relatively novel stimuli of the arm least recently visited. Alternation rates of rats normally average 70-75%. The apparatus used for these measurements is a symmetrical Y maze. The sequence of arm entries as well as the total number of entries is noted, and a percentage alternation score is calculated. An alternation response is defined as the animal's leaving one arm of the maze and entering the least recently visited of the other two.

Accordingly, the effect of neonatal lead exposure on spontaneous alternation performance in mature albino rats (N=16) was studied. The lead was delivered orally in a concentration of 225 mg/kg body wt, from day 1 following birth through day 20. The lead solutions were made up each day so that the appropriate dosage of lead was delivered in a .0025 ml/kg volume of distilled water. Beginning on day 70, the animals were tested daily in 15 minute sessions. After completion of the testing program, the animals were sacrificed and the brains assayed for lead by atomic absorption spectrophotometry. Although the brain lead levels of the experimental animals did not differ from those of controls, both behavioral measures revealed statistically significant differences between lead and non-lead animals, the lead animals exhibiting lower rates of alternation ($p<0.05$) and higher total arm entries ($p<0.05$).

In addition, although littermates were assigned randomly to treatment conditions, hierarchal analysis of the data revealed a significant litter effect ($p<0.05$) on the number of arms entered. This litter effect, which is presumably a result of environmental influences, should be of consideration in any behavioral investigation. It appears that differences in mothering by the dam and other neonatal variables produce relatively long-lasting behavioral effects.

2215 ENHANCED ACUTE TOLERANCE IN RATS TREATED CHRONICALLY WITH OPIATES. H. Kalant* and R.F. Mucha* (SPON: K.E. Livingston). Dept. Pharmacol., University of Toronto, and Addiction Research Foundation, Toronto, Ontario, Canada M5S 2S1.

Tolerance occurs in naive subjects during the action of a single opiate injection. The present study suggests that such acute tolerance is important for the understanding of chronic tolerance.

In Expt. 1, male Wistar rats treated with morphine-SO4 (MS) for 49 days (0, 20 or 200 mg/kg maintenance doses) were tested for analgesia (tail immersion test, 48°C water) after i.p. etorphine-HCl (5-160 µg/kg for 20 and 200 MS groups). Tests at 0.5 hr intervals showed faster within-session loss of analgesia in chronically tolerant than non-tolerant rats. In Expt. 2 these effects were replicated in similarly-treated rats after injection of etorphine into the lateral ventricle (0.1-5 µg, 0.24-4 µg, and 0.6-10 µg/rat for 0, 20 and 200 mg/kg MS groups respectively).

The rapid acute tolerance was not due to repeated testing. Rats treated chronically with MS, 20 and 200 mg/kg, received either saline or MS (10 mg/kg i.v.) pretreatment, followed 1 hr later by i.v. injection of 25 or 50 mg/kg MS and a single tail-flick test 2 min later. Latencies were 50% lower in the MS pre-treated than in saline pre-treated rats. In contrast, MS pre-treatment in chronic saline controls increased the latencies slightly. Similarly, pretreatment with MS (30 µg into the III ventricle), in rats treated chronically with etorphine (200 µg/kg twice daily), reduced the analgesia at 30 min after a test dose of etorphine (200 µg/kg i.p.).

Thus, a very rapid acute tolerance was found in chronically opiate-treated rats. Earlier, we reported (Psychopharmacology, 1978, 60, 59-65) similar findings in ethanol experiments. We suggest that chronic tolerance is an enhancement of acute tolerance. This effect may be critical for estimating treatment-produced changes in opiate sensitivity; log dose/response (LDR) curves for data from Expt. 1 and 2 indicated a tolerance-related shift to the right at short test intervals and shift plus flattening at intermediate intervals. In addition, the nature of the acute tolerance suggested that it could be used to localize sites in the brain responsible for high levels of tolerance to systemically administered opiates. Plugging the cerebral aqueduct with Nivea cream attenuated acute tolerance produced by 30 µg MS injected into the III ventricle in chronic etorphine-treated rats. This attenuation was not seen when MS was injected into the IV ventricle.

2216 ROLE OF THE PERIAQUADUCTAL GRAY IN THE DISCRIMINATIVE STIMULUS PROPERTIES OF METHODONE. M. Kallman, G. Krynock* and J. Rosecrans. Dept. of Pharmacol., Med. Col. of Va., Richmond, VA 23298.

Rats, trained to discriminate methodone injections (1.5 mg/kg, s.c.) from saline injections on a standard two-bar operant task, were assessed for generalization to central administration of methodone and morphine at the site of the periaquaductal gray (PAG). Initially, animals were shaped to respond on one lever following methodone injections (1.5 mg/kg) and on the opposite lever following saline (1 ml/kg) injections during the 15 min. daily sessions. Reinforcement was delivered on a variable interval (VI)-15 sec. schedule for correct-lever responding (0.1 ml sweetened milk). Training continued until discrimination of each drug state was reliable when assessed during 2½ min. extinction sessions. Extinction sessions for generalization testing occurred once a week with continued training under both drug states between generalization tests. Subsequent to discrimination training, animals were anesthetized (40 mg/kg Nembutal) and implanted with stainless steel (24 ga.) cannulae in the PAG for direct drug injection. Surgical recovery and restabilization on the VI-15 sec. schedule were followed by testing for generalization to the methodone cue. PAG injections were accomplished by inserting a 31 ga. needle which extended 1 mm beyond the guide cannulae. All drug doses tested were suspended in a total volume of 1 µl saline for injection. Both dose response and time course data were collected following the direct application of morphine and methodone at the site of the PAG.

Peripheral injections of methodone produced 89.1 ± 6.7% drug-lever responding and saline injections produced 5.1 ± 3.2% drug-lever responding prior to generalization testing at the PAG site. The peripherally administered methodone training cue could not be mimicked by PAG injections of methodone (0, 10, 20 or 40 µg/1 µl) at any of the time parameters examined (0, 15 or 30 min. postinjection). Although the PAG was insensitive to methodone, direct morphine application at the site of the PAG did generalize to the methodone training cue (1.5 mg/kg) at a mean dose of 3.8 ± 1.9 µg. These findings suggest that morphine and methodone produce similar discriminable cues but the role of the PAG in the methodone cue is not clear. The PAG has been implicated in the action of morphine and in the discriminable cue of morphine but the discriminable cue of methodone may be dependent on other central sites. (Supported by U.S.P.H.S. grant #DA-00296-05).

2217 DIETARY TRYPTOPHAN MODULATION AND AGGRESSIVE BEHAVIOR IN MICE. Kathleen M. Kantak, Linda R. Hegstrand and Burr Eichelman. Univ. of Wisconsin and William S. Middleton Veterans Medical Center, Madison, WI 53706.

The effects of a tryptophan-free diet on isolation-induced fighting and predatory cricket killing in mice were examined. The results demonstrated that consumption of a tryptophan-free diet for 18 days 1) decreased both the number of fighters and duration of isolation-induced fighting; 2) increased the number of cricket-killing mice and decreased the latencies to attack and to kill crickets; 3) reduced brain serotonin 27%; 4) increased water intake 38%; and 5) decreased body weight 27%, without affecting food intake. To determine if these effects were due specifically to the lack of dietary tryptophan, other groups of mice were fed a 5% tryptophan load in the standard chow; a 0.15% tryptophan supplement in the tryptophan-free diet; or a 3 grams/day calorically-restricted chow diet. The lack of tyrptophan in the diet specifically produced the almost total inhibition in isolation-induced fighting, the reduction in brain serotonin, and the large decrease in body weight. The other non-specific effects appeared to be related to general factors such as dietary need for the cricket killing or diet composition for the water intake.

2218 LITHIUM DECREASES SELF-STIMULATION AND ESCAPE IN RATS INDEPENDENT OF LOCOMOTOR ACTIVITY. Nilda M. Keene, James J. Keene and Brenda Doble*. Dept. Psychiat. & Dept. Physiol., Sch. Med., Univ. Puerto Rico, San Juan, PR 00936.

The effects of lithium chloride (2 meq./kg.) on self-stimulation and escape behavior elicited by intracranial electrical stimulation of the medial forebrain bundle and the midbrain reticular formation respectively, were tested in chronically implanted rats. In the same test periods, locomotor activity was also measured. A "tilt-box" method allowed the animals to control the amount of brain stimulation (0.25 sec, 100 Hz trains of cathodal pulses delivered at 1 Hz) by its position in the box. Experimental tests began with two hours of pre-drug performance to establish baseline measures for self-stimulation (or escape) and locomotor activity level during the test. Stimulation current was set to elicit moderate performance (40 - 300 uA). Post-drug performance was followed over up to four hours. Throughout, data was tabulated at 8 min. intervals. In 7 experiments (4 rats), pre-drug self-stimulation increased activity compared to periods without brain stimulation; and lithium caused both self-stimulation and activity to decrease. In 7 escape experiments (4 rats), lithium decreased escape although locomotor activity was not changed. At higher stimulus currents eliciting better performance, both self-stimulation and escape were less affected by this dose of lithium. Thus, lithium may be acting to a significant extent directly on affective mechanisms of the brain, and may not be merely sedative in its action, since escape decreased while locomotor activity did not. Supported by NIH Grant RR-08102.

2219 BEHAVIORAL EFFECTS OF LESIONS TO THE MESOLIMBIC DOPAMINE NEURONS. G.F. Koob, L. Stinus, M. Le Moal, D.C.S. Roberts, and F.E. Bloom.. A.V. Davis Ctr. for Behav. Neurobiol., Salk Inst., La Jolla, CA 92037 and Laboratoire de Neurobiologie des Comportements, Universite de Bordeaux, Talence, France.

Previous work has established that 6-hydroxydopamine (6-OHDA) lesions to the nucleus accumbens septi (NAS) produce transient hypoactivity and block the increase in locomotor activity induced by d-amphetamine (AMPH), whereas radio-frequency (RF) or 6-OHDA lesions to the ventral tegmental area (VTA) produce a significant hyperactivity and fail to block AMPH induced locomotor activity. An attempt was made in the present study to determine the substrate for these differential effects. Rats pretreated with pargyline (50 mg/kg) were injected intracerebrally with 6-OHDA dissolved in saline containing 0.2 mg/ml of ascorbic acid. Animals were divided into 8 lesion groups: Sham-operated, 6-OHDA (8ug/2ul of vehicle)-medial NAS, 6-OHDA (8ug/2ul)-posterior NAS, 6-OHDA (2ug/1ul)-VTA, 6-OHDA (3ug/1ul)-VTA, 6-OHDA (4ug/1ul)-VTA, RF-VTA, and RF-VTA with 6-OHDA (8ug/2ul)-medial NAS. All rats were tested for nocturnal activity on day 8 post-lesion, their locomotor response to 1.5 mg/kg AMPH i.p. on day 13 post-lesion, and their locomotor response to 0.1 mg/kg of apomorphine (APO) s.c. on day 15 post-lesion. All testing took place in circular corridor photocell cages. 6-OHDA lesions of the VTA produced significant increases in spontaneous nocturnal activity at the 2ug/1ul dose but no change in nocturnal activity at the 4ug/1ul dose. RF lesions to the VTA produced even greater increases in nocturnal activity which were blocked by the addition of 6-OHDA to the medial NAS. NAS 6-OHDA lesions alone failed to significantly alter nocturnal activity. 6-OHDA lesions to the VTA produced a block of AMPH induced activity that was directly related to the dose of 6-OHDA used with the 4ug/1ul dose producing a 90% decrease. The posterior and medial NAS lesions produced an identical block of AMPH induced activity. The rats with the RF lesions to the VTA were spontaneously hyperactive and remained hyperactive after injection of AMPH. In contrast, the rats with the combined RF lesion and medial NAS 6-OHDA lesion showed a block of AMPH activity identical to that observed with medial NAS lesion alone. All lesion groups that showed a block of AMPH locomotor activity exhibited supersensitivity to APO as measured by a significant increase in locomotor activity. The RF-VTA lesion rats showed a significant decrease in their spontaneous hyperactivity after APO. These results suggest that limited destruction of the mesolimbic dopamine system can produce hyperactivity but that more extensive destruction of this system produces no hyperactivity and an attenuation of the locomotor stimulating effects of AMPH.

2220 EFFECT OF ETHYL ALCHOHOL AND d-AMPHETAMINE ON SOCIAL BEHAVIOR AND THE RESPONSE TO PEER SEPARATION IN RHESUS MONKEYS. G.M. Kraemer, D. Lin‡ N. Kalin‡ M.H. Ebert, and W.T. McKinney. University of Wisconsin, Primate Laboratory, Madison WI 53706 and NIMH, Bethesda MD, 20014 (MHE).

Previous studies from our laboratory have shown that drug treatments which interfere with catecholamine metabolism can significantly alter the response of peer grouped rhesus monkeys to separation from their peer group, in the absence of demonstrable drug effects on group social behavior(J. Affective Disorders, 1,33-54,1979). Specifically, pretreatment of monkeys with alpha-methyl-para-tyrosine(AMPT) in dosages as low as 25 mg/Kg/day appears to increase the levels of despair behavior following separation, while pretreatment with fusaric acid(DBH inhibitor), or tricyclic antidepressants, decreased the level of despair behavior. These results suggested an important parallel between the effects of drugs on the production of separation despair in monkeys and their possible depressant or antidepressant effects in humans.

In subsequent experiments we have examined the effects of a wider spectrum of psychoactive drugs in the peer separation paradigm, and the effects of these drugs on cerebro-spinal fluid(CSF) metabolites of norepinephrine and dopamine. The results of studies with ethyl alchohol and d-amphetamine suggest that these agents alter both social and separation behavior of rhesus monkeys. However, the sedative or activating effects of these agents appeared equally in both social and separation housing conditions. Therefore, the biochemical effects of these agents do not significantly augment or ameliorate the behavioral effects of peer separation in the absence of prior effects on group social behavior. These results provide additional evidence that the interaction of drugs with despair following social separation may depend on specific characteristics of the biochemical alterations produced rather than the overt sedative or activating effects of the drug. Specific alterations in brain catecholamine metabolism may be an important factor. However, our data indicate that important changes in social and separation behavior can occur with very little alteration in the turnover of CSF catecholamine metabolites.

2221 EFFECTS OF L-DIHYDROXYPHENYLALANINE AND D,L-5-HYDROXYTRYPTOPHAN ON TYROSINE FACILITATED AGGRESSION. N. R. Kramarcy[1] and J. B. Thurmond. Dept. of Psych., Univ. of Louisville, Louisville, KY 40208

The administration of tyrosine via the diet has been reported to increase aggression and brain dopamine concentrations in mice (Lasley et al. Neurosci. Abstr. 4, 1978). Employing a resident-intruder aggression test, we have investigated the effects of acute administration of L-dihydroxyphenylalanine (L-DOPA) and D,L-5-hydroxytryptophan (D,L-5-HTP) to resident mice receiving a 4% tyrosine supplemented diet (TYR) or the 12% casein basal diet (CAS) for one week. Residents in both diet conditions were matched for aggression and locomotor activity (test 1) prior to drug test (test 2).

The TYR residents receiving saline in test 2 displayed increased aggression and elevated dopamine concentrations relative to the CAS residents. L-DOPA administration (12.5, 25, 50, 100 mg/kg) increased the aggression of the CAS residents. The TYR residents exhibited increased aggression after 12.5 and 25 mg/kg, but decreased aggression after 50 and 100 mg/kg L-DOPA. The concentration of dopamine (DA) was elevated in all groups. Treatment with D,L-5-HTP (50, 100, 200 mg/kg) produced a marked decrease in aggression in the CAS residents at all doses with little change in locomotion. In contrast, the TYR residents' aggression decreased markedly only at 200 mg/kg D,L-5-HTP. The concentrations of serotonin (5-HTP) and 5-hydroxyindoleacetic acid (5-HIAA) were elevated at all doses in both diet groups, but the increase in the TYR group was reduced relative to the CAS group.

These studies demonstrate that administration of the neurotransmitter precursor tyrosine via the diet can produce changes in aggressive behavior and neurochemistry, alter behavioral responses to L-DOPA and D,L-5-HTP, and reduce the synthesis of serotonin after D,L-5-HTP administration. The increase of dopamine concentrations relative to norepinephrine appears responsible for increases in aggression and the increase of serotonin concentrations relative to dopamine appears important for inhibition of aggression. 2222 EFFECTS OF INTRASTRIATALLY INJECTED THIORIDAZINE ON APOMORPHINE-ELICITED BEHAVIORS. H. Lai* and A. Horita* (SPON: R. M. Quock) Dept. Pharmacol. and Psychiat. & Behav. Sci., Univ. Washington, Seattle, WA. 98195.

Bilateral injection of thioridazine (10 μg) into the neostriata of rats enhanced stereotypic behavior elicited by subcutaneously injected apomorphine (1 mg/Kg), while motor activity of the animals was not affected. This enhancing effect of thioridazine on apomorphine-elicited stereotypic behavior was attenuated by pretreating the rats with α-methyl-p-tyrosine. These results suggest that thioridazine, when injected directly into the neostriatum, can enhance dopaminergic activity probably by increasing release of dopamine from the nigrostriatal dopaminergic pathway.

2223 CORRELATION OF ANTI-PSYCHOTIC DRUG POTENCY AND NEUROLEPTIC RECEPTOR INHIBITION IN POST-MORTEM HUMAN BRAINS. Tyrone Lee and Philip Seeman. Department of Pharmacology, University of Toronto, Toronto, Canada M5S 1A8.

In order to investigate whether anti-psychotic drugs inhibit the binding of ^{3}H-spiperone to neuroleptic/dopamine receptors in human brain in accordance with their clinical potencies, we determined the effect of 22 different neuroleptics in inhibiting the specific binding of ^{3}H-spiperone to caudate and putamen of post-mortem human brain.

All clinically active neuroleptics effectively inhibited the binding of ^{3}H-spiperone. β-flupenthixol, trans-thiothixene and (-)-butaclamol were ineffective even at micromolar concentrations. The potencies of these drugs for inhibiting ^{3}H-spiperone binding correlated very well with their clinical potencies for treating schizophrenia. The 50% inhibitory concentrations (IC_{50}) of these drugs were as follows:

DRUGS	nM	DRUGS	nM
Spiperone	0.3	Metiapine	70
Benperidol	1	Clozapine	150
Trifluperidol	1	Molindone	150
Pimozide	5	Sulpiride	400
Haloperidol	5	cis-thiothixene	3
Moperone	10	trans-thiothixene	>1000
Lenperone	22	(+)-butaclamol	5
Perphenazine	3	(-)-butaclamol	>1000
Fluphenazine	4	α-flupenthixol	9
Triflupromazine	17	β-flupenthixol	600
Prochlorperazine	20		
Trifluoperazine	22	Dopamine	>1000
Chlorpromazine	30	Apomorphine	>1000
Thioridazine	40	Noradrenaline	>1000
Promazine	200	5-HT	>1000
		Carbachol	>1000
		GABA	>1000

It remains to be determined whether such a profile also holds in schizophrenic brain tissues where higher numbers of neuroleptic receptors have been found (Lee and Seeman, Proc. Soc. Neurosci. 1977, 1978). Scatchard analysis using ^{3}H-spiperone indicated that there was no change in receptor affinity in schizophrenic tissues compared to those from normal controls.

2224 IN VIVO EFFECT OF PHENCYCLIDINE ON SYNAPTOSOMAL UPTAKE OF DOPAMINE AND 5-HYDROXYTRYPTAMINE. D. E. Leelavathi, and Robert C. Smith. Texas Res. Inst. Mental Sci., Houston, Texas, 77030.

Phencyclidine (PCP) is a potent psychetomimetic agent and some of this action has been presumed to be mediated by effects on catecholamines. Earlier results (Smith, et.al., Biochem. Pharm., 26:1435, 1977) indicated that PCP significantly inhibited the in vitro uptake of dopamine (DA) and 5-hydroxytryptamine (5-HT) in crude synaptosomal preparations of rat brain. The present investigation was undertaken to study the effects of a single dose of intraperitoneal administration of PCP to rats, at which behavioral effects are observed on the in vivo uptake of DA in striatum and 5-HT in brain stem. Fifteen minutes after administration of PCP (10 mg/kg body weight), there was no effect on the DA uptake in striatum whereas 5-HT uptake was inhibited in brain stem to an extent of 10%. Forty-five minutes after administration of PCP, the behavioral effects are more prominent but there was no effect on 5-HT uptake. This probably indicates that inhibition of uptake of 5-HT at presynaptic level may not be related to the observed behavioral effects by PCP.

2225 BEHAVIORAL AND BIOCHEMICAL STUDIES OF AMPHETAMINE TOLERANCE AND REVERSE TOLERANCE. Nancy J. Leith & Ronald Kuczenski, Dept. Pharmacol., Vanderbilt School of Medicine, Nashville, TN 37232

Leith & Barrett (Psychopharm, 46, 1976) have demonstrated that following chronic administration of d-amphetamine, (increasing doses, 3 times daily for 4 days) tolerance is seen to the facilitating effects of the drug on self-stimulation responding. On the other hand, Segal & Mandell (Pharmacol., Biochem. Behav. 2, 1974) showed that repeated administration (constant dose once daily for 7-14 days) of the drug results in an enhanced response (reverse tolerance) to the locomotor stimulatory and stereotypy - producing effects. These data suggest that the drug effects on self-stimulation responding and motor behavior reflect different actions of amphetamine. However, the chronic regimens used in the two studies were quite different and could have attributed to the dissimilar results obtained. The present study compared both drug regimens on both behaviors to determine which interpretation is accurate.

For the motor activity studies, male Sprague-Dawley rats were injected with .75, 2.0, 3.0 or 5.0 mg/kg d-amphetamine and activity monitored for 3 hours. Half of the animals in each dosage group then received 3.0 mg/kg daily for 6 days and were retested on day 7. The other half received 3 injections daily for 4 days beginning with 1 mg/kg and incrementing by 1 mg/kg at each injection and were retested on Day 7. Regardless of the chronic injection regimen, all animals showed an enhanced response to d-amphetamine when retested. Self-stimulation animals were implanted with electrodes in the MFB and after training, were tested with an acute dose of 0.3 mg/kg. The animals were then treated chronically as stated above. Animals receiving 3 mg/kg daily showed no change in the amphetamine response when retested whereas those treated 3 times daily with increasing doses demonstrated tolerance as previously reported. These data, then, suggest that the two behaviors do in fact reflect different aspects of amphetamine's action.

As a first step in assessing possible biochemical changes that might underlie the behavioral phenomena occurring after chronic administration of amphetamine, we have measured DOPAC and HVA levels in the caudate and mesolimbic area. The chronically treated animals showed a significant decrease compared to controls in both DOPAC and HVA in the caudate but not the mesolimbic region when killed 48 hours after the last drug injection, but the two groups were not significantly different from each other after a challenge dose of 3 mg/kg d-amphetamine. In addition, in an attempt to further characterize the nature of the changes in dopamine function, the responses to Haldol and apomorphine are being evaluated in animals treated chronically with amphetamine.

2226 A PROFILE OF THE CAPSAICIN DESENSITIZED RAT. Marciá G. Levin*, Rodney J. Pelchat and Nancy Wzontek* (SPON: D. Moulton). Dept. Psych., Univ. of Penna., Philadelphia, PA 19104.

Jancsó-Gábor et al. (J. Physiol. 206:495, 1970) reported that rats given large injections of capsaicin (8-methyl-6-nonenoyl-vanillamide) show deficits in thermoregulatory and pain responses which last for a year or more. These animals show abnormally elevated body temperature in warm environments but in neutral and cool environments their body temperature is normal (i.e. matches controls). These animals are also insensitive to peripherally applied chemical irritants. Jancsó-Gábor called this set of symptoms capsaicin desensitization. When we placed desensitized and control rats at an ambient temperature of 32°C, the groups showed equal amounts of saliva spreading. Controls showed large amounts of prone extension whereas desensitates showed none. At an ambient temperature of 38°C desensitates and controls showed equal amounts of prone extension but desensitates had a much longer latency to prone extend. These studies suggest that desensitized rats have elevated thresholds for prone extension and, therefore, that their thermoregulatory deficits are, in part, of central origin. This is in contrast to the contention of Cabanac et al. (Pflugers Archiv. 366: 217, 1976) that the hyperthermia in desensitates at high ambient temperatures is due only to effector deficits. In another study we investigated the specificity of the analgesia observed in desensitates. Latencies to tail flick in desensitized rats were found to be identical to their own pre-desensitization baselines and were also identical to latencies in matched controls. Thus, this measure reveals no effects of capsaicin desensitization on reactions to pain due to heat.

2227 PROPERTIES OF HIGH AFFINITY ^{3}H-DOPAMINE BINDING SITES IN RAT STRIATUM. S. List, M. Titeler and P. Seeman, Department of Pharmacology, University of Toronto, Toronto, Ontario M5S 1A8.

Although a high affinity binding site for ^{3}H-dopamine in rat striatal tissue had been reported by Seeman et al. (Fed. Proc. 33, 1974) to have a K_D of 0.6 nM, the work of Burt et al. (Proc. Nat. Acad. Sci. 72, 4655, 1975) only revealed a low affinity site for ^{3}H-dopamine (i.e. 50% displaced by 380 nM dopamine).

In order to examine this further, we studied the inhibitory effects of various drugs on the binding of ^{3}H-dopamine to rat striatal homogenates. The total binding of ^{3}H-dopamine was reduced by 60% at 500 to 1000 nM dopamine with little further reduction at 10,000 nM dopamine. Thus, specific binding of ^{3}H-dopamine was defined as that displaceable by 500 nM dopamine.

A Scatchard analysis of the specific ^{3}H-dopamine binding sites revealed a K_D of 3 nM and a maximum number of binding sites of 100 fmoles/mg protein. The site appeared to be similar to the ^{3}H-dopamine site labeled in the calf caudate, this site having high affinity for dopaminergic catecholamines and low affinity for neuroleptics (see Table). (Supported by the Medical Research Council of Canada and the Ontario Mental Health Foundation).

	^{3}H-Dopamine IC_{50}	
	Rat Striatum	Calf Caudate
Apomorphine	1.5 nM	1 nM
ADTN	3 nM	10 nM
Dopamine	12 nM	8 nM
LSD	15 nM	40 nM
Haloperidol	200 nM	900 nM
Chlorpromazine	600 nM	1500 nM

2228 ASSESSMENT OF THE ROLES OF RESPONSE RATE AND REINFORCEMENT RATE IN PRODUCING AMPHETAMINE'S SCHEDULE-DEPENDENT BEHAVIORAL EFFECTS. I. Lucki and R. E. DeLong*.
Dept. Psychol., Univ. Iowa, Iowa City, IA 52242.

The rate dependency hypothesis states that baseline rates of responding determine the effects of amphetamine on schedule-controlled operant behavior. However, the correlation between response rate and reinforcement rate under most reinforcement schedules confounds attributing the schedule-dependent effects of amphetamine solely to differences in rates of responding. Two comparisons were performed to independently evaluate the roles of response rate and reinforcement rate in the schedule-dependent effects of amphetamine. The comparisons were complementary, in that multiple schedules were arranged where one variable, either response rate or rate of reinforcement, was held constant and the other variable was allowed to vary.

In the first comparison, a procedure yoked reinforcement availability under a variable-interval (VI) schedule to the temporal pattern of reinforcement under a differential reinforcement of low rate (DRL) schedule (mult DRL 7 sec yoked VI). VI response rates were 3.2 times greater than DRL response rates, at rates of reinforcement that were held relatively constant. Amphetamine increased DRL responding at the same doses that decreased VI responding. This agrees with previous demonstrations of rate-dependent amphetamine effects when these schedules were studied individually, but further indicates that different rates of reinforcement between schedules are not necessary to produce schedule-dependent amphetamine effects.

The second comparison examined the hypothesis that different reinforcement rates could produce independent effects on amphetamine action. A multiple random ratio (RR) schedule (mult RR20 RR50) held rates of responding constant while rates of reinforcement varied by 2.7-fold. Amphetamine affected responding under both random ratio schedules equally, indicating the different reinforcement rates exerted no effects on responding under amphetamine.

The results of the complementary procedures agreed in assessment of the rate dependency hypothesis. The primary determinant of amphetamine's schedule-dependent behavioral effects is the control rate of responding, rather than the control rate of reinforcement.

2229 INFLUENCE OF DOPAMINERGIC NERVE TERMINALS IN NUCLEUS ACCUMBENS ON THE ACQUISITION AND MAINTENANCE OF d-AMPHETAMINE SELF-ADMINISTRATION. W.H. Lyness and K.E. Moore. Dept. Pharmacol. & Toxicol., Michigan State Univ., East Lansing, MI 48824.

The objective of this study was to determine the role of mesolimbic dopaminergic neurons, which terminate in nucleus accumbens, in mediating the self-administration of d-amphetamine. Rats were trained to lever press for i.v. self-injection of 0.125 mg/kg d-amphetamine (FR-1 schedule) during daily 16 hr test sessions. They acquired a stable injection rate in 7-14 days and were tested thereafter in 8 hr test sessions (50-90 injections per 8 hr). In trained rats, noncontingent injections of 1.0 mg/kg d-amphetamine or 0.5 mg/kg apomorphine reduced the number of self-injections for periods consistent with the duration of action of the drugs (90 min for d-amphetamine, 30 min for apomorphine). Replacement of d-amphetamine with saline resulted in a 4-6 fold increase in response rate for several hours followed by cessation of lever pressing. Rats previously trained to self-administer d-amphetamine were given bilateral injections of 6-hydroxydopamine (8 µg/2 µl) or vehicle (0.1 mg ascorbic acid/ml saline) into the nucleus accumbens under Equithesin anesthesia and 25 mg/kg desipramine pretreatment. 6-Hydroxydopamine reduced the dopamine content of the nucleus accumbens to 10% of control. A 14 day recovery period was allowed before self-administration studies were resumed. After this recovery period, vehicle-injected rats immediately resumed rates of self-administration which were comparable to those before the 14 day rest (range 50-95 self-injections per 8 hr). 6-Hydroxydopamine-lesioned rats, failed to reinitiate self-administration behavior (range of only 0-12 self-injections per 8 hr), even when examined for up to 21 days. Replacement of d-amphetamine with saline increased self-injection rates only in rats administered vehicle in nucleus accumbens; rats given 6-hydroxydopamine failed to alter their self-injection rates.

Naive rats with 6-hydroxydopamine lesions of the nucleus accumbens failed to acquire self-administration behavior when examined over a 21 day period following the lesion. The data indicate that dopaminergic nerve terminals in the nucleus accumbens are essential for both the acquisition and maintenance of self-administration of d-amphetamine. (Supported by USPHS grant MH 13174.)

2230 β-ADRENERGIC AGONISTS AND BENZODIAZEPINES STIMULATE MEMBRANE PHOSPHOLIPID METHYLATION IN RAT ASTROCYTOMA CELLS. Pierre Mallorga*, Warren J. Strittmatter*, Fusao Hirata*, John F. Tallman and Julius Axelrod. Biological Psychiatry Branch and Laboratory of Clinical Science, NIMH, Bethesda, MD 20205

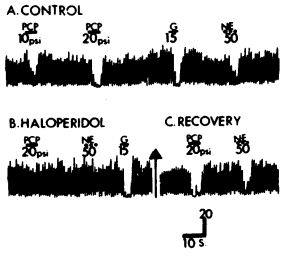
C_6 rat astrocytoma cells contain β-adrenergic and benzodiazepine receptors. The β-adrenergic receptor has been characterized by specific binding of l-[^{3}H]dihydroalprenolol, displacement of this radioactive ligand by various β-adrenergic agonists and increased 3':5'cyclic AMP production in intact cells after incubation with l-isoproterenol. The benzodiazepine receptor has been characterized by specific binding of [^{3}H]diazepam and displacement of this ligand by various benzodiazepines: Ro5-4864 is more potent than clonazepam and chlordiazepoxide.

l-Isoproterenol and Ro5-4864 are able to stimulate the methylation of membrane phosphatidylethanolamine to form phosphatidylcholine in intact cells. Half-maximal stimulation is obtained with approximately 10^{-8} M l-isoproterenol or 10^{-8} M Ro5-4864. If both compounds are added together to the incubation, methylation of phosphatidylethanolamine is additive. This suggests that two different sets of methylating enzymes, and probably two domains of the membrane are involved in the mechanism of action of β-adrenergic agonists and benzodiazepines.

A two-hour exposure of the cells to l-isoproterenol (10^{-5} M) results in a 80-90% loss of responsiveness to a subsequent challenge by l-isoproterenol, although the loss of binding sites is 20%. We were able to block this agonist-induced refractoriness by adding mepacrine, an inhibitor of the phospholipase A_2, to the medium of incubation. Mellitin, an activator of the phospholipase A_2 caused the cells to become refractory to l-isoproterenol.

2231 PHENCYCLIDINE - NEUROLEPTIC INTERACTIONS IN A CENTRAL NORADRENERGIC PATHWAY. J. Marwaha*, M. Palmer, B.J. Hoffer* and R. Freedman* (SPON: T. Dunwiddie). Dept. of Pharmacology, University of Colorado Medical Center, Denver, Colorado, 80262.

The interactions between the "dissociative anesthetics", phencyclidine (PCP), ketamine (K) and the antipsychotic drugs, fluphenazine (F), haloperidol (H), α-flupenthixol (αF) were studied in the cerebellum of urethane-anesthetized rats. The inactive isomer β-flupenthixol was used as a control. Activity of single Purkinje (P) neurons was recorded extracellularly. Since aqueous solubility is a problem with many of these agents, they were ejected from multibarrel micropipettes using air pressure. Locally applied PCP and K decreased the spontaneous discharge of P neurons in a dose dependent manner. In general, the latencies for the depressions were 2 to 3 seconds and recovery was seen 2 to 3 seconds following termination of drug ejection. Ketamine was about one fifth as potent as PCP. Parenteral (0.5 mg/Kg) or local application of F, H and αF reversibly antagonized the depressant effects of PCP and K on P cell discharge whereas βF was ineffective. F, H and chlorpromazine also antagonized the depressant effects of iontophoretically applied norepinephrine (NE) and locus coeruleus stimulation on these same neurons, but not the effects of iontophoretic application of GABA (G).



These results taken together with previous reports that antipsychotic drugs block noradrenergic transmission in the cerebellum suggest that PCP and K depress P cell discharge by altering noradrenergic neurotransmission in the cerebellum and that the cerebellar noradrenergic pathway is a convenient model system to analyze these drugs. (Supported by DA 07043, AA 03527, and Pharmaceutical Manufacturer's Association.)

2232 DIFFERENCES IN BINDING AND ACCUMULATION OF AMPHETAMINE ISOMERS IN HYPOTHALAMIC VERSUS STRIATAL SYNAPTOSOMES. R.T. Matthews and P.A. Shore. Dept. of Pharmacol., University of Texas Health Science Center, Dallas, TX 75235.

A recent study in this laboratory (Fed. Proc. 38:524, 1979) demonstrated stereoselectivity in the accumulation and binding of amphetamine (AMPH) isomers by synaptosomes of the rat corpus striatum. At 37°, accumulation of ^{3}H-d-AMPH was inhibited much more than ^{3}H-l-AMPH by ouabain, unlabeled d-AMPH (but much less so by unlabeled l-AMPH) or by dopamine (DA) neuronal uptake inhibitors. The norepinephrine (NE) uptake inhibitor, desipramine, showed little effect. In the cold (4°), considerable binding of ^{3}H-d-AMPH remained; this was also inhibited by DA uptake inhibitors or by unlabeled d-AMPH. It was concluded that the DA uptake carrier is the site of stereoselective binding and accumulation of d-AMPH in the striatal DA nerve terminal. The stereoselectivity for d-AMPH correlates with the greater electrophysiological and biochemical potency of d-AMPH on nigrostriatal DA neurons.

In the present study, similar experiments were performed using a crude synaptosomal preparation of rat hypothalamus, an area rich in NE nerve terminals. Accumulation of ^{3}H-AMPH isomers (10^{-7}) was observed at 37°, but while this was inhibited by cold, the pattern of inhibition by drugs differed markedly from that seen in the striatal preparation. Thus at 37°, little or no effect of ouabain (10^{-5}M) was observed on d-AMPH. Desipramine (10^{-7}-10^{-6}M) or unlabeled AMPH isomers inhibited d-AMPH accumulation more than l-AMPH, but more meaningful was the finding that ^{3}H-d-AMPH accumulation was inhibited equally by unlabeled d- or l-AMPH (10^{-6}M) as was ^{3}H-l-AMPH accumulation.

These preliminary findings are suggestive that, unlike striatal DA neurons, little active accumulation or stereoselectivity of binding of AMPH isomers exists in the case of hypothalamic NE neurons. The findings are consistent with the known electrophysiological and biochemical equipotency of AMPH isomers on NE neurons as contrasted with nigrostriatal DA neurons where the d-isomer is much more potent than the l-isomer. (Supported by USPHS Grant MH-05831).

2233 EFFECTS OF ATROPINE OR BENACTYZINE ON DRL PERFORMANCE OF MONKEYS. John H. McDonough, Jr.* Neuropsych. Br., U.S. Army Biomedical Laboratory, Aberdeen Proving Ground, MD 21010.

In humans, one of the consistently reported psychopharmacological effects of cholinergic blocking agents is a loss of the "sense of passage of time." The ability of two anticholinergic drugs, atropine and benactyzine, to produce this effect was assessed in Rhesus monkeys using a differential reinforcement of low rates (DRL) operant conditioning schedule. Four adult Rhesus monkeys (2 males, 2 females) were trained to respond for food pellet rewards on a DRL 28 sec schedule for 60 min each day while housed in a sound-attenuated booth. The monkeys had been trained for more than two years to a stable performance baseline prior to these drug tests. They had had some previous experience with these compounds, but had not received any drug for at least 3 months prior to this study. Atropine SO_4 (0.014, 0.044, 0.14, 0.44 mg/kg) or benactyzine HCl (0.054, 0.17, 0.54, 1.7 mg/kg) was administered i.m. on alternate tests with doses administered according to a randomized design. Atropine was given 45 min prior to the sessions, benactyzine 15 min prior to the session. The two sessions prior to each drug test were regarded as controls. The eight control sessions for each drug were averaged to obtain a mean control performance with which to compare the effects of drug treatment. At least one week, and four test sessions, intervened between drug tests. Both anticholinergic drugs had a similar pattern of effect: total responding was not effected by any dose of atropine ($F(4,12) = 0.35$) or benactyzine ($F(4,12) = 0.14$) while both drugs produced reliable reductions in the number of rewards earned (atropine $F(4,12) = 48.3$, $p < .001$; benactyzine $F(4,12) = 10.51$, $p < .01$). The two highest doses of both drugs were responsible for the loss of rewards and reduction in efficiency. While group mean total responding did not reliably change at any of the doses tested, there was a dose-related increase in the variability of responding. When compared to control performance the variance for total responses was increased 16-fold by the high dose of atropine, and 11-fold by the high dose of benactyzine. In all cases the two highest drug dosages produced a flattening and a shift to shorter interresponse times of the unimodal response distribution curves that are typical of well trained DRL performance. There was some evidence of a within-session behavioral tolerance, in that errors under drug tended to occur most frequently in the first half of the session. Atropine was by far the more potent of the two compounds, producing a 71% reduction in rewards earned at the 0.44 mg/kg dose as contrasted with a 39% reduction in rewards produced by 0.54 mg/kg benactyzine. The results indicate the primary effect of these anticholinergic drugs was to produce an underestimation of the DRL interval which resulted in a decrement of efficient performance.

2234 AREA POSTREMA LESION ELIMINATES THE ANTIAGGRESSIVE AND AVERSIVE CONDITIONING PROPERTIES OF LITHIUM. John J. McGlone, Sue Ritter and Keith W. Kelley*. Dept. of Animal Science and College of Veterinary Medicine, Wash. State Univ., Pullman, WA 99164.

Previous experiments have demonstrated the ability of lithium (Li) to reduce aggression in animals. Doses of Li used in animal aggression studies, however, are also effective in producing conditioned taste aversions (CTA), suggesting that malaise and toxicity may contribute to Li's antiaggressive effect. We attempted to test this hypothesis in two experiments. Since many chemicals that produce emesis or malaise do so by their action on the chemoreceptive zone of the area postrema (AP), it seemed possible that some of the side effects of Li might also be mediated at this site. Therefore, in the first experiment, we investigated the possibility that thermal lesions of the AP would reduce Li-induced malaise, as indicated by the CTA test. In the second experiment, the antiaggressive effect of Li was evaluated in AP-lesioned rats. Fifteen female and 12 male rats were used in these experiments. Lesions were confirmed by histology.

In the first experiment, AP-lesioned and sham-operated rats were tested for CTA after pairing of a novel palatable food with lithium chloride (3mEq/kg), scopolamine methyl nitrate (1 mg/kg), d-amphetamine sulfate (2 mg/kg) or saline (.15M). Although strong aversions were demonstrated by sham-operated rats after Li and scopolamine, aversions were not induced by these substances in AP-lesioned rats ($p<.05$). AP-lesioned rats, however, formed strong taste aversions to a novel solution paired with amphetamine ($p<.01$), indicating that their taste aversion deficits after Li and scopolamine cannot be attributed to generalized behavioral or sensory disruption resulting from the lesion. These results suggest that AP lesions may significantly attenuate Li-induced malaise.

In the second experiment, sham-operated and AP-lesioned rats, previously screened in the taste aversion test, received daily intraperitoneal injections of saline or Li (5 mEq/kg) for 5 days prior to aggression tests. Rats were paired by surgical procedure, sex and weight. Pairs were tested for latency and frequency of shock-induced aggression in a chamber where constant current shocks were delivered through the floor grid. Attacks were scored during 2 one-min trials. Our results reveal that Li increased the latency to attack in sham-operated rats, compared to saline-treated shams (18.3 + 3.3 sec vs 7.3 + 3.7 sec, $p<.05$). In contrast, AP-lesioned rats treated with Li attacked with a latency similar to AP-lesioned rats treated with saline (6.2 + 4.3 vs 5.5 + 4.3, $p>.1$). These data suggest that at the doses of Li used in these studies, drug-induced malaise may mediate Li's antiaggressive effects.

2235 INTERACTION OF ℓ-DOPA OR 5-HTP AND IMIPRAMINE ON SCHEDULE PERFORMANCE IN THE RAT. P.S. McGuire* and L.S. Seiden. University of Chicago, Chicago, IL. 60637.

Administration of 10.0 mg/kg imipramine (IMI, 1 hour prior to the experimental session) to rats performing on a differential-reinforcement-of-low-rate schedule (DRL > 18-sec.) of water reinforcement increases reinforcements and decreases responses. To investigate the possible involvement of neurotransmitters in this effect, rats performing on a DRL > 18-sec. schedule were treated with dihydroxyphenylalanine (ℓ-DOPA, 2.5 - 200.0 mg/kg, i.p. and 50 mg/kg RO4-4602, i.p.) or 5-hydroxytryptophan (5-HTP, 2.5 - 200.0 mg/kg, i.p. and 50 mg/kg RO4-4602, i.p.). ℓ-DOPA decreased both response rate and reinforcement rate at doses of 50.0 - 200.0 mg/kg; lower doses had no significant effect. Interresponse time (IRT) distributions for individual rats showed variable effects. In some rats, doses of 2.5 and 25.0 mg/kg ℓ-DOPA decreased the number of short IRTs and increased the number of IRTs longer than 18-sec. Other rats were unaffected. Higher doses of ℓ-DOPA flattened the IRT distributions. 5-HTP increased response rate and decreased reinforcement rate at doses of 50.0 - 200.0 mg/kg. These doses of 5-HTP increased the number of IRTs shorter than 18-sec. and decreased the number of reinforced IRTs. Following determination of dose-response curves for each drug alone, all doses of ℓ-DOPA and 5-HTP were given in combination with 10.0 mg/kg IMI. IMI potentiated both the response rate and reinforcement rate decreases seen with ℓ-DOPA. The response rate increases produced by 5-HTP (50.0 - 200.0 mg/kg) were blocked when 10.0 mg/kg IMI was administered. These data suggest a differential disruption in DRL performance as a function of interference with specific neurotransmitter systems. (Supported by USPHS GRants MH-11191; MH-14274; and 5-K05-MH-10562).

2236 CHARACTERISTICS OF APOMORPHINE-INDUCED HYPOTHERMIA IN MICE. M. K. Menon, Psychopharmacol. Res. Lab., VA Medical Center, Sepulveda, CA 91343.

In male Swiss mice, apomorphine HCl (APO) caused a dose-dependent (0.5--20.0 mg/kg) decrease in the core temperature, a 10 mg/kg dose caused a 2° 8° C drop at 30 min. This dose and time schedule was used in all the following studies. A second dose of APO administered 3 hr after the first dose caused only a 46 percent response. Chlorpromazine (3 mg/kg, 10 min), haloperidol (1 mg/kg, 10 min), pimozide (1 mg/kg, 2 hr) and (+) butaclamol (1 mg/kg, 10 min) blocked both the hypothermia as well as the behavioral responses of APO, but αMT (280 mg/kg, 4 hr), clozapine (3 mg/kg, 10 min) and (-) butaclamol (5 mg/kg, 10 min) failed to do so. Piribedil (20 mg/kg, 10 min) and bromocryptine (3 mg/kg, 10 min) neither produced hypothermia nor did they block APO hypothermia. Phenoxybenzamine (15 mg/kg, 2 hr), propranolol (10 mg/kg, 10 min), methysergide (3 mg/kg, 10 min), cinanserin and xylamidine (both 10 mg/kg, 10 min) and PCPA (3 X 100 mg/kg) potentiated APO effect. The 5-HT receptor agonists quipazine and MK-212 (both 3 mg/kg, 10 min) specifically blocked the hypothermic response. Desipramine (20 mg/kg, 30 min) blocked the APO effect even in animals pretreated with αMT.

A 0.2 mg/kg haloperidol (10 min prior) blocked the hypothermic response of a 5 mg/kg dose of APO, but not that of 20 mg/kg APO which demonstrated that the blockade is surmountable. Chronic haloperidol treatment did not modify the intensity of APO-induced hypothermia but potentiated its behavioral responses. The doses (mg/kg) of neuroleptics required to block 90-95 percent response of APO were as follows: Chlorpromazine, 3.3, (+) butaclamol, 1.0 and haloperidol, 1.0. Trifluperazine, even in doses of 5 mg/kg caused only a 63 percent blockade of APO response. In this regard, the potencies of the two phenothiazines did not correlate with their antipsychotic potency.

2237 DIFFERENTIAL ATTENUATION OF AMPHETAMINE- AND COCAINE-INDUCED STEREOTYPIES AND SUPPRESSION OF PRIMATE SOCIAL BEHAVIOR BY ANTIPSYCHOTIC DRUGS. Klaus A. Miczek and Hiroyuki Yoshimura*. Dept. Psychol., Carnegie-Mellon Univ., Pittsburgh, PA 15213.

Withdrawal from social interactions is one of the striking symptoms of psychosis that has received little experimental attention. The preclinical study of antipsychotic drugs has focussed mainly on their ability to block stereotyped motor acts induced by dopaminergic agonists. It was our objective to induce "psychotic-like" changes in social behavior in members of established troops of squirrel monkeys by repeated administration of d-amphetamine or cocaine, to study the effects of haloperidol, chlorpromazine and physostigmine on psychostimulant-induced suppression of social communication, and to compare these effects to those on motor stereotypies. In the first series of experiments, either d-amphetamine (1 mg/kg) or cocaine (10 mg/kg) were injected p.o. three times within 24 hrs to one of the adult male members of each of four colonies of Saimiri sciureus (n=6-9). The third injection was preceded by administration of chlorpromazine (0.25, 0.5, 1.0 mg/kg, p.o.), haloperidol (0.25, 0.5 mg/kg, p.o.) or physostigmine (0.04, 0.08 mg/kg, i.m.). At the time of peak effect, an uninformed observer, using the focal animal technique, measured the frequency and duration of all social behavioral elements that the drugged monkey initiated or was recipient of (genital display, displacing, grasping, huddling) via a computer-based keyboard system. In addition, the level of motor activity was assessed and rapid head movements were counted as the most prominent stereotypy. We found that d-amphetamine and cocaine severely decreased all social interactions and increased stereotyped head movements. Chlorpromazine, haloperidol and physostigmine blocked the cocaine- and amphetamine-induced stereotypies and changes in motor activity. Haloperidol attenuated social withdrawal due to amphetamine, but produced dyskinesia in cocaine-treated monkeys. Physostigmine increased social behavior that was reduced by cocaine, but less so in amphetamine-treated animals. At doses which blocked stereotyped behavior, chlorpromazine-treated monkeys were sedated and haloperidol-treated monkeys showed dyskinesia. In a second series of experiments, we focussed on agonistic behavior in resident-intruder confrontations and on affiliative behavior toward familiar group members. We employed low doses of haloperidol (0.05, 0.1 mg/kg), chlorpromazine (0.25, 0.5 mg/kg) and physostigmine (0.03, 0.06 mg/kg) which avoided side-effects that interfered with social behavior. Our data provide evidence that psychostimulant-induced changes in primate social behavior are highly sensitive to the action of antipsychotic drugs and may be based on different mechanisms than those for motor stereotypies.

2238 METHADONE EFFECTS ON TWO TYPES OF BEHAVIOR: RELATION TO CATECHOLAMINES. Lawrence D. Middaugh and Larry W. Simpson*. Depts. of Biochemistry and of Psychiatry and Behavioral Science, Med. Univ. of So. Car., Chas., S.C. 29403.

Methadone elevates locomotor activity of C-57 mice at doses up to 7.0 mg/kg. Higher doses of the drug first elevate, then reduce and again elevate activity across time after injection. In DBA mice, however, methadone only reduces activity regardless of the time after injection or the dose of methadone. For both strains of mice, however, the drug is disruptive to lever responding maintained by fixed ratio schedules of reinforcement but has a greater effect on DBA mice. The lack of consistent strain differences in the effects of methadone on locomotor activity vs. the lever response suggests the possibility that the effects on the two behaviors are mediated by separate neural systems.

In subsequent studies we found that the elevated activity noted under some doses and post-injection times for C-57 mice was dependent upon adequate stores of catecholamine since α-methyltyrosine (AMT), although not altering activity itself at the dose used, attenuated the methadone induced elevation of activity. Similar reductions in catecholamine concentrations (approximately 30%), however, had no effect on methadone induced reductions in locomotor activity observed in DBA mice and at higher doses for C-57 mice; or on drug induced disruption of lever responding for either strain. The requirement of catecholamine for methadone induced elevations in activity implicates one of the dopaminergic or noradrenergic tracts in mediating this drug response. The absence of this requirement for the reduction of locomotor activity or disruption of lever pressing following injections of methadone is consistent with the hypothesis that locomotor activity increases are mediated by neural systems different from those mediating the locomotor activity or lever press reductions. (Supported by Grant # DA 01750)

2239 INSENSITIVITY OF THE DORSAL RAPHE TO THE DISCRIMINATIVE STIMULUS PROPERTIES OF LSD. D.J. Minnema*, G. Krynock* and J. Rosecrans. Dept. of Pharmacol., Med. Col. of Va., Richmond, VA 23298.

Previous studies have strongly suggested that the dorsal raphe may be a major site of LSD action. To examine this possibility fourteen male Sprague-Dawley rats were trained to discriminate 96 µg/kg LSD from saline on a VI-15 second schedule of reinforcement for sweetened milk using a two lever operant paradigm. Operant sessions were 15 minutes long. The accuracy of LSD discrimination was determined during a 2.5 minute extinction period which was presented every fourth day preceding the training session. Once reliable discrimination was obtained (i.e. > 80% drug-lever responding with LSD, < 20% drug-lever responding with saline), chronic, indwelling guide cannulas for microinjection were stereotaxically implanted into the area of the dorsal raphe. After reestablishment of reliable LSD discrimination, various doses of LSD were administered via a 31 gauge needle into the dorsal raphe. The LSD was dissolved in artificial CSF and delivered in volumes not exceeding 0.5 µls. Extremely high doses of LSD (∿ 50 µg/kg) administered to the dorsal raphe were needed to produce generalization (∿ 80%) to the drug-lever. A time course study indicated that the duration of LSD generalization of the centrally administered drug closely mimicked the duration of peripherally administered drug. These results suggest that the dorsal raphe is relatively insensitive to the discriminative stimulus properties of LSD when the drug is applied directly at this site. Furthermore, the time-course data suggest that the LSD may be rapidly diffusing away from the site of injection and acting directly, or through the circulation, at other sites in the brain. (Supported by U.S.P.H.S. grant #DA-00296-05).

2240 NORADRENERGIC RESPONSIVENESS IN RAT PINEAL GLAND AFTER SINGLE OR REPEATED ADMINISTRATION OF DESMETHYLIMIPRAMINE. John A. Moyer, Alan Frazer*, Benjamin Weiss, Louise H. Greenberg and Joe Mendels*. Univ. of Pennsylvania Sch. Med., Pennsylvania Med. College, and V.A. Hospital, Philadelphia, Pa. 19104.

The effect of single and repeated desmethylimipramine (DMI) treatment on catecholamine-stimulated production of adenosine 3',5'-monophosphate (cyclic AMP) in rat pineal gland was studied both in vivo and in vitro. Male Sprague-Dawley rats were injected with DMI (10mg/kg, i.p.) either once as a single injection or twice daily for 5 days. Control rats received saline injections for corresponding time periods. Pineal gland concentrations of cyclic AMP were stimulated by the intraperitoneal administration of either isoproterenol (ISO) or norepinephrine (NE) (in vivo experiments) or by incubating glands with different concentrations of ISO or NE.

Acute DMI treatment increased the ability of NE injected in vivo to stimulate pineal cyclic AMP; repeated administration of DMI completely prevented the stimulatory effect of NE or ISO on pineal cyclic AMP in vivo. In pineal glands obtained from rats given DMI for 5 days, the stimulation of cyclic AMP produced by NE or ISO added in vitro was significantly reduced, even at concentrations of the agonists producing maximal stimulation of cyclic AMP.

Acute treatment with DMI had no significant effect on [^{3}H] dihydroalprenolol binding in pineal glands, whereas chronic treatment significantly reduced [^{3}H] dihydroalprenolol binding. Furthermore, when the enzyme adenylate cyclase was measured, it was found that repeated DMI treatment had no significant effect either on basal or NaF-stimulated enzyme activity, but NE-stimulated activity was reduced.

Repeated DMI treatment reduces the ability of ISO or NE administered either in vivo or in vitro to elevate the concentration of cyclic AMP in pineal glands. This effect is due, at least in part, to a decreased number of ß-adrenergic receptors and reduced NE-stimulated adenylate cyclase activity in pineals exposed to repeated DMI treatment. 2241 REINFORCING EFFECTS OF INTRAVENOUS AND INTRACRANIAL OPIATES REVEALED BY A PLACE PREFERENCE PARADIGM. R.F. Mucha* and D. Van der Kooy (SPON: M.A. Linseman). Departments of Pharmacology and Anatomy, University of Toronto and Addiction Research Foundation, Toronto, Ontario, Canada. M5S 2S1

The bases of opiate reinforcement are still not known; its neuroanatomy, its relation to other opiate effects, and the role of tolerance and physical dependence in its production remain poorly understood. Since this deficiency largely reflects the lack of suitable paradigms for studying these aspects of opiate reinforcement, the present study demonstrated the suitability of the place preference paradigm for such a purpose. It was based on the demonstration that rats prefer environments in which they received i.p. morphine over other environments (Reid et al., Soc. Neurosci. Abt. 1978, 4, 501). Intravenous (i.v.) administration, the route most commonly used to produce reinforcement, was initially studied. Male Wistar rats were placed in one of two distinct environments: a black 40x40x37 cm box with a Plexiglas floor or a similar white box with a sawdust floor. Through implanted cannulae, each rat then received 0, 0.5 or 10 mg/kg morphine -SO_4, infused over 2 min. These training trials lasted 30 min. and occurred daily for 4 days. Noninfusion training trials were also given each day in the other box. Morphine infusions produced hypoactivity in all the rats. In the 10 mg/kg rats immobility and analgesia were noted at the end of the training trials. On day 5 the rats were tested by providing simultaneous access to both treatment environments for 15 min. These were found at the ends of a 90x40x37 cm test box, separated by a 10x40x37 cm neutral area with grey walls and grid floor. The 10 mg/kg group displayed a clear preference for the environment in which they received morphine, spending 3 times as much time on this side of the test box compared to the side associated with the noninfusion.

Intracranial administration of opiates was studied next. Morphine was administered into the lateral hypothalamus (0.5 ug in 0.5 ul, bilaterally over 2 min with 30 gauge inner cannulae) and rats were trained as above in the place preference paradigm. In contrast to i.v., hypothalamic morphine produced marked hyperactivity, "in vacuo" mouth movements, and frantic grooming. On the test day clear evidence of a positive reinforcing effect was seen. These data indicate that analgesia and immobility are not necessary for opiate reinforcement. Thus, the place preference paradigm may be a powerful tool for exploring the central motivating properties of opiates because of its ability to detect reinforcing effects in a few discrete drug exposures. We are currently using this paradigm to explore the reinforcing effects of other intracranial sites and will report some of the data.

2242 BEHAVIOURAL SUPERSENSITIVITY TO DOPAMINE-MIMETICS AFTER REPEATED AGONIST OR ANTAGONIST TREATMENT. INVOLVEMENT OF AUTORECEPTORS. Pavel Muller, Torgny H. Svensson and Arvid Carlsson*. Dept. of Pharmacol., University of Göteborg, S-400 33 Göteborg, Sweden.

Long-term treatment with both dopamine agonists and antagonists induces augmented behavioural responses to dopamine mimetics. This phenomenon has been attributed to sensitization of postsynaptic dopamine receptors. However, the postsynaptic receptor changes after long-term neuroleptic treatment develop much later than the behavioural sensitization for which they were proposed to account. Thus, an enhanced response to apomorphine was reported already 24 hours after single injections of neuroleptics. In addition, long-term amphetamine treatment does not appear to produce any postsynaptic receptor supersensitivity. We report here the results of behavioural and electrophysiological experiments designed to study the function of dopamine autoreceptors in rats following single or repeated agonist or antagonist treatment. Our experiments indicate that 24 hours after a single injection of haloperidol (0.5-5 mg/kg) the autoreceptor response to exogenously administered apomorphine is reduced, probably due to blockade of these receptors by residual haloperidol. Long-term amphetamine treatment (5 mg/kg daily for 2 weeks, 48 h withdrawal) induced desensitization of the autoreceptors, while leaving the postsynaptic dopamine receptors apparently unaffected. The blockade of the autoreceptors by haloperidol or their desensitization after chronic amphetamine treatment implies a reduced "presynaptic" inhibition of dopamine neurons by exogenously administered dopamine-mimetics. Thus, more dopamine will be available to stimulate the postsynaptic receptors together with the exogenous agonist. Consequently, an augmented behavioural response to exogenously administered dopamine-mimetics such as apomorphine may be the outcome of a reduced dopamine autoreceptor function.

2243 SYSTEMIC OR INTRACEREBRAL ADMINISTRATION OF d-AMPHETAMINE DECREASES ACTIVITY IN HYPERACTIVE, SPONTANEOUSLY HYPERTENSIVE RATS. Richard E. Musty, Michael M. Myers*, Janice A. Forgays* and Edith D. Hendley. Depts. Psychology and Physiology & Biophysics, Univ. Vermont, Burlington, VT 05405.

A number of recent studies have shown that the spontaneously hypertensive rat (SHR), a strain derived from the normotensive Wistar Kyoto rat (WKy), is hyperactive as well as hypertensive. Increased locomotor activity in the open field test was found in both young (4 - 5 wk) and older (9 - 13 wk), male and female SHR (Myers et al., Fed. Proc. 36, 1977). We now report that both peripheral and central injections of d-amphetamine decrease locomotor activity in the SHR.

In the first study 10 - 12 wk old SHR and WKy rats were injected with d-amphetamine (5 mg/kg i.p.), and after 45 min were tested for 5 min in an open field. We found that while the WKy gave the expected increase in locomotor activity, SHR demonstrated a significant reduction in activity. In a second experiment SHR and WKy rats were given systemic d-amphetamine in dosages of 1.0, 2.0 or 5.0 mg/kg i.p., and then tested in an automated activity box for 1 h following injection. As in the previous study, WKy increased while SHR decreased their activity in a dose-dependent fashion and at all doses tested.

In the next experiment we sought to localize a central nervous system structure involved in these effects of d-amphetamine. The nucleus accumbens is known to be important in the control of spontaneous locomotor activity, and it is known that d-amphetamine injection into this area increases locomotor activity (van Rossum et al., Adv. Biochem. Psychopharm. 16:201, 1977). Female SHR and WKy rats were bilaterally implanted with cannulae in the n. accumbens, and 1 wk later were infused with either saline (1 µl) or d-amphetamine in saline (10µg in 1 µl), bilaterally in the n. accumbens. Results indicated that following saline infusion, activity of the SHR was significantly greater than the WKy. However, after infusion of d-amphetamine, WKy rats increased their activity while SHR showed a dramatic decrease in activity.

These data suggest that the SHR may provide an animal model for examining the paradoxical responses to d-amphetamine found in hyperactive children.

2244 DIFFERENTIAL OPIATE EFFECTS ON INTRACRANIAL SELF-STIMULATION THRESHOLDS IN SUBSTANTIA NIGRA (A-9) AND VENTRAL TEGMENTUM (A-10). Jules M. Nazzaro*, Thomas F. Seeger* and Eliot L. Gardner. Depts. of Psychiatry, Neuroscience and Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, New York 10461.

In order to differentiate the roles of the nigro-striatal and mesolimbic-mesocortical dopamine systems in the action of opiates on dopaminergically mediated intracranial self-stimulation (ICSS), the effects of chronic morphine and acute naloxone on ICSS was tested in rats with electrode placements in the substantia nigra pars compacta (A-9) and the ventral tegmentum (A-10). To control for non-selective alterations in motor activity, arousal level or coordination, a rate-independent threshold reward titration paradigm for ICSS was utilized.

At the doses used, rats with electrodes in A-9 showed a large increase in ICSS threshold following both acute and chronic morphine treatment. Little or no tolerance to this threshold elevating effect of morphine was observed with 5 days of chronic administration. The threshold elevation was not reversed by naloxone given 0.5 hour after the final morphine treatment. In contrast, acute morphine significantly lowered self-stimulation threshold in rats with A-10 placements. Tolerance to this facilitatory effect was evident with chronic administration. Naloxone attenuated the lowering of threshold caused by opiate administration in these A-10 animals. Also, acute naloxone, administered prior to initiation of the morphine regimen, had no effect on basal self-stimulation threshold in either brain locus.

The present data suggest a specificity of action of opiates on different brain systems subserving reward and reinforcement. These findings also suggest that the mesolimbic-mesocortical system may constitute one focal area mediating the rewarding properties of morphine. (Supported, in part, by USPHS grant DA 01560.)

2245 NALOXONE REVERSIBILITY OF ETHANOL'S EFFECTS ON SEXUAL BEHAVIOR OF THE FEMALE SYRIAN HAMSTER. Jeffrey L. Nelson*, Nancy L. Ostrowski, Ralph G. Noble*, and Larry D. Reid. Dept. of Psychol., Rensselaer Polytechnic Institute, Troy, NY 12181.

This study evaluated the potential for naloxone to reverse ethanol's suppression of female sexual reflexes. The subjects were 24 ovariectomized, estrogen and progesterone-primed female hamsters, randomly assigned to 4 groups. Each group received two injections: (a) ethanol and naloxone, (b) ethanol and saline, (c) saline and naloxone, or (d) saline and saline while measurements of sexual behavior were made before and after each injection. Each subject's sexual reflexes were tested immediately before and again 10 min after a subcutaneous (sc) injection of ethanol (1.5 ml/kg in 10% solution) or physiological saline (15 ml/kg). Sexual reflexes, as measured by lateral displacement (the amount of lateral movement obtained when a tactile stimulus is applied to a female's perineal region while in a lordotic posture), were reduced about 50% with this dose of ethanol [saline vs ethanol, $t(22) = 7.47$, $p < .001$].

Following the 2nd test, i.e., the test for ethanol's effects, each subject received a sc-injection of naloxone hydrochloride (4 mg/kg) or physiological saline (1 ml/kg). Then they were again tested at 5 min and 20 min after this 2nd injection. Comparing subjects' difference scores (found by subtracting a subject's baseline score from the score in question) between groups getting naloxone or saline after ethanol yielded a $t(10)$ for the measurement 5 min after 2nd injection = 2.03, $p < .05$; $t(10)$ for 20 min after 2nd injection = 3.32, $p < .01$. The difference scores for subjects receiving ethanol and then naloxone were (a) under ethanol = -26.8, (b) under ethanol and naloxone, 5 min after injection = -8.5, and (c) under ethanol and naloxone, 20 min after injection = -4.5 compared to the same measurements of subjects receiving ethanol and then saline of -29.8, -29.2, and -32.3, respectively. Hamsters not receiving ethanol typically showed scores at or above baseline with injections and multiple measurements.

These results suggest the possibility of opioid involvement in ethanol's capability to modify female sexual behavior. A preliminary test with males provides some support for the idea that the effects may not be limited to female sexual behavior. (Supported by NSF grant BNS 78-17860.

2246 BEHAVIORAL COMPENSATION, MUSCARINIC RECEPTORS AND TOLERANCE DEVELOPMENT TO PHYSOSTIGMINE. David H. Overstreet* and Grant D. Schiller* (SPON: Tim Schallert). School of Biological Sciences, Flinders University, Bedford Park, South Australia 5042 Australia.

The contribution of behavioral compensation to tolerance development to physostigmine (0.5 mg/kg once daily) in rats was assessed by comparing the rates of tolerance development to physostigmine's suppressant effects on operant behavior (responding for water reward on an FR5 schedule) in groups treated chronically either before or after the operant session. The groups exhibited comparable rates of tolerance development to physostigmine, indicating that behavioral compensation does not plan a major role.

Challenges with the muscarinic receptor agonist, pilocarpine, revealed that the operant responding of the physostigmine-tolerant and control groups was suppressed to comparable degrees, suggesting that a decrease in the sensitivity of muscarinic receptors does not play a role in tolerance development to physostigmine. Binding assays with the specific muscarinic antagonist, ^{3}H-Quinuclidinyl benzilate, revealed similar densities of muscarinic binding sites in the tolerant and control groups, suggesting that a change in muscarinic receptor properties is also not involved in tolerance development to physostigmine.

These findings suggest that behavioral compensation and alterations in muscarinic receptors are unlikely mechanisms underlying tolerance to physostigmine. Therefore, mechanisms underlying tolerance to carbamate anticholinesterases appear to be different from those underlying tolerance to organophosphate anticholinesterases (See Schiller, Life Sciences 24, 1159-1164, 1979). (supported by a grant from the Australian Research Grants Committee to D.H. Overstreet and USPHS grants to H.I. Yamamura).

2247 CENTRAL CYCLIC NUCLEOTIDE SYSTEMS: MODIFICATION BY DIHYDROXY CHLORPROMAZINES. Gene C. Palmer, S. Jo Palmer* and Albert A. Manian*. Dept. Pharmacol., Univ. So. Ala. Col. Med., Mobile, AL 36688 and the Psychopharmacol. Res. Br., NIMH, Rockville, MD 20857.

Chlorpromazine (CPZ) is used primarily to treat symptoms of psychosis. The central action of CPZ is thought to be due to an antagonism of dopamine (DA) and norepinephrine neurotransmitter actions via a blockade of postsynaptic receptors coupled to the adenylate cyclase systems. A large number of metabolites of CPZ have been shown to possess varying degrees of pharmacological activity toward central adenylate cyclase systems. One such group, the dihydroxy CPZs, especially 7,8-dioxo- and 7,8-diOH- and 3,7,8-triOH-CPZs display potent antagonism of various components of the adenylate cyclase receptor complex, i.e., basal, receptor and fluoride-sensitive catalytic sites. Our interest has been to understand the molecular action of this highly active group. The kinetic profile of 7,8-diOH-CPZ inhibition of basal or DA activated adenylate cyclase (homogenates of rat frontal cortex) appeared to be noncompetitive with respect to ATP concentration. The elevation by Mg^{++} of basal, GTP and DA components of adenylate cyclase were all antagonized by 7,8-diOH-CPZ, an event not overcome by adding excess Mg^{++}. Increasing the concentration of Ca^{++} elevated basal activity but reduced stimulation by DA and GTP analogs. 7,8-diOH-CPZ did not influence enzyme activity by increasing the content of Ca^{++}. Alternatively in recent work, a number of diOH analogs (3,8-diOH; 3,7-diOH; 6,9-diOH; and 7,9-diOH) appeared to elevate both basal and DA-activation of adenylate cyclase. These compounds were subsequently shown to inhibit cyclic AMP-dependent phosphodiesterase (high Km, low Km and the high Km-Ca^{++}-dependent activator form). The latter enzyme subtype was especially susceptible to inhibition. The findings indicate a complex series of interactions by diOH-CPZs at synaptic sites involving central catecholamine mechanisms. As to how these effects influence the therapeutic or adverse profile of the parent compound in patients remains an unanswered question. (Supported by the Epilepsy Foundation of America).

2248 KANAMYCIN EFFECTS ON EXPLORATION, AGGRESSION, AND SEIZURE SUSCEPTIBILITY IN MICE. V. P. Perdue*, W. W. Eastman*, K. M. Michels*, E. A. Fink*, P. J. Donovick and R. G. Burright*. Dept. Psych., SUNY Binghamton, Binghamton, N.Y. 13901.

Kanamycin is an antibiotic which has effects similar to streptomycin. It shares broad range antimicrobial properties of streptomycin and related compounds and has similar side effects including ototoxicity and nephrotoxicity. Both cochlear and vestibular functions may be impaired. Loss in high frequency perception is the most common auditory side effect. The present investigation examined the behavior of adult mice as a consequence of the administration of kanamycin.

Singly housed adult male Binghamton heterogeneous stock (HET) mice, were injected daily for twenty days, continuing until the mice were approximately 70 days of age when behavioral testing began. Mice received either 400 mg/kg of kanamycin sulfate (supplied by Dr. M. J. Weinstein, Schering Corporation) or equal volume saline injections. The two consecutive days of behavioral testing included home cage observations, open field exploration measures, and aggression testing. For aggression testing, pairs of either kanamycin or saline injected mice were separated from each other by a barrier in a single cage for two days. On the third day the barrier was removed and agonistic behavior observed for 30 minutes. Most mice fought and latency to contact and fight was approximately equal for the two treatment groups. However, kanamycin mice fought much more frequently during the first 15 minutes of the test period. The rate of fighting per minute was less in the saline control group and distributed more evenly throughout the entire 30 minute test period.

In their home cage kanamycin treated mice were less active under these conditions than their control counterparts. However, when tested in the open field for 3 minutes, kanamycin treated mice were more active than their control counterparts. The introduction of a flashing light during the second minute of testing had differential effects on the two groups. Finally, frequency and duration of transcorneally induced seizures was enhanced by kanamycin.

These results suggest that prolonged administration of kanamycin affect a wide range of behaviors. We are currently examining the effects of kanamycin injection in preweanling animals and their ability to recover from such trauma. We are also in the process of attempting to differentiate the auditory consequences of kanamycin injections from its other undesirable side effects.

2249 ANTICHOLINERGIC ACTIVITY OF IMIPRAMINE ANALOGS AT MUSCARINIC RECEPTORS OF CULTURED MOUSE NEUROBLASTOMA CELLS. Ronald C. Petersen* and Elliott Richelson (SPON: B. Westmoreland) Mayo Medical School, Depts. of Psychiatry and of Pharmacology, Mayo Fdn., Rochester, MN 55901

The interaction of tricyclic antidepressants with neurotransmitter receptors may explain their therapeutic and/or adverse pharmacological effects. Previously, we studied a number of these drugs for their ability to antagonize muscarinic acetylcholine and histamine H_1 receptors. To obtain more definitive structure-activity information for the anticholinergic activity of tricyclic antidepressants, we studied imipramine and several of its analogs for their ability to inhibit muscarinic receptor-mediated cyclic GMP (cGMP) synthesis by mouse neuroblastoma cells (clone N1E-115) with the use of an assay technique described in detail elsewhere.[1] For these experiments different groups of cells were incubated with increasing concentrations of antagonist (i.e., the imipramine analogs) for 30 min in a shaker bath at 37° prior to stimulation with carbamylcholine (250 µM) for 30 sec. The concentration of antagonist required for half-maximal inhibition of cGMP synthesis was determined and the inhibition constant (K_i) was calculated assuming competitive inhibition at the muscarinic receptor and using a K_A = 200 µM for carbamylcholine (E. Richelson, unpublished data). The K_i's were essentially identical to the equilibrium dissociation constants (K_B) as determined by the dose-ratio method for the compounds which were tested by both techniques. The rank order of potency of these drugs as muscarinic antagonists was as follows: imipramine = 3-chlorimipramine > desmethylimipramine > 3-chloro-2-hydroxyimipramine ≥ 2-hydroxyimipramine >> didesmethylimipramine. The most potent drugs, imipramine and 3-chlorimipramine, were about 30 times more potent than the least potent compound, didesmethylimipramine. These results suggest the following structure-activity relationships for imipramine and its analogs: 1) The type of amine on the side chain is predictive of antimuscarinic activity with tertiary > secondary > primary; 2) 2-hydroxyl ring substitution markedly reduces activity of these compounds; and 3) 3-chloro and N-oxide substitutions have no effect on antimuscarinic activity. These structure-activity relationships for imipramine and its analogs at the muscarinic receptor may have important implications for predicting some side effects of these drugs in vivo. (Supported by Mayo Foundation and USPHS Grants MH 27692 & DA 1490)

[1]Richelson, E., Prendergast, F.G. and Divinetz-Romero, S. Muscarinic receptor-mediated cyclic GMP formation by cultured nerve cells: Ionic dependence and effects of local anesthetics. Biochem. Pharmacol., 27:2034-2048, 1978.

2250 THE EFFECT OF AMITRIPTYLINE ON BRAIN ETHANOL CONCENTRATIONS. S. Preskorn, and P. Alward* Dept. Psy., Sch. Med., KUMC, Kansas City, KS 66103

Tricyclic antidepressants (TCA) are known to interact with ethanol. However, these interactions are unpredictable. Both enhancement and antagonism have been reported. Recently TCA have been shown to increase the cerebral extraction fraction of diffusion-limited substances such as water and ethanol (Preskorn and Hartman, Biol. Psychiat. 14:235, 1979). For amitriptyline (AMI) this increase results from an augmentation in capillary permeability (Preskorn et al., Neuroscience Abstracts 5:500, 1978).

Based upon these findings, it was hypothesized that the AMI-induced enhancement of permeability would increase brain ethanol concentrations if ethanol is administered in conjunction with AMI. To test this hypothesis, rats were given intraperitoneally (i.p.) either: (I) ethanol alone (2gm/kg) or (II) ethanol plus AMI (62.5µmols/kg). Animals were decapitated at 5',15',30',45', and 60'. The brain and plasma ethanol concentrations were determined by gas chromatography.

The results are as follows. The absolute plasma ethanol concentrations did not differ between the two groups, indicating that AMI did not alter intraperitoneal absorption of ethanol. However, AMI did increase the brain:plasma concentration ratio at 5',15' and 30' (Table I, $0<0.001$). Ratios at 45' and 60' were lower than at 30' but still elevated above the control condition.

	Brain:Plasma Ethanol Concentration Ratio			
Time	Ethanol Alone	(n)	Ethanol + AMI	(n)
5'	0.72±0.03	(3)	0.96±0.00	(3)
15'	0.75±0.04	(4)	0.90±0.03	(6)
30'	0.77±0.02	(7)	0.93±0.01	(6)
45'&60'	0.74±0.02	(3)	0.84±0.05	(3)

Thus, AMI increases not only the diffusion of alcohol across the cerebral capillary but also results in a net influx of ethanol into the brain. This new observation has both clinical and basic neuroscience implications with regard to understanding drug interactions such as TCA and ethanol.

2251 BEHAVIORAL EFFECTS OF CHRONIC EARLY LEAD EXPOSURE IN MONKEYS. Deborah C. Rice* (SPON: V. G. Laties). Dept. Health and Welfare, Health Protection Branch, Tunney's Pasture, Ottawa, Ontario, Canada.

Monkeys (Macaca fascicularis) dosed orally from birth with 500 ug/kg/day of lead as lead acetate showed deficits compared to controls on a series of 20 form discrimination reversals at 2-3 years of age. There was no difference between groups in the effect of "overtraining" trials introduced between reversals. Treated monkeys also behaved differently than controls during initial sessions of a multiple fixed interval (FI) 8 min. - time out schedule of reinforcement, with lead exposure producing increased FI response rates, a "bursting" pattern of FI responding, and increased time out responding. Subtle differences in the pattern of FI responding persisted throughout the course of the study as evidenced by differences in inter-response time distribution. Blood lead levels at the time of behavioral testing were 20-40 ug/dl, which are comparable to lead levels of many children.

2252 THE EFFECT OF 6-OHDA LESIONS OF THE NUCLEUS ACCUMBENS ON COCAINE FACILITATION OF INTRACRANIAL SELF STIMULATION AND SELF ADMINISTRATION. D.C.S. Roberts, G.F. Koob, H.C. Fibiger, M.E. Corcoran, and F.E. Bloom. (SPON: R.Nick Hogan) A.V. Davis Ctr. for Behav. Neurobiology, Salk Inst., La Jolla, CA 92037 and Div. of Neurological Sciences, Univ. of British Columbia, Vancouver, Canada.

The effect of bilateral infusions of 6-hydroxydopamine (6-OHDA) into the n.accumbens was assessed on two measures of cocaine reinforcement: intravenous self-administration and facilitation of intracranial self-stimulation (ICSS).

Male Wistar rats were prepared with intravenous cannulae and trained to self administer cocaine at a dose of 0.75 mg/kg/inj. Injections were delivered with each depression of a lever during a daily 3 hr session. After self injection of cocaine had stabilized each rat received bilateral infusions of 6OHDA into the n.accumbens. All rats (N=15) showed an initial abstinence from cocaine self-administration. However, many rats showed a gradual recovery of cocaine intake. The number of post lesion days required to reach 50% recovery of pre-lesion cocaine intake correlated (r=0.81) with dopamine (DA) content remaining in the n.accumbens. The same rats which failed to respond for cocaine continued to self administer apomorphine (0.6 mg/kg/inj.) at pre lesion rates.

In an effort to establish if these lesions would also block the facilitation of ICSS from cocaine, 16 rats were prepared with electrodes in the posterior hypothalamus. Each day rats were allowed to press a lever for intracranial electrical stimulation and were tested for 5 min at eight current levels in a descending series. Half of the animals received bilateral injection of 6-OHDA (8ug/2ul) into the n.accumbens while the remaining half received vehicle injections (saline containing ascorbic acid, 0.1mg/ml). Twelve days following the lesion the animals were injected with cocaine (10mg/kg) 15 min prior to the test session. In the control animals, cocaine produced a significant shift to the left of the rate/intensity function. By contrast, the 6-OHDA group showed an attenuation of this cocaine facilitation of ICSS. These results add further support to the hypothesis that mesolimbic dopamine serves a critical role in cocaine reinforcement.

2253 AMPHETAMINE SENSITIZATION, STRESS AND GENETIC HYPERTENSION. N. Rowland, A.J. Eichler, S.M. Antelman, J. Shipley, D.Kocan and L. DeGiovanni. (SPON: J.R. Jennings). Western Psychiatric Institute & Clinic, Univ. of Pittsburgh, PA 15260.

Animals are known to exhibit sensitization with repeated amphetamine (AM) administration: in particular, single doses of AM can cause enhanced stereotyped behavior to a subsequent dose several days later. In man, AM psychosis closely resembles some forms of schizophrenia, a disease whose etiology is a combination of genetic factors and environmental stress.

In the first set of experiments, we have investigated whether stress and AM may act upon the same neural substrate(s) involved in sensitization in rats. We have already shown (Neurosci. Abstr. #1544, 1978) that repeated application of a mild stress, tail pressure (TP) produces an enhanced stereotyped response to a single dose of AM. We now report the converse experiment; a single dose of AM can produce a long-lasting "sensitization" of TP-induced eating and gnawing. That is, when tested up to 30 days after the AM injection, rats show a smaller haloperidol (HALO; 0.4 mg/kg)-induced suppression of TP behaviors than do vehicle injected controls. Similarly, a single session of footshock stress produced an enhanced AM stereotypy response two weeks later and a decreased efficacy of HALO in the TP test. To identify brain structures which might be associated with sensitization, we examined the effect of another stressor, chronic self-stimulation, which offers the advantage of site specificity, on the ability of AM later to induce stereotyped sniffing and anorexia. Nucleus accumbens and medial frontal cortex self-stimulators (but not rats with A-9 placements) showed a significant enhancement of each of these effects of AM when tested 24 hr after the last stimulation day. Since we have previously reported that food deprivation stress can produce similar sensitization, it appears that a wide variety of stress can induce the effect.

In a second experimental series we have investigated the behavioral effects of AM in spontaneously hypertensive rats (SHR) which are known to show enhanced behavioral and adrenomedullary responses to stress and therefore may be thought of as a genetic or naturally stressed preparation. We report that single doses of AM produce more intense and prolonged stereotyped behavior in SHR rats than in either WKY or Sprague Dawley (SD) controls. HALO was less effective in blocking TP behavior in SHRs than in controls, but was more effective in inducing catalepsy in these animals. This last finding suggests that the level of activation of the testing situation is an important variable in assessing the reactivity of brain catecholaminergic systems.

2254 EFFECTS OF CHRONIC ADMINISTRATION OF MORPHINE ON THRESHOLDS FOR ESCAPE BEHAVIOR MAINTAINED BY INTRACRANIAL STIMULATION. Stephen Sasson*, Howard S. Wheeling*, and Conan Kornetsky. Laboratory of Behavioral Pharmacology, Boston University School of Medicine, 80 E. Concord St., Boston, MA. 02118

It has been previously demonstrated that acute doses of morphine lower the threshold for intracranial self-stimulation (ICSS) and raise the threshold for escape from stimulation to "aversive" areas of the brain (Marcus & Kornetsky, Psychopharm., 38:1, 1974). Work in our laboratory has also shown that tolerance does not develop to the threshold lowering effect of morphine on ICSS (Esposito & Kornetsky, Science, 195:189, 1977). The present study is an attempt to determine whether or not tolerance develops to the threshold raising effect of morphine for escape from aversive brain stimulation. Six male albino rats were implanted with bipolar electrodes aimed at the mesencephalic reticular formation (RF). They were then trained to turn a wheel manipulandum in order to escape RF stimulation. Thresholds were determined by means of a modification of the psychophysical method of limits. After training and prior to the initiation of daily morphine injections, data were collected for at least 5 days in which saline was administered. Animals were given daily doses of morphine (4-20 mg/kg, s.c.) for 14 to 40 days. Starting with the first day and every 2 to 3 days thereafter, thresholds were determined before and 25 min after a test dose of morphine. The dose of morphine selected as the test dose initially raised the threshold at least 2 standard deviations above the mean saline level for the respective animal. Results indicate that tolerance does develop to the threshold raising effect of morphine; however, this loss of threshold raising effect is often contaminated by the disruption of behavior caused by abstinence. These results show that the phenomenon of tolerance to the antinociceptive effect of morphine is observable whether peripherally or centrally applied noxious stimuli are utilized. 2255 ^{3}H-SEROTONIN RECEPTOR BINDING IN RAT BRAIN: DIFFERENTIAL EFFECTS OF MONOAMINE OXIDASE INHIBITORS AND SEROTONIN RE-UPTAKE INHIBITORS Daniel D. Savage*, Alan Frazer*, and Joe Mendels* (SPON: G.B. Koelle). Dept. Pharmacol., Univ. of Penn. and Veterans Administration Hospital, Phila., Pa. 19104.

The effect of repeated administration of monoamine oxidase inhibitors and serotonin reuptake inhibitors on 5-hydroxytryptamine (serotonin; 5HT) concentration and serotonin receptors in rat cerebral cortex and pons was examined. Serotonin concentrations were measured by the fluorometric technique of Curzon and Green (Brit. J. Pharmacol. 39:653, 1970). The receptor binding assay of Bennett and Snyder (Mole. Pharm. 12:373, 1976) was used to measure serotonin receptors.

While the administration of amitriptyline (10mg/kg, bid, for 16 days) caused no significant alteration either in the concentration of serotonin or the binding of ^{3}H-5HT in the brain regions examined, injection of the monoamine oxidase inhibitor tranylcypromine (5mg/kg/day) for an equivalent period of time caused a significant reduction in ^{3}H-5HT binding, both in cerebral cortex and pons.

At no time up to 16 days of administration, did either of the serotonin reuptake inhibitors fluoxetine (10mg/kg, bid) or chlorimipramine (10mg/kg, bid) change ^{3}H-5HT binding in comparison with that measured in control rats. In contrast, a significant reduction in ^{3}H-5HT binding and an increase in the concentration of serotonin was measured in cerebral cortex and pons 24 hours after single injection of the monoamine oxidase inhibitor nialamide (40mg/kg). This effect persisted up to 16 days of treatment with nialamide.

Treatment with the relatively selective A type monoamine oxidase inhibitor clorgyline (1.0mg/kg/day, for 4 days) resulted in a significant increase in brain serotonin and a reduction in ^{3}H-5HT binding, while treatment with the B type inhibitors deprenyl (1.0mg/kg/day, 4 days) or pargyline (0.5mg/kg/day, 4 days) resulted in no change either in binding or brain serotonin concentrations.

Analysis by the method of Scatchard of the changes seen in cerebral cortex due to clorgyline treatment for four days indicated an increase in the apparent binding constant (K_D) with no change in the maximum specific binding capacity (B_{max}). Treatment of rats with nialamide for 16 days resulted both in an increase in the K_D value and a decrease in B_{max}.

In conclusion, chronic treatment of rats with serotonin reuptake inhibitors has no effect on ^{3}H-5HT binding, while type A monoamine oxidase inhibitors caused significant elevations in brain serotonin levels and decreased ^{3}H-5HT binding. (Supported by Research Funds from the Veterans Administration, NIMH Grant 29094, and USPHSGM 07302).

2256 ACUTE EFFECTS OF NEUROLEPTICS ON BRAIN SELF-STIMULATION CURRENT THRESHOLDS IN RATS. Gerald J. Schaefer and Richard P. Michael, Dept. Psychiatry, School of Medicine, Emory University and Georgia Mental Health Institute, Atlanta, GA 30322.

Rats were implanted with stimulating electrodes in the medial forebrain bundle and trained in a brain self-stimulation procedure. Each response on a conventional lever produced an electrical stimulus that was initially set at a suprathreshold intensity. Every fifth lever-press reduced the stimulation current by 5 μAmp and animals could reset the current to its initial intensity by pressing an omnidirectional lever (reset lever). The average current intensity at which the animal pressed the reset lever was defined as the reinforcement threshold. After thresholds stabilized, dose-response curves were obtained for five neuroleptic drugs, each representing a different chemical family of antipsychotic compounds. Haloperidol (0.01-0.10 mg/kg) and loxapine (0.03-0.56 mg/kg) produced dose-dependent increases in reinforcement thresholds which were accompanied by reductions in response rates (behavioral performance). Chlorpromazine (0.10-3.0 mg/kg) did not produce significant changes in reinforcement thresholds, but did produce dose-dependent reductions in response rates. Behavioral disruption (when animals failed to make any resets) occurred at the two highest doses (1.75 and 3.0 mg/kg). Although dose-dependent reductions in response rates also occurred with pimozide (0.1-1.75 mg/kg), an increase in threshold only occurred at the highest dose. The 1.75 mg/kg dose also produced behavioral disruption. Clozapine produced increases in reinforcement thresholds from 0.10-1.75 mg/kg without significant changes in response rates. When 3.0 mg/kg of clozapine was administered, a marked disruption of behavior occurred. Thus, neuroleptics differ with respect to their effects on reinforcement thresholds and on behavioral performance. The three patterns were: (1) an increase in reinforcement thresholds with a corresponding decrease in response rates (haloperidol and loxapine), (2) no changes in reinforcement thresholds, but a marked, dose-dependent decrease in response rates (chlorpromazine and pimozide), and (3) an increase in reinforcement thresholds without any changes in response rates (clozapine).

A distinction can, therefore, be made between the effects of neuroleptics on central reinforcement thresholds and on motor behavior which helps us interpret the relation between chemical and clinical potency.

2257 DIFFERENTIAL EFFECTS OF ANTIANXIETY AND ANTIPSYCHOTIC DRUGS ON TWO DISTINCT SUBSYSTEMS OF AROUSAL. T. Schallert, C. H. Wang*, S. Hsiao* & I.Q. Whishaw. Depts. of Psychology, Univ. Illinois, Champaign, IL 61820, Univ. Arizona, Tucson, AZ and Univ. Lethbridge, Alberta Canada.

So-called active states of consciousness such as arousal, alertness, and wakefulness traditionally have been defined, in large part, by the presence of cerebral activation (i.e., desynchronized neocortical EEG activity), movement or an upright standing posture, open eyes, and behavioral responsiveness to sensory stimuli. Recently Vanderwolf and others have shown that there are two pharmacologically distinct inputs to the cortex, each one of which is capable of producing cerebral activation, and each has different relations to behavior. One is active during immobility and the other is active during "voluntary" movement. The present study was designed to determine whether antianxiety drugs (e.g., chlordiazepoxide) could affect the immobility-related system without influencing the movement-related system. To do this, we developed a technique that involves the use of an antipsychotic drug (haloperidol), which we found could centrally inactivate the movement-related system so that the immobility-related system can be studied in isolation (that is, without permitting the animal to stay "aroused" simply because movement occurs; agents such as curare that stop movement peripherally are not useful in this regard because although the animal cannot overtly move, it can still "try" to move, which activates the movement-related input to the cortex). To measure arousal, or the lack of it, during immobility, we recorded the EEG and behavioral indices such as posture, eye closure, and reactivity to sensory stimuli. The primary results were that low doses of antianxiety drugs exert profound deactivating effects on behavior during immobility, while having no effect on behavior or EEG when the animal, without the influence of haloperidol, freely moves around. Clinical implications will be discussed.

2258 THE BEHAVIORAL PHARMACOLOGY OF 5-METHOXY N,N-DIMETHYLTRYPTAMINE (5-MeODMT) IN PRIMATE SOCIAL COLONIES. R.F. Schlemmer, Jr., N. Narasimhachari, C.B. Tyler, & J.M. Davis, Illinois State Psychiatric Institute, Chicago, IL 60612.

5-MeODMT is a hallucinogenic substance which has been postulated as an endogenous psychotogen in humans. We have previously reported that 5-MeODMT induces abnormal behavior & significantly alters normal affiliative behavior when administered to selected members of primate social colonies (Comm. Psychopharmacol. 1:105, 1977). The present studies were designed to examine the role of certain neurotransmitter systems in the mediation of 5-MeODMT-induced behavior in monkeys. All expts. were performed using stable social colonies of 4-5 adult Stumptail macaques. Each expt. began with at least a 5-day baseline observation followed by administration of 5-MeODMT 0.25 mg/kg to 2-3 monkeys daily for 1 wk. Then the agent to be studied was given both alone & concomitantly with 5-MeODMT for 1 wk. All drugs & saline were given i.m. (except phenelzine). Drugs tested in the study included: the serotonin (5-HT) antagonists, cinanserin (CINAN) 5 mg/kg & metergoline (METER) 0.3 mg/kg, the dopamine (DA) antagonists, haloperidol (HALO) 0.15 mg/kg & trifluoperazine (TRIFLUO) 0.04 mg/kg, methiothepin (METHIO) 0.15 mg/kg, a 5-HT & DA antagonist, the central cholinesterase inhibitor, physostigmine (PHYSO) 0.06 mg/kg + methscopolamine 0.01 mg/kg, the anticholinergic, atropine (ATROP) 0.2 mg/kg, the antihistamine, promethazine (PROMETH) 4 mg/kg, the sedatives, pentobarbital (PENTO) 7.5 & 10 mg/kg & diazepam (DIAZ) 1 mg/kg, & the MAO inhibitor, phenelzine (PHEN) 4 mg/kg given n.g. All expts. were conducted using a cross-over design so that each monkey in the colony received each treatment. Behavioral observation by a "blind" observer began 5 min. after 5-MeODMT or saline injection & lasted for 1 hr. daily. 5-MeODMT-induced abnormal behavior - body shakes & limb jerks - was antagonized by CINAN, METER, METHIO, HALO, TRIFLUO, & PHYSO. However, 5-MeODMT-induced increase in submissive gestures given by treated monkeys was antagonized by only HALO, TRIFLUO, & METHIO. METER was the only agent tested which at least partially reversed 5-MeODMT-induced social withdrawal & decreased social grooming. On the other hand, PENTO, DIAZ, PROMETH, & ATROP - agents which all possess sedative properties - did not return any 5-MeODMT-induced behavioral change to baseline levels. Inhibition of MAO by PHEN significantly potentiated 5-MeODMT-induced body shakes, limb jerks, increased submissiveness, & reduction in social grooming. These results suggest that the major behavioral changes induced in monkeys by 5-MeODMT are mediated via 5-HT & DA systems. In addition, cholinergic systems may also play a modulatory role in the mediation of 5-MeODMT-induced abnormal behavior in monkeys.

2259 REVERSAL OF DOPAMINERGIC BEHAVIORAL SUPERSENSITIVITY: EFFECTS OF CHRONIC L-DOPA AND LITHIUM. Thomas F. Seeger* and Eliot L. Gardner, Depts. of Pharmacology, Psychiatry, and Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461.

We have previously demonstrated that chronic haloperidol treatment (21 days at 1 mg/kg/day) causes an increase in intracranial self-stimulation (ICSS) rate in rats implanted with electrodes in the ventral tegmental nucleus. This increase persists for three weeks at full magnitude, before declining to baseline rates at four weeks after the termination of haloperidol treatment. This long-lasting period of supersensitivity allows for the testing of pharmacological agents which may modify or reverse the neuroleptic-induced increase in ICSS rate. In the first experiment, 31 rats which demonstrated ICSS at high rates were given three consecutive tests to establish a baseline rate. 16 of the rats were then given three weeks of haloperidol injections. The rats were retested at 3, 5 and 7 days after haloperidol withdrawal, and at this time demonstrated an average 50% increase in ICSS rate. After the test on day 7, 8 of these rats were given 100 mg/kg L-DOPA plus 20 mg/kg Carbidopa daily for the next seven days. These rats showed a progressive decline in ICSS rate, leveling off at 120% of baseline rate, and persisting at this level for one week after the last L-DOPA treatment. The 8 rats which received haloperidol, but not L-DOPA, maintained their supersensitive response rate (50% of baseline) during this period. 5 rats given L-DOPA and Carbidopa for one week without previous haloperidol treatment showed no change in ICSS rate either during or after the L-DOPA treatment. 10 control animals given saline injections for three weeks also showed no significant changes. These results indicate that chronic L-DOPA treatment can cause a reversal of neuroleptic-induced behavioral supersensitivity, at a dosage level which does not by itself cause subsensitivity (i.e. a decrease in ICSS rate). In the second experiment, 8 rats were given daily lithium carbonate in their food (1600 mg/kg of powdered chow) concurrently with three weeks of haloperidol injections (1 mg/kg/day). In this group, a small but significant increase in ICSS rate was seen at 3 and 5 days after the last haloperidol injection, with the rate declining to baseline levels at day 7. This result suggests that lithium treatment attenuates both the magnitude and time course of neuroleptic-induced supersensitivity. The current results demonstrate the reversal of supersensitivity in a behavior mediated by the mesolimbic dopamine system, and agree with the findings of other investigators who have used behaviors mediated by the nigro-striatal dopamine system. They suggest the possible usefulness of pharmacological desensitization in disease states which may involve abnormal receptor sensitivity, such as tardive dyskinesia and schizophrenia. (Supported, in part, by USPHS research grant DA-02089).

2260 PLATELET MAO IN HYPERACTIVE BOYS TREATED WITH D-AMPHETAMINE. Walid O. Shekim, Leonard G. Davis, Javaid Javaid, Eric G. Brunngraber, and Lucy Fikes*. Dept. of Psychiatry, Sch. Med., Univ. Missouri, Columbia, MO 65212 and Illinois State Psychiatric Instit., Chicago, IL (Dr. Javaid).

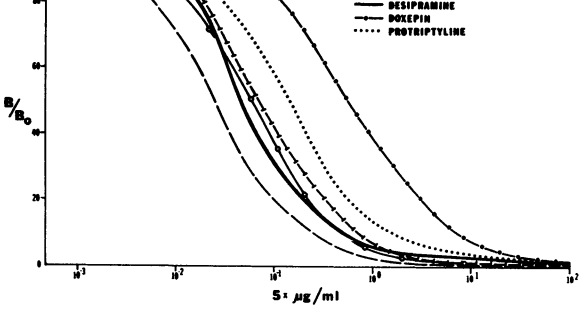
The monoamines are thought to play an important role in the pathophysiology of hyperactivity in children. Recent studies are suggesting a role for serotonin, norepinephrine (NE), and dopamine (DA) in the etiology of childhood hyperactivity. We recently have presented data suggesting possible involvement of NE and DA in the etiology of hyperactivity (Shekim et al., Am. J. Psychiat., 134:1276, 1977; Shekim et al., Sci. Proc. Am. Psychiat Assn., 132, in press, 1979). We found that urinary 3-methoxy-4-hydroxyphenylglycol (MHPG), the main metabolite of CNS NE was significantly lower in hyperactive boys than controls. We also found that MHPG correlated negatively with urinary homovanillic acid (HVA), the main metabolite of DA. The administration of d-amphetamine significantly decreased MHPG excretion.

Hyperactive boys were admitted to a Clinical Research Center (CRC) after being free from medications for at least two weeks. They were placed on VMA and serotonin free diet from day 1 of admission. Bloods were drawn in the A.M. while still in bed and fasting on the 4th and 5th day of admission for assay of MAO. They were discharged and then placed on d-amphetamine 0.5 mg/kilogram body weight divided over two doses daily for two weeks, and were readmitted at the end of the two weeks to the CRC. They were placed on VMA and serotonin free diet from day 1 of admission and bloods were drawn on the 4th and 5th day in a similar fashion to the first admission. MAO was assayed according to the method of Murphy et al (Biochem. Med. 16, p. 254, 1976). Platelet MAO levels were lower at baseline than after treatment with d-amphetamine. The administration of d-amphetamine increased platelet MAO values in 8 children of the first 9 studied. These findings are discussed in terms of the relationship of MAO to hyperactivity and urinary MHPG levels as well as the catecholamine hypothesis of hyperactivity in children.

Supported in part by NIH Grant RR-00287-12 to the General Clinical Research Center, UMC, and by a grant from the Missouri Institute of Psychiatry, Univ. of Missouri-Columbia, to Dr. Shekim.

2261 TRICYCLIC ANTIDEPRESSANT DETERMINATIONS BY RADIOIMMUNOASSAY William F. Shivers* and Charles J. Hannan, Jr. (SPON: Gerald O. Carrier) Department of Psychiatry and Clinical Investigation Service, Eisenhower Army Medical Center, Ft. Gordon, GA 30905.

An antiserum was produced in rabbits which was found to be adequate to determine plasma levels of all the clinically available tricyclic antidepressants (TCA). This tool provides a means of titrating the proper TCA plasma levels in depressed patients and maximizes the chances of a successful treatment. Antigen was prepared by conjugating desipramine to bovine serum albumin (BSA) via succinic anhydride and a carbodiimide reaction. The conjugate, after purification by dialysis, was shown to contain desipramine by UV and fluorometric spectroscopy. Six rabbits were innoculated subcutaneously with a divided dose of 2 mg conjugate in a slurry with Freund's complete adjuvant. After eleven weeks a booster injection was given to each rabbit. One week later animals were exsanguinated by cardiac puncture and the serum collected. Diluting with phosphate buffered saline (PBS), pH 7.5, the optimum concentration of antiserum was found to be 1:300 with our assay conditions, which are as follows in the order they are added: 0.2 ml 0.05 M EDTA in PBS with 1:400 normal rabbit serum; 0.015 ml ^{3}H-imipramine, 2.5 uCi/ml; 0.01 ml unknown or standard; 0.2 ml antibody, 1:300 dilution; 0.5 ml PBS with 1% BSA. This was incubated at 4°C for 2 hours with appropriate control tubes and a second antibody used to separate the free from the bound fraction.



2262 EFFECT OF SOME AMPHETAMINE ANALOGUES IN RATS TRAINED TO DISCRIMINATE LSD. Peter B. Silverman and Beng T. Ho. Tex. Res. Institute of Mental Sciences, 1300 Moursund, Houston, TX 77030.

Adult, male Sprague-Dawley rats, food deprived to about 80% of their free feeding weight, were trained to bar press in a two-lever operant box on a fixed ratio (FR) 20 schedule for food reinforcement. Fifteen minutes prior to daily, 20-minute training session, animals were injected i.p. with 75µg/kg LSD (as the free base) or 1.0 ml/kg saline. In those sessions following LSD administration, reinforcement was provided for operating one lever, while in sessions following saline, reinforcement was provided for operating the other lever. Responses on the incorrect lever were counted, but had no consequence. Acquisition of the discrimination between LSD and saline was assessed by determining the number of responses on the lever paired with LSD, out of the first 20 responses (i.e., prior to any reinforcement).

When subjects had acquired the discrimination, and performance was stable, test sessions were interposed among training sessions. Fifteen minutes prior to a test session, subjects were injected with a dose of (+)-, (-)- or (±)-2,5-dimethoxy-4-methylamphetamine (DOM, "STP"), (±)-2,5-dimethoxy-4-bromoamphetamine (DOB), (±)-2,4,5-trimethoxyamphetamine (TMA-2) or (+)-amphetamine. The number of responses on the lever paired with LSD, out of the first 20 total responses, was recorded. A dose response curve for each compound was generated in this manner. With the exception of (+)-amphetamine, all the compounds showed generalization with LSD, i.e., an average of ≥16 of the first 20 responses were emitted on the LSD lever. The order of potency for generalization with LSD was found to be DOB > (-)-DOM > (±)-DOM > (+)-DOM > TMA-2. This order parallels psychotomimetic potency in human beings, with the exception of (+)-DOM which reportedly has neither stimulant nor psychotomimetic activity in man (Shulgin, J. Pharm. Pharmac. 25, 1973). Treatment with the serotonin antagonist, cinanserin, prior to (+)-DOM or (-)-DOM completely blocked the generalization of these compounds with LSD, showing that the two isomers produce their LSD-like effect via the same mechanism. The finding of (+)-DOM generalization with LSD opens to further question the nature of the "hallucinogenic stimulus" in rats.

2263 EFFECTS OF AGE AND CHRONIC NEUROLEPTICS ON RECEPTOR BINDING IN RAT BRAIN. Robert C. Smith, Chandra H. Misra, Harnath Shelat*, Behav. Neurochem.,Tex. Inst. of Men. Sci., Houston, TX 77030

Older-age is associated with changes in catecholamine neurons and neurotransmitters and their receptors. Tardive dyskinesia, one long-term toxic effect seen after chronic administration of neuroleptics to man is much more prevalent in older-age humans. To investigate whether receptor changes may be involved in these phenomenon, we are studying the effects of age and chronic neuroleptic drugs on receptor binding in rat brain. Fisher 344 rats, treated chronically with fluphenazine or saline, sacrificed 9-10 after termination of chronic injections, were used in all experiments. Receptor binding for dopaminergic, adrenergic, and cholinergic receptors was assayed using tritiated spiperone, DHA, WB-4101, DHE, and QNB using established techniques. Our preliminary results show a significant decrease in specific binding of DHA, and WB-4101 in the cortex of old age rats, a significant decrease in spiperione binding in the striatum of old age rats. Kinetic analysis showed a decrease in B_{max} but no change in K_d in the spiperone binding in the striatum of old rats. Specific binding of DHE in the cortex and QNB in the hippocampus showed a curvilinear pattern in relation to age. Prior treatment with chronic neuroleptics increased spiperone binding in the striatum, with a greater relative effect in 10 month as compared to 4 month old rats. Chronic neuroleptics slightly increased DHA binding in the cortex of young rats, but significantly decreased DHA binding in the cortex of old rats. Further kinetic studies of adrenergic and dopaminergic binding, and the interaction of age and chronic neuroleptics on cholinergic vs dopaminergic binding are currently being pursued.

2264 EFFECTS OF CHLORPROMAZINE ON ESCAPE AND AVOIDANCE RESPONSES: A CLOSER LOOK. W. Spirduso, L. Abraham, and M. Wolf*. Dept. of Physical & Health Ed., Univ. of Texas, Austin, TX 78712.

Chlorpromazine (CPZ) has been reported to decrease or abolish avoidance responses, while not influencing escape responses of rats in a shuttle box. Closer analysis reveals that rigorous time constraints placed on rats trained to release a bar from a learned position yield three basic responses; Escape Responses (ER) to the unconditioned stimulus (2.5 mA shock), Avoidance Responses (AR) to a conditioned stimulus (light and buzzer), and Orienting Responses (OR) to both the conditioned and unconditioned stimuli. In this study the effects of CPZ on ER, OR, and AR were analyzed using a highly trained response approaching the animal's speed capacity.

Holtzman rats (15) were trained over a 6 day period to depress and hold a lever and to release it when the auditory/visual stimulus was presented. Minimal latency responses were obtained by reducing the CS-UCS interval in stages from 1000 to 200 msec. Following training, animals were pretested over 50 trials at decreasing intervals, then were injected with CPZ (Thorazine, 3.5 mg/kg). After 40 minutes the animals were retested, ER and AR latencies were determined by bar release, while the latency of the movement initiation was detected by high speed cinematographic analysis. Film analysis also provided characteristics of the movement patterns for ER, AR, and OR.

Avoidance responses increased during training to 60($\pm$ 10)% occurrences by the 6th day for all rats. CPZ produced increased decrements in percent avoidance with decreased CS-UCS intervals, and at the 200 msec. interval only 4 animals were capable of avoiding. Contrary to previous reports, CPZ significantly delayed escape responses. CPZ avoidance latencies were slower only at the least constrained CS-UCS interval of 1000 msec. and at the shortest interval for those few animals capable of avoiding. The most striking of the qualitative differences between ERs and ARs was that the initial component of the ER was a total body jump, while the initial component of the AR was an independent movement of the head and/or forelimbs. A major effect of CPZ on the movement pattern was a change in starting position, which may have been related to the CPZ-induced tendency to begin the AR with a postural adjustment. Finally, film analysis confirmed that CPZ delayed the onset of the AR and expanded the temporal aspects of the movement pattern.

These results show that when escape and avoidance behaviors (a) are initiated at speed capacity, (b) start from a learned and maintained ready position, and (c) are cinematographically analyzed, CPZ produces results that deviate from those previously reported. (Supported by University Research Institute, UT Austin)

2265 EFFECTS OF NALOXONE ON FEEDING AND DRINKING IN RATS. J. M. Stapleton, M. D. Lind*, J. R. Quinan*, T. L. Foley*, M. F. Wu*, and L. D. Reid. Dept. of Psychol., Rensselaer Polytechnic Institute, Troy, NY 12181.

Naloxone decreases certain appetitive behaviors (Holtzman, J. Pharm.Exp.Ther., 1974). Such decreases may be due to naloxone's modification of endorphinergic systems or these effects may be nonspecific, e.g., due to illness-producing effects. This presentation summarizes results of several studies of the effects of naloxone on feeding and drinking, one of which addresses the issue of specificity.

Naloxone reduces water consumption in fluid-deprived rats, using doses as low as 0.5 mg/kg, subcutaneously (sc). Furthermore, naloxone produces decreases in drinking induced by injection of hypertonic saline solution (5 ml/rat of 1.5 M NaCl). Naloxone also probably produces some malaise in rats since it can sustain a conditioned taste aversion (CTA) (LeBlanc & Cappell, Pharmacol.Biochem.Behav., 1975). Since there are stable individual differences in extent of CTA and naloxone's suppression of drinking, we reasoned that if the reductions in drinking were due to the nonspecific illness-producing effects indexed by the CTA-test, we would find a significant positive correlation between these two measures. A group of 19 male rats were tested for CTA using naloxone and subsequently tested for naloxone suppression of drinking. There was no reliable relationship between the two measures, rho = -.03. These results are concordant with the results of Frenk and Rogers (Behav.& Neural Biol., in press) who found that lithium chloride produces a strong CTA but does not suppress drinking, when given under the same testing parameters as naloxone.

Naloxone also produces a decrease in consumption of a 10% sucrose solution by nondeprived rats. A summary of dose-response relationships for this effect will be presented for both systemic and intracerebroventricular administration of naloxone. Doses smaller than 2 mg/kg sc appear to be effective. Also, naloxone reduces the intake of sucrose solution in rats deprived of food and water for 22 h/day.

Diazepam and sodium pentobarbital both induce feeding in rats. Naloxone, in doses as low as 0.25 mg/kg sc blocks feeding induced by diazepam (25 mg/kg, intragastrically) while it does not affect diazepam-induced sedation. Naloxone does not completely block feeding induced by sodium pentobarbital (5 mg/kg sc) in doses up to 10 mg/kg sc.

These results suggest that naloxone may have relatively specific effects on only certain ingestive behaviors and support a hypothesis of endorphinergic modulation of certain appetitive behaviors.

2266 ANTIDEPRESSANTS ATTENUATE A CONDITIONED IMPAIRMENT OF PERFORMANCE. L. K. Stefany*, J. K. Saelens and M. Roffman. Research Dept., Pharmaceuticals Div., CIBA-GEIGY Corp., Summit, NJ 07901

Seligman and Beagley (J. Comp. Physio. Psych. 88: 534, 1975) demonstrated that rats previously exposed to inescapable shock were impaired in their ability to learn a simple shock-escape task. These findings have been confirmed using a modification of their "learned helplessness" model. Further it has been found that this conditioned impairment of performance (CIP) can be attenuated by certain psychoactive drugs, particularly antidepressants.

During conditioning sessions, male, Sprague-Dawley rats (170-200 g) were exposed to 80 trials of inescapable footshock (1.7 mA, 30 sec, VI = 1 min) in an operant chamber either without a lever or with an inoperable lever. Twenty-four hr following the conditioning session the lever was inserted or activated and the animals were tested for 40 trials (1.7 mA, 60 sec, VI = 1 min) for their ability to learn to escape footshock by lever pressing. For the first 10 trials a single lever press terminated the shock (FR 1). For the remaining 30 trials, two responses were required to terminate the shock (FR 2). Rats subjected to the conditioning procedure on day 1 exhibited a CIP on day 2 when compared to those not subjected to this procedure. The presence of an inoperable lever (as opposed to no lever) during the conditioning procedure reduced the variation among animals in second-day performance and thus further differentiated between these two groups.

Intraperitoneal administration of d-amphetamine (1 mg/kg), desipramine (15 mg/kg), imipramine (30 mg/kg), iprindole (30 mg/kg) and fluvoxamine (10 mg/kg) prior to testing on day 2 attenuated the CIP in studies where the lever was not present during conditioning on day 1. In subsequent experiments where the lever was present but inoperable on day 1, iprindole (30 mg/kg), mianserin (30 mg/kg) and welbatrin (30 mg/kg) also attenuated the CIP. Diazepam (10 mg/kg) and scopolamine (1 mg/kg) failed to attenuate the CIP in both paradigms.

The CIP model appears to be sensitive to a wide range of antidepressants, of diverse mechanisms of action, which are useful in the treatment of affective disorders. The results tentatively suggest that drugs capable of facilitating monoaminergic transmission attenuate the CIP. Since monoamines have been implicated in affective disorders, the CIP may be an animal model of depression and is useful in detecting new antidepressants.

2267 SUPPRESSION OF PROLACTIN SECRETION IN MAN AND RAT BY BUPROPION HCL (WELLBATRIN®), A NOVEL ANTIDEPRESSANT. Warren Stern, Judith Rogers*, Victor Fang* and Herbert Meltzer. Burroughs Wellcome Co., Research Triangle Park, NC 27709 and Univ. Chicago Sch. Med., Chicago, IL 60637.

Bupropion HCl, a non-tricyclic compound with antidepressant properties in man, was evaluated for effects on plasma prolactin (PRL) and growth hormone (GH) levels in normal human subjects, and for effects on plasma PRL levels in a series of pharmacological studies in normal rats. Single oral doses of 50 or 200 mg of bupropion given to 6 male and 12 female normal volunteers produced a marked suppression (up to 70% decrease) of plasma PRL levels for at least 4 hours (see Table). At the end of 24 hours plasma PRL levels were still below normal values. At one hour after drug administration there was a +.56 correlation ($p < .05$) between bupropion plasma levels and the percentage decrease in PRL levels. On the other hand, GH only showed small and erratic changes in plasma levels. In the rat, single doses of 10 or 25 mg/kg, i.p., of bupropion failed to lower PRL levels. However, bupropion at 25 mg/kg, i.p., significantly decreased PRL in rats in which baseline PRL levels were elevated by pretreatment with alpha-methyltyrosine (AMT at 150 mg/kg, i.p.), 5-hydroxtryptophan (5-HPT at 100 mg/kg) or quipazine (10 mg/kg; see Table). Overall, the results in man and rat are consistent with the view that bupropion has significant dopamine agonistic properties. Whether bupropion is a directly or indirectly acting dopaminergic agonist cannot be determined from the present results.

2268 LOCUS COERULEUS LESIONS DIFFERENTIALLY ALTERS MORPHINE'S EFFECTS ON SELF-STIMULATION BEHAVIOR IN RATS. Ann Tempel*, Steven J. Ellman, Robert Pierro*, Douglas Ocheret*, and Solomon S. Steiner. Behavioral Physiology Lab., Dept. Psych., The City College of New York, New York, N.Y. 10031.

Drugs of abuse have been shown to modulate mechanisms of reward through their action on catecholaminergic systems. The following experiment was designed to examine the effect of chronic morphine administration on self-stimulation (ICSS) in the rat after discrete lesions to the locus coeruleus (LC).

Rats were stereotaxically implanted with 2 pairs of bipolar stainless steel electrodes aimed at one of the following combinations: fields of forel (ff) & crus cerebri (cc); medial forebrain bundle (mfb) & ff; mfb & cc. Stimulation consisted of biphasic rectangular pulse-pairs. Each bipolar electrode was used in a monopolar fashion, with each tip serving as cathode to a cortical screw anode. After response rates stabilized, each animal received 7 days saline, 7 days morphine, 1 day morphine + naloxone and 6 days post-drug saline. Morphine doses were 1.25 and 2.5 mg/kg injected sc 40 min before the beginning of the ICSS session. Naloxone dose was 1 mg/kg. Rats were then given d- and l-isomers of amphetamine alternated in an ABBA series. All doses were 1 mg/kg. Acute LC lesions were then made unilaterally in all animals. Following the lesion, rats were run for 21 days of saline to allow for complete fiber degeneration and neuroheumoral depletion. ICSS drug paradigms post-lesion were identical to the pre-lesion paradigm.

It was found that some ICSS sites which had in common that they were both equally potentiated by the d- and l-isomers of amphetamine and also showed a facilitation under morphine, no longer were facilitated by morphine administration after the LC lesion. Conversely, sites which showed a greater facilitation to d- rather than the l-isomer of amphetamine and also showed a facilitation under morphine, maintained their morphine facilitation, which was naloxone reversible, after the LC lesion.

Relevance of this data to the effect that opiate centers modulate catecholamine effects on ICSS will be discussed.

2269 SOLUBILIZATION OF THE BENZODIAZEPINE BINDING SITE FROM MAMMALIAN BRAIN. John W. Thomas, M.Ayub Khan Yousufi*, and John F. Tallman. Biological Psychiatry Branch, NIMH, Bethesda, MD 20205

The high-affinity binding site for benzodiazepines in mammalian brain has been solubilized using a non-ionic detergent. In a single step approximately 60% of the binding sites are solubilized, while maintaining a high-affinity for [^{3}H]diazepam (K_D of 11 nM as compared to 4 nM for the membrane-bound binding sites). The order of potency of benzodiazepines in inhibiting [^{3}H]diazepam binding is identical for the solubilized and membrane-bound binding sites, and both the solubilized and membrane-bound binding sites have a higher affinity for [^{3}H]diazepam at 4°C than 37°C. However, γ-aminobutyric acid which enhanced [^{3}H]diazepam binding to membrane fractions was without effect on the solubilized binding site.

The molecular weight of the solubilized binding site was determined by gel filtration on Sephadex G-200. The calculated molecular weight of the solubilized binding site was 220,000 daltons; however, this may represent an overestimate, since it is not known how many molecules of detergent or other proteins remain associated with the receptor.

Several other factors which might influence the stability of the receptors were examined. Neither sulfhydryl groups nor carbohydrate moieties seem critical for binding, but both urea and guanidine-HCl were capable of totally inhibiting binding, and this inhibition was partly reversible.

2270 AGONIST POTENCIES AT THE DOPAMINE RECEPTORS. M. Titeler and P. Seeman, Department of Pharmacology, University of Toronto, Toronto, Ontario M5S 1A8.

A series of ergot derivatives have been assayed for their ability to compete for the specific binding, in calf caudate homogenates, of ^{3}H-spiperone, a dopamine receptor antagonist (1), ^{3}H-dihydroergocryptine (^{3}H-DHEC) a dopamine receptor agonist (2,3), and ^{3}H-dopamine, the neurotransmitter. Bromocryptine has been shown to be a potent dopamine receptor agonist in vivo (2) and in vitro (3), and this drug demonstrates a 10-20 fold higher affinity for the ^{3}H-spiperone and ^{3}H-DHEC specific binding sites than for the ^{3}H-dopamine binding site. Dihydroergocryptine has also been shown to be a potent dopamine receptor agonist in vivo (1) and in vitro (2) and this drug demonstrates a 16-40 fold higher affinity for ^{3}H-spiperone and ^{3}H-DHEC specific binding sites than for ^{3}H-dopamine sites. These data along with other data on location and function of these sites indicate that ^{3}H-DHEC and ^{3}H-spiperone label the same site, the post-synaptic dopamine receptor, and 3H-dopamine labels another dopamine neuronal structure, possibly the dopamine autoreceptor (4). These data cannot possibly be interpreted in terms of the two-state model of the dopamine receptor, as has been suggested (5).

2271 ACUTE AND CHRONIC TOLERANCE TO A BEHAVIORAL EFFECT OF NICOTINE IN RATS. Glenn Daniel Todd* and John A. Dougherty* (SPON: Ralph E. Miller). VA Medical Center, Depts. Pharmacology and Psychiatry, Univ. of Kentucky, Lexington, Ky. 40507.

Acute and chronic tolerance to the behavioral suppressant effects of nicotine were examined by injecting the drug twice daily for several weeks in male Wistar albino rats. The daily interdosing intervals were 1,2,4, or 8 hours, with a different group of rats used at each dosing interval. Each i.p. nicotine injection was followed immediately by a 30-minute session of water-reinforced lever pressing according to a fixed-ratio 50 schedule. The rats were maintained at 80% of their free-feeding weight by giving supplemental water access after the second daily session. The overall response rate after saline pretreatment was used as a predrug baseline with which to compare the effects of nicotine dosing.

The first nicotine injection(200 ug/kg, BASE) decreased overall response rate by about 50% in all four groups. However, the second nicotine injection, 1,2,4, or 8 hours later on the same day had no significant behavioral effect. On the second day this pattern was repeated, with nicotine again decreasing the responding after the first, but not the second injection. Over nine consecutive days, the response rates after the first daily drug injection gradually recovered to within predrug ranges, while the behavior after the second injection remained unchanged or slightly stimulated when compared to controls. There were no differences between the 1,2,4, or 8 hour interval groups either on the initial effect, the response to the second daily injection, or the rate of tolerance development over nine days.

Analysis of the behavioral pattern showed that an initial period of no responding after the first daily drug injection was primarily responsible for the lowered overall response rate. After the initial pause, responding was abruptly resumed at the predrug rate. This pause was unrelated to motor impairment. The pause gradually decreased in duration over the nine day period and was not apparent after any of the second daily injections.

A subsequent dose increase to 350 ug/kg(BASE) twice a day reinstated the initial suppression with the development of tolerance over nine days again following the same pattern as seen with the lower dose of nicotine.

These results indicate that a rapid tolerance occurs to the suppressant effects of nicotine within one hour and persists up to eight hours, but not for 16 to 23 hours. A more gradual tolerance also occurs after 6 to 9 days of injections. This biphasic development of tolerance suggests that more than one process may be involved.

2272 ASCORBATE ATTENUATES THE L-DOPA SUPPRESSION OF RAT PLASMA PROLACTIN AND LH LEVELS. L. C. Tolbert, T. N. Thomas, L. D. Middaugh, J. G. Ondo*[O], and J. W. Zemp, Neurosci. Prog., Univ. Alabama in Birmingham, B'ham, AL., 35294. Depts of Biochem., Psych. and [O]Physiol., Med. Univ. of South Carolina, Charleston, S.C., 29403.

We have previously reported that ascorbate inhibits dopamine-sensitive adenylate cylase without an effect on norepinephrine-sensitive adenylate cyclase in vitro. Additional studies indicated that intraperitoneal (IP) injections of pharmacologic doses of ascorbic acid elevate levels of ascorbate in the brains of experimental animals in a time and dose-related manner and that this elevation modified dopamine-mediated behaviors without an effect on norepinephrine-mediated behaviors. Subsequently, we demonstrated that ascorbate increased the relative turnover of dopamine, in vivo, without affecting the turnover of norepinephrine. In the present study, experiments were designed to test whether ascorbate could influence the suppression of prolactin secretion normally produced by L-Dopa as well as the suppression of LH reported by some people.

Male rats were first injected with RO4-4602/1, a peripheral decarboxylase inhibitor. Animals were then given L-Dopa (100 mg/kg IP). Thirty minutes before decapitation animals were injected with ascorbate (1 or 2 g/kg IP) or vehicle. Plasma prolactin and LH levels were determined by radioimmunoassay from the trunk blood of these animals.

L-Dopa produced a significant reduction in both prolactin and LH levels. Ascorbate, by itself, had no effect on prolactin or LH levels. Ascorbate (2 g/kg) significantly attenuated the L-Dopa induced suppression of prolactin and LH levels ($p < .02$). A smaller dose of ascorbate had a lesser, non-significant, effect.

This study indicates that ascorbate can alter certain neuroendocrine responses mediated by dopamine and is compatible with our previous demonstrations of the ability of pharmacologic doses of ascorbate to antagonize CNS dopaminergic activity.

2273 DISCRIMINATION OF PURE NARCOTIC ANTAGONISTS BY PIGEONS. Valentino, R.J.,* Herling, S.* and Woods, J.H. Dept. of Pharmacology, Univ. of Mich., Ann Arbor, Mi. 48109

Pigeons were trained to discriminate an intramuscular injection of naltrexone (NTX; 32 or 56 mg/kg) from saline by reinforcement of responses on one of two keys. Following NTX administration, 20 consecutive responses on the appropriate key resulted in 4 sec access to grain, while responses on the other key were reinforced when saline was administered. During test sessions, 20 consecutive responses on either key resulted in grain delivery. Naloxone generalized to NTX in 4 out of 5 pigeons and was equipotent to NTX. Administration of behaviorally active doses of cyclazocine, amphetamine, and ethylketazocine did not result in drug-appropriate responding. Quaternary NTX produced saline-appropriate responding in 3 out of 5 birds. One bird generalized completely to quaternary NTX, while another responded only partially on the drug-appropriate key. UM-1046 (3-cyclopropylmethyl-1,2,3,4,5,6-hexahydro-8-hydroxy-6-methyl-3-benzazocine) produces a syndrome resembling the narcotic abstinence syndrome in narcotic-naive monkeys. In the isolated guinea-pig ileum preparation, UM-1046 produces a contraction resembling the contraction produced by naloxone in ileal preparations which have been exposed to morphine (Valentino and Smith, Fed. Proc. 38:587, 1979). The administration of UM-1046 to naltrexone-trained pigeons produced complete NTX-appropriate responding in 2 of the animals and partial generalization in two others. UM-979 ((-)-5,9-dimethyl-2-(3-furylmethyl)-2'-hydroxy-6,7-benzomorphan), a drug with narcotic-antagonist properties, produced results similar to the administration of UM-1046. These data indicate that naltrexone has discriminative effects in nondependent animals which may be distinguished from those of other narcotic agonists and mixed narcotic agonist-antagonists. Characterization of narcotic antagonists using drug discrimination procedures may be useful in determining the effects of these drugs in both the naive and narcotic-dependent state. (Supported by NIDA grants DA 00154 and 00254)

2274 STIMULATION OF SYNAPTOSOMAL TYROSINE HYDROXYLASE ACTIVITY BY PHENCYCLIDINE. Thomas W. Vickroy* and Kenneth M. Johnson. Dept. of Pharmacol. and Toxicol., Univ. of Texas Med. Branch, Galveston, TX 77550.

Phencyclidine(PCP) is a CNS active agent which possesses psychomotor-stimulant properties in rodents and sedative-hypnotic, hallucinogenic, and anesthetic properties in primates. Like d-amphetamine, PCP produces increased locomotor activity, stereotypic behavior, and ipsilateral turning in rats with unilateral lesions of the nigro-striatal pathway. Each of these PCP effects can be inhibited by haloperidol. These data strongly suggest that dopamine(DA) is involved in the mediation of these effects.

The purpose of this study is to examine the effects of PCP on tyrosine hydroxylase(TH), the rate-limiting enzyme in the synthesis of DA. A crude synaptosomal homogenate was prepared by homogenizing pooled striata from untreated male Sprague-Dawley rats in 20 vol. of 0.32 M sucrose. The synaptosomal tissue was collected by centrifugation and resuspended in 20 vol. of either 37 C or ice-cold physiological phosphate buffer(pH 6.8) containing o-benzylhydroxylamine(134 uM), an inhibitor of DOPA decarboxylase. Either saline or PCP was added and preincubated for 20 min. The reaction was initiated by the addition of tyrosine(20 uM) containing 1 uCi L-(3,5-^{3}H)-tyrosine and was stopped after 20 min. by the addition of glacial acetic acid. Tritium-labelled water, which was formed following hydroxylation of L-(3,5-^{3}H)-tyrosine by TH, was separated from tritium-labelled tyrosine and its metabolites by ion-exchange chromatography and quantified by liquid scintillation spectrophotometry. TH activity assayed in this manner was completely inhibited by 3-iodotyrosine(2 uM).

PCP was observed to stimulate TH activity in a dose-related manner over the range of 0.1 uM to 100 uM with maximal stimulation(100%) occurring at 10 uM. On the other hand, PCP had no effect on the uptake of ^{3}H-tyrosine at these concentrations. However, little or no stimulation of TH activity was observed at any PCP concentration tested when the synaptosomal preparation was allowed to preincubated for 20 min. at 37 C, suggesting that PCP may be acting indirectly via the release of DA which normally inhibits TH. These effects are similar to those previously reported for d-amphetamine on synaptosomal TH activity.

2275 PRODUCTION OF PHYSICAL DEPENDENCE IN THE ALCOHOL-PREFERRING AND -NONPREFERRING LINES OF RAT. Marshall B. Waller, William J. McBride, Lawrence Lumeng* and Ting-Kai Li.* Institute of Psychiatric Research and Depts. of Psych., Biochem. and Medicine, Indiana Univ. School of Medicine and VA Medical Center, Indianapolis, IN 46223.

One of the criteria for an animal model of alcoholism is that ethanol (EtOH) consumption ultimately leads to physical dependence, manifest upon withdrawal by the appearance of abnormal behavioral and physical signs. We have raised by selective breeding and free-choice testing with 10% EtOH and water, two lines of rats, the alcohol-preferring (P) and -nonpreferring (NP) lines. This study examines the effect of caloric restriction and flavoring of 10% EtOH solution upon EtOH intake and whether chronic free-choice drinking can produce physical dependence in these lines of rats. In the first experiment, both P and NP rats were weight-reduced to 80% of their free-feeding weight and given free-choice between water and a 10% EtOH solution flavored with saccharin, 0.125 g%, and NaCl, 1 g%. EtOH consumption increased from 7 to 14 g/kg/d in the P rats and from 1 to 12 g/kg/d in the NP rats. After 8 weeks, alcohol was discontinued and the animals were tested for withdrawal. Physical signs, e.g., tremor, wet dog shakes, teeth chattering, Straub tail, were observed in 8 of 9 rats of the P-line. Sound from a bell (100 db) induced seizures in 3 animals while 2 others exhibited hyperreactivity to this stimulus. Physical signs were seen in all NP animals. The bell induced seizure in one animal and two showed increased sensitivity to the sound for up to 72 hours post-withdrawal. These signs appeared within the first day. Subsequently, behavioral impairment in the runway test appeared in 7 of 9 P animals and 7 of 8 NP animals. Head-poke and rearing activity were depressed at 24-72 hours post-withdrawal in 7 of 9 P rats and 6 of 8 NP animals tested. In the open field, one P animal exhibited hypoactivity while 7 animals became hyperactive. By contrast, 7 NP animals were hypoactive and only one was hyperactive in this test. In a second experiment, 8 rats of the P-line were given food ad libitum and the free-choice drinking of unflavored 10% EtOH and water for 13 weeks. Ethanol intake remained constant in 3 animals while 5 exhibited a progressive rise in alcohol consumption from 5 to 9 g/kg/d. When alcohol was discontinued, physical signs of withdrawal appeared in 6 of the animals on the first day. Disrupted behavior was exhibited by at least 5 of 8 animals in the open field, head-poke and rearing activity, or the runway test. These data indicate that chronic EtOH consumption, with or without food restriction and flavor additives in the EtOH solution, can produce physical dependence in the selectively bred, alcohol-preferring line of rats. (Supported by USPHS Grant No. AA003243).

2276 BRAIN SEROTONIN, BODY WEIGHT AND ISOLATION-INDUCED AGGRESSION IN MICE ON A TRYPTOPHAN-FREE DIET. James K. Walters, Maria Lavooy* and Robert Posch.* Biology Department, William Paterson College of New Jersey, Wayne, NJ 07470.

Diets lacking the essential amino acid, L-tryptophan, significantly deplete brain serotonin (5-HT) in rats and have been shown to influence pain sensitivity, acoustic startle, sexual behavior and mouse killing. No previous studies of the effects of tryptophan-free (TF) diets in mice have been reported. One mouse behavior thought to involve 5-HT mechanisms is aggression induced by prolonged isolation. Isolation-induced aggression can be decreased by depleting brain 5-HT with raphe lesions or p-chlorophenylalanine or by administering 5-HT receptor blockers. The present study determined the effects of a TF diet on isolation-induced aggression in two different strains of mice.

Forty Swiss-Webster (SW) and 48 SJL/J mice were isolated in plastic cages. Each mouse had powdered lab chow and water freely available. Two weeks later half of the mice from each strain were randomly switched to a powdered TF or tryptophan control (TC) diet. After 12 days, pairs of mice from the same strain and diet condition were placed in single divided cages for two more days. The divider and food cups were then removed for a 15 minute test period during which latency to fight, fight duration, tail lash duration and chase duration were recorded. Brains from five pairs of mice in each strain and diet condition were removed after testing and assayed for brain 5-HT concentration.

The TF diet significantly ($p < .01$) depleted brain 5-HT in both SW (34%) and SJL (45%) mice. The TF diet produced a 17% decrease in mean body weight for SJL mice after two weeks, and a 26% decrease for SW mice. The TC diet reduced SJL body weights by only 3% and SW weights by 17%. Significant effects on body weights were found for Diet ($p < .001$), Strain ($p < .001$) and Diet X Strain interaction ($p < .05$). Despite the significant brain 5-HT depletions, there were no significant effects of diet on any of the behavioral measures for either strain of mice.

This study shows that a TF diet depletes brain 5-HT in mice but also produces considerable weight loss over a two week period. Strain differences in acceptance of the diet were evident from the differential weight losses. The degree of brain 5-HT depletion which resulted from eating the TF diet may not have been sufficient to reduce isolation-induced aggression. Such was the case for acoustic startle in rats which could only be affected by tube feeding the TF diet (Walters, Davis & Sheard, Psychopharmacology, 1979, in press).

This study was supported by a William Paterson College Summer Research Fellowship.

2277 A BEHAVIORAL MODEL OF EARLY ENCEPHALOPATHY IN THE END-TO-SIDE PORTACAVAL SHUNTED RAT. John D. Warbritton, III, Mark A. Geyer, Bengt Jeppsson* and Josef E. Fischer*. Dept. of Psychiatry, Univ. Calif. San Diego, La Jolla, CA, Dept. of Surgery, Harvard Medical School, Boston, MA, and Dept. of Surgery, Univ. Cincinnati Medical Center, Cincinnati, OH 45267.

Although models of hepatic failure in large and small animals abound, models of early hepatic encephalopathy (HE) are difficult to create. A rat with an end-to-side portacaval shunt (PCS) is an extensively used experimental animal for characterization of biochemical alterations following diversion of portal flow from the liver, but few behavioral abnormalities have been detected. Biochemical changes observed in rats after PCS include increased plasma and brain levels of the serotonin (5-HT) precursor tryptophan, with increased brain serotonin and its metabolite 5-hydroxyindoleacetic acid (5-HIAA). Accumulating evidence indicates that serotonin may be involved in the modulation of the startle response in the rat. In the following study, the magnitude of startle responses to both tactile and auditory stimuli were shown to be abnormally decreased in chronic PCS rats and suggest that such studies may be used to advantage in the study of HE. End-to-side PCS were carried out in groups of 20 rats by a non-suture technique. Rats were studied at weekly intervals 4 and 5 weeks following PCS utilizing a tactile startle stimulus, an air puff administered through a solenoid activated valve, and auditory startle consisting of 110 dB tones. The results suggest that animals with end-to-side portacaval shunts exhibit decreased responsivity to both tactile and auditory stimuli. The simplicity of these tests, when carried out under reproducible experimental circumstances , suggest that they may be used to assess the effects of pharmacological manipulation of PCS rats in the treatment of hepatic encephalopathy.

2278 ALTERATIONS IN STEREOTYPY AND LOCOMOTOR ACTIVITY IN THE RAT WITH MULTIPLE DAILY INJECTIONS OF d-AMPHETAMINE. Susan B. Weinberger* and David S. Segal. Dept. Psychiatry, Sch. Med., UCSD, La Jolla, CA 92093.

Repeated single daily injections of d-amphetamine in the rat have been reported previously to produce a progressive augmentation in stereotypy and locomotion (Segal and Mandell, 1974; Segal, 1975).

However, since amphetamine-induced psychosis in humans is typically associated with shorter intervals between successive amphetamine administrations, we have extended our previous studies by characterizing the progressive behavioral changes associated with multiple daily amphetamine injections.

Male Wistar rats, housed individually in sound-attentuated chambers, received 30 successive s.c. injections of either d-amphetamine sulfate (2.5 mg/kg of free base) or saline at 4 hr intervals, followed 4 hr later in all animals by 2.5 mg/kg d-amphetamine. Locomotor activity was monitored continuously with the use of a Nova 1200 computer; stereotyped behaviors (sniffing, repetitive movements, and oral stereotypies) were assessed at 10 min intervals for 3 hr after the last amphetamine injection.

Multiple daily amphetamine injections produced a progressive decrease in latency to onset of the stereotypy phase and an increase in intensity of the stereotyped behaviors. These alterations in the amphetamine response pattern are similar to those produced by repeated single daily administration of amphetamine. In addition, the durations of both the stereotypy and the post-stereotypy hyperactivity periods were markedly shortened with multiple daily injections. When the animals were retested with the same dose of amphetamine 5-8 days after discontinuation of chronic treatment, the time of offset of these latter two phases had recovered to acute amphetamine treatment values, whereas the more rapid onset of stereotypy persisted.

These data suggest that the pattern of enhanced behavioral responsiveness produced by both single and multiple daily amphetamine injections might represent an animal model for the schizophrenia-like behavioral syndrome that develops with repeated amphetamine administration in humans.

2279 DRUG TOLERANCE WITHOUT PRIOR DRUG TREATMENT: INDUCTION OF BEHAVIORAL TOLERANCE TO DIAZEPAM BY A BEHAVIORAL TREATMENT. J.R. Wenger* and S.C. Woods* (SPON: N.J. Kenney). Dept. Psychol., Univ. Wash., Seattle, WA 98195

Learning theory can explain drug tolerance by proposing compensatory skill-learning as the mechanism underlying behavioral tolerance to drugs, i.e., behavioral tolerance is the result of learning to compensate behaviorally for drug-induced impairment of behavior. This suggests that animals given the opportunity to learn to cope with other, non-pharmacologically-induced but otherwise similar, impairments of behavior would be tolerant to drug-induced behavioral impairment. The present experiment tested and confirmed this prediction. Drug-naive rats, previously trained to walk on a treadmill in order to avoid footshock, were spun daily for 3-min at 120 rpm to render them dizzy and then immediately made to walk on the treadmill. Their performance improved over a 10-day treatment period suggesting that they were becoming tolerant to the effects of the rotation treatment. They were then tested on the treadmill after an injection of diazepam (9 mg/kg ip), an ordinarily disabling dose, and found to be behaviorally tolerant relative to appropriate control animals. Since this was the first time these animals had ever received drugs, classical mechanisms of tolerance were eliminated as potential explanations. Hence, these data support the learning theory interpretation of behavioral tolerance to drugs.

2280 INTRACRANIAL DETECTION THRESHOLDS FOR ELECTRICAL STIMULATION: EFFECTS OF CHLORPROMAZINE. Howard S. Wheeling*, and Conan Kornetsky. Laboratory of Behavioral Pharmacology, Boston University School of Medicine, 80 E. Concord St., Boston, MA. 02118 (SPON: Steven Matthysse)

Detection thresholds for intracranial electrical stimulation to the rat were determined by means of a modified psychophysical method of constant stimuli. Animals were implanted with two bipolar electrodes, one aimed at either the mesencephalic reticular formation (RF), a negatively reinforcing site, or the caudate nucleus (CN), a positively reinforcing site, and the second electrode aimed at the medial forebrain bundle (MFB). Non contingent delivery of a 0.5 sec train of current (0-40 μA, 40-60 Hz) to either the RF or the CN (S1) signalled the availability of a contingent reinforcing stimulus (S2) to the MFB. Intensities of MFB stimulation were selected that would maintain responding to detectable intensities of S1. Detection thresholds were computed from the presence or absence of a response to S1, the intensity of which was randomly varied in equally spaced steps over a predetermined range. Latency to respond and intertrial responding served as measures of drug effects unrelated to threshold changes. The current levels employed here are lower than those we find necessary to maintain escape from RF stimulation. Chlorpromazine causes dose-related (0.125 - 2 mg/kg, s.c.) increases of detection thresholds. Minimally effective doses for raising detection threshold are generally lower than those we find are necessary for elevating self-stimulation thresholds. The chlorpromazine induced elevation of intracranial stimulation detection threshold may be related to the attentional disruption observed in both animals and man to peripherally signalled, go-no-go tasks after drug administration.

2281 FENFLURAMINE AS A DISCRIMINATIVE STIMULUS IN RATS. Francis J. White and James B. Appel. Behavioral Pharmacology Lab., Dept. Psych., University of South Carolina, Columbia, SC 29208 USA

In a two-lever, water-reinforced drug discrimination task male albino rats (n = 15) were trained to discriminate 1.0 mg/kg of fenfluramine (FF) from saline. Within 16 sessions all animals reached a criterion of at least 85% correct responding. Generalization (transfer) testing, conducted during extinction, revealed an orderly increase in per cent FF responding following doses of .25, .50 and .75 mg/kg FF. Three serotonin agonists, quipazine (QP), LSD and MK 212 were also administered during transfer tests. Each of these compounds showed dose-related generalization to the FF cue: responding on the FF-appropriate lever reached 82% following a dose of 2.0 mg/kg of QP; 66% FF responding occurred following .16 mg/kg of LSD and 88% FF responding was observed after 1.0 mg/kg of MK 212. Thus, at the doses tested, the order of transfer potency was MK 212 > QP > LSD. These results confirm reports that FF exerts its behavioral effects primarily by interacting with the serotonergic neuronal system, although this interaction may be indirect (Ann. NY Acad. Sci. 305:222, 1978).

2282 DISINHIBITION OF PREDATORY ATTACK IN KITTENS BY OXAZEPAM. David L. Wolgin and Susan Servidio.* Dept. Psychol., Florida Atlantic Univ., Boca Raton, Fla. 33431.

The development of predatory attack in kittens was analyzed. Film analysis revealed that at each stage of development, attack consists of reflexive components of approach and withdrawal. Components of approach include orientation of the head and body, extension of the head and upper torso, approach involving the whole body, trapping with the forepaws and/or seizing with the mouth, and biting. The sequential appearance of these components in ontogeny appears to depend, at least in part, on the ability to maintain an adequate level of endogenous arousal. Similarly, once development is complete, the recruitment of components that appear late in ontogeny (seizing with the mouth, biting) appears to require reafferent activation from the repetition of components that develop earlier ("warm up").

Components of withdrawal include retraction of the head and upper torso, withdrawal involving the whole body, and swiping. These components inhibit seizing with the mouth and biting, and produce a more playful or defensive pattern of attack. They are more prominent in kittens tested with live prey (vs dead prey), in satiated kittens (vs food deprived kittens), and in naive kittens (vs experienced kittens).

Oxazepam in doses of 1 and 3 mg/kg greatly facilitates attack in both experienced and naive kittens by reducing components of withdrawal and increasing the intensity of attack. Unlike muscarinic cholinergic drugs, however, oxazepam does not facilitate reflexive biting to touch of the lip. These results suggest that oxazepam disinhibits predatory attack.

2283 AN ECONOMICAL SCREEN FOR PHENETHYLAMINE TYPE HALLUCINOGENS: MOUSE EAR SCRATCHING. G.K.W. Yim, T.E. Prah*, W.R. Pfister*, and D.E. Nichols[1]. Dept. Pharmacology, Toxicology and Med. Chem-Pharmacog.[1], Purdue University, W. Lafayette, IN 47907.

Stereoselectivity for the (-) isomers of DOM and of its cyclopropyl analog in eliciting either mouse ear scratching or cat limb flicks was observed in our earlier study in which single doses of the compounds were tested (NIDA Research Monograph 22: 70-81, 1978). THis study was aimed at further evaluating mouse ear scratching as an animal model for predicting hallucinogenic activity. Doses calculated for eliciting 100 scratching episodes in 30 min were: 0.7 mg/kg for (-) DOM; 1.2 g/kg for (+) DOM; 7.0 mg/kg for escaline and 24 mg/kg for mescaline. Head twitches, but no ear scratches were observed with either (+) DOM or quipazine. Thus the mouse ear scratch response was stereoselective and ranked the phenethylamine-type compounds in order of observed human potency. Phenycylidine induced a low level of scratching activity. Both LSD (0.1-125 ug/kg) and psilocybin (1.5 and 6 mg/kg) failed to elicit the scratching response. Though not sensitive to tryptamine-type compounds, the mouse ear scratch response may be an inexpensive and convient initial test for predicting potential hallucinogenic activity of phenthylamines. (Supported in part by USPHS Grant DA0191601 and a Purdue Research Foundation Fellowship (to W.R.P.).

2284 ABSTINENCE FROM L-ALPHA-ACETYLMETHADOL (LAAM), NOR-LAAM AND DINOR-LAAM IN DEPENDENT RATS: EEG AND BEHAVIORAL CORRELATES. Gerald A. Young, George F. Steinfels and Naim Khazan. Dept. of Pharmacol. and Toxicol., Univ. of Maryland Sch. of Pharmacy, Balto., MD 21201

We have previously studied and compared EEG and behavioral correlates during self-administration of LAAM, nor-LAAM and dinor-LAAM in dependent rats (Young et al, J. Pharmacol. exp. Ther., in press). The results demonstrated that the pharmacodynamic profile of LAAM differed from those of its two N-demethylated metabolites. LAAM disrupted behavior the least during self-administration. In the present report we extended these studies to a comparison of EEG and behavioral correlates during abstinence from LAAM, nor-LAAM and dinor-LAAM in dependent rats.

Adult female Sprague-Dawley rats were prepared with chronic intravenous cannulas and cortical and temporalis muscle electrodes. They were made tolerant to and physically dependent on morphine by a series of automatic hourly injections that progressively increased in dose. Each rat was then trained to lever press in order to self-administer morphine (10 mg/kg/inj) on an FR-20 schedule of reinforcement. Upon stabilization of morphine self-administration, LAAM, nor-LAAM or dinor-LAAM, each at a dose of 1 mg/kg, was substituted for morphine for an additional one to two weeks, and continuous EEG and EMG recordings were collected. Saline was then substituted for each of these narcotics which, thus, precipitated abstinence.

Upon abstinence from nor-LAAM, REM sleep was severely suppressed from the 18th through 28th hrs. In contrast, during abstinence from LAAM and dinor-LAAM, REM sleep was moderately suppressed for two days. Increases in lever pressing during abstinence from nor-LAAM occurred earlier and was more prolonged than for LAAM and dinor-LAAM. The incidence of head shakes peaked earlier and was higher for nor-LAAM and dinor-LAAM during abstinence than for LAAM.

These results demonstrated further pharmacodynamic differences between LAAM and its two N-demethylated metabolites. Our findings suggest that in dependent rats abstinence from LAAM was least severe when compared with abstinence from nor-LAAM and dinor-LAAM. (Supported by NIDA Grant DA 01050.)

2285 Chronic Amphetamine Treatment and Intracranial Self-Stimulation: Response Sesnsitization and Depression. Robert M. Zacharko* and Larry Kokkinidis* (Spon. T.B.Wishart). Dept. Psych., University of Calgary, Calgary, Alberta, and Dept. Psych., University of Saskatchewan, Saskatoon, Saskatchewan, Canada.

Long-term amphetamine treatment results in tolerance to some drug-induced behaviors, (e.g., anorexia), whereas other drug-induced behaviors do not undergo tolerance (e.g., stereotypy). In fact, following chronic exposure to amphetamine, drug-induced stereotypies are exacerbated. Although the enhanced stereotypies following chronic amphetamine treatment may involve several factors, it appears that the increased neuronal efficacy of dopamine (DA) transmission induced by chronic exposure to drug plays a primary role in this respect. In the present study we examined the effects of chronic amphetamine treatment on intracranial self-stimulation (ICSS) from the substantia nigra in order to determine whether chronic drug treatment would modify ICSS and whether these changes parallel those observed with stereotypy. Baseline rates of responding were determined at a standard current intensity of 30 uA, 100 Hz biphasic square wave for all animals (n=40). Following baseline testing one-half of the surgically prepared animals received intraperitoneal (i.p.) injections of d-amphetamine sulphate (7.5 mg/kg) twice daily for 5 consecutive days. The remaining half were chronically treated with saline. On test day (Day 6) the animals were subdivided further such that half the animals in each group were tested with a test dose of 0.3 mg/kg d-amphetamine sulphate while the other half received saline. This chronic drug treatment/test sequence was continued for 5 sessions (30 days). Rats chronically treated with saline and tested with d-amphetamine (0.3 mg/kg) showed comparable self-stimulation rates relative to animals chronically treated and tested with saline on all test days with the exception of test day 4. Among rats chronically treated with the test dose of d-amphetamine a significant facilitation of self-stimulation relative to the remaining groups was observed on four of the five test days. In contrast, rats chronically treated with amphetamine and tested with saline showed a depression of self-stimulation rates relative to control animals Thus,within the same self-stimulation paradigm both response depression and sensitization were observed as a consequence of long-term amphetamine administration. It appears that when animals are tested with a low dose of amphetamine, which ordinarily has no behavioral consequences, ICSS responding is enhanced (sensitization), presumably due to a hyperactive dopamine system (receptor supersensitivity) resulting from chronic exposure to the drug. In the absence of the drug on test day the dopamine system remains hypoactive and consequently a depression of ICSS is observed.

2286 SPECIFIC [^{3}H] PHENCYCLIDINE BINDING IN THE RAT CENTRAL NERVOUS SYSTEM. Stephen R. Zukin* and R. Suzanne Zukin* (SPON: W. T. Norton). Department of Psychiatry, Downstate Medical Center, Brooklyn, N.Y. 11203 and Department of Biochemistry, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Phencyclidine (PCP), a leading drug of abuse, has anesthetic, analgesic, cardiovascular and psychotomimetic effects. In order to investigate the mechanisms of CNS actions of PCP, we studied binding of [^{3}H] PCP to rat brain membrane preparations. [^{3}H] PCP binds specifically and with high affinity (K_D = 1.5 x 10^{-7} M at pH 7.4) to a saturable class of binding sites. Specific binding constitutes approximately 70% of total binding at 0° and 33% of total binding at 37° (at 10^{-8} M [^{3}H] PCP). This binding can be displaced by nonradioactive PCP and a series of ten PCP analogs with relative potencies that closely parallel those determined in vivo in mouse rotarod ($p < 0.005$) and rat drug discrimination ($p < 0.001$) tests. Muscarinic cholinergic ligands inhibit [^{3}H] PCP binding, but only at high concentrations (IC_{50}s = 10^{-4} - 10^{-3} M) and in rank order at variance with that determined for their binding to muscarinic receptor sites or for their pharmacological potencies. Other centrally acting drugs including opiates are unable to displace specifically bound [^{3}H] PCP at > 10^{-4} M concentrations. In subcellular fractionation experiments, [^{3}H] PCP binding is most enriched in the crude synaptosomal membrane fraction (3.3 times higher than in the mitochondria-myelin fraction; 5.1 times higher than in the whole brain homogenate). In regional binding distribution studies, [^{3}H] PCP binding is about three times higher in hippocampus (region of highest density) than in cervical spinal cord (region of lowest density); intermediate levels are found in hypothalamus > caudate nucleus > frontal cortex > cerebellum > medulla/pons, amygdala. Binding of [^{3}H] PCP to some peripheral tissues does occur but displacement of this binding by PCP analogs fails to correlate with the CNS binding or with pharmacological properties. Trypsin, pronase, N-ethylmaleimide, iodoacetamide, acidic pH, high temperature, and calcium reduce specific [^{3}H] PCP binding. Thus, PCP and its analogs may exert their CNS effects via binding to specific CNS receptor sites.

PSYCHOPHYSICS

2287 ROLE OF POSITION SENSE IN DIRECTION DETECTION ON THE SKIN. D.A. Dreyer, G.H. Duncan*, and C.L. Wong*. Dental Research Center; Dept. of Oral Surgery, School of Dentistry; Dept. of Physiology, School of Medicine; Neurobiology Program, University of North Carolina, Chapel Hill, N.C. 27514.

Somesthetic discriminatory capacity is generally recognized to be optimal when the stimulating object is moving parallel to the skin's surface. An experimental model of this mode of stimulation is the ability to correctly identify the direction of a brush stroke across the skin. Previous studies with this model have shown that the accuracy of direction discrimination improves with increasing length of skin contacted by the brush. This may be due to the increased surface area of stimulus contact or to the increasing separation of the extreme points of stimulus contact. The present study investigates these two possibilities.

Discrimination of brush stroke direction was assessed in normal human subjects for stimuli applied to the ventral forearm. The independent variables studied were the velocity of brush movement and the area of skin contacted by the brush. A servomotor moved the brush at any of nine velocities ranging from 0.5 to 250 cm/sec; velocity and direction of movement were randomized within each block of 180 trials. Area of skin contacted by the brush was controlled by plates with 0.5 cm wide apertures of different lengths. These apertures consisted of either a single slot (1-6 cm long) or two short slots split by a solid midportion. Thus the 4 cm. split aperture, for example, was identical to the 4 cm. continuous aperture except for the central 3.5 cm. which shielded the skin from brush contact. The subjects' reports of perceived brush direction were elicited by a forced-choice procedure.

The results of the present study indicate that, at slow brush velocities the ability to identify the stimulus direction was comparable for the continuous and split apertures, although the amount of skin exposed to the stimulus in the split apertures was from 50-91% less than that exposed in a continuous aperture of comparable length. At faster velocities, discriminative ability fell off sharply with both aperture types, but the performance decline with the split aperture was much more pronounced. These results are interpreted as evidence for the importance of position detection in correctly identifying the direction of a moving stimulus. Although the total area of stimulus contact remained constant for all split-aperture plates, direction discriminability increased with increasing distance between the two apertures.

2288 NON-ANALGESIC EFFECTS OF NITROUS OXIDE ON SOMESTHETIC SENSITIVITY AND PERCEPTION OF SENSITIVITY. G.H. Duncan*, D.A. Dreyer, and J.M. Gregg* (SPON: J.S. Hanker). Dental Research Center; Oral Surgery, School of Dentistry; Dept. of Physiology, School of Medicine; Neurobiology Program, UNC, Chapel Hill, N.C. 27514

Subanesthetic levels of nitrous oxide (N_2O) have been shown to produce impairments in auditory and visual acuity, psychmotor performance, short-term memory, and reaction time. A single study involving stationary somatosensory stimuli reported that 25% N_2O impaired warmth and pressure thresholds in three subjects. It is generally acknowledged that the capacity to identify an object is optimal when the object and skin are in tangential motion relative to each other (identification of a coin by passing the fingers across its surface). This study investigates the effects of N_2O on somesthesia as measured by an experimental model of tangential stimulus movement.

Ten volunteers were each tested under two conditions -- 100% O_2 and 30% N_2O/70% O_2. All sessions were otherwise identical and consisted of 100 brush strokes presented to the thenar eminance. A servomotor moved the brush at any of 5 velocities ranging from .4 to 150 cm/sec.; velocity and direction of movement (either proximal to distal or the reverse) were randomized within each session. The area of skin contacted by the brush was defined by a rectangular aperture 0.5 cm. wide and 1.5 cm. long. The subject reported the perceived direction of brush movement past the aperture by pushing a switch in the appropriate direction. Following each session, the subject estimated his performance and his level of sedation on visual analogue scales.

Subjective reports of sedation levels ranged from 35-90% during the N_2O sessions as compared to 0-30% during the O_2 sessions. Nine of the ten subjects reported that 30% N_2O significantly altered their ability to detect brush direction. Analysis of the actual performance data revealed no significant differences in the subjects' ability to differentiate brush directions at any of the 5 velocities. Thus at 30% N_2O, which resulted in moderate sedation and altered preception of performance, actual discriminability on this somesthetic test was not greatly effected. These results are consistent with previous reports of subjective increases and objective decreases in auditory acuity with N_2O sedation. The previous report of decreased pressure sensitivity due to N_2O used a stationary threshold measure, whereas discrimination of brush stroke direction involves temporal and spatial evaluation of a suprathreshold moving stimulus. Performance in this integrative task may not be as sensitive to the effects of N_2O as the simple identification of pressure thresholds. Supported by DE 02668, RR 05333, DE 07018, DE 00011 and the Alfred P. Sloan Foundation.

2289 SPATIAL SUMMATION IN THE COLD SENSE. Joseph C. Stevens. John B. Pierce Fndn. Lab. and Yale Univ., New Haven, CT 06519.

This study revealed that the level of cold sensation that a person experiences depends almost as much on the areal extent of skin stimulated as on the amount of skin cooling. Under the right circumstances a person cannot tell how large is the area of stimulation, because area registers not as apparent area, but as level of cold sensation. These findings were obtained through the use of a set of stimulators composed of cold copper disks (2 to 20 cm^2) surrounded by a ring of styrofoam of such size as to make the total area of contact a constant 24 cm^2. Groups of subjects made magnitude estimates of cold sensation level (C) aroused by various amounts of skin cooling (ϕ) and various areas (A). Most of the results come from the forearm, with secondary results from the face and the back. Subjects almost never came to realize that the thermal area was being varied. Also, it turned out that, for any constant A, cold grows approximately as a power function of ϕ (average exponent = 1.07) and that given any constant ϕ, cold grows as a power function of A (exponent = 0.82). A single equation applies to all the results, namely: $C = k\phi^{1.07}\, cA^{0.82}$. For any constant C (termed K) we can write the equation $K = \phi A^{0.82/1.07}$ or $K = \phi A^{0.77}$, showing how level and area trade to preserve constant cold sensation. This equation shows that the cold sense summates well (but imperfectly) the neural effects of stimulation over wide areas. However, the amount of cold experienced tends toward an asymptote when A and ϕ together become large enough. This latter result suggests that the "ceiling" on cold sensation is imposed by a neural mechanism more central than the cold receptors. The findings concerning cold contrast with earlier findings concerning spatial summation of warmth (Stevens et al., Physiol. & Behav., 13, 825, 1974). For warmth, the rules of summation are more complex. For the absolute threshold, area and level trade according to a nearly perfect reciprocity. As the criterion level of warmth is progressively increased, area counts less and less relative to level. At the threshold of pain, area counts little or none at all, i.e., there is negligible spatial summation. The areal dimensions of pure warmth stimulation, as for cold, are very difficult to perceive. The available evidence so far suggests that the basic features of spatial summation in both thermal senses take shape in the central nervous system.

2290 ADAPTATION LEVEL IN NORMALS & SCHIZOPHRENICS TESTED BY A PRODUCTION OF EQUAL TIME INTERVALS METHOD. George A. Vroulis. Behavioral Neurochemistry Section, Texas Research Institute of Mental Sciences, Medical Center, Houston, TX 77030.

According to the concept of adaptation as it was developed by Helson, adaptation level represents the zero or origin to which gradients of stimulation are referable. The steeper the gradient the greater the impact of the stimulus on the organism and the greater the response to it. In summary the level of adaptation is the pooled effect of (a) focal stimuli, (b) background stimuli and (c) residual stimuli.

When normal subjects are instructed to produce equal time interval, (TI), by counting 4 beats in 20 consecutive trials, their performance is described by a sawtooth function. (The TI decreases progressively during the first 3 or 4 trials but it increases abruptly during the 4th or the 5th trial. This pattern is repeated throughout the 20 trials).

The progressive decrease of the TI is attributed to the residual stimulation of the previous trial, (focal and background stimuli are constant), while the sudden decrease of TI (or increase of speech rate) every 3 or 4 trials is a self-corrective response of the subject's awareness of "mispronounciation" as the rate of speech increases.

The above mentioned task will be given to inpatient schizophrenics before and during the administration of antipsychotic medication. The slope of the progressive decrease of the TI will be used as a measure of adaptation level and may prove a helpfull behavioral rating device when correlated to the blood level measurement of various antipsychotic medications.

In addition subjects will be scored on: "Reaction Time", "Finger Tapping Speed", "Brief Psychiatric Rating Scale" and "Modified New Haven Schizophrenia Scale".

2291 SEMANTIC FUNCTIONAL MEASUREMENT OF PAIN: INTEGRATING PERCEPTION & LANGUAGE. P.J. Wolskee* and R.H. Gracely* (SPON: G.J. Bennett). Neurobiology & Anesthesiology Br., NIDR, NIH, Bethesda, MD 20205.

This study used Functional Measurement (FM) scaling procedures to demonstrate that subjects can scale and integrate pain that is produced by an electrical tooth pulp stimulus and symbolized by a word. Unlike conventional psychophysical scaling methods, FM includes a testable integration criterion that must be met before the scale is accepted. This method does not require physical measures of stimulus intensity and can produce direct scales of sensory input of non-metric stimuli such as words or pain experience. We required subjects to respond to the average of a metric and a non-metric stimulus set: 1) painful electrical stimuli (metric stimulus) applied to the tooth pulp (1 sec trains of 100 Hz, 1 msec monophasic monopolar pulses) and 2) verbal descriptors (non-metric stimulus) of sensory intensity (weak, mild, moderate, strong, intense) and unpleasantness (annoying, uncomfortable, dreadful, horrible, agonizing) that symbolize different dimensions of the pain experience. Eighteen subjects received all possible pairs of 1) 5 tooth pulp stimuli ranging in equal log steps from pain threshold to tolerance, plus 2) 5 descriptors of sensory intensity or unpleasantness twice each for a total of 50 stimulus pairs. Each subject rated the average sensory intensity or unpleasantness of each tooth pulp-word pair by squeezing a hand dynamometer. The ability to average the perceptions and the validation of both the task and resultant scales can be tested by a statistical test (2 way ANOVA). A nonsignificant interaction term validates the test and resultant interval scales of both stimulus sets. Statistical analyses of sensory intensity responses showed significant main effects of tooth pulp stimuli ($F(4,36) = 12.87$ $p<0.0001$) and words ($F(4,16) = 25.20$ $p<0.0001$) and nonsignificant interaction ($F(16,144) = 1.11$ $p<0.3483$). Analyses of the unpleasantness responses also showed significant main effects of tooth pulp stimuli ($F(4,28) = 4.84$ $p<0.0043$) and words ($F(4,16) = 12.99$ $p<0.0001$) but the interaction was only marginally nonsignificant ($F(16,112) = 1.73$ $p<0.0508$). This result shows that subjects can use the intensity of a sensation or a word that symbolizes sensory intensity interchangeably in an averaging scaling task, supporting the use of verbal descriptors of sensory intensity in the assessment of pain. Unpleasantness scaling shows that these word scales are not integrated with actual stimuli as easily as sensory words. We conclude that subjects can integrate the pain produced by a tooth pulp stimulus with pain symbolized by a word and that this integration varies with the type of words used. FM methods may provide a new and promising tool for the assessment of pain experience.

REGENERATION

2292 THE CONTROL OF REGENERATION SPECIFICITY IN EARTHWORM GIANT AXONS
Stewart C. Birse* and George D. Bittner, (Spon:H.M. Eisenberg) Dept. of Zoology, Univ. of Texas, Austin, Texas 78712

We have previously reported that transected and ablated giant axons in the earthworm ventral nerve cord (VNC) regenerate by growing neuronal processes which arise from the severed stumps of the giant axons, traverse the lesion site and contact a giant axon on the opposite side of the lesion (Birse and Bittner, 1976,1977, 1978). Furthermore, the specificity of giant axon reconnection was very high in that every physiological recording from a giant axon which demonstrated regeneration, also showed that the appropriate giant axons had reconnected and that no inappropriate functional contacts were made.

To examine the morphological basis for the high degree of regeneration specificity, we injected Lucifer Yellow CH intracellularly into a giant axon in 22 animals with VNC transections and 15 animals with VNC ablations. The injections filled neuronal processes, many of which crossed the lesion site and established appropriate contacts on the opposite side of the lesion, as we have previously reported. However, some neuronal processes grew for 1-2 VNC segments beyond the lesion or grew away from the lesion site. In some cases, the neuronal processes of an injected giant axon appeared in close proximity to an inappropriate giant axon. We also observed that as postoperative time increased, regenerating giant axons produced greater numbers of axonal processes.

Our observation of occasional misdirected axonal outgrowth is at variance with our observation of highly specific functional reconnection. This paradox might be resolved, however, if some mechanism were to insure that only the correct contact were permitted to establish a functional connection. The probability of making a correct contact is increased by extending many processes from a regenerating giant axon. If only the correct contact established function, regeneration specificity would be very high, even when the control of outgrowth was not always directed appropriately. The high degree of regeneration specificity we observed in the earthworm, then, might be the result of a highly selective mechanism for establishing functional contacts, not a highly directed growth mechanism.

(This research was supported by NIH Grant # NS-14412 and an RCDA to G.D.B.)

2293 THE MECHANISM OF AXONAL REGENERATION IN CRAYFISH MOTOR NEURONS.
George D. Bittner, Michael S. Bouton*. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

Previous studies have shown that the distal segment of a severed crayfish motor axon may survive for 100-250 days following separation from its cell body. Regeneration of the severed motor axon occurs by reconnection of the proximal stump with the surviving distal stump via mechanisms as yet unknown (Hoy, et. al., Sci., 1967; Kennedy and Bittner, Cell Tiss. Res., 1974). Axonal regeneration in these animals has been associated with the presence of multiple profiles assumed to arise from the severed proximal stumps and to grow within the glial sheaths of surviving distal segments (Nordlander and Singer, Z. Zellforsch, 1972). Similar phenomena have been reported in the leech (Van Essen and Jansen, Cold Spring Harbor Symposia, 1976; Frank, et al., J. Comp. Neurol. 1975; Carbonetto and Muller, Nature, 1977) and the earthworm (Birse and Bittner, Brain Res., 1976).

Several theories have been proposed to account for regeneration in these various preparations:

1) The proximal stump grows out for a greater or lesser distance and morphologically fuses or makes electrotonic connections with the surviving distal stump. A new set of synapses are never formed (Hoy, et.al., Sci., 1967; Bittner and Kennedy, Cell Tiss. Res., 1974; Frank, et. al., J. Comp. Neurol., 1975).

2) The proximal stump grows out as described above, but eventually reaches the target tissue and makes a new set of synapses. The original distal stump may or may not degenerate (Nordlander and Singer, Z. Zellforsch, 1972; Carbonetto and Muller, Nature, 1977).

We have initiated a series of experiments to determine more precisely the mechanism of regeneration in crayfish motor neurons. We are examining the distal stumps of severed motor axons at various times up to 400 days after regeneration. In reconnected cases, we have found more multiple profiles near the target muscle at 400 days than at 50 days after regeneration is first noted. We are injecting the proximal and distal stumps of regenerated motor axons to determine the origin and specificity of these multiple profiles.

2294 THE EFFECT OF A REPEATED OPTIC NERVE INJURY ON THE RETINAL GANGLION CELL RESPONSE IN THE NEWT (Notophthalmus viridescens).
T. O. Brock, III and J. E. Turner, Jr, Dept. of Anat., Bowman Gray Sch. of Med. of Wake Forest Univ., Winston-Salem, NC 27103

Optic axon outgrowth from the lesioned newt retinal ganglion cell (RGC) can be enhanced by administering a second optic nerve lesion proximal to and 4 days after the initial lesion. The newt RGC responds after a single or double lesion of its axon with a visible time course of chromatin changes that corresponds to an increase in cell activity. These chromatin pattern changes progress in a linear fashion from a homogeneous to a heterogeneous state with over 50% of the cells demonstrating prominent changes by 14 days after lesion. The nuclear reactivity plateaus until day 21 and then decreases to control values by 90 days after lesion. A series of experiments was designed to ascertain if a second optic nerve lesion administered 21 days after the initial lesion would maintain the cells in an extended period of heightened activity. In these experiments all animals received an initial optic nerve crush and then were divided into single lesion (control) and double lesion (experimental) groups. Controls were sacrificed at various times between 24 to 90 days after lesion. Experimental animals received a second crush just proximal to the initial lesion at day 21 and were sacrificed at various times between 3 to 69 days after second lesion. In each case the total survival time was the same in control and experimental groups. Results indicate that the second optic nerve lesion maintains the number of RG cells demonstrating prominent chromatin changes for periods of time twice as long as those receiving a single lesion. EM morphometric analysis of cells in the RGC layer during this extended plateau period revealed that perikaryal area, nucleolar area and number and, the perikaryal to nuclear ratio were significantly greater than in controls of the same survival period.

2296 RATES OF GROWTH AND COMPOSITION OF AXONALLY TRANSPORTED PROTEINS IN REGENERATING OLFACTORY NERVE. P. Cancalon and J. S. Elam. Dept. Biol. Sci., FSU, Tallahassee, FL., 32306.

Previous ultrastructural and biochemical studies of the olfactory nerve have indicated that axonal injury causes total degeneration of the mature neurons followed by replacement with new neuronal cells arising from undifferentiated mucosal cells. (Graziadei, P.P.C. and Graziadei, G.A., in Neuronal Plasticity, 1978). Intra-axonal transport of 35S methionine labeled protein was used to study regeneration in the unusually long garfish olfactory nerve.

Results indicate that nerves crushed 1.5 cm from the cell bodies produce three distinct populations of regenerating fibers. The first traverses the crush site one week postoperative and progresses along the nerve at a rate of 5.8 ± 0.3 mm/day for the leading fibers of the group and 4.9 ± 0.2 mm/day for the majority of axons. The second group of fibers traverses the crush site after 2 weeks postcrush and advances for 60 days at the constant rate of 2.1 ± 0.1 mm/day for the leading fibers and 1.9 ± 0.1 mm/day for the bulk of the axons. The velocities subsequently fall to 1.6 ± 0.2 and 0.8 ± 0.1 mm/day for the leading and main population of fibers respectively. Electron microscopy of the proximal and distal regions of a regenerating nerve at 100 days indicates that each of the two most rapid phases of growing fibers represents between 2 to 5% of the original population of axons. They both are typically characterized by small fascicles of axons surrounded by glial cells and large amounts of collagenous material. The leading fibers of a third group of regenerating axons traverse the crush site after 4 weeks and advance at a constant rate of 0.8 ± 0.2 mm/day. The fibers appear to represent 50-70% of the original axon populations.

Analysis of fast axonal transport of radioactive proteins in the most rapidly growing phase of regenerating fibers indicates that the rate of transport is unaffected by regeneration. However preliminary calculations indicate that this phase may contain as much as 8 to 16 times more radioactivity per fiber that unoperated controls. Subcellular and polypeptide analysis were also performed on material accumulating at the tip of the most rapidly growing fibers. Although there was general similarity to results in intact nerves, a shift of radioactivity from higher to lower density membranous fractions was observed. This may reflect a relatively lower proportion of protein in immature nerve cell membrane (Pfenniger and Bunge, J. Cell Biol. 63:180, 1974). Small but significant differences were also observed in the molecular weight distribution of transported polypeptides. (Supported by the National Paraplegia Foundation and NIH grant NS 11456).

2297 MORPHOLOGY OF LAMINA IX NEURONS OF THE RAT THORACIC SPINAL CORD FROM DAY 14 OF GESTATION TO ADULTHOOD. John P. Cummings* and Dennis J. Stelzner. Department of Anatomy, SUNY-Upstate Medical Center, Syracuse, New York 13210.

Following rat spinal hemisection, Bernstein and Bernstein(Experimental Neurology 30:336-351) proposed that neurons proximal to the lesion "de-differentiate" to a more primitive state in which the neuron is once again capable of accepting synapses. From day 10 to day 90 following hemisection motor neurons were observed to have decreased dendritic fields, loss of dendritic branches and an increased number of dendritic varicosities along the entire length of their dendrites. The current study was undertaken to study the maturation of lamina IX neurons in the rat thoracic spinal cord from day 14 of gestation to adulthood so that the stages of differentiation of lamina IX neurons could be compared with the stages of "de-differentiation" described by Bernstein and Bernstein.

From day E-14 to day E-18 the primary dendrites of lamina IX neurons appear to be adult in number. However, they are short in length and have varicosities of uneven diameter. Hair-like structures protrude from these varicosities. From day E-18 until postnatal day 2 the more proximal parts of the dendrites retain these varicosities, and, in addition are invested with long hair-like processes up to 5μm in length. These structures are also occasionally found on the cell body while the more distal dendrites retain the morphology found earlier. Between postnatal days 2 and 12 the secondary and tertiary dendrites develop dendritic spines which are greater in number but shorter in length than those found earlier on the primary dendrites. The primary dendrites at this stage have a much smoother appearance and shorter spines than are found on the more distal dendrites. Beginning with postnatal day 12 there is a gradual shortening and reduction of dendritic spines on all parts of the neuron accompanied by a reduction in the diameter of the dendritic varicosities until the adult morphology of lamina IX neurons is obtained between postnatal days 24 and 30.

Thus immature lamina IX neurons resemble the "de-differentiated" cells reported by Bernstein and Bernstein in certain respects, but the stages of maturation are not directly comparable with the stages of "de-differentiation" that they found. Possibly the correlation would be more exact if lamina IX neurons were studied over a larger number of intervals following spinal cord injury. Such a study is in progress comparing neurons after spinal transection in the newborn and weanling rat. (Supported by Grant NS-14096)

2298 ENDOGENOUS LECTINS IN COCKROACH MUSCLES-CANDIDATE RECOGNITION MACROMOLECULES. Jeffrey L. Denburg. Dept. Zoology, Univ. of Iowa, Iowa City, IA 52242.

One biochemical model for the intercellular recognition process between motor neurons and muscles involves lectin-like macromolecules that may function as intercellular cross-bridges. The coxal depressor muscles of the cockroach Periplaneta americana, offer an ideal system for testing this hypothesis. They are innervated by identified motor neurons in the thoracic ganglia which upon crushing their axons regenerate until the original innervation pattern is reformed (Pearson and Bradley, Brain Res. 47: 492, 1972). This pattern consists of muscles 178, 179 innervated by a single motor neuron D_f, muscles 177d,e innervated by a single motor neuron D_s and muscles 177d',e' which are a homogeneous population of fibers innervated by both D_f and D_s (Pearson and Iles, JEB 54: 215, 1971).

Lectins have been detected in homogenates of each of the cockroach muscles using the microtiter assay for agglutination of human red blood cells. The lectin in muscles 178, 179 has a carbohydrate binding site of different specificity from that in muscles 177d,e. This is determined by the ability of sugars to inhibit hemagglutination. Galacturonic acid (1mM) can inhibit the lectin of muscles 178, 179 by 50%. At least 10mM concentration of this sugar is needed to produce the same amount of inhibition of lectin from muscles 177d,e. These muscles on the other hand are preferentially inhibited by amino sugars. These muscle hemagglutinins are insoluble and may be localized to the basement membrane as inferred from the inability to solubilize them with non-ionic detergents. They are heat labile and inactivated by treatment with proteolytic enzymes.

Evidence for the role of such macromolecules in intercellular recognition comes from the following observations: 1) Correlation between presence in muscle of lectin with particular sugar specificity and innervation by particular identified motor neuron; 2) Denervation of muscles results in a lowering of levels of hemagglutinin which recover as reinnervation occurs; and 3) Detection in neuronal extracts of soluble, heat stable, protease insensitive macromolecules that inhibit hemagglutination by muscle macromolecules.

2299 ENHANCEMENT OF AXONAL OUTGROWTH BY A PRIOR ("CONDITIONING") LESION: EFFECT OF LESION INTERVAL. D. Louise Edwards*, Roberta M. Alpert*, Peter G. Mandelson*, Irvine G. McQuarrie, and Bernice Grafstein. Dept. Physiol., Cornell University Medical College, New York, NY 10021

The rate of outgrowth of goldfish optic axons is enhanced by a prior lesion of the same axons (I.G. McQuarrie & B. Grafstein, Soc. Neurosci. Abstr. 4: 533, 1978). This enhancement was found to be maximal when the "testing" lesion from which outgrowth is measured (crushing the optic nerve) was preceded by a "conditioning" lesion (cutting the optic tract) 14 days earlier. Lesion intervals of 7 and 21 days were less effective. These results were obtained by measuring the time required for recovery of visual function following the testing lesion. Recovery of function was defined as the appearance of a startle response to light after a 20 minute period of dark adaptation. For other indicators of visual function, e.g. the dorsal light reflex and food localizing behavior, which recover more slowly than the startle response, the recovery times did not vary with the interval between testing and conditioning lesions.

2300 REGENERATION OF SPECIFIC NEUROMUSCULAR CONNECTIONS IN THE CRAYFISH. Pamela Ely* and Samuel J. Velez. Department of Biological Sciences, Dartmouth College, Hanover, N.H. 03755

In the projection of six motoneurons to a flat sheet of 40 muscle fibers, the superficial flexor muscle of the crayfish Procambarus clarkii, the probability that a given axon innervates a given muscle fiber is a simple function of the position of the fiber in the muscle sheet (Velez & Wyman; J. of Neurophys. 41: 75-96). The specificity of these connections makes this a very suitable system in which to study the regeneration of connections between identifiable cells. The third superficial root was cut as the nerve crossed between some muscle fibers, leaving the proximal stump anchored to the muscle and some neuromuscular junctions intact. The presence of these few remaining junctions facilitated nerve regeneration; in their absence, with an unattached nerve, degeneration of the proximal stump occurred. The animals were allowed to recover, and analysis was performed on isolated abdomens on a weekly basis by recording the spontaneous activity of the nerve with an extracellular oil electrode and measuring junction potentials (jp's) with 3M KCl microelectrodes. Regeneration was first found in animals 2-3 weeks post-op. The small axons (1, 2 and 3) regenerated first, the large axons (4 and 6) regenerated later. By 5-6 weeks the entire plane of the muscle was innervated by at least one of the axons (usually a small one) though there were 'holes' in the map, i.e., some muscle fibers innervated by certain axons in controls were not innervated in regenerated animals. JP's of 10-20 mV in size, giant relative to controls (1-5 mV in size), were invariably found on a few muscle fibers in regenerating animals. The region of these giant jp's varied with the post-operative age of the animals. Methylene blue staining revealed that the region of giant jp's corresponded to the area of the growing tip of the nerve. It was further noted that the regenerated nerve was initially a single process; branching was rare until relatively late in the course of regeneration. The regenerated nerve frequently ran ventral to the plane of the muscle fibers, in contrast to controls where the nerve always ran dorsal to the plane of the muscle fibers. Regeneration was complete, and comparable in connection specificity to control animals, by 9-10 weeks.

2301 RESTITUTION OF LONG DESCENDING TRACTS AND NORMAL BEHAVIOR FOLLOWING SPINAL CORD TRANSECTION IN ANURA. Cynthia J. Forehand* and Paul B. Farel (Spon: D.L. McIlwain). Neurobiol. Prog. and Dept. Physiol., Sch. Med., Univ. N. Carolina, Chapel Hill, NC 27514.

Midthoracic spinal cord transection in bullfrog tadpoles produces behavioral deficits that persist until metamorphosis, regardless of the developmental stage at which the transection is performed. In contrast, operated tadpoles allowed to go through metamorphosis are, as juvenile frogs, behaviorally indistinguishable from unoperated animals. Similarly, we have, in horseradish peroxidase (HRP) studies, found no evidence of long tract regeneration in tadpole; however long descending fibers are clearly demonstrable in previously transected, metamorphosed animals.

Following transection of tadpole spinal cord, gross anatomical continuity of the cord is restored in 1-2 weeks. For periods up to 60 days postoperative, however, righting reflexes are sluggish, responses are difficult to evoke by visual stimuli, and there is little swimming in the absence of stimulation. Injection of HRP into the lumbar enlargement of the previously operated tadpole reveals heavy labeling of fibers caudal to the thoracic transection site but no fibers bridging this region are labeled. While in the unoperated tadpole, cell bodies in the vestibular nuclei and brainstem reticular formation are consistently found, cells in these areas are not labeled in the previously transected tadpoles. Electrophysiological evidence indicates functional connection between the previously severed halves in tadpole stages may be mediated by short axons of propriospinal neurons crossing the gap.

Transected tadpoles held through metamorphosis showed the same pattern of behavioral deficits before completion of metamorphosis. Following the 2-3 week metamorphic period, these animals showed behavioral recovery such that they were indistinguishable from unoperated controls in their walking, leaping and swimming. Righting reflexes were brisk, and scratch reflexes were properly directed and of normal threshold. HRP injection into the lumbar enlargement labeled fibers in the ventral funiculus that traversed the transection site. Somata were labeled in the vestibular nuclei and throughout the reticular formation as far rostral as the midbrain.

Two possible explanations of the differences between tadpoles and juvenile frogs can be considered. First, the stimulus necessary for regeneration of long tracts is present only during metamorphosis. Alternatively, different brainstem neurons might project to lumbar regions in tadpole and frog. During metamorphosis these new descending connections could develop in both unoperated and previously transected tadpoles to form the substrate of normal behavior in both groups of animals.

2302 SYNAPTIC RECEPTORS IN THE DEGENERATING AND REGENERATING VISUAL PATHWAY. Andrew Francis* and Nisson Schechter. Department of Neurology, Cornell University Medical College, New York, 10021 and Department of Psychiatry and the Long Island Research Institute, SUNY, Stony Brook, New York 11794.

After optic nerve crush, regeneration and apparent specific reconnection of optic axons occurs at the optic tectum in goldfish. Critical to an understanding of the molecular basis of reconnection is an analysis of the disconnection and reconnection processes at the synaptic level. We have been employing established synaptic receptor ligands in the effort to follow changes in the number, concentrations, and type of synaptic molecules during the disconnection and reconnection process, focusing on the cholinergic system. Nicotinic-cholinergic receptor activity was estimated by the binding of alphabungarotoxin (aBuTx) and muscarinic-cholinergic activity by quinuclidinyl benzilidate (QNB) binding. After optic nerve crush in goldfish, there is an initial rapid loss, followed by a later recovery of aBuTx binding which correlates with regeneration of the optic nerve; after eye removal, which produces a permanent disconnection of the optic tectum, the same rapid loss in aBuTx binding occurs, but is permanent (Brain Res., 166, 57). In parallel experiments, analysis of QNB binding indicated that there were no changes in binding activity of goldfish optic tectum during optic nerve degeneration. We have also observed the same pattern of rapid loss in aBuTx activity with stable QNB activity after similar disconnections of the retinotectal system in developing and adult birds, as well as in the retino-collocullar pathway in rats. In these systems, we have not observed loss of choline acetyltransferase activity, although in the goldfish system, there are small, consistent losses in activity which recover as optic nerve reconnection proceeds (in press). These results suggest that there may be some important biological significance to the plasticity of nicotinic-cholinergic receptor activity in these systems, which is in contrast to the marked stability of the muscarinic-cholinergic activity. It would appear that the nicotinic receptors are closely involved in the primary retinotectal synapse, possibly presynaptic or postsynaptic at the retinotectal terminals. The muscarinic receptors may be in another independent tectal system of afferents of intrinsic neurons. Therefore, nicotinic-cholinergic receptor activity may represent a useful and selective biochemical probe for retinotectal synapses and their dynamics.

2303 THE EFFECT OF N^6,O^2-DIBUTYRYL ADENOSINE 3',5'-MONOPHOSPHATE ON THE DEGENERATION AND REGENERATION OF CRUSH-LESIONED RAT SCIATIC NERVES. M. R. Gershenbaum* and F. J. Roisen* (SPON: S. Rosner). Dept. of Anatomy, Rutgers Medical School-CMDNJ, Piscataway, NJ 08854.

The ability of N^6,O^2-dibutyryl adenosine 3',5'-monophosphate [$(But)_2$cAMP] to stimulate nerve development in vitro prompted us to study the effects of the nucleotide on the in vivo degeneration and regeneration of crushed rat sciatic nerves. The animals received daily intramuscular injections of either $(But)_2$cAMP (50mg/Kg) or 0.9% saline after operation and were tested daily for the return of sensorimotor function (SMF). An index of SMF was obtained by placing the foot of the lesioned limb over the aperture of a shutter-controlled high intensity light box. The time required for foot withdrawal was recorded to the nearest second. $(But)_2$cAMP and saline-treated rats showed little difference in the rate of return of SMF for 10 days, but by day 12, the response times for the nucleotide-treated animals diverged from those in the saline-treated group. Nucleotide-treated animals appeared to be completely recovered by day 16, while saline treated rats did not exhibit full recovery until day 26. To investigate the morphological changes that accompanied this functional recovery, rats were sacrificed 3, 10, 18, and 32 days following crush and their nerves prepared for transmission and scanning electron microscopy. These observations, fiber counts and measurements of fiber size indicated that $(But)_2$cAMP accelerated the initial processes of Wallerian degeneration and enhanced the rates of regeneration and maturation of the peripheral nerve fibers. In general, the crushed nerves of nucleotide treated animals appeared 7-8 days more advanced in their degenerative and regenerative processes than the saline controls. Previous workers who found no effect of $(But)_2$cAMP on nerve regeneration probably did not allow enough time to pass for these effects to express themselves, since morphological and physiological differences between regenerating nerves of nucleotide and saline treated rats appeared only after 8-10 days post lesion.

2304 OBSERVATIONS ON THE CENTRAL CANAL AREA OF YOUNG RATS FOLLOWING SPINAL CORD INJURY. Shirley A. Gilmore and Jane E. Leiting*. Dept. Anat., Univ. Arkansas Med. Sci., Little Rock, AR 72201.

Ependymal proliferation plays an important role in regenerative processes in the spinal cords of some vertebrates. Proliferative capacities of ependyma in mammalian spinal cord in normal or injured states is poorly documented. There is little evidence that proliferation occurs later than the periods of normal marked developmental activity in the wall of the neurocele. Several years ago a study was undertaken to evaluate the responses of the immature rat spinal cord to a lesion in the lateral aspect of one hemisection. One of the observations was that the central canal and its surrounding wall had undergone marked changes in general appearance and orientation. Variations in thickness of the cellular wall suggested that proliferation had occurred. Because of the paucity of data regarding this area and its response to injury in the mammalian spinal cord, additional studies were undertaken.

Charles River CD^{R} rats, 3 to 4 weeks old, were used. Under Nembutal^{R} anesthesia a unilateral laminectomy was performed at T_{12} and L_1. A small wound was made with a microscalpel in the lateral or dorsolateral portion of the spinal cord; if the wound was shown later to include the central canal area, the material was not considered in this study. These animals and their sham-operated controls were perfused with 10% phosphate-buffered formalin from 2 days to 6 weeks post-operative. Spinal cords were embedded in paraffin and stained by a variety of histopathologic techniques. Since cellular proliferation was suspected, ^{3}H-thymidine was injected into some animals 2 hours prior to autopsy. Autoradiographs were prepared by the dipping technique.

The central canal area of the normal 3- or 4-week-old rat resembles that of the adult. The canal is usually round or oval with its long axis oriented dorsoventrally. The walls are composed of cells in pseudostratified arrangement usually with two, sometimes three, layers of nuclei. After injury the canal changes shape and orientation so that a flattened wall, as originally seen laterally, "faces" the lesion. The arrangement of the cells is no longer uniform. The lateral wall often appears to have only one cell layer, whereas the poles have an aggregate or clustering of nuclei. In general, the walls lose their uniformity in thickness and cellular arrangement. Preliminary autoradiographic findings show that at 2 days post-operative 5.75% of the cells are labeled as opposed to 0.21% labeling in the sham-operated or intact controls. Mitotic figures are also evident. By 5 days post-operative, 0.85% of the cells are labeled and by 7 days or more the proliferative activity is at the control level. (Supported by USPHS Grant NS 04761.)

2305 MORPHINE-ENHANCED REGENERATION OF CENTRAL NORADRENERGIC NERVES FOLLOWING 6-HYDROXYDOPA TREATMENT OF RAT PUPS. Craig T. Harston, Judy C. Hardin* and Richard M. Kostrzewa. Dept. of Pharmacology, College of Medicine, East Tennessee State University, Johnson City, Tennessee 37601.

The locus coeruleus which provides the noradrenergic innervation to the cerebellum is known to be innervated by serotonergic, substance p- and endorphin-containing neurons. Because of the possibility that neurosecretory substances from these nerves could serve as neuromodulators on the development of the locus coeruleus, we investigated the effect of morphine, an endorphinomimetic, on development of the noradrenergic innervation in cerebellum. Morphine sulfate (20 µg/g i.p.) was injected into intact and neurotoxin-treated (i.e., 6-hydroxydopa {6-OHDOPA} 60 µg/g i.p.) rat pups on the day of birth or three days after birth. Norepinephrine (NE) levels in the cerebellum, pons-medulla and hippocampus of these rats (8 weeks after birth) were assayed by either a spectrophotofluorometric or radiometric method. It was found that morphine sulfate potentiated the recovery of NE levels in the cerebellum and pons-medulla of the rats treated with 6-OHDOPA on the day of birth and in the pons-medulla of the rats treated with 6-OHDOPA on the third day after birth. No effect of morphine was found on the NE content of the hippocampus of control or 6-OHDOPA treated rats. The cerebellar effect was morphine dose-related (0.25 - 20. µg/g i.p.) in rats treated on the day of birth and was apparent by 14 days of age. The morphine-induced increase of NE in the cerebellum was corroborated by increased density of histofluorescent fibers (glyoxylic acid method) in the cerebellum of adult rats. These data show that acute morphine treatment potentiated the recovery of the noradrenergic system in the brain following neonatal damage with 6-OHDOPA. These results suggest that neurosecretory agents (e.g. endorphins) could modulate regeneration of damaged neural systems. (Supported by the National Foundation March of Dimes)

2306 COMPLEX ACTION POTENTIALS AFTER RECOVERY FROM NERVE LIGATION. Kenneth Horch. Dept. Physiol., Univ. Utah, Salt Lake City, UT 84108.

En passant, whole nerve recording of activity in Aα fibers in one branch of the femoral cutaneous nerve of a cat was made with a monopolar hook electrode 16 months after the branch had been ligated with 6-0 silk thread. At the time of the recording, there was no trace of the ligature and no sign of damage to the nerve when examined under 25x magnification. The nerve branch innervated 18 type I receptors (domes), each of which produced a typical continuous, but irregular train of discharges when stimulated with an 80 mg von Frey hair. The stimulus did not excite neurons other than those innervating the domes. For 17 of the domes, the action potentials appeared normal. For one, however, a complex action potential waveform was seen (see below). The spacing of these "complex action potentials" indicates that only one axon innervated the dome and was excited there by the mechanical stimulus. Speculation is invited as to whether this represents ephaptic coupling of large myelinated axons, or an oscillatory process in the membrane of a single axon.

Legend. Each figure was made by action potential-triggered superposition of 20 or more sweeps during sustained, mechanical stimulation of the dome. The waveform did not change with changes in tension on the nerve or changes in the firing rate of the axon. (A) Initial recording site, about 30 mm proximal to the dome. Sweep speed: 0.2 msec/div. (B) The electrode was moved distally to a point about 23 mm from the dome. Sweep: 0.5 msec/div. (C) The electrode was moved back to near the original recording site. Sweep: 0.5 msec/div.

2307 A STUDY OF NEURAL SOMATA REGENERATION - A TEST OF THE NEURONAL ADDITION HYPOTHESIS. C. E. Hulsebosch* and G. D. Bittner (SPON: T. Viancour). Dept. of Zoo., University of Texas, Austin, TX 78712.

One hypothesis which may account for the capacity of a species to regenerate neural somata is the neuron addition hypothesis (Hulsebosch, C. E. and G. D. Bittner. Soc. for Neurosc. Abst., 4: 532, 1978; Leonard, R. B., et al., J. Comp. Neurol. 179(1): 13-22, 1978). This hypothesis states that species which add CNS somata during ontogeny may be more likely to regenerate somata in response to injury than those species which have a constant or decreasing number of CNS somata.

To test the neuronal addition hypothesis, we selected two species of marine polychaetes with similar life styles; however, one species, *Nereis virens*, adds body segments (and consequently neural somata) and one species, *Clymenella torquata*, has a constant number of body segments. Using ultrastructural and histological techniques, we counted the number of neurons (as opposed to glial and connective cells) in a particular ganglion in mature individuals of each species. From these counts, we determined that neither species add neural somata to ganglia of the mid-body region. We then performed ganglionic ablations and determined that somata regeneration does not occur in *Nereis virens* allowed to survive for up to three months after lesioning. Conversely, neural somata did regenerate in *Clymenella torquata* within two weeks after ganglionic ablation. To test that nerve cells in the ablation site of *Clymenella* are a result of regeneration and not a result of somata rearrangement from adjacent uninjured regions, we counted the number of neurons in the ablation site and adjacent CNS regions of controls and regenerates. Our counts demonstrate that neural somata in the ablation site are a product of regeneration and not of rearrangement.

Our results in *Nereis virens* indicate that the addition of neural somata in one region of the neuraxis can not provide for somata regeneration in another region of the neuraxis. Furthermore, our results in *Clymenella torquata* indicate that CNS somata addition is not a necessary prerequisite for somata regeneration. Hence, our experiments demonstrate that the neuronal addition hypothesis alone can not account for CNS somata regeneration.

2308 FOREIGN NERVE INNERVATION OF A MUSCLE FIBER POPULATION IN THE CRAYFISH. William P. Hunt* and Samuel J. Velez. (SPON: H. L. Borison) Department of Biological Sciences, Dartmouth College, Hanover, New Hampshire 03755.

The six motoneurons that innervate the 40 muscle fibers of the superficial flexor muscle of the crayfish Procambarus clarkii can regenerate their connections within 9-10 weeks with a high degree of specificity (Ely & Velez, Neurosciences Abstracts, 1979). Experimental manipulation of this system during regeneration can give us insight on the processes that influence the formation of specific connections between identifiable cells. The third superficial root that innervates the left superficial flexor muscles of the third segment (to be referred to as 'the foreign nerve') was transplanted to the contralateral superficial flexor muscles of the same segment. In some experiments, the innervation of the recipient muscle was left intact, while in others the muscle was denervated. Animals were left to recuperate, and analysis was performed on a weekly basis by monitoring the spontaneous activity of the nerve in isolated abdomens with an extracellular oil electrode, stimulating the nerve with a suction electrode, and recording muscle junction potentials (jp's) with 3M KCl microelectrodes. Foreign nerve innervation occurs earlier in denervated muscle than in innervated muscle. In both cases, the small axons appear to grow first, followed by the large axons. Initial innervation spreads over the entire field leaving some 'holes' in the map, just as was observed when the original nerve reinnervates the muscle after it has been cut (Ely & Velez, ibid). The initial synapses made by the foreign nerve are characterized by gigantic jp's (10-20 mV in size when compared to 1-5 mV in size in control animals), little facilitation (when comparing jp sizes at 1 Hz and 10 Hz stimulation) and some misses in firing (no jp's produced even though the axon is firing). The presence of the original nerve in a muscle fiber seems to have no effect on the ability of the foreign nerve to make connections with that fiber as jp's produced by the foreign nerve could be larger than those produced by the original nerve on the same fiber. Innervation by the foreign nerve is complete across the muscle field for the first growing axons by 8 weeks, and the connectivity map appears to be the same as the map of the original nerve.

2309 Association of Spermidine with Axonally Transported 4S RNA in Regenerating Optic Nerves of Goldfish. N.A. Ingoglia, P. Jaggard*, C. Perez* and J. Sturman. Dept. of Physiology and Neurosciences, New Jersey Medical School, Newark, N.J. 07103, and Dept. of Pathol. Neurobiol., Institute for Basic Research in Mental Retardation, Staten Island, N.Y. 10314

Recent experiments have shown that during regeneration of the optic nerves of goldfish, spermidine (Spd) is axonally transported (AT) in both an unbound TCA soluble, as well as a TCA insoluble form. We have proposed that TCA insoluble Spd is associated with AT 4S RNA. The present experiments were performed to test this hypothesis.

In one set of experiments, inhibition of retinal RNA synthesis by intraocular injections of 10μg of cordycepin, blocked the AT of both ^{3}H-RNA and ^{14}C-Spd by about 65% 6 and 14 days after injection. Intraocular injections of Vinblastine, (0.1, 0.5 or 1.0μg) an agent which interrupts AT of proteins, had no effect on retinal RNA synthesis nor on the amount of ^{14}C Spd incorporated into the TCA insoluble fraction of retinal extracts. However, the AT of both ^{3}H-RNA and ^{14}C-Spd was effected in a dose dependent fashion; the inhibition of both was approximately 80% at the higher dose. Further evidence for an association between AT 4S-RNA and Spd came from experiments in which regenerating optic axons were cut and allowed to degenerate 6 days after injection of ^{3}H-Spd into the eye. The loss of optic axons from the tectum 7 days after cutting the nerve resulted in an 86% loss of TCA insoluble Spd, indicating a largely intra-axonal locus for Spd. A similar loss of 4S RNA was found in identical experiments following injections of ^{3}H-uridine into the eye. Finally, experiments were performed in which ^{3}H-Spd was injected into both eyes of 12 fish whose optic nerves had been regenerating for 18 days. Six days later, fish were sacrificed and RNA was extracted from tectal homogenates by hot phenol and ethanol precipitation. The major stable RNA species were separated by SDS polyacrylamide disc gel electrophoresis and radioactivity was determined by extraction of 2.0 mm gel slices. Results showed co-migration of ^{3}H radioactivity only with the 4S RNA optical density peak, and not with 28S and 18S ribosomal RNA peaks, suggesting that Spd may be AT along with 4S RNA.

The data indicate that some Spd which is transported during regeneration of goldfish optic nerves is probably associated with 4S RNA, perhaps complexed in a manner similar to that described for Spd and bacterial tRNA.

2310 COMPARISON OF GROWTH PATTERNS OF CULTURED SYMPATHETIC NEURONS FROM PERINATAL AND POSTNATAL RATS. M. Johnson and V. Argiro*. Dept. of Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, Missouri 63110.

Long term cultures of superior cervical ganglion (SCG) neurons can now be obtained from not only embryonic but also postnatal rats, including fully adult animals (Nature 267: 536, 1977). This allowed the study of the relative growth capacities of neurons from rats of different ages. Explants of the SCG from 21-day embryo and postnatal rats were grown in the same dish on an air-dried collagen substrate and fed either standard feed containing human placental serum and embryo extract or feed with added antimitotic agents to eliminate nonneuronal cells. All feeds contained NGF. The onset and rate of neuritic outgrowth were monitored sequentially by photography and the data analyzed by computer. Explants from perinatal rats exhibited vigorous neuritic outgrowth (by 6 hours) with an average growth rate of 35mm/d. The neuritic outgrowth from explants of adults was delayed in onset (56 hours) and lengthened at .19mm/d. The growth pattern of neurons from 5 week old rats was intermediate between the perinatal and adult (32 hours; .21mm/d). When antimitotic agents were present in the feed the rate of growth was slowed in all age groups. Further studies are in progress to determine whether antimitotic agents act directly on the neurons or by removing nonneuronal cells from the environment. This system will also allow the evaluation of other possible influences on regenerating neurites including that of NGF.

2311 NON-SPECIFIC AXONAL GROWTH IN THE OPTIC TECTUM OF ADULT FROGS. Elliot I. Kaplan* and Carmine D. Clemente. Brain Research Institute and Department of Anatomy, UCLA School of Medicine, Los Angeles, California 90024.

The reestablishment of appropriate synaptic connections in regenerating CNS tissue is a requisite to functional recovery. That some form of recognition exists between growing axons and their potential target cells has been postulated in numerous studies of the retinotectal system of several lower vertebrates. Such interactions may be highly specific as reflected by the accurate retinotopic organization of regenerated ganglion cell terminals upon the dendritic fields of tectal neurons. However, studies of CNS plasticity following lesions frequently indicate that specificity of cellular interactions may not always prevail. While such a reorganization of synapses might compensate for lesion-induced deficits, it might also interfere with functional recovery.

In an effort to investigate neuronal non-specificity, experiments were performed to determine whether aberrant axonal growth and synapse formation can occur in the optic tectum of the adult frog, Rana pipiens. The right mandibular nerve was exposed and severed and its proximal stump inserted through a cranial opening overlying the right optic tectum. The dura-arachnoid was opened and in some animals the pia was pierced. The peripheral nerve was then placed onto the rostro-dorsal surface of the tectum with its longitudinal axis oriented parallel to the tectal surface. The skin was closed and operated animals placed in individual cages and maintained on a 12-hour light/dark cycle at 18-20° C for 2-12 weeks post-surgery (WPS). Light microscopic data are reported from 30 animals whose tecta have been stained to reveal nerve fibers by means of a reduced silver technique. Approximately 90% of these specimens are judged successful, the criteria being survival and growth of the grafted nerve, and the maintenance of its position.

By 2 WPS a connective interface between nerve and tectum, 350-450 μ in diameter, was established. Several regenerating peripheral fibers invariably deviated nearly 90° from the longitudinal orientation of the nerve and entered superficial layers 8 and 9 of the tectum. The growth reaction appeared most pronounced at 6 WPS and was greater in tecta with opened pia than in intact tecta. While most peripheral fiber growth was restricted to the outer layers of the tectum, some fibers occasionally penetrated as deep as the periventricular region. These observations demonstrate that a highly ordered CNS may support non-specific axonal growth and, perhaps, even encourage it under certain conditions. Present investigations are aimed at better elucidating the time course of the interaction, observing the possible trophic effects of controlled tectal denervation, and analyzing the fate of regenerated fiber terminals ultrastructurally.

2312 GANGLIONIC LOCALIZATION OF CELLS CONTRIBUTING TO ANOMOLOUS SYMPATHETIC INNERVATION IN TRANSECTED HIPPOCAMPUS. James D. Lindsey* and Rebekah Loy (SPON: W.T. Schlapfer). Dept. Neurosciences, University of California at San Diego, La Jolla, CA 92093.

Following transection of the fornix or anterior hippocampal formation (HF), large noradrenergic fibers grow into the neuropil predominantly in the ventral HF. These fibers concentrate their plexus in the infragranular hilus, the inner molecular layer of the dentate, and in stratum lucidum of CA3. There are three possible origins of these noradrenergic fibers: locus coeruleus (LC), other noradrenergic brainstem nuclei, or the superior cervical ganglia (SCG). The latter normally innervates extracerebral vessels in the lateral ventricle adjacent to the HF. To test the cellular origin of this anomolous innervation we injected 0.05 ul of 30% horseradish peroxidase (HRP) into the ventral HF of rats 30 to 60 days after transection. 48 hours later the brains as well as both SCG were processed for HRP using benzidene dihydrochloride as the substrate. We then analyzed the normal noradrenaline-containing brainstem nuclei as well as the SCG for evidence of transported reaction product.

When compared with controls, the number of labeled cells in the ipsilateral LC appears unaltered by anterior HF transection. However, the number of labeled cells in the contralateral LC is drastically reduced in transected animals. This reduction suggests that the primary path of this crossed projection is through the fornix and/or the cingulum bundle. The existence of an alternate decussating pathway(s) is suggested by the persistence of a very few labeled cells in the contralateral LC. Aside from the above described patterns in LC, no cells were labeled in the other known noradrenaline-containing nuclei of transected animals.

Examination of the SCG's revealed distinctly labeled cells in the ipsilateral SCG. These multipolar cells are located primarily in the rostral portion of the ganglion. Other work has shown the axons of cells in this region leave the ganglion via the internal carotid nerve. This nerve follows the internal carotid artery into the skull to innervate extracerebral arteries.

Thus, the large noradrenergic fibers innervating the ventral HF after anterior HF transection do not arise from central noradrenergic nuclei. Rather, these fibers arise from branching rami from the sympathetic innervation of the blood vessels serving the brain. This possibility is supported by the rostral position of the labeled SCG cells.

2313 ANOMALOUS SYMPATHETIC TERMINALS ON HIPPOCAMPAL VASCULATURE FOLLOWING FIMBRIAL DAMAGE. Rebekah Loy and Robert Y. Moore. Dept. Neurosciences, Univ. Calif. San Diego, La Jolla, CA 92093

Following lesions of the septum or fimbria, anomalous, noradrenaline (NA)-containing axons grow into the hippocampal formation (HF). These fibers appear to originate from a normal sympathetic innervation of the longitudinal hippocampal arteries. Fluorescence histochemistry reveals that the large caliber NA-containing axons are confined to the arteries within the subarachnoid space of the lateral ventricle. Two weeks following a fimbrial lesion, fluorescent axons also accompany penetrating branches of the internal and external transverse hippocampal arteries into the HF at the obliterated hippocampal fissure and the fimbria-dentate fissure.

In order to determine the localization of any synaptic contacts formed by this anomalous sympathetic innervation, we have compared brains from normal rats and rats which 15-90 days previously had received an aspirated transection of the fimbria. Some animals of each group received an intraventricular injection of 5-hydroxydopamine (5-OHDA) 1 hr prior to perfusion, to produce small granular vesicles (SGV's), which have been shown to contain NA in central axons. The HF was sectioned transverse to its longitudinal axis, leaving intact the meninges, choroid plexus and vasculature within the lateral ventricle.

Electron microscopic examination of normal rat brains showed many varicosities containing SGV's adjacent to the basal laminae surrounding the smooth muscle of ventricular arteries. In lesioned brains similar SGV-containing varicosities appear immediately adjacent to the basal laminae of smooth muscle surrounding subpial arteries and arterioles. Other SGV-containing varicosities appear adjacent to the basal laminae of capillary pericytes or of endothelial cells directly. Similar varicosities are present within the neuropil as well, however these are most common in perivascular areas. No SGV-containing varicosities are present immediately adjacent to hippocampal vessels in normal brains not pre-treated with 5-OHDA, although a small number of such varicosities appear scattered in the neuropil of the dentate hilus.

In conclusion, normal sympathetic innervation of arteries supplying the HF is restricted to the extracerebral vessels of the lateral ventricle. Following a transection of the fimbria, which presumably damages a distal segment of this normal plexus, NA-containing axons leave the subarachnoid space and accompany penetrating arteries into the capillary bed of the hippocampus itself. Such anomalous innervation may have significant consequences for the regulation of cerebral blood flow and capillary permeability following CNS damage.

2314 MEMBRANE PROPERTIES OF A REGENERATING AXON. H. Meiri*, M.E. Spira* and I. Parnas* (SPON: M. Devor) Neurobiology Unit, The Hebrew University of Jerusalem, Jerusalem, Israel.

Cobalt injections into Giant axons from the cockroach Periplaneta americana reveals that 8-10 days after cutting the axon, the proximal cut end regenerates and sprouts. The membrane properties of the regenerating tip of the severed axon (20-40 μmdiameter) were studied by conventional electrophysiological techniques. One hour after axotomy the membrane resting potential and input resistance are greatly decreased (-80mV to -10mV; and 4MΩ to 0.3 MΩ correspondingly) close to the cut end. The membrane potential and input resistance gradually recover and reach normal values on about the 8th day post-axotomy. During the recovery process the membrane properties are altered in the following sequence: (a) 1-4 hr post-axotomy the axon tip is permeable in a non-selective way to all ions. The spike generation mechanism seems to be normal as it is possible to evoke TTX sensitive spikes after hyperpolarization of the membrane; (b) 4-24 hr post-axotomy, the resting Na^+, K^+ and Ca^{++} conductances are increased (Na^+ from 0.03 to 0.55; K^+ from 0.2 to 0.32; Ca^{++} from close to 0-0.38 x 10^9 Se.) while Cl^- remains constant. During this period, the normal Na^+ dependent regenerative action potential could not be evoked even with strong hyperpolarization, and Ca^{++} dependent spikes (not sensitive to TTX and blocked by Co^{++}) appeared; (c) 60 hr post-axotomy the Ca^{++} dependent spikes disappear and there is a gradual recovery of the Na^{++}dependent spikes and resting conductances for Na^+, K^+, Ca^{++}. These changes are restricted to the regenerating tip of the axon (0.2-0.5 mm).

2315 AN AUTORADIOGRAPHIC STUDY OF EPENDYMAL CELL PROLIFERATION IN THE REGENERATING SPINAL CORD OF XENOPUS TADPOLES. M.E. Michel* and P.J. Reier, Dept. Anat., Sch. Med., Univ. of Maryland, Baltimore, MD. 21201.

Axonal elongation in the injured spinal cords of amphibian species has been shown recently to entail the development of a cellular substrate within the lesioned area of the cord. In Xenopus tadpoles, for example, neuritic outgrowth between the cut ends was associated with a concurrent emergence of ependymal cells derived from central canal diverticula within the rostral and caudal stumps (Michel and Reier, J. Neurocytol., In Press). The following autoradiographic study was undertaken in order to characterize the proliferative response of ependymal cells to spinal cord injury in this animal model. A 1 mm segment of the lumbar spinal cord was resected in Stage 54 tadpoles which were then divided into two groups. The first (G1) received a single intraperitoneal injection of ^{3}H-thymidine (5μCi/gm; Sp.Act. 70Ci/mM) at 5 days post-operatively (d.p.o.) and were sacrificed either 4 hours later or at 14 d.p.o. Tadpoles in the second group (G2) were injected at 3, 5, and 7 d.p.o. and were sacrificed at 14 and 21 d.p.o. Four hours after a single injection of thymidine at 5 d.p.o., numerous heavily-labeled ependymal cells were seen within the dorsal and ventral aspects of the ventricular layer immediately adjacent to the cut edge of the cord. In contrast fewer labeled cells were seen at more rostral and caudal levels; the majority of them were located within the alar aspect of the ventricular layer. A similar pattern of labeling was seen in normal spinal cords. By 14 d.p.o. (G1 and G2) the lesion zone was repopulated by ependymal cells. The majority of these cells were labeled; however, more silver grains overlaid nuclei of cells at the rostral and caudal cut ends. No significant change in thymidine labeling was observed at more rostral and caudal levels of the cord. At 21 d.p.o. (G2) a similar pattern of labeling was obtained, although fewer grains were seen above nuclei within the reconstituted segment than at 14 d.p.o. These results indicate that: (1) ependymal cell mitotic activity following injury to the cord increases above normal developmental levels; (2) the initial proliferative response is confined to the rostral and caudal stumps where even relatively inactive basal ependymal cells begin to divide; and (3) based upon the pattern of label dilution most ependymal proliferation is confined to the reconstituted segment.

2316 SYMPATHETIC REGENERATION INTO THE HIPPOCAMPUS: EFFECT OF LESION SITE. Teresa A. Milner* and Rebekah Loy. (SPON: S. Barondes). Department of Neurosciences, University of California, San Diego, La Jolla, California 92093.

Regeneration of severed axonal projections and reestablishment of terminal connections are essential prerequisites for recovery of function in many neuronal systems. Previous experiments have examined reorganization of the hippocampus following selective deafferentation and have found that existing, undamaged afferent systems invade the partially deafferented area following entorhinal cortex lesions. Recent studies have found in addition to this intrinsic reorganization, that sympathetic fibers of the peripheral nervous system (PNS) appear to innervate the hippocampal dentate hilar area and stratum lucidum of CA3 following destruction of the fornix or anterior hippocampus. The pattern exhibited by these PNS fibers is selective and does not correspond to any other innervation patterns from hippocampal afferent projections. The present study investigates more fully the conditions necessary and sufficient to produce this anomalous growth of PNS fibers into the hippocampus following injury.

Various combinations of afferent and efferent pathways of the rat hippocampus were selectively destroyed. After 10 to 30 days, the brains of these animals were analyzed using the glyoxylic acid method of fluorescence histochemistry.

Anomalous growth occurs in the hippocampus following destruction of either septal or combined septal/commissural fibers. No growth follows disruption of commissural fibers alone, entorhinal cortex, or vasculature and cortex overlying the anterior hippocampus. Following combined entorhinal cortical lesions and septal/commissural fiber disruption, no anomalous hippocampal innervation was observed; however, a minimal but significant number of the peripheral fibers grow into the caudal part of the cerebral hemisphere around the lesioned area. Lesioning the perforant path along with septal/commissural fibers, without damaging the caudal cerebral vasculature, produced anomalous innervation of PNS fibers into the hippocampus. These findings suggest that anomalous innervation requires (1) damage to afferents at the rostral end of the hippocampus and (2) intact vascular innervation in the caudal end of the structure.

2317 REGENERATION OF THE OPTIC NERVE AXONS AND THEIR TERMINALS IN GOLDFISH. Marion Murray and Wendy Battisti* Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

The optic axons of goldfish regenerate when crushed intraorbitally. They innervate the tectum and subserve visual function within 5-7 weeks post-crush. Previous studies have suggested that these regenerating axons branch repeatedly so that an excessive number of regenerating axonal sprouts enters the tectum and should then be potentially available to reinnervate tectal neurons.

In this study the right optic nerve of 6-8 inch goldfish was crushed within the orbit. Animals were allowed to survive from 6 days to 8 months, perfused, and the optic nerves, tracts and tecta prepared for EM. Observations on: 1) the number and size of regenerating axons, 2) the percent of them which are myelinated, 3) the amount of glial cytoplasm present in the nerve distal to the crush and in the stratum opticum, 4) the numbers and types of synapses and 5) the proportions and types of neural and non-neural elements present in the tectal neuropil (SFGS) during the course of regeneration suggest the following: The normal optic nerve is composed almost entirely of myelinated axons which are organized in fascicles. At 2 weeks post-operatively large numbers of glial cells are present between the fascicles of degenerating fibers. Within the fascicles the degenerating fibers and glial cells are located peripherally, while bundles of regenerating axons form the core of the fascicle. Estimates at this time show that the number of regenerating axon profiles increases over the normal number of axons. During the ensueing weeks and months the amount of debris and glial cytoplasm decreased markedly and the size of regenerating axons increases; the number of regenerating axons appears to remain considerably in excess of normal values. By 6 months postoperatively the optic nerve has begun to regain its preoperative appearance.

Regenerating axons have entered the tectum by 5-7 weeks post-operatively. The number of the unmyelinated axons in SO and SFGS is greatly encreased but the number of axon terminals making synapses in the SFGS is less than normal. By 6 months post-operatively the number of axons in the SFGS is still greater than normal but the number of axon terminals approaches normal levels. It appears that although an excess number of axonal sprouts are formed and grow into the tectum, they do not hyperinnervate the SFGS. This suggests that the tectal cells have the capacity to accept only a limited number of retinal connections.

2318 SUBSTANTIA NIGRA GRAFTS REDUCE MOTOR ABNORMALITIES PRODUCED BY DESTRUCTION OF NIGRO-STRIATAL DOPAMINE SYSTEM. Mark J. Perlow, William J. Freed, Farouk Karoum, Barry J. Hoffer, Ake Seiger, Lars Olson and Richard Jed Wyatt. Lab. of Clin. Psychopharm., NIMH, St. Eliz. Hosp., Wash. D.C. 20032; Dept. Pharmacoloyg, Univ. of Colorado Med. School, Denver, Colo; Dept. Histology, Karolinska Institute, Stockholm, Sweden.

The principal pathology common to all forms of Parkinson's Disease is neuronal cell loss and gliosis in the zona compacta of the substantia nigra (SN). As a result of the loss of these cells, there is a decrease in the concentration of DA in the striatum and SN. Replacement for this missing DA is the conceptual backbone of current therapy. The peripheral administration of L-DOPA and dopaminomimetic agents unfortunately is only partially effective and is associated with side effects. Since the ideal therapy would be a circumscribed infusion of DA into DA-deficient areas of the brain, we wondered if it would be possible to achieve this result by grafting DA-producing cells into DA-deficient areas.

To test our idea, we used the rotating rat model of Parkinson's Disease. In this model the SN is lesioned unilaterally by 6-hydroxydopamine. Ipsilateral to the lesion there is a reduction in the concentration of DA in the striatum and an electrophysiological, biochemical and behavioral supersensitivity. The latter is manifest by contralateral rotation in response to the DA agonist, apomorphine. We hypothesized that if we were able to graft DA-containing and secreting cells from the SN to the DA-denervated striatum, there would be a reversal of these well described events.

Following the grafting of fetal rat SN (17-day gestation) to SN-lesioned adults rats, we found: (1) Histofluorescentally, all SN grafts survived and contained catecholamine (CA) and indoleamine producing cells. The CA containing cells had matured and sent axons into the brain tissue adjacent to the graft with heaviest innervation into the caudate nucleus. (2) Biochemically, all the grafts contain DA; the amount of DA in the lesioned caudate was increased in those animals with SN grafts, especially in areas adjacent to the graft. (3) Behaviorally, the apomorphine induced turning was reduced in SN grafted animals.

Except for the presence of lipofusin granules in the host caudate nucleus, the behavioral and microscopic picture observed at 8-9 months post-grafting was unchanged from that observed at 2 months post-grafting. There was no evidence of tissue rejection.

Current efforts are being undertaken to determine if similar grafting techniques can be used in the non-human primate.

2319 COMPETITION BETWEEN FOREIGN AND NATIVE REINNERVATION OF AUTONOMIC NEURONS. W. Proctor, B. Taylor* & S. Roper, Depts.Anatomy, Physiology, Univ.Colo. Health Sciences Ctr.,Denver, CO 80262

In some regions of the vertebrate nervous system, such as mammalian autonomic ganglia, damaged axons can regenerate and restore appropriate functional connections. On the other hand, regeneration elsewhere, for example motor innervation, is generally non-specific, and inappropriate connections are formed. We are investigating reinnervation of the parasympathetic cardiac ganglion of the frog to elucidate the cellular mechanisms underlying the reestablishment of appropriate synaptic connections after nervous tissue damage. We have shown (Neuroscience Abstracts 4, 533, 1978) that hypoglossal motor axons can synapse with denervated parasympathetic neurons in the heart. Here we report that when vagal preganglionic axons reinnervate the cardiac ganglion after hypoglossal innervation has been established, foreign (hypoglossal) innervation disappears.

The surgical operation for these experiments consisted of sectioning both vagi and suturing the left hypoglossus to the distal stump of the left vagus. Regenerating hypoglossal axons innervate parasympathetic neurons in the cardiac ganglion in about 8 weeks. After a further delay of a few weeks, we allowed axons from the right vagus nerve to reinnervate the ganglion. At intervals from 8-52 weeks after the operation, animals were killed and cardiac ganglia removed. Neurons were impaled with microelectrodes to record synaptic input from hypoglossal and/or regenerating vagal axons. Ganglia were subsequently fixed for light and electron microscopy.

Animals were divided into three groups corresponding to early (8-20 weeks), middle (21-30 weeks) and late (31-52 weeks) stages of reinnervation. The proportion of neurons receiving vagal innervation at these stages were 13±5%, 56±12%, and 76±17%, respectively. The proportion receiving hypoglossal innervation at the corresponding stages were 73±5%, 57±13%, and 14±10% (N=15 animals, values are means ± s.e.m.). These data show (1) regenerating vagal axons restore functional connections despite the presence of foreign innervation, and (2) hypoglossal innervation disappears concomitant with restoration of vagal inputs.

Electron microscopy show that vagal terminals reestablish synapses on the axon and cell body region of ganglion cells. These synapses were similar to those in ganglia from unoperated animals. Hypoglossal terminals, on the other hand, contacted only the axons of parasympathetic neurons. We speculate that the difference in the location of foreign and native synapses is fundamental to the observed selectivity in the reinnervation of cardiac ganglia, and that the glial cell which envelopes the ganglion cell body acts as a barrier to inappropriate terminals but not to native ones.

2320 ANALYSIS OF THE TECTAL PROTEINS IN THE VISUAL PATHWAY OF GOLDFISH BY 2D GEL ELECTROPHORESIS. Wolfgang Quitschke*, Andrew Francis*, and Nisson Schechter (SPON: I. Fand). Departments of Biochemistry and Psychiatry and the Long Island Research Institute, SUNY at Stony Brook, New York 11794; and (A.F.) Cornell University Medical College.

In goldfish, after optic nerve crush, regeneration and specific reconnection of the optic nerve to the tectum occurs. This paradigm is emerging as an important model system for the study of neuronal specificity. One critical aspect of this problem is the role of unique or specific proteins involved in the reconnection process. Right-sided enucleation or intraorbital optic nerve crush was performed on large (10-12 cm) common goldfish maintained on a standard diurnal cycle. Protein separation patterns were obtained from the affected (contralateral) as well as the intact (ipsilateral) tectum by two-dimensional isoelectric focusing-gel electrophoresis described by O'Farrell. After coomassie blue staining, analysis of the gel patterns revealed at least one protein, having a molecular weight of 57,000, whose presence paralleled optic innervation. This protein was lost from the tectum after enucleation, and appeared to be present in tecta after optic nerve regeneration and reconnection. Further analysis indicated that the protein could not be detected from whole brain preparations or spinal cord, forebrain, cerebellum, vagal lobes, or medulla. The protein was detectable only in the optic nerve and tectum of the goldfish. The protein was associated with a membrane fraction of the optic nerve and with both a membrane and soluble fraction of the tectum. With known standards it did not comigrate with either actin or tubulin. Studies are in progress to determine the site of synthesis and possible axonal transport phenomena of this protein.

2321 REINNERVATION OF SCIATIC NERVE GRAFTS TO THE RAT SPINAL CORD. Peter M. Richardson, Ursula M. McGuinness* and Albert J. Aguayo. Department of Neurology and Neurosurgery, McGill University, Montreal, Canada.

In young adult female rats, a segment of the rat spinal cord was resected and replaced by an autologous sciatic nerve graft. Twenty-four animals were sacrificed from 10 days to 4 months later and the grafts and their junctions with the spinal cord were examined with the light and electron microscope. All grafts of more than 3 weeks duration were richly innervated with myelinated and unmyelinated axons even in 8 animals in which the spinal roots entering the pia at the graft site were avulsed together with their ganglia. At the border of the CNS tissue, dome-shaped structures were present, each filled with astrocytic processes and surrounded by a basal lamina. Myelinated and unmyelinated fibres frequently lay within these neuroglial domes. Occasional nodes of Ranvier were seen in which one heminode had peripheral myelin and the other had central myelin. In a further group of rats, horseradish peroxidase was injected into the spinal cord immediately adjacent to the graft (of 2 - 4 months duration). Two days later some neurons in the spinal cord on the other side of the graft were labelled with the enzyme. These results suggest that at least some axons of the central nervous system can grow into a peripheral nerve graft and be ensheathed by Schwann cells.

2322 AUTORADIOGRAPHIC DEMONSTRATION OF THE CENTRAL ORIGIN OF REGENERATING FIBERS INTO IRIS TISSUE IMPLANTS IN THE RAT MESENCEPHALON. A. R. Schonfeld* and R. Katzman. Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Central monoaminergic fiber systems have the ability to sprout and regenerate in response to mechanically or chemically induced injury (e.g. Katzman, Bjorklund, Owman, Stenevi and West, Br. Res. 25:579, 1971). One model which has proven particularly suitable for demonstrating regeneration is that in which peripheral tissue, particularly the iris, is implanted into the brain or spinal cord (for a review see Svendgaard, Bjorklund and Stenevi, Adv. anat. embryol. Cell Biol. 51:7, 1975). In previous work, identification of some regenerating fibers as adrenergic has been established by histofluorescent, histochemical and ultrastructural techniques. The purpose of the present study is to demonstrate by histofluorescence and by autoradiography that axons projecting from the locus coeruleus are capable of regenerative growth into iris tissue implants placed into the caudal mesencephalon.

Briefly, heterologous iris implants were inserted in the caudal mesencephalon in the region of the dorsal tegmental bundle in female rats previously subjected to ipsilateral superior cervical sympathectomies. Previous histofluorescent work had shown that the implantation procedure severed the dorsal noradrenergic bundle (Katzman, Broida and Raine, Br. Res. 138:423, 1977). In order to observe regeneration of adrenergic fibers into in situ implants, half of the specimens were freeze dried and treated according to the histochemical fluorescence method of Falck and Hillarp. To establish the origin of these regenerating noradrenergic fibers, the remainder of the subjects received injections of ^{3}H-leucine into the ipsilateral locus coeruleus 2 days before sacrifice and the brains were prepared for autoradiographic analysis according to the method of Cowan, Gottlieb, Hendrickson, Price and Woolsey (Br. Res. 37:21, 1972).

We observed the presence of many bright green fibers running from the dorsal catecholaminergic tract and penetrating into the iris tissue implant. Microspectrofluorometric analysis indicated that these fibers were noradrenergic. These findings, which confirm the initial observations of Bjorklund and Stenevi (Br. Res. 31:1, 1971), indicate that noradrenergic axons are capable of sprouting and regeneration after injury. The results of the autoradiographic study, which will be presented in detail, suggest that some of these fibers originate in the locus coeruleus.

2323 LIMITED TARGET CELL INFLUENCES ON AXONAL GROWTH IN THE CNS OF THE LEECH. Sheryl A. Scott and Kenneth J. Muller. Dept. of Embryology Carnegie Institution of Washington, Baltimore, Md. 21210.

In each segmental ganglion of the medicinal leech there is one S-interneuron; it extends an axon both anteriorly and posteriorly halfway down the connectives that link ganglia to make an electrical synapse exclusively with the tip of the next S axon. When an S-cell axon is severed it regenerates along its surviving distal axonal stump to synapse selectively with its usual target. The target does not grow and remains electrically coupled to the severed axonal stump. We have investigated whether the target directs S-cell regeneration, and whether maintained contact with the stump prevents the target from sprouting. Single S-cells were selectively removed from the nervous system of an otherwise intact leech by injecting the somata with a protease; the axon of one or both adjacent S-cells was then severed. Axonal growth was followed by dissecting chains of ganglia at various times after the operation, and injecting the S-cells through recording electrodes filled with horseradish peroxidase, Lucifer Yellow or both for examination with light and electron microscopy.

When the target S-cell was destroyed, the adjacent injured axon regenerated as usual along its severed but persistent distal stump to the old synaptic region, and then stopped growing. Axons never regenerated beyond the region of normal synapse or the end of the distal stump. Physiological recordings and injections of Lucifer Yellow, which readily crosses normal and regenerated S-cell synapses, indicated that regenerated cells did not make aberrant synapses. Thus, axons in the CNS can regenerate in a normal fashion to the usual site of synapse in the absence of the target cell, and they do not choose alternative synaptic targets.

Axons of intact S-cells that had been connected to killed cells neither grew nor retracted and did not make other connections. Surprisingly, such intact axons could be stimulated to sprout and extend along the connective if another, distant axon of the same cell was injured. Together these results suggest that during normal regeneration the intact target cell still would not grow if the distal stump were removed. Moreover, injury apparently turns on a growth mechanism that can be expressed throughout the cell by those axons, injured or not, which have lost contact with their target.

2324 THE TIME COURSE OF INCREASED GLUCOSE UTILIZATION IN HYPOGLOSSAL NUCLEUS NEURONS DURING REGENERATION. Philip A. Singer and Sharon Mahler*. Dept. Neurology, Kansas City Veterans Medical Center, Kansas City, Mo. 64128.

Motorneurons undergo major anabolic changes during regeneration. Watson (J. Physiol. 180:741, 1965) and others have shown increased uptake of RNA and protein precursors beginning 48 hours following axotomy. The energy metabolism during this reaction is controversial however, with some single neuron studies showing increases in oxidate metabolism in both axotomized and control nuclei (Hamberger and Sjostrand. Acta Physiol. Scand. 67:76, 1966) and others showing decreases. (Watson J. Neurochem., 13: 849, 1966) Numerous histochemical determinations of respiratory enzymes likewise show both increases and decreases. However, glycogen disappears from large anterior horn cells 72 hours after axotomy (Campa and Engel. Science 171:198, 1971) indicating increased glucose use. Other studies suggest that glycolysis (Watson. J. Physiol. 198:77, 1968) and the hexose monophosphate shunt (Nandy Arch Neurol. 18:423, 1968) are increased.

We used the 14C2 deoxyglucose technique to study glucose utilization. The left hypoglossal nerve was sectioned at the level of the carotid artery in 150 gm male rats. 14C2 deoxyglucose, 15uCi/100 gm, was injected in awake or nembutol anesthetized rats at 24 hours, 36 hours, 48 hours, 72 hours, and 14 days. The animals were sacrificed 45 minutes later and frozen sections of the brainstem exposed to x-ray film. The autoradiographs were enlarged and the optical densities of the sectioned and control hypoglossal nuclei determined. There was a marked increase in glucose utilization 48 hours after axon section which was maximal at 72 hours but unabated at 14 days. This data indicates that glucose utilization is increased very early and energy metabolizing enzymes may be the initial target of the signal for regeneration.

The studies listed above suggest that glycolysis and the hexose monophosphate shunt may be the only pathways for this increased metabolism. However, the magnitude of the increase suggests that oxidative systems may also be increased.

2325 ADULT CEREBELLAR PLASTICITY: REGENERATION OF PURKINJE CELL DENDRITES IN REHABILITATED UNDERNOURISHED MICE. Lucy Singer-Beck* and J. J. Pysh. Dept. Anat., Northwestern Univ. Med. & Dent. Schs.

It is well established that postnatal undernutrition reduces the final number of granule cells and the growth of Purkinje cell dendrites in the cerebellum. The purpose of this study was to investigate the capacity for regrowth of Purkinje cell dendrites previously retarded by postnatal undernutrition.

This study utilized a total of 22 B6D2F1 hybrid mice which were randomly cross fostered to enable littermate pairs, matched for sex and parentage, to be raised from birth to 60 days of age with different nutritional intake. Control litters were normally nourished while experimental litters were undernourished before weaning by the method of enlarging nursing litter size and after weaning by restricting access to mouse chow. At 60 days of age, undernourished animals weighed 70% less than controls. At this point rehabilitation was initiated by reinstating ad lib access to mouse chow. One group of experimental and control mice were sacrificed at 145 days of age and another at 250 days of age for a morphometric cerebellar analysis utilizing the Golgi-Kopsch technique.

At the end of 145 days of age, partial recovery of all parameters was noted including body weight (-15%), brain weight (-12%) vermis sectional area (-15%), granular layer area (-19%), molecular layer area (-11%), Purkinje cell field areas (-9.4%) and Purkinje total dendritic length/cell (-9.6%). By 250 days of age a significant difference was still noted in brain weight (-9.0%), vermis area (-8.5%) and granular layer (-11.8%) however, almost complete recovery occurred in the area of the molecular layer (-5.8%), Purkinje cell dendritic field area (-1.4%) and total dendritic length/Purkinje cell (-1.3%).

It is remarkable that the cerebellar molecular layer and Purkinje cell dendritic tree maintain their plasticity and can be induced to regenerate in the adult. Since it is unlikely that new granule cells could be formed during the rehabilitation period, it would appear that parallel fibers must be capable of lengthening and producing new presynaptic processes which induce further growth in the Purkinje cell dendritic tree.

These data offer evidence that the Purkinje cell dendritic tree retains a capacity for plasticity into the adult period.

2326 INFLUENCE OF CULTURED NEURAL AND NON-NEURAL CELLS AND COLLAGEN ON RAT SCIATIC NERVE REGENERATION. Barry H. Smith, Vivian A. Betton*, Calvin S. Hawkins*and Arthur M. Banks*. SNB, NINCDS, NIH Bethesda, Maryland 20205.

Several factors influence the success or failure of peripheral nerve regeneration. In an effort to better understand the cellular factors involved we have utilized a vein graft to repair rat sciatic nerves. The vein graft serves as a chamber into which to introduce various agents such as collagen or cultured human or rat neural or non-neural cells to determine what effects they may have on nerve regeneration.

Both Osmond-Mandel and inbred Fisher rats have been utilized. The sciatic injury is produced by sharp transection in the thigh and the vein graft is taken from a segment of the inferior vena cava of a second rat of the same or different line, depending on the desired conditions. After a heparin flush, the vein so obtained is sewn to the proximal and distal ends of the transected nerve using four 8-0 Ethilon sutures. Microcrystalline collagen ("Avitene") is placed in the graft prior to suturing the graft. Cultured cells in phosphate-buffered saline or Hanks are injected into the graft after it is in place.

Cells for injection into the graft cavity have consisted of human glioma tumor cells (line L.M.), reactive post-injury rat peripheral nerve cells, and fetal rat cells derived from dorsal root ganglia, spinal cord, cerebellum, and cortex as well as fibroblastic elements. All cells were originally obtained as surgical specimens and then grown in Ham's F-10 medium with 10% fetal calf serum in a 5% CO_2 - 95% air humidified atmosphere at 36^{0}C and characterized in our laboratory by light as well as electron microscopic techniques. Controls have consisted of simple transection, suture reapproximation and vein-graft only groups. Animal are followed for periods of time beginning at 1 week and extending to six months. Quantitative light and electron microscopic techniques are being utilized to determine extent of regeneration.

Results to date include determination of an inhibitory effect of microcrystalline collagen on regeneration within the vein graft. This may be due in part to a mechanical problem but also involves a prominent cellular reaction in the graft. Use of an Osmond-Mandel vein graft in a Fisher rat nerve (or vice versa) is clearly deleterious to regeneration as is the presence of any infection. The presence of human glioma tumor cells appears to produce improved regeneration patterns from four to twelve weeks post-injury, although the tumor cells themselves are quiescent in the graft and disappear after several weeks. We are currently investigating the influence of the various rat fetal and adult lines on the regeneration process.

2327 SYNAPTIC RESTORATION IN THE RAT SUPERIOR CERVICAL SYMPATHETIC GANGLION FOLLOWING NEONATAL PREGANGLIONIC CHAIN SECTION. Arnold J. Smolen. Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

The superior cervical sympathetic ganglion (SCG) of rats was studied during the process of synaptic restoration which follows neonatal preganglionic chain (PGC) section. Litters of rat pups, aged 3 days, were divided into 3 groups. In one group, the left PGC was sectioned, a procedure which we have previously shown results in the eventual recovery of normal synapse numbers in the SCG. In the second group, the entire length of the left PGC in the neck was removed. This procedure was designed to prevent regeneration of the preganglionic axons. The third group served as unoperated controls. The litters of rats were killed on days 7, 15, 21 and 29, and the left SCGs were processed for electron microscopy. Quantitative ultrastructural methods were used to yield estimates of the numbers of synapses and postsynaptic membrane specializations (PMSs) unapposed by a presynaptic terminal (presumably vacated PMSs).

In both groups of operated animals, 90% of the synapses were lost by the 4th postoperative day. The remaining synapses presumably belong to intrinsic ganglionic neurons. In the rats in which the PGC was sectioned, restoration of synapse number began at 21 days. However, in the animals in which the PGC was removed, there was no restoration of synapse number. Thus, the intrinsic ganglionic neurons failed to sprout to produce additional synapses in response to the massive deafferentation caused by removal of the preganglionic input.

The number of vacated PMSs equalled only about 10% of the number of lost synapses in both groups of operated neonatal animals on the 4th postoperative day. This is in contrast to the findings in the deafferented SCG of the adult rat, where vacated PMSs equal about 50% of the number of lost synapses.

These findings demonstrate that the mechanism of synapse restoration in the neonate differs from that in the adult. In the adult, the regenerated presynaptic terminals reestablish contact with the vacated postsynaptic sites. In the neonate, however, the vacated postsynaptic sites are lost and synapse restoration appears to recapitulate normal synapse development.

2328 INDUCED PLASTICITY IN VISUAL CORTEX OF ADULT CATS. D. N. Spinelli, Frances E. Jensen* and Leanna Standish*, Department of Computer and Information Science and Psychology, University of Massachusetts, Amherst, MA 01003.

During the critical period of development (6 to 10 weeks) the visual cortex of kittens exhibits remarkable plasticity. Kittens viewing vertical lines with one eye and horizontal lines with the other during this period lose binocular cells in visual cortex and exhibit instead neurons which are monocular and selective for lines of orientation similar to that viewed by the eye that activates them. These effects cannot be reproduced in adult cats, suggesting that plasticity and neuronal growth might be related. Colchicine has been shown to produce temporary chromatolysis, nucleolar enlargement, retraction of presynaptic terminals and loss of synaptic transmission when applied locally to neural tissue. These effects are reversible in 3 to 4 weeks. We wanted to investigate the possibility that during recovery plasticity might be present. To this end, a solution of colchicine (1 millimole) was applied to the visual cortex of one hemisphere in adult cats for 30 minutes. After recovery from surgery the cats were exposed to goggles, with vertical lines for one eye and horizontal lines for the other, 4 hours every day for a period of 2 months. The animals were kept in a dark room at all other times. At the end of two months, single cells were recorded from the visual cortex of the colchicine-treated hemisphere and from the untreated one, which served as control, and their receptive fields were mapped. The data shows that extensive reorganization of receptive field orientation, sensitivity and binocularity took place in the colchicine-treated hemisphere. Here, cells were mostly monocular and responded to bars of the same orientation viewed by the driving eye during recovery. A few cells were found that responded to vertical lines when tested through the eye that had viewed vertical lines, and also to horizontal lines when tested through the eye that had viewed horizontal lines. These cells are never found normally. Cells in visual cortex of the untreated hemisphere exhibited normal properties and receptive field types, i.e., they were mostly binocularly driven, and were distributed evenly in terms of orientation sensitivity. Histologycal analysis indicates that some neuronal rearrangement had taken place in the treated cortex. The results will be discussed in terms of the interaction between experience and the induced neuronal modifications.

2329 AUTORADIOGRAPHIC AND VISUAL ANALYSES OF TWO TYPES OF IPSILATERAL RETINOTECTAL PROJECTIONS IN GOLDFISH. Alan D. Springer. Dept. Physiol., Univ. Ill. Med. Ctr., Chicago, IL 60680

Following ablation of a hemitectum in goldfish, the severed optic nerve fibers regenerate and innervate the remaining ipsilateral hemitectum (IOT). Both the pattern of IOT innervation and the pathways taken by regenerating fibers to reach the IOT were examined with autoradiography. Two types of surgical preparations were examined: Type I - one eye and hemitectum ablated on the same side of the fish and Type II - both eyes intact and one hemitectum ablated.

Examination of tectal labeling in Type I fish revealed a normal laminar pattern of innervation in most, but not all fish. The majority of the regenerating nerve fibers appeared to reach the IOT via the ipsilateral optic tract (IOTr). In contrast, the IOT projection in Type II fish was discontinuous and few fibers appeared to reach the IOT via the IOTr. Discontinuity of the IOT projection in Type II fish may have resulted from the presence of the contralateral optic nerve fibers mechanically blocking the regenerating nerve fibers from reaching the IOT via the IOTr. Thus, the discontinuous IOT projection may in part be a consequence of a large number of fibers failing to reach the IOT, rather than of all fibers reaching the IOT and subsequently becoming restricted to discrete patches of the optic tectum.

A further experiment in Type II fish injected with labeled proline into the contralateral eye revealed that the existing projection, which had not been surgically altered, had become discontinuous as a consequence of superinnervation. Fish injected with labeled proline into both eyes indicated that the entire remaining hemitectum was innervated in a continuous fashion by both eyes.

Visual testing of Type I fish following regeneration indicated that most animals responded to an overhead moving shadow by reducing their respiration. Fish that had a sparse IOT projection, on the basis of subsequent autoradiographic analysis, did not respond to the shadow. Type II fish responded equally well with either eye in the shadow test. However, an optomotor response could only be elicited from the contralateral, but not the ipsilateral eye. These results suggest that the IOT projection in Type II fish is only partially functional.

2330 REGENERATING DORSAL ROOT AXONS ARE BLOCKED BY SPINAL CORD ASTROCYTES. L.J. Stensaas, P.R. Brugess and K.W. Horch. Dept. Physiol., Univ. Utah Col. Med., Salt Lake City, UT 84108.

Axons regenerate rapidly in the dorsal root of the adult cat after an injury to the nerve several centimeters from the spinal cord. Regenerating axons are associated with Schwann cells in endoneurial portions of the nerve and eventually become remyelinated by them. However, the nerve fibers do not enter the spinal cord. They stop growing precisely at the root entry zone which represents the boundary between central and peripheral nervous tissue. Regenerating axons were not observed to penetrate the layer of astrocyte processes at the surface of the spinal cord in animals surviving up to two years. Myelinated and unmyelinated axons at the root entry zone end blindly. Many contain organelles characteristic of regenerating axons, some have terminal enlargements, but none give rise to the unmyelinated axons characteristic of a neuroma. The fact that astrocytes block the regenerating nerve fibers even though the initial injury was situated some distance away from the root entry zone and did not produce a glial scar indicates that they possess growth inhibiting properties. The results of this investigation suggests that the mature astrocyte may constitute the principal impediment to axon regeneration in the central nervous system of mammals.

2331 RETINAL GANGLION CELL RESPONSE TO NERVE GROWTH FACTOR AND ITS ANTISERUM IN THE INTACT AND REGENERATING VISUAL SYSTEM OF THE GOLDFISH. James E. Turner, Rebecca K. Delaney and James E. Johnson. Dept. Anat., Bowman Gray Sch. Med., Wake Forest Un., Winston-Salem, N.C. 27103

In recent publications we have reported pronounced effects elicited by NGF and its antiserum (anti-NGF) on the retinal ganglion cell body response to axotomy and optic nerve regeneration in the newt. In this abstract we wish to report that NGF and anti-NGF produced opposing and pronounced changes in the goldfish retinal ganglion cell body response to axotomy. Adult goldfish received one 4 µl intraocular injection of 2.5S NGF into the intact eye or at the time of optic nerve crush. Anti-NGF was delivered as a 3.0 mg intraocular injection administered at either the time of nerve crush, at 7 days post axotomy (i.e. 7 DPA) or as a multiple series of injections given at 3, 6, 9, and 12 DPA. NGF controls received 4 µl BSA (1 mg/ml) and anti-NGF controls were injected with preimmune rabbit serum (3 mg/eye). Retinas were prepared for electron microscopy at 7 DPA in the NGF group and at 14 DPA in the anti-NGF groups. Electron microscopic morphometric analyses were performed on randomly selected retinal ganglion cells. NGF treatment elicited a dramatic hypertrophy of the goldfish retinal ganglion cell at 7 DPA. The cytoplasmic area was increased by a factor of approximately 2.0 with accompanying significant increases in the nuclear area, the cytoplasmic/nuclear ratio and the nucleolar area. Mitochondrial, Golgi field, RER and nucleolar densities were the same for both NGF and control groups at 7 DPA. NGF elicited no detectable alterations in the retinal ganglion cells whose axons have not been crushed but remain intact. Anti-NGF treatment given as a multiple series of injections caused a significant reduction in the cytoplasmic area of neurons at 14 DPA. There was also an accompanying decrease in the nucleolar area and some evidence for retinal ganglion cell necrosis. These NGF and anti-NGF mediated changes, although similar to those seen in the regenerating newt visual system are more pronounced and dramatic. These results have led us to conclude that an NGF-like molecule may be ultimately important in the successfully regenerating vertebrate visual systems.

2332 VIABILITY OF PNS TISSUE TRANSPLANTED INTO THE CNS. Ellen L. Weinberg* and Dr. Cedric S. Raine. Albert Einstein College of Medicine, Bronx, New York, NY 10461.

Previous studies from this laboratory (Brain Res.:138,423,1977) have shown that rat iris tissue transplanted into the autologous rat midbrain will be innervated by CNS axons, some of which have PNS myelin formed by graft Schwann cells. The present experiment follows a similar protocol. Segments of rat peripheral nerve were transplanted into rat midbrain. Animals were anesthetized and, under sterile conditions, tibial nerve grafts 3mm in length were placed through a burr hole in the cranium into the midbrain at the edge of the periaqueductal gray matter, in a rostral-caudal position. The overlying skin was sutured. Animals remained healthy and showed no clinical abnormalities. Animals were perfused at 3 weeks and 6 weeks post-implantation and the midbrain tissue was prepared for morphological study.

The implants became vascularized rapidly. The original axons of the graft had undergone Wallerian degeneration, and the myelin debris was degraded by graft Schwann cells and hematogenously-derived macrophages. At three weeks, there was clear evidence by EM of regenerating axons throughout the graft in association with Schwann cells. Elongated Schwann cell processes encircled individual axons or groups of axons.

At six weeks, the regenerated axons in the graft had PNS myelin around them, distinguishable from CNS myelin by its periodicity and the presence of a basal lamina. Several groups of remyelinated axons were fasciculated in the pattern of a regenerating peripheral nerve.

In the CNS parenchyma bordering the implant, myelination of the regenerating CNS axons was observed. Along most of the border of the implant was a clearly-defined rim of recently-proliferated oligodendroglial cells and thinly-myelinated CNS axons presumably en route to the transplanted tissue.

The findings of this study are consistent with the concept that transplanted myelinating cells may produce soluble factors which are attractive to regenerating axons.

2333 EFFECT OF TRIIODOTHYRONINE ON THE AMINO ACID UPTAKE OF THE BRAIN AND SPINAL CORD AFTER SPINAL HEMISECTION IN ADULT RATS. M. R. Wells, S. A. Lofton* and J. J. Bernstein. Dept. Neurosci., Coll. Med., Univ. of Fla., Gainesville, FL 32610

The thyroid hormones triiodothyronine (T_3) and L-thyroxine have been used to enhance regeneration in the peripheral nervous system (Cockett and Kiernan (1973), Exp. Neurol. 39:389) and in the central nervous system (Harvey and Srebnik (1967) J. Neuropath. Exp. Neurol. 26:661). The following experiments were designed to examine possible metabolic substrates for the action of T_3 on the central nervous system which may result in enhanced regeneration. Adult male rats (200-250g) were divided into experimental groups of unoperated animals, animals subjected to a vertebral laminectomy at T_2, or animals receiving a left spinal hemisection at T_2, to be examined at 1, 3, 7 and 14 days post-operation. Animals received a daily injection of vehicle or 1 µg/kg body weight of triiodothyronine in a bicarbonate buffer for the postoperation or equivalent time period. One hour prior to utilization, animals were given a subcutaneous injection 200 µci of [^{3}H]lysine. Tissue samples of brain taken bilaterally from somatomotor and occipital cortices. Spinal cord samples were taken bilaterally extending 14 mm rostral and caudal from the site of spinal hemisection. Samples were dissolved and the protein precipitated in 5% trichloroacetic acid (TCA). The radioactivity of TCA precipitable protein and TCA soluble fraction were determined by scintillation counting. In measurements adjusting the protein radioactivity to the soluble pools by ratio (relative radioactivity, RR), the protein uptake of [^{3}H]lysine in the brain and spinal cord of unoperated T_3 injected animals was highest ($p < 0.05$) at 3 days. In T_3 treated animals only, the RR in both brain and spinal cord of laminectomized and spinal hemisected animals showed significant differences over time post-operation. In spinal hemisected, T_3 treated animals, a hemispheric assymetry of [^{3}H]lysine uptake was present in brain at three days postoperation. The right hemisphere is somatomotor cortex had a higher ($p < 0.05$) protein radioactivity than the left. These data suggest that T_3 may affect some aspect of amino acid metabolism in the central nervous system of adult animals. Furthermore, there are indications that protein metabolism of CNS intrinsic neurons which have been axotomized may be stimulated by T_3 similar to peripherally projecting axotomized neurons (Rhodes et al. (1964) Exp. Neurol. 10:251).

2334 RESPONSE OF LAMPREY DORSAL CELLS TO AXOTOMY. H.S. Yin*, K.K. Wellerstein* and M.E. Selzer. University of Pennsylvania, Philadelphia, PA 19104.

Both by antidromic activation and by retrograde labeling with horseradish peroxidase, it was determined that at least 85-90% of dorsal cells in the larval sea lamprey, P. marinus, project to the rostral spinal cord. Therefore axotomy of more caudally located dorsal cells was achieved by transection of the spinal cord at the level of the last gill. Following varying recovery times in fresh water at 22°C the dorsal cells were examined either histologically, in toluidine blue stained wholemounts, or physiologically, by intracellular recording. Light microscopic changes were maximal at about three weeks and were seen in progressively fewer cells at increasing distance from the transection site. These changes included: 1) loss of most cytoplasmic staining and concentration of chromophilic substance in a thin ring around the nucleus, 2) an increase in the proportion of cells with eccentric nuclei (defined as nucleus contacting the outer cell margin), 3) an increase in nuclear size and a decrease in cell diameter with a consequent striking increase in nucleus/cell diameter ratio from .34 to .43 in the first 5 mm caudal to the transection. By comparison, electrophysiological changes were less striking, and showed little correlation to the distance of the cell from the transection. Input resistance (Rn) increased by about 33% at between three and five weeks (control Rn = 8.67 MΩ), and thereafter returned to normal. It is possible that this change is in part related to the reduction in cell size. Resting membrane potentials decreased slightly from a control value of -56 mV ± .56 s.e.m. to -49 mV ± .59 at four to six weeks, and then increased to 61 mV ± 1.15 by eleven weeks. Both voltage and current threshold for spike activation dropped slightly, then greatly increased at between four and six weeks and thereafter returned toward normal. Axonal conduction velocities gradually increased from .51 m/sec ± .01 s.e.m. to .66 m/sec ± .02 at six weeks, and then returned toward normal. These and other electrophysiological changes could not be interpreted as representing any single change in basic membrane properties. The histological and electrophysiological changes noted above occurred during the period of behavioral recovery and axonal regeneration previously reported in the spinal transected larval lamprey. It is not yet known whether these changes are functionally related to the process of axonal regeneration.

(NIH grant # NS14257, NS14837, NS11083)

2335 SELECTIVE REGENERATION OF OPTIC NERVE FIBERS INTO THE OPTIC TECTUM AFTER TECTAL REIMPLANTATION OR TRANSPLANTATION IN ADULT GOLDFISH. Myong G. Yoon and F. A. Baker*. Dept. of Psychology, Dalhousie University, Halifax, N.S., Canada.

In normal goldfish, a majority of optic fibers invade the tectum via the stratum opticum, and terminate at the stratum fibrosum et griseum superficiale in a consistent topographic pattern. In the present study, the passages of regenerating optic fibers within the altered cytoarchitecture of the surgically operated tectum are examined after reimplantation of the tectal tissue, or reciprocal transplantations between a tectal piece and a cerebellar or forebrain tissue in adult goldfish. If a tectal tissue is reimplanted after 90° or 180° rotation around the dorsoventral axis, the tectal reimplant receives those regenerating optic fibers which previously innervated the reimplanted area. These ingrowing optic fibers are eventually redistributed within the rotated graft according to the original topographic polarity of the tectal tissue. These tectal reimplants, stained by Golgi methods, show that their neurons and radial glial cells remain in a more or less normal orientation with respect to the dorsoventral axis. Autoradiographic examination of the operated tectum after intraocular injection of H^3-proline reveals that only the stratum opticum and the stratum fibrosum et griseum superficiale are intensely labelled within the reimplanted tectal tissue. This suggests that regenerating optic fibers selectively invaded the tectal reimplant via their normal passages. On the other hand, if a piece of tectal tissue and a similar piece of cerebellar or forebrain tissue are reciprocally transplanted, regenerating optic fibers do not invade the transplanted cerebellar or forebrain tissue. Instead, they bypass the interposed foreign tissue by making dramatic detours on their way towards their appropriate target zones in the caudal tectum. In further experiments, a piece of tectal tissue is reimplanted after inversion of its entire laminar structure. Golgi stainings of these inverted tectal reimplants show no sign of reorganization in their cytoarchitectures. Neurones and radial glial cells within the tectal graft remain inverted upside-down (for as long as one and a half years). Autoradiographic examination of the operated tectum reveals that a group of incoming optic fibers abruptly dip towards the optic ventricle to find the stratum opticum within the inverted tectal tissue, and invade it via the proper passages inspite of its inversion. These results suggest that advancing tips of regenerating optic fibers are able to select not only the proper tectal tissue from other neural tissues but also the particular layer for their passages within the tectal tissue. (Supported by grants from NRC and MRC of Canada.)

SENSE ORGANS

2336 DISTRIBUTION AND HISTOCHEMISTRY OF "ONE BAG" SPINDLES IN DORSAL NECK MUSCLES OF THE CAT. G.J. Bakker* and F.J.R. Richmond, Department of Physiology, Queen's University, Kingston, Ontario. Canada. K7L 3N6.

The intrafusal fibre complement of most mammalian muscle spindles includes at least two nuclear bag fibres which may be differentiated by their histochemical and ultrastructural profiles. In most muscles however a small number of spindles contain only one nuclear bag fibre and these "one-bag" spindles account for a large proportion of spindles in dorsal neck muscles of the cat. Serial reconstruction of biventer cervicis has shown that 19% (71/369) of the spindles contained only one nuclear bag fibre. In complexus and splenius such spindles account for 34% (138/192) and 31% (146/466) of the population respectively.

The histochemical profiles of nuclear bag fibres have been examined in spindles of biventer cervicis and complexus using an ordered battery of staining techniques: myofibrillar ATPase (mATPase); mATPase subsequent to acid preincubation; mATPase subsequent to alkali preincubation. These techniques differentiate the nuclear bag fibres of two-bag spindles into 2 types in agreement with descriptions of spindles in cat hindlimb. One of the bag fibres (bag_1) reacts intensely for mATPase activity following acid preincubation but shows only light staining following alkali preincubation. The second fibre (bag_2) stains intensely following alkali preincubation and with moderate intensity following acid preincubation. By comparing the staining profiles in one-bag spindles with the profiles of two-bag spindles, the type of bag fibre present in one-bag spindles can be determined. In all one-bag spindles which have been so far reconstructed in complexus, the nuclear bag fibre which is present has a staining profile consistent with that of a conventional bag_2 fibre. Whether the loss of bag_1 fibres in these spindles has a major effect on the encoding properties of the primary ending remains to be determined.

2337 A REGULATORY MECHANISM FOR OTOCONIAL GROWTH. Joanne Ballarino* and Howard C. Howland, Division of Biological Sciences, 136 Langmuir Laboratory, Cornell University, Ithaca, New York 14853.

Preliminary studies of otolithic organ growth in centrifuged chicks indicated that embryos of day 17 or older had significantly lighter otolithic organ weights than stationary controls (Howland & Ballarino, in press).

In this study we have repeated and refined this preliminary experiment by: a) performing all dissections in such a fashion that the dissector did not know the nature of the embryo being dissected; b) weighing the dissected otolithic organs twice, namely before and after dissolution of the otoconia in dilute HCl in order to calculate true otoconial weight; c) comparing the otoconial weights of rotated experimental animals raised at 2 g net acceleration with otoconial weights from both stationary embryos and embryos rotated at the center of the centrifuge grown at 1 g.

Under these conditions the mean otoconial weight (n=56) of the experimental animals was 11.6% lighter than that of the stationary controls (n=55, $p \leq 0.05$, 1 tailed T test) and 14.7% lighter than that of the rotated controls (n=47), $p \leq 0.0005$, 1 tailed T test).

Scanning electron micrographs were taken of the utricular otolithic organ of experimental and control embryos of 20 days of age. The otolithic organ of a 20 day old control embryo was found to have a few shrunken otoconia, similar to those found in adult guinea pigs by Lim (1973). Two experimental embryos of the same age had otoliths with cracked and shrunken otoconia. Further scanning electron micrographs of the otoliths of control and experimental embryos will be presented.

2338 PERIPHERAL AND CENTRAL EFFECTS OF TONIC VIBRATORY STIMULI TO DORSAL NECK AND EXTRAOCULAR MUSCLES IN THE CAT. H. Barbas and B. Dubrovsky. Neurophysiol. Lab., Allan Memorial Institute, McGill Univ., Montreal, P. Q. Canada.

Extraocular and dorsal neck muscle afferents show converging excitatory and inhibitory effects on neurons of the frontal cortex of chloralose anesthetized cats at latencies of 5-50 ms (Exp. Neurol. 55: 680-693, 1977; Neurosc. Abstr. III: 468, 1977). We now report that neurons in these regions, which correspond with the frontal eye fields, also respond to vibratory stimuli (25-350 Hz, 20-200 μm) applied to extraocular and dorsal neck muscles. The observed evoked neuronal responses occurred 18-90 ms following the onset of vibration, and were characterized either by a phasic burst of cellular activity, or tonic responses which lasted for the duration of stimulation. Neurons could be further classified into those whose response depended on the frequency of vibration, and those that did not. In 12 cats 37 neurons showed consistent responses to vibration of either the biventer cervicis or the rectus capitis dorsalis major muscles of the dorsal neck. Of these nine showed an increase in firing activity as the frequency of vibration was increased (100-300 Hz) at amplitude displacements of 20-50 μm. Intravenous injection of the depolarizing neuromuscular blocking agent succinylcholine (30-40 μg/kg), known to activate preferentially the primary endings of muscle spindles, also activated these neurons. In nine cats 39 neurons responded to vibration of the superior rectus muscle of the eye at amplitudes of 50-140 μm, and 25-300 Hz frequencies, or 0.5-1.5 mm single stretches of the muscle. Consistent increases in firing activity with increases in vibration frequencies (100-300 Hz) were observed in seven of these neurons, including two which showed increased responses to faster single pulls of the muscle. The majority (69%) of the responsive neurons to extraocular muscle vibration showed tonic responses. The vibratory stimuli induced tension increases (40 mg - 2 g over the baseline) and electromyographic activity in the rectus capitis dorsalis major muscle of the dorsal neck, and the superior rectus muscle of the eye, which was abolished with administration of the paralytic agent gallamine triethiodide. This result demonstrated that a tonic stretch reflex can be elicited in both dorsal neck and extraocular muscles with vibratory stimuli, suggesting the presence of a proprioceptive feedback control system in both of these muscle structures. The neuronal responses to low threshold afferents originating in muscle receptors further suggests that small head and eye movements can activate these frontal brain regions, which may participate in mechanisms underlying coordinated eye and head movement.

2339 MOTION SICKNESS IN SQUIRREL MONKEYS: EFFECTS OF ROTATIONAL RATE, PHENOTYPE, SEX, DIURNAL CYCLES, AND ABLATION OF AREA POSTREMA ON INCIDENCE OF EMESIS. T. Beavers, K. R. Brizzee, W. R. Mehler, J. M. Ordy and P. M. Klara*. Delta Regional Primate Research Center, Covington, LA 70433, NASA-Ames Research Center, Moffett Field, CA 94035, and Dept. Anat. Tulane University, New Orleans, LA 70112.

To determine the susceptibility of the squirrel monkey to motion sickness, combined horizontal rotation and vertical motion tests were carried out to determine the specific effect of 10, 25 and 50 r.p.m. rotational rates with a vertical excursion of 6" every 2 seconds, Colombian and Bolivian phenotype, sex, morning and afternoon diurnal cycles, repeated exposure to motion tests, and ablation of area postrema (AP) on the incidence of emesis. The highest incidence of 80% emesis was observed in the Bolivian phenotype at 25 r.p.m., compared to 30% at 50, and 20% at 10 r.p.m. ($p<.05$). The incidence of emesis was also significantly higher in Bolivian males than in females ($p<.01$). No significant effects on incidence of emesis were observed in early morning compared to late afternoon tests, or with repeated test exposure involving a one day interval between tests. Following complete bilateral ablation of the AP, three monkeys from a group of 12 that exhibited an emetic response to 50 r.p.m. did not respond one month after postoperative recovery. Of six monkeys with partial ablation of AP, three monkeys did not respond to 50 r.p.m., whereas three others did respond. Three sham-operated controls that exhibited an emetic response to 50 r.p.m. before the operation, also continued to respond one month after postoperative recovery. From the results of this study, it can be concluded that the Bolivian squirrel monkey can be used succesfully as a model for determining the effects of lesions and drugs on emetic mechanisms related to motion sickness in a higher diurnal primate that is of the same taxonomic order as man. Supported by NASA-Ames Grant No. NSG-2139.

2340 FREQUENCY RESPONSE OF DEITERS' NEURONS TO NATURAL STIMULATION OF NECK AND MACULAR LABYRINTH RECEPTORS. R.Boyle* and O.Pompeiano. Ist. Fisiol. Umana, Catt.II, Univ. di Pisa, 56100 Pisa, Italy.

Frequency response of Deiters' (LVN) neurons to stimulation of neck and labyrinth receptors has been evaluated in precollicular decerebrate cats during sinusoidal rotation (10° peak amplitude at 0.026 Hz): a) of the cervical axis while maintaining the head horizontally (neck input), b) of the whole animal in both directions of the median plane (labyrinth input), and c) of both the head and neck while maintaining the body horizontally (neck and labyrinth input). 70 out of 120 units (58.3%) tested during neck stimulation and 77 out of 102 units (75.5%) tested during labyrinth stimulation showed a periodic modulation of the firing rate in response to the sinusoidal inputs, the phase angle being mainly related to the extreme neck or head position. The average sensitivity of the responses, expressed in per cent increase of the mean firing rate per degree of displacement, was higher for the neck (3.26 ± 3.77, S.D.) than for the macular input (2.54 ± 2.71, S.D.). Among the units responsive to the neck input, 34/46 (i.e., 73.9%) were located in the rostroventral LVN (cLVN) (sensitivity: 3.84 ± 4.54, S.D.), while 36/74 (i.e., 48.6%) were located in the dorsocaudal LVN (lLVN) (sensitivity: 2.73 ± 2.84, S.D.). Among the units responsive to the labyrinth input, 31/34 (i.e., 91.2%) were located in cLVN (sensitivity: 3.62 ± 3.4, S.D.), while 46/68 (i.e., 67.6%) were located in lLVN (sensitivity: 1.81 ± 1.83, S.D.). It appears therefore that the sensitivity to the neck and labyrinth inputs is greater in the forelimb (cLVN) than in the hindlimb (lLVN) region of Deiters' nucleus.

Among 100 units tested to neck and labyrinth stimulation, 52 responded to both inputs and were mainly positional sensitive, most of these units (73.5%) were excited during side-down tilt of the animal, while fewer units (46%) were excited during side-down rotation of the neck. Rotation of the head alone, leading to combined stimulation of neck and macular receptors, yielded a response whose sensitivity and phase angle were significantly correlated with the expected vectorial values derived from the analysis of the individual responses. Due to the significant convergence and predictable interaction of both neck and macular inputs, the LVN represents an important premotor structure for the integration of the two inputs during the cervical and labyrinthine control of posture.

2341 VISUAL-VESTIBULAR INTERACTION IN VERTICALLY SENSITIVE OTOLITH-DEPENDENT UNITS. N.G. Daunton, D.D. Thomsen*, and C.A. Christensen. NASA-Ames Research Center, Moffett Field, CA 94035 and Vassar College, Poughkeepsie, NY 12601.

The effects of combined visual and vestibular stimulation in the horizontal plane on otolith-dependent units in cat vestibular nuclei have been discussed in an earlier paper (Daunton, Thomsen and Christensen, Neurosci. Abs. 4: 610, 1978). These studies have shown that in units responding to horizontal translational motions, the addition of congruent visual input results in an increase in the gain of the response and a shift in response phase toward maximum velocity of motion, as compared with gain and phase obtained without visual input.

In the present study responses of units sensitive to both visual and vestibular sinusoidal stimulation along the vertical axis were recorded under the following conditions: 1) vestibular stimulation; 2) visual stimulation; 3) congruent visual-vestibular stimulation, produced by moving the animal in the lighted but stationary visual enclosure. In addition, responses to vestibular, visual and congruent visual-vestibular stimulation along right-left and fore-aft horizontal axes were recorded, if a unit was sensitive to horizontal motion. These recordings were obtained from chronically prepared cats relaxed with Flaxedil and artificially ventilated.

Results show that the addition of the congruent visual input increased the gain of responses to vertical linear acceleration in a majority of units. However, the actual amount of the gain increase was less than that found with horizontal stimulation. Analyses of phase relationships with vertical stimulation show that unlike the horizontal stimulus condition no consistent shift in phase toward maximum stimulus velocity was found. These analyses also show that the magnitude of phase shift was smaller for vertical than horizontal stimulation.

The data suggest that vision plays a less important role in sensing vertical motion than it does in sensing horizontal motion. Several hypotheses may explain these findings. They may be due to differences between utricular and saccular function or to differences in the nature of the vertical vs. the horizontal vestibular stimulation (pure linear acceleration vector vs. rotating linear acceleration vector). A three-dimensional vectorial display of unit responses will be used to aid the evaluation of potential hypotheses.

2342 FAST-ADAPTING STRETCH RECEPTOR ORGANS: PERIODIC STIMULATION WITH AND WITHOUT PERTURBATIONS. Oscar Diez-Martinez* (SPON: J. P. Segundo). Department of Anatomy and Brain Research Institute, University of California, Los Angeles, CA 90024.

Isolated fast-adapting stretch receptor organs (FAO) of crayfish were submitted to sinusoidal length modulations with depths of .09 to .75 mm and frequencies of .2, 1.0, 3.0 and 10.0 cps. Sinusoids were imposed either by themselves ("clean") or perturbed by fast, erratic length flunctuations or "jitter." Different jitter amplitudes were explored from x.05 to x.66 of the modulation. Afferent discharge rate was measured over "bins" of about 1/10 of the period, and plotted as a function of time. Average Lissajous displays of rate vs. length and rate vs. velocity were examined.

Experiments without jitter: At .2 and 1.0 cps, shallow modulations caused no discharge. With deeper modulations, the rate vs. length display commonly had a clockwise loop with a flat extension to the left. Occasional loops were counterclockwise. At 3.0 cps, "phase-locking" occurred very frequently, and at 10.0 cps almost invariably. The peak rate increased with the modulation depth except when extremes were achieved, in which case it decreased. The bin-rate variability was low for bins with high rates. The rate vs. velocity plots were counterclockwise loops with a base upon the abscissa. Sensitivity at different frequencies (evaluated by comparing the rate-swings using identical bin-widths and depths) was contingent upon bin-width: with small bins it was highest for 10.0 cps, but for large ones it was highest for .2 cps.

Experiments with jitter: Jitter changed the response at all frequencies. At low frequencies, when clean modulation did not produce discharges, jitter elicited firing; in every case it reduced or eliminated contacts with the abscissa and converted the displays into folium-like loops; bin-rates and peak-rates were increased. At high frequencies, jitter eliminated "locking", and frequently reduced peak-rates, rate-swings and the variability in the bins with high variability without jitter. The effect upon rate vs. length plots was to displace the loops from the abscissa and to flatten them.

2343 HORSERADISH PEROXIDASE IDENTIFICATION OF FOUR SEPARATE GROUPS OF VESTIBULAR EFFERENT NEURONS IN THE ADULT PIGEON. Avrim R. Eden and Manning J. Correia. Depts. Otolaryng., Physiol. and Biophys. Univ. Tex. Med. Br., Galveston, TX 77550.

Horseradish peroxidase (HRP) was injected and confined (16-21 hrs.) to the endolymphatic space of one labyrinth in five adult pigeons. Amounts of 0.5µl of 50% HRP were delivered through a micropipette glued into the transsected anterior duct every 10-15 mins. (total 7-10µl). HRP-stained endolymph was seen exiting both ends of the transsected posterior duct confirming circulation. The brain and labyrinth were fixed by bilateral transcardiac intracarotid catheterization. HRP was reacted by the tetramethylbenzidine (TMB) blue reaction process. Schwartz et al (Brain Res. 155:103-107, 1978) injected HRP into the lateral crista of one pigeon and reported a bilateral cluster of DAB-labelled vestibular efferent neurons in the nucleus reticularis pontis caudalis. Using the techniques described above, we have extended these findings by identifying four distinct ipsilateral and two distinct contralateral groups of labelled vestibular efferent neurons.

Within the reticular formation the labelled, large multipolar efferent neurons were distributed equally bilaterally in all 5 pigeons (mean ± SD no. of cells each side: 49±25). The majority of these cells were clustered close together in the nucleus reticularis pontis caudalis immediately ventro-latero-caudal to the abducens nucleus. A separate, smaller cluster of labelled, similar sized, multipolar neurons was also noted within the same nucleus, adjacent and medial to the nucleus paragigantocellularis lateralis and ventro-latero-caudal to the first group of labelled cells.

Within the ipsilateral vestibular nuclear complex, labelled efferent neurons (mean ± SD no. of cells: 77±25) were noted to cluster in distinct groups in 3 of 5 pigeons. A group of medium sized bipolar labelled neurons were located within the tangential nucleus, adjacent to and intermingled with, larger multipolar labelled neurons in the latero-caudal part of the inferior (descending) vestibular nucleus. A second group of large multipolar labelled neurons (Deiter's cells) interspersed with labeled medium-sized round and triangular cells were noted to cluster in the medial pole of the lateral vestibular nucleus adjacent to the nucleus laminaris.

A further group of small, labeled neurons were also noted in the ipsilateral nucleus laminaris and may represent cochlear efferent neurons. (Supported in part by the Deafness Research Foundation and NASA Contract NAS 9-14641.)

2344 STIFFNESS COEFFICIENT OF THE CUPULA IN THE SEMICIRCULAR CANAL OF THE SKATE. Lawrence S. Frishkopf and Richard D. Kunin*. Department of Electrical Engineering and Computer Science and Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, MA 02139.

Cupula displacements have been measured in the semicircular canal of the skate, Raja erinacea, under known loads. The cupula stiffness coefficient -- the ratio of applied torque to angular displacement -- has thereby been directly determined. All procedures were carried out in artificial skate perilymph. The excised labyrinth was dissected to expose the ampulla which was cut from the canal with fine iris scissors. The ampulla was trimmed to enlarge the openings at both ends; contact with the cupula was carefully avoided. Attachment of the cupula at both the crista and at the vault of the ampulla and the integrity of the hair cell cilia were assessed using Nomarski interference contrast optics. Preparations which by these criteria appeared undamaged were studied further under the Nomarski microscope.

Small pieces of aluminum foil were placed upon the cupula and resulting cupula displacements at one or more points were measured. Displacements were in the range from 10 to 160 micrometers, large compared to estimates of the physiological upper limit (3-5 micrometers) in the same species. Displacements at different points were consistent with the notion that the cupula moves as a unit about an attachment region at the crista. The location of the foil allowed estimation of the torque about the crista and thereby determination of the stiffness coefficient of the cupula. In some preparations several pieces of foil were placed upon the cupula and thereby successive increments of displacement were measured; the stiffness coefficient increased as additional load was placed on the cupula. Measured stiffness coefficients were between 4×10^{-4} and 4×10^{-3} dyne-cm/rad in different preparations. These values are consistent with those that have been inferred in other species by less direct means. (Supported by NIH Grant NS11080).

2345 ANALYSIS OF THE HORIZONTAL VESTIBULO-OCULAR REFLEX OF THE ALERT RHESUS MONKEY AS A FUNCTION OF ROTATIONAL ACCELERATION MAGNITUDE. Joseph M. Furman, Dennis P. O'Leary. Dept. Otolaryngology, Div. of Vestibular Disorders, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15213 and James W. Wolfe. USAF School of Aerospace Medicine, Brooks AFB, San Antonio, Texas 78235.

The horizontal vestibulo-ocular reflex (VOR) of three adolescent male rhesus monkeys was evaluated with rotational acceleration in the dark. Vestibular stimulation included single frequency sinusoidal as well as pseudorandom binary sequence (PRBS) rotational acceleration of various amplitudes. Each animal performed a behavioral task during the experiment. Eye position was measured from chronically implanted bitemporal ball electrodes with a D/C coupled amplifier. A PDP 11/40 computer controlled the vestibular stimulus and simultaneously stored eye position using a 12 bit A/D converter sampling at a rate of 100 Hz.

A computer analysis related slow phase eye velocity to the rotational stimulus velocity in order to yield gain and phase estimates at discrete frequencies in the range 0.008 to 1.28 Hz. The magnitude of the vestibular stimulation was varied from 8 degrees/second/second to 256 degrees/second/second in order to elucidate the amplitude dependencies of the VOR. Gain and phase estimates revealed that over the range of stimulus amplitudes employed, no consistent amplitude dependencies were evident; This was found for both sinusoidal and PRBS testing.

These results suggest that the slow phase movements of the VOR can be effectively studied with linear systems techniques over a wide range of stimulus intensities.

2346 VISUAL INFLUENCES ON VESTIBULAR COMPENSATION. David W. Jensen, T. Kubo* and M. Igarashi. Baylor College of Medicine, Houston, Texas 77030.

After a unilateral vestibular neurectomy in guinea pigs, the intensities of spontaneous eye nystagmus and lateral head deviation abate in consistent and quantifiable manners. This is part of a process called Vestibular or Equilibrium Compensation. We have begun to examine the influence of certain visual deprivations upon the compensatory rates of eye nystagmus frequency and lateral head deviation over the first 24 post-operative hours, when approximately 90% of the "tonic compensation" takes place. All animals of this study had chronic Ag-AgCl ball electrodes which were used to record eye nystagmus. Three of these individuals also had skull screw electrodes over the left and right visual cortices, where visual evoked potentials were readily obtained. These three animals subsequently had their corneas opacified to eliminate pattern vision. Three groups of animals were analyzed: (i) 8 normal-sighted individuals that compensated in light, (ii) 3 corneal opacification individuals that compensated in light, and (iii) 3 normal-sighted individuals that compensated in darkness. Eye and head asymmetries of Group (i) individuals immediately decreased from maximum values recorded 1 hour post-operatively and by 24 hours had compensated 89 and 86 percent, respectively. In contrast eye and head asymmetries of Group (ii) individuals remained near their maximum values for several hours post-operatively and by 24 hours had compensated 52 and 36 percent, respectively. Eye and head asymmetries of Group (iii) individuals also remained near their maximum values for the first few post-operative hours and by 24 hours had compensated 74 and 62 percent, respectively. Also, Group (i) and (iii) individuals were capable of visually suppressing spontaneous nystagmus (tested 24 hrs. post-op) while Group (ii) individuals were not.

Thus, vestibular compensations of eye and head asymmetries in guinea pigs are affected by conditions that influence the visual system. Two interpretations of the data are possible: The faculty of pattern vision is necessary for vestibular compensation to proceed normally, and/or visual deprivations cause a decreased alertness which slows compensation.

This research was supported by a Baylor Biomedical Research Support Grant, USPHS RR-05425.

2347 TRANSFER CHARACTERISTICS OF PRIMARY-AFFERENT SEMICIRCULAR-CANAL UNITS IN THE PIGEON. Jack P. Landolt and Manning J. Correia D.C.I.E.M., Downsview, Ontario, Canada M3M 3B9 and UTMB, Galveston, TX, 77550.

Analyses of single unit activity from semicircular canal units in the pigeon to sinusoidal accelerations indicate that the transfer function, G(s), relating output (neural activity) to input (angular acceleration) of each unit is of the form $G(s) = Cs^k/(T_L s+1)$, for frequencies f = 0.01 to 10 Hz. (s^k is a fractional order differential operator with $0<k<1$, C is a gain constant with units in impulses $.s^{-1}$/degrees $.s^{-2}$, and T_L is the so-called long time constant of the classical torsion pendulum model (tpm).) This transfer function differs in two ways from that of the classical tpm that is used to describe semicircular canal function: i) T_L is not single-valued as it is in the tpm; rather it is unit dependent and takes on a range of values from T_L = 4.45 s to T_L = 18.61 s (mean ± SEM = 10.24 ± 1.20 s; a value comparable to T_L derived from biophysical properties). This indicates that individual or small groups of contiguous receptor cells (units) likely have different mechanical properties from those of other groups. This suggests that information is coded and passed to the central nervous system differently in different regions of the vestibular epithelium and may be important in orientation. ii) The classical tpm does not include the term s^k, which can be expanded as a transfer function containing product terms in s in the numerator (zeros) and denominator (poles). The first term in this expansion is of the form, $H(s) = KT_1 s/(T_1 s + 1)$, where T_1 is an adaptation time constant and K is a gain constant. This expression had previously been defined from nystagmoid studies (Malcolm, '68) as the input-output transfer function, H(s), for the phenomenon of "adaptation" -- an unusual response degradation probably resulting from within the receptor cell (which is not predicted by the tpm). A mean (±SEM) T_1 = 77.18 (±13.06)s was determined. The data indicate that adaptation is not only unit dependent but also that it is much more complex at the neural level than is envisaged from the form of H(s). It appears likely that s^k represents a relaxation phenomenon comprising of a time-varying intracellular Na^+/K^- process; components of which are summed with the generator potential in the receptor hair cell. Further analyses indicated that the degree of regularity of the spontaneous discharge, as determined by the coefficient of variation, CV, was significantly correlated with k in G(s). The larger the CV, the larger is the corresponding k and, consequently, the amount of adaptation.

2348 NON-VISUAL CONTROL OF VESTIBULO-OCULAR REFLEX SUPPRESSION IN MAN. Ruth A. Maulucci* and Richard M. Herman. Dept. Rehab. Med., Temple Univ. Health Sciences Center, Philadelphia, PA 19140.

In man, when retinal information is coupled to head motion, suppression of the vestibulo-ocular reflex (VOR) is marked at low frequencies of oscillation (e.g., gain of 0.1 at 0.1 - 0.5 Hz). In the absence of retinal information, image of the coupled visual signal yields a nystagmus pattern with VOR gains enhanced four to sevenfold. In the dark, when head movement is associated with knowledge of the motion of the eyes in the orbit (induced by sensory feedback training) rather than with an image of the visual signal, VOR gain and fast phase saccades are suppressed to a level equivalent to the response observed with retinal information. This magnitude of suppression persists without further training for a considerable period of time (at least 12 months). Attempts to distract the subject by cognitive tasks do not lead to marked alteration in VOR suppression. Phase advance of eye displacement relative to head displacement, observed with retinal information, is modified under all test conditions in the dark to an in-phase response. The results suggest that under these test conditions: 1) non-visual control of VOR suppression can be achieved by matching a "sense of eye movement or fixation" to head motion, and 2) gain and phase control of the VOR may function independently.

2349 CORRELATIONS OF SPONTANEOUS ACTIVITY CHARACTERISTICS WITH INNERVATION PATTERNS IN THE ISOLATED GUITARFISH HORIZONTAL SEMICIRCULAR CANAL. Dennis P. O'Leary and Robert F. Dunn. Dept. Otolaryngology, Div. of Vestibular Disorders, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15213.

Spontaneous activity of different VIIIth nerve semicircular canal fibers shows a wide range of mean (μ), standard deviation (σ) and coefficient of variation (CV = σ/μ) of interspike intervals. We investigated whether these parameters were correlated with spatial position of fibers in the guitarfish horizontal ampullary nerve (HAN), shown previously to be comprised of 5 to 9 separated bundles (O'Leary, Dunn and Honrubia, Nature 251: 225-227, 1974) Epochs of 40 seconds of spontaneous activity from 280 afferent neurons were digitized on a PDP 11 computer system, with an interspike interval resolution of 100 microseconds, and edited to remove artifacts. Interspike interval histograms and parameters μ, σ and CV were computed for each afferent. Each parameter was tested separately, using the Kruskal-Wallis test, to determine whether it was distributed uniformly among 7 different bundle areas of the HAN.

The results showed that both σ and CV were distributed differently in the nerve ($p < 0.0002$), with greater values ("irregular" cells) occurring in central HAN nerve bundles, and lesser values ("regular" cells) occurring in extreme rostral and caudal HAN bundles. Differences in μ distributions were not significant at an acceptable level. The systematic differences in σ and CV can be correlated also with the projection patterns of the guitarfish HAN to the crista described by Dunn (J. Comp. Neurol., 183: 779, 1979), and with differences in HAN dynamic response characteristics described by O'Leary, Dunn and Honrubia (J. Neurophysiol., 39: 631, 1976). In general, fibers from central HAN regions projecting toward the crista crest, have faster response dynamics and exhibit "irregular" spontaneous activity. Fibers from peripheral HAN regions projecting toward the crista slopes, have slower response dynamics and exhibit "regular" spontaneous activity.

2350 REGIONAL INNERVATION DIFFERENCES IN THE UTRICLE OF THE GOLDFISH INNER EAR. Janet F. Ott* and Christopher Platt. Dept. Biological Sci., Univ. Southern California, Los Angeles, Calif. 90007.

The utricle of the vertebrate inner ear is an otolith organ that generally is considered a gravistatic receptor. Fishes have only the cylindrical Type II hair cells in their vestibular sensory epithelia, but within each otolith organ macula there are some structural distinctions between different regions. The utricular macula usually has a band, the striola, in which the hair cells are larger, with larger ciliary bundles, than elsewhere in the macula. We now have investigated whether goldfish have a pattern of utricular innervation showing distinctions between striolar and non-striolar regions.

Utricles and their attached branch of the eighth nerve from goldfish 40-50 mm long were fixed and imbedded by techniques conventional for electron microscopy. Blocks were sectioned either transversely or along the axis of the nerve trunk. Light microscopy was used for 1 μm sections stained with toluidine, and electron microscopy was used for thin sections stained with uranyl acetate and lead citrate.

Nerve fiber diameters range from less than 1 μm up to 15 μm. In the utricular trunk leading to the macula, fibers of up to 5 μm diameter tend to be clustered in bundles in the core of the nerve, while the largest fibers occur around the periphery. The fibers in the core of the nerve appear to interdigitate with the large fibers, as these small fibers course up to and through the basement membrane in non-striolar regions. Large fibers penetrate the basement membrane under the striolar region of the macula. There are roughly 200 fibers of more than 5 μm diameter in the utricular branch of fish of this size; these represent less than 20% of the total fiber population in the utricular branch.

We conclude that the goldfish utricle has a distribution of innervating fibers suggesting from their diameters that the fastest conduction times and shortest latencies might arise from striolar regions. The sparse numbers of large fibers to the abundant hair cells of the striola also suggests great convergence, which could provide high sensitivity by averaging a signal from a field of inputs.

2351 BEHAVIOR OF SEMICIRCULAR CANAL PRIMARY NEURONS SUGGESTS NEW MODEL B.N. Segal* & J.S. Outerbridge* (SPON: G. Mandl). Dept. Otolaryngol. & Biomed. Eng. Unit, McGill Univ., Montreal, Canada H3G 1Y6.

The activity of 51 single neurons innervating the horizontal semicircular canal of the bullfrog was examined during prolonged, horizontal-plane, angular velocity stimuli, both sinusoidal and triangular, having different amplitudes (10-320°/s) and frequencies (0.01-0.3 Hz). During the prolonged stimulation of most cells, the peak neural response in successive cycles gradually declined over a 1-4 min. interval and thereafter remained essentially constant. The late, non-declining response was considered to be the steady state neural response, and attempts were made to fit it with a model composed of a linear element, corresponding to the Goldberg & Fernandez equations (J. Neurophysiol.34:661, 1971), followed by a biased rectifier element. This model was inadequate since the slope and x-intercept of the fitted biased rectifier were strongly dependent on stimulus magnitude, which would imply that neural sensitivity and threshold were input dependent. Moreover, it can be shown that such neural behavior cannot be explained by any model composed of an arbitrary linear system followed by an arbitrary static nonlinearity (eg. power law, etc.).

Simulation studies based on this data suggest a new form of model for the rotational afferent pathway, which is consistent with findings of others. It is well known that an essentially static nonlinearity exists at the level of hair cell transduction. Furthermore, recent studies suggest that adaptation and high frequency lead are introduced proximal to this nonlinearity. Therefore, it appears that the rotational afferent pathway can be modelled, to a first approximation, by a linear Steinhausen element, representing the semicircular canals; a static nonlinear element representing hair cell transduction; a linear, adaptation-like, high frequency lead element, possibly representing the hair cell primary afferent synapse, and finally, a biased rectifier representing primary afferent action potential generation. This model could be approximately fitted to the steady state responses of 8 out of 12 suitably selected cells, thus explaining the apparent dependence of neural sensitivity and threshold on input amplitude. Furthermore, the presence of the static nonlinearity preceding the adaptation element in the new model accounts for the decline in neural response observed during prolonged stimulation, and appears to explain a number of previously reported nonlinear phenomena in several animals. Finally, the model supports the notion that nonlinear behavior is more commonly reported in cold-blooded than in warm-blooded animals because hair cells of warm-blooded animals are biased to normally operate in the more linear portions of their transduction characteristic.

SLEEP

2352 EFFECTS OF ELECTRICAL STIMULATION OF AREA POSTREMA/NUCLEUS OF THE SOLITARY TRACT ON RAPHE UNIT ACTIVITY AND CORTICAL EEG IN THE ANESTHETIZED RAT. J. D. Bronzino*, P. J. Morgane, A. Johnson*, and W. C. Stern. (Spon: W. L. McFarland) Trinity College, Hartford, CN 01606, Worcester Fndn. Exptl. Biol., Shrewsbury, MA 01545 and D. Dix Hosp., Raleigh, NC 27610.

It is well established that electrical or chemical stimulation of the area postrema/nuc. tractus solitarius (AP/NTS) of the medulla produces EEG cortical synchronization and/or sleep. Recently, an anatomical projection from the NTS to the nucleus raphe dorsalis was identified in the rat using the horseradish peroxidase method (Brain Res. 1977, 122: 229-242). Because of the involvement of the anterior raphe and AP/NTS in sleep mechanisms and the indication of an anatomical projection to the raphe from the AP/NTS we investigated whether stimulation of the region of the AP/NTS would influence the activity of single units of the anterior raphe nuclei.

Fourteen adult male rats were anesthetized with urethane, 1000 mg/kg, and had the dorsal medulla exposed for positioning of stimulating electrodes. Results from 44 raphe units showed that in these acute preparations stimulation of the AP/NTS at 0.1-0.3 mA, 1 Hz or 10 Hz (occasionally 1.0 mA was used) was without marked effects. Approximately 50-60% or the units showed no change in firing rates, 30-40% exhibited temporal suppression of firing, and 10-20% were excited during the stimulation. For all units the average duration of suppression was 57 and 16 msec at 1 Hz and 10 Hz, respectively. The magnitude of the suppression was only about 1/3 to 1/2 that previously observed after stimulation of the lateral habenula or substantia nigra (Stern et al., 1979, Exptl. Neurol. and Brain Res. Bull. in press). Also, in several instances there was a complete dissociation between changes in raphe unit activity and cortical synchronization or desynchronization. Cortical synchronization was often observed to occur without a change in raphe unit activity, and in some cases raphe unit activity was altered without a change in cortical EEG waves.

In summary, the present data suggest that in the rat there is not a strong influence of AP/NTS region on anterior raphe units, and that the cortical EEG synchronization produced by electrical stimulation or the AP/NTS is not mediated by changes in unit activity in the anterior raphe. (Supported by NSF grant ENG 77-04271.)

2353 MACROMOLECULAR REGULATION OF REM SLEEP AND ITS INTERACTION WITH CHOLINERGIC MECHANISMS. Georges Dreyfus C.*, Rosa María Espejel*, Donají Gutierrez*, Laura Chavez-Noriega*, René Drucker-Colín. Depto. de Neurociencias Centro de Investigaciones en Fisiología Celular, UNAM, México, D.F. México.

Recently we have gathered evidence showing that protein synthesis inhibitors(PSI), produce a specific decrease of REM sleep, and that such decrease comes about through a reduction of the frequency of REM periods without affecting their duration. In addition we have shown that PSI reduce some of the phasic elements of REM sleep such as eye movements(EM), and multiple unit activity(MUA) bursts(Drucker-Colín et.al. Exp. Neurol., 63, 458 1979). The purpose of these experiments is to gather further evidence for the role of macromolecules in REM sleep and to determine their interaction with cholinergic systems. In the first series of experiments 14 cats were administered 100mg/Kg Chloramphenicol for 12consecutive days and their sleep-wake cycle was determined in days 1,5,9,10,11,12, and compared to baseline recording; the results showed that there was a specific decrease in REM sleep of 42,25,30,17,31 and 27% respectively on each of the above mentioned days, no rebound effect was seen, and slow wave sleep (SWS) was unaffected. Since chronic administation of PSI may have a peripheral effect, 6 cats implanted with cannulae in midbrain reticular formation were topically administered 3mg, 1.5mg, and 300ug of anisomycin, the results of these experiments showed a dose dependent decrease of REM sleep, while again SWS was unaffected. In a third series of experiments 24 cats, were sleep deprived(SD) of REM sleep for 72 hours, following they were administered either 2mg of atropine, 100 mg/Kg of Chloramphenicol, both drugs or saline; the results showed that for the chloramphenicol group, REM sleep rebound seen after SD was blocked, and both EM and MUA bursts decreased. REM rebound under atropine was unaffected but PGO waves were reduced by 57%. Combination of drugs produced a further decrease of REM and phasic events. Results suggest that macromolecular systems interact with cholinergic ones to trigger REM sleep.

2354 **ASSAYS OF MONOAMINE METABOLITES IN LUMBAR CSF SAMPLES FROM NORMAL HUMAN CONTROLS AND HYPERSOMNIAC PATIENTS.** **Kym F. Faull,* Christian Guilleminault, Patricia J. Anderson* and Jack D. Barchas. Dept. Psychiatry, Sch. Med., Stanford Univ., Stanford, CA 94305.**

At the Stanford Sleep Disorders Clinic 35% of the patients who complained of Excessive Daytime Sleepiness (EDS) did not fulfill the criteria for narcolepsy or obstructive sleep apnea syndrome. In this group of patients, the EDS was the sole symptom and this was objectively confirmed by multiple sleep latency test scores. In an attempt to find a CNS neurochemical defect characteristic of this disabling yet poorly-defined hypersomniac condition, we collected lumbar CSF samples from 8 patients and 15 normal control subjects. At an interval of 24 hours, two lumbar punctures (LP) were performed on each individual; the second LP was performed after an oral probenecid dose. The samples were assayed by gas chromatography-mass fragmentography to determine the concentrations of the neutral and acidic monoamine metabolites HVA, DOPAC, MHPG, and 5-HIAA. Results indicated that after the probenecid dose there was a significantly elevated concentration of HVA and 5-HIAA in the CSF samples taken from the patient population, suggesting increased turnover of dopamine and serotonin.

2355 THE EFFECT OF AN EXPANDING EPIDURAL MASS ON THE INTRACRANIAL PRESSURE PROFILE IN THE SLEEPING MONKEY. Gündüz Gücer and Chandrasekharan Nair*. Division of Neurological Surgery, Baltimore City Hospitals, Baltimore, Maryland 21224.

Normal intracranial pressure waves called plateau waves have been demonstrated to occur almost exclusively during desynchronized sleep epochs (Gucer and Viernstein). The average amplitude of these waves are 170.6 + 6.04 mm H_2O, the average duration is 6.8 + 1.38 minutes. It is felt that they reflect the increase cerebral blood flow which occurs during desynchronized sleep. During slow wave sleep infrequent one per minute waves whose amplitudes are 50 - 100 mm H_2O occur normally (1).

We have studied in five Macaque monkeys trained to fall asleep in primate chairs the intracranial pressure profile during sleep as a mass is slowly expanded in the epidural space. All monkeys were fitted with telemetric intracranial pressure monitor, EEG, EOG, EMG, and epidural balloons under general anesthesia. Each animal had two days of baseline recording to obtain the normal profile before expansion of the balloon.

Consistent finding were that during slow-wave sleep ICP waves at one per minute appeared whose amplitude ranged from 100 - 500 mm H_2O and appeared to be identical to Lundberg B-waves. During desynchronized sleep waves appeared whose shape and characteristics appeard to be like plateau waves. However, amplitudes of these waves were 500 - 1000 mm H_2O. Their duration increased to 5 to 20 minutes. After deflation of the balloon a period of persistent abnormal wave phenomenon was followed by a return to normal intracranial pressure profile.

2356 A NEW APROACH TO THE STUDY OF THE BIOCHEMICAL REGULATION OF REM SLEEP: IMMUNOLOGICAL STUDIES. María del Carmen Gutiérrez, Marietta Tuena*, Georges Dreyfus C.*, René Drucker-Colín. Depto. de Neurociencias, Centro de Investigaciones en Fisiología Celular, UNAM, México D.F., México.

Several lines of evidence from our laboratory have suggested that macromolecules may participate in the regulation of REM sleep (Drucker-Colín et al. Exp. Neurol. 63, 458, 1979). The experiments to be described below provide a novel approach to the study of sleep, and one that provides a more direct corroboration of the role of macromolecules. Sixty cats were used in this study half of those cats were perfused with a push-pull cannula in the midbrain reticular formation (MFR). The perfusates were dialyzed, liophylized and resuspended in Ringer. This material was then inyected into rabbits and antibodies obtained by standard procedures. These antibodies were purified in a DEAE-celulose column, and were then concentrated in a millipore filter (45 um). These antibodies were then inyected into the MFR at 10,50,100,500, and 1000 ug/50 ul doses. The effects of these antibodies on the sleep-wake cycle was compared to Ringer pre-immune serum, antibodies to cat serum, antibodies neutralized with whole antigen, or partial antigen from serum. All concentrations were identical. The results of these experiments showed that the 100,500 and 1000 ug dose of antibodies to MRF proteins decreased REM sleep by 70% without affecting slow wave sleep (SWS). However the two highest doses affected SWS transiently through an increase in its latency. This decrease in REM sleep came about through a decrease in the frequency but not in duration of REM periods. In addition it was observed that this antibodies decrease the phasic events of REM sleep, i.e eye movements and multiple unit activity much in the same way as protein synthesis inhibitors do. Since antibodies neutralized with whole antigen did not affect REM sleep whereas partial neutralization with cat serum antigen did, it can be suggested that a special class of brain proteins seem to be involved in the triggering mechanisms of REM sleep.

2357 DEVELOPMENT OF COUPLING BETWEEN AUTONOMIC, CNS AND SOMATIC VARIABLES IN INFANTS AT RISK FOR THE SUDDEN INFANT DEATH SYNDROME. R. M. Harper, B. Leake*, T. Hoppenbrouwers*, M.B. Sterman and J. Hodgman* (SPON: H. Lesse). Dept. Anat. & Brain Research Inst., UCLA, and Newborn Division, LAC/USC Med. Ctr., Dept. Pediatr., Los Angeles, CA 90024.

Disturbance in the normal organization of physiological parameters that define sleep state, such as the absence of muscle tonus during epochs of quiet sleep (QS) or the absence of respiratory variation during active sleep has been observed in acutely ill infants (Monod et al., Biol. Neonate 11:216-247, 1967). Victims of the Sudden Infant Death Syndrome (SIDS) frequently succumb during sleep at a developmental period (3 months) associated with rapid changes in sleep-state organization. Since SIDS victims may have experienced some degree of disorganization in physiological parameters used to characterize sleep, establishment of trends in coalescence of physiological parameters could aid in identifying factors that differentiate infants at risk for SIDS. Therefore, we examined the degree of coupling between physiological parameters at ultradian periodicities during development. Twelve-hr polygraphic recordings were obtained in 21 normal infants and 21 siblings of SIDS victims. Recordings were obtained at 1 week and at 1,2,3,4 and 6 months of age. Heart and respiratory rate and their variability, somatic activity, including EOG and EMG, filtered and integrated EEG at 13, 4 and 1.5 Hz were digitized and compressed for each min of every 720 min of recording. The resulting 720-point time series were subjected to spectral analysis, and coherence values between pairs of selected variables were calculated at ultradian periodicities from 0.1 to 5 cycles/hr. ANOVA procedures were used to assess statistical trends over age and between risk groups. Coupling between physiological variables, as measured by coherence, was very high at low frequencies over all ages; coherences at higher frequencies tended to be lower. At higher frequencies, several peaks appeared with development. A principal peak was noted at 1 cycle/hr. Although coupling at this frequency was present as early as the first week of life for some pairs of variables, it did not become prominent in other pairs of variables until 3 months of life. Differences in coupling between pairs of variables were observed between the normal group and SIDS-risk group. These included decreased coupling between pairs of physiological variables at frequencies higher than 1 cycle/hr in the SIDS group, reflecting a difference in organization of sleep states between normal and risk infants.

2358 EFFECT OF ACUTE HEROIN WITHDRAWAL ON SLEEP AND OTHER BEHAVIORAL PARAMETERS IN HUMANS.[1] Richard C. Howe, Jerry L. Phillips* and Frederick W. Hegge*†. Dept. of Physiology, Eastern Virginia Medical School, Norfolk, VA 23501 and †Dept. of Military Medical Psychophysiology, Walter Reed Army Institute of Research, Washington, DC 20012.

The purpose of this study was to evaluate the effects of acute heroin abstinence on sleep and other overt behaviors in humans. Electrophysiological data were recorded on a 24-hour per day basis for 5-7 continuous days. Behavioral observations were also noted throughout the study. An observation was noted only when it differed from the preceding one. Recording environment was an isolated hospital ward. Data were collected from young heroin dependent individuals who were generally in good health, had short heroin use histories (1-3 months), used few other drugs concurrently, and were addicted to 95-98% pure heroin. Matched drug-free control subjects were simultaneously studied. Informed consent was obtained from all subjects. All EEG records were scored according to standard techniques in one-minute epochs and were transferred to a PDP8E computer for subsequent analyses.

The heroin dependent patients during withdrawal showed a severely disrupted sleep-waking pattern which peaked on Day 2 of withdrawal. The disrupted sleep in these patients was also associated with frequent attempts at sleeping throughout the 24-hour day. Total sleep per 24-hour day was 304 minutes in the drug dependent patients during withdrawal compared to 456 minutes in the controls. Sleep Stages II, III and IV averaged 218 minutes per 24-hour day during withdrawal compared to 295 minutes in the controls. The heroin dependent patients during withdrawal showed 29 minutes of REM sleep per day whereas the controls averaged 94 minutes. Analysis of the behavioral observation data also confirmed that the heroin dependent patients during withdrawal were awake more of the time and considerably more active. The following behavioral observation categories were significantly higher in the heroin dependent patients during withdrawal than in the controls: drinking, excretion, in bed, out of bed, prone, restless, and rolling.

These results suggest that the central nervous system mechanisms responsible for the normal sleep-waking patterns have been markedly disrupted during heroin withdrawal. This disruption is further reflected by the increase in overt behavioral activities observed in the heroin dependent patients during withdrawal.

2359 POSITIVE RESULTS IN TWO CASES OF NARCOLEPSY TREATED WITH THYROTROPIN-RELEASING HORMONE (TRH). J.L. Jurado*, J.M. Rhodes, A. Fernández-Guardiola and C. Valverde-R*. Inst. Nal. de Neurol. & Neurocirug., Unidad de Investigaciones Cerebrales, Mexico 22, D. F.

The action of thyrotropin-releasing hormone (TRH) on serial sleep recordings in two Narcoleptic patients was evaluated. In one case, 20 mg of TRH, v.o., was given for seven days and in the other case for eleven days. Both cases reported alleviation of Excessive Day-Time Sleepiness and associated symptoms. In contrast to normals, both subjects showed increase in Delta sleep. In one case with early onset REM, the latency was shifted to a normal or longer period with a return to early onset at the cessation of TRH. The other case showed one early onset REM after beginning TRH. It is proposed that TRH is acting as Neuroregulator in a balancing fashion. Further, that TRH may be useful in both the diagnosis and treatment of Narcolepsy.

2360 SLEEP CIRCADIAN RHYTHMICITY FOLLOWING ENRICHED AND IMPOVERISHED REARING: RELATIONSHIPS BETWEEN PARADOXICAL SLEEP AND MEMORY STORAGE PROCESSES. David R. Kleinman, Baruch M. Gutwein* and William Fishbein. Psychobiology Lab., Dept. Psych., The City College of New York, New York, N.Y. 10031

Sleep cycle circadian rhythmicity following either enriched or impoverished environmental rearing is examined in this study. Mice are reared in either super-enriched (SEE), regular enriched (REE), social control(SC), or isolate environment (IE) for 30 days. SEE and REE groups show a general increase in total slow-wave sleep (SWS) in the 24 hr. cycle but the number of SWS episodes, mean duration of SWS episodes, and per cent SWS of total sleep time(TST) is not significantly different from the SC group for the day cycle (0700-1900). Enriched rearing produces a significant and selective increase in the number of PS (Paradoxical Sleep or REM sleep) episodes, mean duration of PS episodes, total amount of PS time, and percent PS/TST throughout the 24 hr. cycle. IE reared mice also show a general increase in SWS primarily during the day with significant reductions in all measures of PS occurring exclusively in the day cycle. It is suggested that alterations of chronobiological sleep rhythms after differential rearing may be mediated by the interaction of the suprachiasmatic nucleus (SCN) with the Gigantocellular Tegmental Field (FTG) and locus coeruleus (LC). Our results provide additional support for the hypothesis that PS occuring over a protracted time period is a requisite neurobiological mechanism for the processing, maintenance, and storage of long-term memory.

2361 CONSCIOUSNESS AND LUCID DREAMS. Fred K. Lenherr. Berkeley Brain Center, Box 2249, Berkeley, CA 94702.

The phenomenon of lucid dreams offers a number of tantalizing clues concerning the brain mechanisms underlying human consciousness. A so-called "lucid" dream is one in which the dreamer is clearly aware, while the dream is still going on, that he or she is dreaming. Lucidity generally arises out of an on-going normal dream. Three classes of factors may precipate lucidity. First, extreme terror or other strong emotion may cause one to realize that "this is only a nightmare." Subjects commonly report that they are then able to escape by waking themselves up. Secondly, extreme illogicality or bizarreness in the events of the dream can sometimes cause the dreamer to become lucid. Finally, unusually active manipulation of the dream environment by the dreamer sometimes results in lucidity. In all cases, the dreamer, once lucid, is able to control and explore the dream world with considerable freedom from the physical constraints of the real world, and usually reports a general increase in the vividness and verisimilitude of the dreamscape.

These findings suggest that significant interactions between frontal, pre-frontal, limbic, and reticular areas may be present during some dreams, and that the dream state and the waking state may be more closely related than hitherto believed. A further finding is that experienced subjects can sometimes retain ego consciousness, while still asleep, even after the lucid dream ends. Whether this occurs during NREM periods or only during tonic REM periods (REM periods lacking phasic REMs) is unclear at present. In any case, it appears possible that higher cortical functions like planning (manipulation) and language (logic) are able to function during normal dreams, and that when these functions are triggered by suitable events in the dream, they are able to alter the pattern of ascending reticular activation to produce an experience similar to normal waking consciousness in the almost total absence of external sensory inflow.

2362 RESPIRATORY NEURONS OF THE PNEUMOTAXIC CENTER DURING SLEEP AND WAKEFULNESS

Ralph Lydic and John Orem, Department of Physiology, Texas Tech University School of Medicine, Lubbock, Texas 79430.

Extracellular recordings, using tungsten microelectrodes, were made from the pneumotaxic center (PNC) of intact, unanesthetized cats during sleep and wakefulness. Contrary to previous work using decerebrate cats (Feldman et al. Brain Res. 104: 341, 1976) the awake, intact cat demonstrated respiratory neuron activity which was stongly respiratory modulated. During wakefulness, phasic neuronal bursts with average frequencies up to 50 Hz were observed superimposed on a tonic background. There was a decline in the activity of these cells during sleep. This decreased activity began in NREM sleep and was more fully expressed in REM sleep where the discharge rate was only 30-40% of the wakefulness value. These results suggest a loss of respiratory drive to the PNC during sleep.

2363 PARADOXICAL SLEEP WITHOUT ATONIA IN CATS IS ACCOMPANIED BY EXCESSIVE EXPLORATORY BEHAVIOR IN WAKEFULNESS. Adrian R. Morrison, Graziella Mann*, Joan Hendricks*, and Catherine Starkweather*. Laboratories of Anatomy, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA 19104 USA

Paradoxical sleep without atonia is a dramatic phenomenon created by small bilateral lesions in the pons (centered at P2.1, L2.0, H-3.5, Berman[1]) in cats and is characterized as follows: After slow wave sleep, when paradoxical sleep with muscle atonia would normally appear, cats raise their heads, make body righting movements, exhibit alternating movements of the limbs, and even attempt to stand. Throughout an episode, which shows all other aspects of paradoxical sleep, including unresponsiveness to visual stimuli, cats act as if they are being startled, searching and sometimes attacking an object. In wakefulness they show minor cerebellar signs. We have postulated that the lesions disrupt pontine excitation of the medullary inhibitory area and inhibition of a brainstem locomotor center during paradoxical sleep.[2]

In six cats we tested whether these sleep effects were transferred in some way to wakefulness. All exhibited in wakefulness an increase of 23-127% in exploratory locomotor activity, which consisted of moving about a room marked into squares and investigating various parts of the room rather than aimless pacing. This behavior was measured 1 hour/day for 5 days pre- and postoperatively.

The existence of a parallel effect in wakefulness and paradoxical sleep produced by pontine lesions supports our hypothesis that events of normal paradoxical sleep, which is a hyperalert brain state, are the result of exaggeration of a brainstem mechanism designed to dampen responses to sudden, novel stimuli in wakefulness lest the animal over react and run blindly into danger prior to stimulus analysis. The results also suggest that paradoxical sleep without atonia is more than a simple abolition of the brainstem inhibition of spinal motor neurons which occurs in normal sleep and that the animals are not acting out normal "dreams".

2364 MEDULLARY RESPIRATORY NEURON ACTIVITY: RELATIONSHIP TO TONIC AND PHASIC REM SLEEP

John M. Orem, Ph.D., Department of Physiology, Texas Tech University School of Medicine, Lubbock, Texas 79430.

This study analyzed the relationship of brain stem respiratory neuron activity to the tonic and phasic events of rapid eye movement (REM) sleep. Dorsal and ventral medullary respiratory neurons were recorded in sleeping cats. Discharges of inspiratory and expiratory cells increased in number and average frequency with increases in ponto-geniculo-occipital (PGO) spiking (phasic REM activity). The correlations between PGO wave frequency and respiratory neuron activity were positively related to the discharge levels of the neurons: the more active the cell, the greater the relationship to PGO activity. Tonic REM influences on respiratory neurons were calculated by extrapolating from the regression line relating PGO frequency and neuron activity to the hypothetical state of no PGO activity. These calculated levels, when compared to non-REM sleep levels, showed that tonic REM mechanisms decruited some neurons and activated others. Decruited cells tended to be found in the ventral medullary respiratory group; activated cells were generally in the dorsal group. These results demonstrate an association of brain stem respiratory activity to non-respiratory REM sleep variables.

2365 NUCHAL MUSCLE TONUS DURING SLEEP, WAKEFULNESS AND TONIC IMMOBILITY IN THE RABBIT. R.T. Pivik, P. Sussman* and C. Braun*. Dept. of Psychiatry University of Ottawa, School of Medicine, Faculty of Health Sciences, School of Psychology, University of Ottawa.

A cardinal characteristic of paradoxical sleep (PS) in mammals is inhibition of nuchal or facial muscle tonus. Tonic immobility (TI), a reversible state of immobility induced by rapid dorsoflexion and characterized by loss of righting reflexes and relative unresponsiveness, is reported to exhibit tonic inhibition of nuchal musculature and spinal reflexes similar to that occurring during PS. Previous reports examining muscle tonus in the rabbit have been descriptive and have not provided quantitative inter-or-intrastate comparisons. In the present study nuchal EMG activity was quantified by means of resetting integrators and comparisons made between states of sleep, wakefulness and tonic immobility.

Seven (7) New Zealand White adult male rabbits were chronically implanted for recording EEG, nuchal EMG (teflon coated stranded stainless steel wire) and EOG activity. Recordings began one week after surgery. Spontaneous sleep-waking cycles were recorded in unrestrained animals in a light, sound and temperature controlled environment. TI was induced by rapidly inverting the animals in a "V" shaped trough. TI data were gathered in the late afternoon or early evening after sleep recordings. EMG activity was quantified (resets/second) by a resetting integrator pulses from which are proportional to EMG voltage. Quantified muscle activity was categorized according to the following conditions: active wakefulness (AW), quiet wakefulness (QW), transition to sleep (drowsy, D), slow wave sleep (SW), PS and TI. The transition from SW to PS was also examined. Statistical comparison among states was conducted using analyses of variance with post-hoc t tests when appropriate.

Muscle activity progressively decreased from AW through states QW, D, SW and PS. EMG activity during PS was least of all conditions, but differred significantly ($p < .001$) only from AW. Muscle activity decreased during the transition (1 minute) from SW to PS, but the reduction during PS relative to the immediately preceeding SW epoch was not statistically significant. Tonic muscle activity during TI was at a level more similar to SW than PS.

Tonic levels of nuchal EMG activity during PS and TI were quite variable. In our experience, neither state is consistently characterized by tonic atonia.

2366 EFFECT OF SLEEP ON BENZODIAZEPINE BINDING IN BRAIN. M. K. Poddar, D. A. Urquhart and A. K. Sinha. Department of Physiology & Biophysics, College of Medicine and Dentistry of New Jersey-Rutgers Medical School, Piscataway, N.J. 08854, USA.

In vitro specific ^{3}H-diazepam binding was determined in the cerebral cortex (C), upper brain stem (UBS), cerebellum (Cr) and pons-medulla (P-M) of adult, male, hamsters (body wt. 100-120 g) after sleep and wakefulness. Animals were decapitated following 20 or 50 min. of non-rapid-eye-movement sleep or a comparable period of wakefulness. Immediately after sleep the specific binding of diazepam increased in all four regions of brain in contrast to liver, kidney and lung were no changes in specific binding of ^{3}H-diazepam were detected between sleep and wakefulness. This increased diazepam binding was found to be dependent on length of the sleeping time.

Sleeping time	% increase of ^{3}H-diazepam binding in brain regions			
(min)	C	UBS	Cr	P-M
20	36	21	64	57
50	54	34	107	87

The increased diazepam binding in brain regions after sleep may be due to (1) a change in the number of binding sites (Bmax) and/or (2) a change in the binding affinity ($1/K_D$). Schatchard plot analysis of diazepam binding in cerebral cortex, upper brain stem and pons-medulla showed a significant increase in the affinity of the receptor for the ligand after sleep whereas no significant change was found in the number of binding sites between sleep and wakefulness.

Brain regions	% increase (with respect to awake) after 50 min sleep	
	K_D	Bmax
C	37.30 ($p<0.01$)	NS
UBS	20.30 ($p<0.05$)	NS
P-M	30.47 ($p<0.05$)	NS

This increased diazepam binding affinity in brain regions after sleep suggested that there may be a possibility of an increase in concentration of gamma-aminobutyric acid and/or a decrease in concentration of diazepam binding inhibitors, including any possible endogenous ligand for the benzodiazepine receptor. Studies on cross mixing experiments of diazepam binding with synaptic membrane in presence of 30,000 g supernatant of sleeping and awake brain regions indicate the presence of a diazepam binding inhibitor in awake brain. Further studies are now in progress to characterize the inhibitor present in the 30,000 g supernatant of the awake animal's brain. [Supported by grants from NSF (BNS-76-18615) and from NIH (NS 13118)]

2367 EFFECT OF ALCOHOL ON SLEEP AND NIGHT-TIME PLASMA GROWTH HORMONE AND CORTISOL LEVELS. T. A. Roehrs*, P. N. Prinz, E. D. Weitzman and M. Linnoila* (SPON: W. Dong). Univ. of Wash., Seattle, WA 98195, Montefiore Hospital, Bronx, NY 10467 and Duke Univ., Durham, NC 27710

The acute and chronic effects of alcohol and alcohol withdrawal on sleep patterns and on growth hormone and cortisol fluctuations occurring during sleep were studied. Before going to bed five healthy men, aged 21 - 26, received a placebo drink for three baseline nights, alcohol (1g/kg) for eight nights, and no drink on a final withdrawal night. After two adaptation nights in the laboratory, standard all night polygraphy sleep recordings and blood samples, obtained every 20 minutes through indwelling venous catheters, were collected for one night each in the baseline, acute (alcohol night 1), chronic (alcohol night 8), and alcohol withdrawal conditions.

On both drug nights mean blood alcohol levels peaked within an hour of bedtime at 80 mg percent and the effect of alcohol on sleep stage percentages was confined to the first half of the night. Acute and chronic alcohol significantly reduced REM sleep. Slow wave sleep (stage 3 and 4) was increased significantly after acute alcohol, but returned to baseline levels on the chronic alcohol night. On the withdrawal night there was a slight, but non significant, increase in REM sleep and no change in slow wave sleep relative to baseline levels. The other sleep stage measures were not altered significantly by alcohol administration and withdrawal.

Alcohol, on both the acute and chronic nights, significantly suppressed (by 70%) plasma growth hormone levels across the whole night. All measures of the growth hormone response, total for the night, hourly rate, and peak level, were affected similarly by alcohol. There was no rebound in growth hormone levels on the alcohol withdrawal night. Night-time plasma cortisol levels were not affected by acute and chronic administration and withdrawal of alcohol.

The theoretical and clinical implications of the alcohol effects on sleep patterns and on growth hormone release will be discussed.

2368 VESICULATION OF ASTROGLIAL CELLS IN HAMSTERS FOLLOWING 24-HR SLEEP DEPRIVATION. Arabinda K. Sinha, Ching-Shin Lee*, and Bijan K. Ghosh. Dept. Physiol. & Biophysics, CMDNJ-Rutgers Med. Sch., Piscataway, NJ 08854

Five male hamsters (120 g) were sleep deprived for 24 hr by manual or mechanical manipulation. Their brains were fixed in situ by perfusing a mixture of glutaraldehyde and formaldehyde through the heart. Control animals were prepared identically. Pieces of frontal cortex, occipital cortex, and liver were treated with osmium tetroxide, dehydrated and embedded. This sections were examined by electron microscope. Stereological analysis was performed by taking low power (5,600 x) pictures of randomly encountered neurons and astroglial cells in five different areas of the frontal cortex of both the control and experimental animals. The partial volumes, relative surface areas and relative number of subcellular components were determined in the micrographs projected on a standard morphometric test-grid.

The cell-bodies of neurons from the IVth and Vth layers of frontal and occipal cortex were scanned for structural alterations. Nuclear membrane, chromatin distribution pattern, mitochondria, Golgi apparatus, and cell membrane show no changes. The partial volumes of endoplasmic reticular cisternae and the surface area of the endoplasmic reticulum remained constant in the neurons of sleep deprived animals. Also, the number of neuronal lysosome decreased by 46% in frontal cortex. No changes in the liver cells were detected. The astroglial cells of the sleep deprived animals were found to contain large clear vacuoles. In 80% of the sleep deprived astroglial cells the endoplasmic reticulum vesiculated with partial desolution of its membrane as compared to only 14% in the control animals. There is no change in the surface area of endoplasmic reticulum. The volumes of astroglial endoplasmic reticular cisternae increased by 162% in frontal cortex and 122% in occipital cortex of the sleep deprived animals. The fact that the surface area of the endoplasmic reticulum remains the same but the volume increases gives support to the idea that the membrane bound spaces seen in the astroglial cytoplasm are vesiculation of the endoplasmic reticulum rather than its new formation. Incapacitating behavioral decrement associated with sleep loss may be a consequence and symptomatic expression of the type of subcellular disorganization observed in this study. (Supported by grant #78-3532A from Air Force Office of Scientific Research).

2369 ON GENERATION OF PONTO-GENICULO-OCCIPITAL(PGO) WAVES, RELATIONSHIP BETWEEN THE GENICULATE AND OCCIPITAL PGO AND THE EFFECTS OF NON-VISUAL SENSORY STIMULI. Clara Torda. N.Y.C.PA.TR., N.Y., N.Y., 10028.

PGO waves coincide with rapid eye movement sleep(REM), PGO-type waves with the saccades of alert animals. Therefore, PGO waves may be manifestations of a mechanism designed for image holding and related processes. The here presented work addressed some of the characteristics of PGO waves, e.g. their composition and sensitivity to non-visual sensory stimuli. The effects of various interventions on the occipital PGO waves were studied in the cat following a combined method of Brooks and Gershon (Neuropharmacol., 11:499, 1972) and Calvet et al. (J.Neurophysiol., 28:893, 1975). Intracellular recordings were obtained from the pontine tegmentum by the method of Segundo et al. (J.Neurophysiol., 30:1194, 1967) and from the lateral geniculate nucleus (LGN) and marginal gyrus following the method of Singer (Brain Res., 35:55, 1973). The occipital PGO (recorded from the marginal gyrus) was compared to both: (1) the PGO recorded from the pons and the LGN, and (2) the "directly" transmitted PGO waves recorded from the marginal gyrus of cats either after surgical removal of the LGN, or transsection of the geniculo-cortical pathways. Two methods were used to study the effects of non-visual stimuli on the geniculate and the two types of occipital PGO waves: (1) electrical stimulation of the medial part of the ventral LGN, and (2) non-visual sensory stimulation (clicks, skin of foot, etc.) administered in presence and absence of reserpine. The results suggest that a potential mechanism for encoding PGO waves consists of vestibular activation of specific neurons of the pontine paramedian tegmentum under the influence of a specific set of pontine pacemaker cells. The occipital PGO waves of intact animals result from combination of the geniculate and the "direct" occipital PGO waves (a cortical activity under the direct influence of the pontine PGO that ascended by bypassing the LGN). The differences between the "direct" occipital PGO and those of intact cats are statistically significant and consist of the presence of a first positive going spike and greater differences in shape and amplitude of the occipital waves found in the intact cat. Mathematical treatment of the data suggested that the occipital PGO is a vectorial sum of the geniculate and "direct" occipital PGO. The first positive going spike seems to be related to the activity of the intrageniculate terminal of the optic tract as changed in amplitude and shape by the activity of LGN. The PGO waves were affected by endogenous and exogenous non-visual sensory processes, more in the LGN than in the occipital cells alone.

2370 INTERSPECIES COMMONALITIES IN MOTILITY PATTERNS DURING SLEEP AND WAKEFULNESS. Lewis P. Zeidner* and Evelyn B. Thoman. Dept. of Biobehavioral Sciences, University of Conn., Storrs, Ct.06268.

Motility recordings of infant and adult rats and rabbits, and of human infants from birth to six months of age were used to demonstrate commonality in motor expression of sleep and waking states. The analog output from a motility sensor was produced on a single channel, with respiration signals apparent during quiescence and motor movements superimposed on respiration during activity. The resulting composite patterns of motility were judged for quiet sleep, transitional sleep, active sleep, sleep-wake transition, and quiet or active wakefulness. Judgements of state in each species were made from motility recordings only, and judges were unfamiliar with state observations in that species. Comparisons of judgements with records obtained by direct state observation during the motility recording were used to assess the validity of the judgements. Although the behavioral expression of states across ages and in different species varies, the quality of motility patterns reflect a basic organismic expression of state that shows continuity phylogenetically and ontogenetically.

SOMATOSENSORY SYSTEMS

2371 DEGENERATION OF TRIGEMINAL PRIMARY SENSORY NEURONS AFTER SKIN REMOVAL. Jan Arvidsson* and Gunnar Grant. Department of Anatomy, Karolinska Institutet, S-10401, Stockholm, Sweden.

In previous studies it was shown that transection of peripheral branches of trigeminal primary sensory neurons in adult rats and cats resulted in degeneration of their centrally projecting branches. Ultrastructural studies of this type of axonal degeneration, termed transganglionic degeneration, revealed alterations similar to those occurring during Wallerian degeneration. Studies of the trigeminal ganglion following peripheral nerve transection showed a substantial cell loss at the light microscopical level, as well as ultrastructural signs of degenerating and dying nerve cell bodies. Since the transection in those studies was made far out peripherally, the question was raised whether simply disconnecting the nerve cell body from its receptors might itself induce transganglionic degeneration. As a first approach small areas of skin were removed supraorbitally (2 rats), infraorbitally (2 rats) and in the mental region (2 rats). The edges of the incisions were apposed and sutured. After postoperative survivals of 14 or 24 days the rats were perfused and sections from the brain stem processed according to the Fink-Heimer technique. In all cases there were small amounts of degeneration in the rostral part of the ipsilateral trigeminal nucleus caudalis. There was no degeneration in other trigeminal nuclei. The location of the degeneration was strictly within the same dorso-ventral and medio-lateral areas as after supraorbital, infraorbital or mental nerve transection shown in previous studies. The results support the view that disconnection of the nerve cell body from the receptor area may be an important factor for provoking transganglionic degeneration. Degeneration in the central nervous system of adult animals following skin removal does not seem to have been shown before. It clearly demonstrates the possibility of using this approach for mapping the body surface on the primary sensory relay nuclei. Hopefully further studies will give an answer to the question whether this approach will be useful also for mapping the central representation of different types of receptors.

Supported by the Swedish Medical Research Council, Project No. 553.

2372 SYMPATHETIC EFFERENT MODULATION OF FACIAL MECHANORECEPTORS IN THE CAT. David J. Barker and Paul D. Shepard*. Dept. of Physiology, North Texas State University Health Sciences Center/Texas College of Osteopathic Medicine, Fort Worth, TX 76107.

Chronic hyperactivity of the sympathetic innervation of a tissue is often a prevalent finding in many clinical conditions, including post-traumatic pain syndromes. In previous work (Bereiter & Barker, Soc. Neurosci., 1976, 2, #946) we found that the estrogen induced enlargement of cutaneous receptive fields could be duplicated by chemical or surgical lesions of the sympathetic innervation. The present study was undertaken to examine the quantitative effects of sympathetic efferent stimulation on rate and pattern of firing in cat first-order facial mechanoreceptors.

Single units were recorded from the trigeminal ganglion of anesthetized cats. Cutaneous mechanoreceptors were stimulated with controlled mechanical stimuli (trapezoid, pulse, sine) before and after electrical stimulation of the cervical sympathetic trunk, which was dissected free of the vagus and cut centrally. Both mechanical and electrical stimulus parameters were systematically varied.

Among 25 neurons studied intensively (2 to 10 hours) we observed the following results: (1) Intervals between repeated mechanical stimuli of less than 20 sec. resulted in significant decreases in firing rate, possibly due to fatigue. No changes were observed for interstimulus intervals of 1 min. or more. (2) Adaptation rate could be varied with stimulus amplitude. (3) Sympathetic stimulation lasting longer than 1 sec. can produce significant artifacts due to mechanical movement of the tissue. (4) Many rapidly adapting units showed a decrease in rate of firing and increased latency to firing following sympathetic stimulation. (5) Many slowly adapting units show an increase in firing rate following sympathetic stimulation. (6) "Stroke" units (responds to movement across the field) show variable or no effects of sympathetic stimulation. (7) Sympathetic stimulation can result in changes in interspike interval pattern. The effects of sympathetic stimulation can be both transient and maintained, and can be blocked with phentolamine. Our results are consistent with previous findings in the frog (Roberts and Carlof, Soc. Neurosci., 1977, #1572) that some units are facilitated while others are inhibited by sympathetic stimulation. Our results also suggest that great care must be taken in choosing both mechanical and electrical stimulus parameters in order to minimize the possibility of artifacts. The present findings show that in addition to cat vibrissae (Nilsson, Acta physiol. scand., 1972, 85, 390-397), other types of cutaneous receptive fields (glabrous rhinarial skin, fur patch) can be influenced by sympathetic efferent stimulation. Supported by AOA Grant 78-11-169.

2373 CONTROL OF SENSORY TRANSMISSION BY ELECTRICAL STIMULATION WITHIN THE CAUDAL RAPHE NUCLEI OF THE CAT. P.S. Blum. Department of Physiology, Thomas Jefferson University, Philadelphia, PA 19107.

Sensory-evoked activity of single spinothalamic tract neurons can be inhibited by electrical stimulation within the nucleus raphe magnus, nucleus raphe pallidus, and nucleus raphe obscurus (caudal raphe nuclei, CRN), Willis et al., J. Neurophysiol. 40: 968, 1977. The present experiments were designed to investigate the location within the CRN where electrical stimulation can inhibit the activity in ascending pathways evoked by sensory stimulation and to determine whether or not the inhibition is directed preferentially to sensory-evoked activity in the spinothalamic tract. Adult cats were anesthetized with chloralose (60 mg/kg) and prepared for acute electrophysiological experiments. Single shock electrical stimuli were delivered to the superficial radial (SR) nerve (50 to 500 microamp) via a hook electrode and to nine sites in the CRN (25 to 100 microamp) with an array of three bipolar concentric electrodes. The compound action potential was monitored with a hook electrode on the SR nerve and averaged slow-wave recordings were taken contralateral to the SR nerve from the medial lemniscus (ML) at the midbrain and spinothalamic tract (ST) at C1. The amount of sensory-evoked activity in the ML and ST was determined by measuring the height of the initial monopolar portion of the averaged ST and ML response following SR stimulation. The height of the evoked potentials following SR stimulation was compared to the height of the potentials when the SR stimulus was preceeded by stimulation at each of the 9 CRN sites. Reduction in the size of the SR-evoked potential by CRN stimulation was defined as inhibition. In a total of five experiments, 37 brain stem sites were stimulated within the CRN. Stimulation at 19 of these sites produced inhibition of the sensory-evoked ST potential, while stimulation at three sites produced inhibition of the sensory-evoked ML potential. No sites were found where stimulation caused an inhibition of both sensory-evoked potentials. Within each experiment, the total percent inhibition of the ST was calculated for each CRN stimulus site. The inhibition-producing sites were ranked and a value of 100% of maximum inhibition was assigned to the site producing the greatest total inhibition in each experiment. Sites that showed 90-100% of maximum ST inhibition were located within the ventral part of nucleus raphe magnus and the rostral part of nucleus raphe pallidus. These data suggest that activity originating from neurons in the ventral part of nucleus raphe magnus and the rostral part of nucleus raphe pallidus function to reduce the amount of sensory-evoked activity in the spinothalamic tract.

2374 EFFECTS OF TEMPERATURE ON NEUROPHYSIOLOGICAL AND PSYCHOPHYSICAL FREQUENCY CHARACTERISTICS IN THE SOMATOSENSORY SYSTEM. S. J. Bolanowski, Jr.* and R. T. Verrillo. Institute for Sensory Research, Syracuse University, Syracuse, NY 13210.

The effects of temperature on both the neurophysiologically measured frequency characteristics of isolated mechanoreceptors (Pacinian corpuscle) and the vibrotactile frequency response obtained psychophysically on humans are compared. The neural frequency characteristics established for a criterion of approximately 1 spike/stimulus cycle are U-shaped functions that shift toward higher frequencies with increasing temperature. The best frequencies for these functions are directly proportional to temperature. The low-frequency slopes do not change significantly with temperature but remain at about 12 dB/octave. The U-shaped functions do not shift significantly along the intensity axis as a function of temperature. Similar results were obtained for lower firing rate criteria. The psychophysical frequency characteristic shows a flat, low-frequency (10-50 Hz) portion of low sensitivity and a U-shaped, high-frequency (50-700 Hz) portion of high sensitivity at normal skin-surface temperatures (30°C). A breakpoint in the curve occurs where the two portions meet (∿50Hz). Considerable evidence indicates that the high-frequency portion of the characteristic is mediated by the Pacinian corpuscle population. For skin temperatures below normal physiological levels, the best frequency (high-frequency portion) of the vibrotactile frequency characteristic is shifted to lower frequencies. Skin temperatures above normal produce shifts toward higher frequencies. These results are in fundamental agreement with the neural data. Because the shape of the psychophysical curve reflects interactions of at least one other receptor population, graded temperature effects produce additional changes not seen in the physiological data from individual Pacinian corpuscles. Below normal surface temperatures, the low-frequency (flat) portion is elevated and both the bandwidth and sensitivity of the high-frequency portion are decreased. This produces a shift to lower frequencies in the breakpoint between the flat and U-shaped portions of the frequency characteristic. For temperatures above normal, the bandwidth of the high-frequency portion is increased without much effect on the overall sensitivity. These additional effects may be explained in terms of different cutaneous receptor populations, all of which are effected by temperature.

2375 INTRACORTICAL AND THALAMIC CONNECTIONS OF THE SUPPLEMENTARY SENSORY AND SUPPLEMENTARY MOTOR AREAS IN THE MONKEY. R.M. Bowker*, E.A. Murray and J.D. Coulter. Marine Biomedical Institute, Departments of Psychiatry & Behavioral Sciences and Physiology & Biophysics, University of Texas Medical Branch, Galveston, Texas 77550.

Recent studies from this laboratory have described the organization of spinal projections from the medial posterior parietal cortex of area 5, termed the supplementary sensory area, and from the medial cortex of area 6 comprizing the supplementary motor area in primates. Here we report the intracortical and thalamic connections of these two cortical areas determined by the retrograde horseradish peroxidase (HRP) and anterograde autoradiographic tracing methods.

Cortical HRP injections were made by multiple penetrations with 0.3-0.6 µl of 25-50% HRP solution. The tissue sections were then reacted with the tetramethylbenzidine technique. Anterograde studies were performed by injections of 0.03-0.07 µl (100 µCi/µl) of a mixture of tritiated proline and leucine into either cortical region followed by routine processing of the tissues for autoradiography.

The supplementary sensory area receives somatotopically organized projections from the posterior parts of SI (mainly areas 1 and 2), from the lateral part of area 5, from the lateral area 6 on the convexity of the hemisphere and from the medial part of area 6 comprizing the supplementary motor area. The supplementary motor area similarly receives somatotopically organized projections from the SI cortex (mainly areas 1, 2 and 3a), from the lateral part of area 5, from the primary (area 4) motor cortex (MI) and from the supplementary sensory area (medial area 5).

Thalamic afferents to the supplementary sensory area arise primarily from the dorsolateral part of the lateral posterior nucleus (LP) with a small number of neurons being seen scattered as far anterior as the caudal ventrolateral nucleus (VLo) and as far posterior as the caudal ventroposterolateral nucleus (VPLo). Thalamic afferents to the supplementary motor area arise from the lateral and dorsal parts of the ventrolateral nucleus (both VLc and VLo), extending forward into the ventral anterior nucleus (VA) and caudally into the lateral-most part of the ventroposterolateral nucleus (VPLo).

Both the thalamic, as well as intracortical pathways (with the exception of part of the SI projection) for the supplementary sensory area and supplementary motor area are reciprocal.

In view of the connections of these two cortical areas, the supplementary sensory area and supplementary motor area would appear to be capable of analyzing and programing complex sensory and motor behavior. (Supported by NS12481).

2376 AN AUTORADIOGRAPHIC STUDY OF THE ASCENDING PROJECTIONS OF THE PRINCIPAL SENSORY TRIGEMINAL NUCLEUS IN THE RAT. William C. Broderick*, Leo C. Massopust, and Paul A. Young. Francis and Doris Murphy Neuroanat. Res. Lab., Dept. Anat., Sch. Med., St. Louis Univ., St. Louis, MO 63104.

The purpose of this study was to investigate the ascending projections of the principal sensory trigeminal nucleus in the rat. Tritiated leucine was ejected iontophoretically from a glass micropipette into the nucleus using a surgical stereotaxic approach. The tissue was processed according to the method described by Cowan et al. (1972). Three sets of projections were seen coursing from the ejection site. The first projection was a small group of diffuse fibers which coursed dorsomedially through the pons immediately ventral to the abducens nucleus and locus coeruleus. Some fibers terminated in the ipsilateral pontine reticular formation while others decussated and synapsed in the contralateral pontine reticular formation. The second group decussated, ascended rostrally and dorsally, and terminated in a diffuse pattern in the region of the inferior medial geniculate nucleus or the posterior thalamic region of Lund and Webster, (1967), the adjacent reticular formation and the pretectal nuclear complex. The third projection was a large ventral tract which decussated between the level of the principal sensory trigeminal nucleus caudally and the level of the interpeduncular nucleus rostrally. This tract took a position dorsomedial to the medial lemniscus. The trigeminal tract continued rostrally through the midbrain located between the red nulceus and the substantia nigra. Projections from this tract terminated densely in the ventral part of the zona incerta and to a lesser degree in the posterior thalamic area. The remainder of the trigeminal tract terminated in the medial portion of the ventral posterior nucleus of the thalamus. Even though it has been suggested that there is an ipsilateral projection to the thalamus from the principal sensory trigeminal nucleus in the rat, there was no evidence in this investigation to support that claim.

2377 ABSENCE OF ALTERATIONS OF DORSAL HORN SOMATOTOPY AFTER UNILATERAL L_7 SECTION IN CAT. Paul B. Brown, H. Richard Koerber , and Robert P. Yezierski . Dept. of Physiology and Biophysics, West Virginia University Medical Center, Morgantown, WV 26506.

Single units were recorded in laminae I-VI of the left dorsal horn of adult cats at various survival times after ipsilateral section of L_7 dorsal root, using T_{12}-spinalized, urethane-anesthetized animals. Light touch receptive fields were mapped on standard cat leg drawings, spontaneous activity was characterized, and recording sites were marked by the Prussian Blue method. Statistical analysis revealed no changes in the somatotopic map (distance from tips of toes as a function of mediolateral position of cell for each segment), spontaneous activity, or receptive field geometries (area and length/width ratio as functions of distance from tips of toes), at survival times ranging from 0 to over 200 days, compared with normal data from earlier studies. However, at early survival times it was difficult to find cells with receptive fields within the focus of the L_7 dermatome (the toes), especially in the L_7 segment, where the toes are most heavily represented.

It is concluded that, with regard to light touch receptive fields, the somatotopy of the dorsal horn is not significantly altered after cutting one root (L_7), even though dendritic changes have been demonstrated in these cells after L_7 section (Brown, Busch and Whittington, 1977, 1979). This is presumably due to the overlap of the L_7 dermatome by other dermatomes. Future experiments will examine the physiological effects of cutting two, three, and four dorsal roots. Ongoing experiments are examining sprouting of afferents and propriospinal connections in the same preparations.

This research was supported by a West Virginia University Senate Research Grant, a West Virginia University Medical Center Research Grant, and USPHS Grant NS12061.

2378 PHASE DEPENDENT GATING OF SOMATIC SENSORY INPUT TO SMI CORTICAL CELLS DURING LOCOMOTION By John K. Chapin and Donald J. Woodward, U. Tx. Health Sci. Ctr. at Dallas, Dallas, Texas 75235

This study was conducted to test the postulate that statically defined receptive field properties in SmI cortical neurons of awake, freely moving rats may be subject to internal gating according to specific parameters of movement.

Cells with purely tactile receptive fields on the ventral surface of the forepaw were isolated and post-stimulus time histograms (PSTH's) were generated by repetitively touching the skin with a manually held probe. The responsiveness of these cells to "active touch" of their receptive fields was tested by averaging unit activity around foot contact during locomotion. About 56% of these cells were found to respond strongly at footfall (Strong FF cells), but 43% discharged only weakly at footfall (Weak FF cells) even though they responded strongly to equivalent parameters of passive touch stimulation. In subsequent studies, the somatic responsiveness of such units was also tested by electrical stimulation of receptive field areas through subcutaneously implanted bipolar electrodes. The latency and form of the PSTH's produced by this method were very similar to those derived from natural touch with a probe. For this reason such electrical stimulation was considered to be a reliable means of quantitatively testing the transmission of somatic sensory input during movement. The quantitative level of the excitatory responses of these cells to electrical stimulation delivered at 1-3 Hz during various phases of the forelimb step cycle were plotted by computer. In this method the baseline level of unit activity for each step cycle phase was calculated and automatically subtracted from the averaged post-stimulus excitatory responses. The "peri-footfall stimulus effectiveness plots" generated by this technique showed that the sensory responsiveness of most cells was modulated over the step cycle. In particular, the responsiveness of the "Weak FF" cells were found to be phasically deppressed 10 to 50 msec before footfall. These units responded vigorously to tactile or electrical stimuli delivered during the early swing phase. Conversely, the "Strong FF" cells were found to be phasically facilitated just before footfall. Such neurons could not be driven by any form of stimulation during the early swing phase.

These findings suggest that this sample of cells may be partitioned into separate perceptual systems. One group may be actively configured to respond only to the anticipated floor contact of the foot occurring during locomotion, whereas the other may respond only to unanticipated stimuli delivered during other phases.

This study was supported by grants AA 0390 to D.J.W. and the Biological Humanics Foundation)

2379 PROPERTIES OF DIRECTION-SENSITIVE NEURONS IN PRIMARY SOMATOSENSORY CORTEX OF ALERT MONKEYS. Richard M. Costanzo and Esther P. Gardner, Dept. of Physiology & Biophysics, NYU School of Medicine, New York, NY 10016.

In SI cortex of alert monkeys, we recorded from 60 direction-sensitive neurons (DSNs) which were effectively driven by moving stimuli traversing the receptive field in particular directions, but responded poorly to punctate cutaneous stimuli. Fine brushes or calibrated bars (2-30 mm in length) were used to define the direction of movement eliciting the strongest response (on-direction) and that evoking the weakest activity (off-direction). On- and off directions were usually diametrically opposed, but in a few DSNs were separated by only 90 deg. Individual DSNs responded to trajectories within a range of angles from 90-360 deg. Responses were graded with angular displacement from the on-direction, becoming progressively weaker as the off-direction was approached. DSNs with hand receptive fields tended to be more narrowly tuned than those on the forearm. All directions of movement were represented in our sample. On the forearm, 2/3 of the direction preferences were oriented along the distal-proximal axis; hand direction preferences were uniformly distributed.

Three classes of DSNs were found: 1) Multidirectional neurons (37%) responded to movements in all directions, but were preferentially excited by those in the on-direction. 2) Unidirectional cells (57%) gave strong responses to on-direction stimuli, and only 0-4 spikes to off-direction stimuli. 3) Opponent direction cells (6%) were spontaneously active, increasing their firing rate to on-direction trajectories, and decreasing firing below spontaneous levels to off-direction stimuli. All three cell types fired continuously and uniformly throughout the stimulus trajectory. Instantaneous frequency histograms showed no peak in responsiveness as the stimulus crossed the field center, or any other individual point in the field. Thus DSNs seem to ignore information about the exact position of the stimulus at any moment in the trajectory.

In addition to coding direction of movement, many DSNs were able to differentiate parallel trajectories in the on- and off-directions. Only some DSNs with on-directions oriented transversely across the forearm or hand showed position insensitivity. 2/3 of DSNs tested also discriminated the size of moving bars, some preferring narrow, others wide bars.

The broad tuning properties, plus the multiplicity of information encoded in the firing patterns of individual DSNs (direction, specific trajectory, size of stimulus), suggest that activity distributed across the population of DSNs must be evaluated to determine the precise characteristics of the moving stimulus.

2380 SPINOTHALAMIC TERMINATIONS IN THE VENTROPOSTEROLATERAL NUCLEUS OF THE CAT. A.D. Craig, Jr. and H. Burton. Depts. of Anatomy-Neurobiology and Physiology-Biophysics, Wash. Univ. Sch. Med., St. Louis, MO 63110

Recent evidence of a projection from n. caudalis to the ventroposteromedial n. in the cat thalamus (Burton et al., JCN '79) prompted a reconsideration of the reported absence (Boivie, EBR '71; Jones & Burton, JCN '74) of spinothalamic projections to the ventroposterolateral n. in this species. Following single or multiple injections of horseradish peroxidase (HRP) into individual or conjoint spinal levels and/or laminae, the distribution of labeled terminal projection zones was examined after the application of the highly sensitive tetramethylbenzidine chromogen reaction. These procedures enabled visualization of anterogradely transported label and often permitted observation of terminal, pericellular arborizations and "boutons" with Golgi-like clarity. These experiments confirmed the most recent previous studies in that terminals occur in the spinal part of the ventrolateral n., medial part of the posterior n., magnocellular part of the medial geniculate n., and the centrolateral and parafascicular nuclei. Several additional termination zones have been identified. One of these is VPL, in which labeled terminals are distributed in two patterns. First, isolated small patches of terminals are seen sparsely scattered within the central portion of the topographically appropriate part of VPL. A second narrow zone of terminals can be observed within the extreme ventral aspect of VPL where they surround the cells (many of which are small) found in this location; these terminations are also distributed somewhat topographically. Recordings obtained from single neurons in this ventral zone indicate that some of these cells respond to a wide dynamic range of cutaneous stimulation.

These results, along with the recent results on projections from n. caudalis (Burton et al., '79; Ganchrow, JCN '78), suggest that spinothalamic terminations in the ventroposterior nuclei of the cat and monkey are qualitatively homologous in both their spinal and trigeminal components.
Supported by NIH grants NS09809 and NS11384.

2381 PROJECTIONS OF HINDLIMB DORSAL ROOTS TO SPINAL CORD OF CAT. James L. Culberson and Paul B. Brown. Depts. of Anatomy and Physiology/Biophysics, West Virginia University Medical Center, Morgantown, WV 26506.

The Fink-Heimer degeneration stain was used to study projections of dorsal roots L_3-S_2 to segments L_2-S_3 of the cat spinal cord. Unilateral dorsal root section was effected transdurally between the ganglion and entry of the root into the intrathecal space. In each animal, one dorsal root was sectioned, on the left side; roots L_3-S_2 were sectioned, each of them in at least two animals. The animals were perfused transcardially with 0.9% saline and 10% formalin 5-7 days after rhizotomy, and the cords were stored in 10% formalin for at least two weeks. Cords were cut into blocks at intersegmental boundaries, and serial 40 μm thick frozen sections were cut in the transverse plane. Alternate serial sections were stained by the Fink-Heimer method, and with cresyl violet acetate.

Degeneration was seen in all laminae, although it was uncommon in ventral lamina II - dorsal lamina III, and lamina VIII. Excluding projections to Clarke's column, the rostrocaudal extent of degeneration observed for each root was: L_3 projects to segments L_2-L_6 (examined L_2-S_2); L_4 root to segments L_2-L_5 (L_2-S_1 examined); L_5 to segments L_2-S_2 (examined L_2-S_2); L_6 root to L_3-S_2 (examined L_3-S_2); L_7 root to L_4-S_2 (examined L_7-S_2); S_1 root to L_4-Ca_1 (examined L_3-Ca_1); and S_2 root to L_6-S_3 (L_5-S_3 examined). Ventral horn distributions were usually limited to the deafferented segment ± segment.

Since it is now known from HRP injections of cutaneous nerve fibers (A. G. Brown et al.) and peripheral loading of cutaneous nerves with HRP (Brown and Koerber) that large cutaneous fibers end in laminae III-IV and that deep afferents do not (A. G. Brown et al.), projections to laminae III-IV were plotted on dorsal view maps of left dorsal horn to examine their somatotopy. No simple rule can be devised to describe the projections of all dorsal roots, either in terms of anteroposterior or mediolateral extent. Thus, for example, there is no consistent medial or lateral shift of projections rostral or caudal to entry segment of a given root. However, cutaneous afferents in a single root project consistently to the same dorsal horn region in different cats. The projection target is predictable on the basis of somatotopy: a dorsal root projects to those regions of dorsal horn where the root's dermatome is represented in physiological mapping experiments.

This research was supported by USPHS Grant NS12061 and grants from the West Virginia University Medical Center.

2382 TEXTURED SURFACES EXPLORED WITH THE MOVING FINGERTIPS: THEIR REPRESENTATION IN THE DISCHARGE OF DIGITAL NERVE FIBERS. Ian Darian-Smith, Linda Oke*, Ian Davidson* and Kenneth Johnson. Sensory Processes Laboratory, Department of Physiology, University of Melbourne, Parkville 3052, Australia.

Textured surfaces actively explored with the fingers, or moved across the stationary finger, are among the commonest stimuli that we identify and characterise tactually. Experiments were designed to examine the representation of the spatial and temporal features of two geometrically patterned surfaces moving across the skin in the discharge patterns of single mechanoreceptive fibers, and in assemblies of these fibers. The stimulator used in these experiments applied the moving surface to the skin for a specified time with a particular contact force and at a particular velocity. The surfaces used were fine gratings defined by their spatial frequency, and geometric arrays of elevated 'dots' defined by the dot diameter and the spacing of these dots.

Single mechanoreceptive fibers innervating the fingertip pad were isolated by dissection of the median nerve in the anesthetised monkey (Macaca nemestrina). Each fiber was then identified as a slowly adapting (SA), quickly adapting (QA), or Pacinian afferent.

Fibers responded to gratings moving across the fingertip with a very regular discharge which, however, reflected the temporal frequency (spatial frequency x velocity) rather than the spatial features of the surface. The spatial characteristics of the surface could be represented only in the discharge pattern of a spatial assembly of these fibers. Coarse gratings moving slowly across the skin (temporal frequency of 20 - 40 Hz) were best represented in the responding SA fiber population; fine gratings moving at a high velocity across the skin (temporal frequency > 100 Hz) were best represented in the discharge of the Pacinian fiber population, and stimulus combinations generating a temporal frequency in the range 30 - 100 Hz were precisely represented by discharge in the QA fiber population.

Specification of the mechanoreceptive fiber responses to the two-dimensioned dot patterns involved a more complex data collection. With each successive stimulus presentation the moving surface was translated 125 microns laterally relative to the direction of movement of this surface. The response array generated by this procedure defined the representation of the stimulus surface both along an axis at right angles to its line of movement, and in the line of movement.

2383 OCULAR COUNTERROLLING DURING CONSTANT VELOCITY ROLL IN NORMAL HUMANS AND IN PATIENTS WITH UNILATERAL VIII NERVE SECTIONS. Shirley G. Diamond and Charles H. Markham. Dept. Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

Nine subjects were rolled about their naso-occipital axes at a constant velocity of 3°/sec after having been securely strapped into a rotating chair. The head was positioned and stabilized by a bite bar. Trials began with a roll to 90° right ear down, reversed and rolled to 90° left ear down, again rolled to 90° right ear down, then back to 90° left ear down, and finally back to the upright baseline. At each 90° position, subjects were held steady for 30 sec before being rolled to the opposite direction. A camera mounted on the rotating chair photographed both eyes at each 10° of roll, and at each 10 sec while subjects were held motionless at 90° tilts.

Counterrolling was measured by a dual projector system described in an earlier study (Diamond, Markham, Simpson & Curthoys, Acta Otolaryngologica, in press, 1979). Mechanical accuracy of the measuring device is 1 minute of arc; practical accuracy is 15 minutes.

Results in six normal subjects showed that contrary to general belief, the counterrolled position of the eyes is not held constant as long as the tilt is maintained. During the 30 sec intervals when subjects were held motionless at 90°, 28 observations were recorded and 22 of these showed the subjects' eyes continued to make occasional rotational movements. This torsion during the stationary interval was as much as 5°, with 2° being common. Direction of change during the static period was about equally divided between more and less counterrolling. When subjects began rotation back toward the upright baseline, frequent torsional eye movements in the "wrong" direction were observed. These were corrected fairly rapidly, and no normal subject showed "wrong" direction torsion in the area bounded by 30° to the right or left of the upright position. The amplitude of counterrolling was approximately equal on both sides.

Three patients with right vestibular nerve sections performed 2 to 5 years earlier showed distinctly abnormal patterns when they were rolled contralateral to the lesion, i.e. left ear down. These abnormal patterns consisted of reduced amplitude and/or more instability in the form of irregular "wrong" direction torsion, persisting longer than in the normal subjects and appearing closer to the upright position. Counterrolling was not conspicuously different than normals when patients were rolled to the side ipsilateral to the lesion, i.e. right ear down. Further studies are underway to delineate the differences between normals and persons with unilateral lesions to aid in the diagnosis of utricular dysfunction. 2384 ORGANIZATION OF THE SOMATOSENSORY CORTEX IN CEBUS MONKEYS. D.J. Felleman*, R.J. Nelson, M. Sur* and J.H. Kaas, Depts. of Psychology and Anatomy, Vanderbilt Univ., Nashville TN 37240.

The somatotopic organization of the post-central somatosensory cortex was revealed by determining receptive field locations from approximately 2700 recording sites in four (4) Cebus monkeys, (Cebus albifrons). As in previous studies in macaque, squirrel and owl monkeys, two separate representations of the cutaneous body surface were found. In position, these representations appear to correspond to architectonic Areas 3b and 1. As in other monkeys, the two representations are essentially mirror-images of each other, with receptive field positions matched for recording sites along the common border. Both representations show a similar medio-lateral organization to other primates studied, with tail and hindlimb represented medially and forelimb and face represented laterally. Glabrous digit tips point rostrally in the anterior representation and caudally in the posterior representation. As in macaques (Sur et al., Neuro. Abst. 4:559,'78), the occiput is represented medial to the arm in the rostral representation. The tail representation is unusually large, occupying at least 12 sq. mm spanning both representations. Much of the tail representation is occupied by the tip of the tail. The ventrum of trunk is represented anteriorly and caudally with the dorsal midline represented at the junction of the two representations. The inner arm and thigh are represented rostrally and caudally in the two representations respectively; the lateral surfaces of the limbs are represented at the common border. All regions of the face are represented in each of the cutaneous representations.

Comparisons between previously studied species indicate that there are two basic patterns of organization of the representations of the hairy surfaces in monkeys, while the orientation of the glabrous digits appears to be consistent. Thus, the distal digits are represented at the extremes of the representations and the proximal surfaces are represented at the border of the two representations in all monkeys. However, in cebus and squirrel monkeys, the ventral trunk and the medial limb surfaces are represented at the rostral and caudal extremes. The remaining surfaces of the limbs and trunk are systematically represented, either from ventral to dorsal, by way of the lateral surface, in the case of the trunk, or from medial to lateral, by way of the anterior surface, in the case of the limbs. The opposite is true of the organization of the representation of the hairy surfaces in macaques. Therefore, while there appears to be a common pattern of organization for the glabrous surfaces, the hairy surfaces may vary, in toto in the cortical representations across species.

2385 FUNCTIONAL MODIFICATION OF CAT SOMATIC SENSORY-MOTOR CORTEX (SmI) BY SELECTIVE DEAFFERENTATION. Joel Ira Franck*[1] and Jacqueline Metzler (SPON: Carole C. LaMotte). Dept. Neurosurgery, Yale Univ. Sch. Med., New Haven, CT 06510.

In order to further analyze the somatotopic projection to SmI, single units were recorded from 6 awake, paralyzed, adult cats, using N_2O analgesia and mechanical stimulation. Chronic recording chambers were implanted over the left SmI. Cells were classified as to whether they responded to superficial stimulation (S cells), such as hair movement or light touch, or to deep stimulation (D cells), such as pressure or joint manipulation.

The 144 units studied during 9 control recording sessions revealed that SmI is organized in a highly specific manner, with 93% of the cells belonging to a single submodality and having a discrete receptive field (RF). The body surface is represented in SmI as a series of overlapping strips, oriented at about 45° relative to the cruciate sulcus, with rostral body segments lying caudo-laterally and caudal segments rostro-medially. D cells were concentrated rostro-laterally and S cells caudo-medially. Within each segmental strip, cells with dorsal RF's tended to be located caudo-medially while cells with ventral RF's were found rostro-laterally.

All dorsal roots caudal to L3, with the exception of L7, were then intradurally sectioned on the right side in 3 cats, 2 of which had been studied as controls. These animals were examined several times over the next 8 to 55 days, during which time 169 units were isolated in 9 sessions. Nearly 67% of the post-rhizotomy cells had the highly specific patterns of activity observed in the control recordings. However, 33% of the units studied after deafferentation, as compared to 7% of those examined in the control preparations, exhibited unusual properties which emerged within 8 days of dorsal-root section. These cells responded in a nonspecific manner to stimulation, often to multiple subclasses, of uncharacteristically shaped, large, or stocking-like, contralateral, bilateral or multiple RF's. The somatotopic map of SmI changed progressively over time. Rostral body segment representations in the lateral regions of SmI "migrated" into the partially deafferented medial regions of SmI which had represented the hind limb in the control state. Previous reports indicate that the widespread connections unmasked in this chronic study may be present throughout the somatosensory system of intact animals but are usually latent or ineffective (Wall, 1977, Philos. Trans. R. Soc. Lond. B 278: 361-372).

2386 QUANTITATIVE EXAMINATION OF PRESYNAPTIC PROFILES CONTAINING FLATTENED VESICLES IN NUCLEUS GRACILIS OF GALAGO. D. J. Friedenbach. Dept. Anat., Sch. Med., UND, Grand Forks, ND 58202.

The rostral portion (RG) of nucleus gracilis of Galago has been examined by quantitative methods. Six bushbabies were routinely prepared for electron microscopic examination. A series of thick and thin sections were taken from RG for orientation and examination purposes. Sections were randomly selected and photographed to produce 100 micrographs at a final magnification of 40,000X. The point reticule method of Weible was used to determine the percent area of identifiable neuropil for three classes of synapses: axodendritic (FD) or axosomatic (FS) with flattened vesicles, and axoaxonic (AA). For each identified synapse several parameters were directly measured. ANOVA was used to examine for significant differences ($P<0.05$) between synaptic classifications or parameters within animals, among animals or significance ($P<0.05$) between synaptic types. AA synapses (5%) compose the smallest percentage of presynaptic elements defined as having flattened vesicles (FD-19%, FS-14%). No other differences were detected when comparing the size of the presynaptic profiles (1.9-2.6μm^2) or the number of synaptic sites found on each presynaptic profile (1.1-1.3). AA synaptic lengths (28nm) were shorter than either FD (410 nm) or FS (680nm) synapses. A significantly higher percentage of AA synapses (99%) were characterized as Gray type II synapses (FD-62%, FS-50%). By shape criteria FD synapses (1.2) were significantly more round than FS (1.8) or AA (1.7). The cross-sectional area of vesicles in FS terminals ($1.9 \times 10^3 nm^2$) was larger than in FD or AA synapses (1.5 and $1.4 \times 10^3 nm^2$). There were no differences in the variance of these parameters: the arc of the synapse (1.2-1.3), the percent of the area of the presynaptic profile occupied by vesicles (42-54%), or the number of vesicles per presynaptic profile (12-19).

Inhibitory afferents have been demonstrated to the rostral nucleus gracilis of other animals. If the flattened vesicle-containing profiles are inhibitory then it is plausible that they represent inputs from three different sources. Work is currently underway to investigate the nature of the terminals differentially terminating in RG.

This work was supported by a BRSG grant to Dr. Bruce C. Albright.

2387 PATTERNS OF PROJECTIONS OF THALAMIC VENTROBASAL NEURONS TO THE FIRST SOMATIC SENSORY AREA OF MACAQUES. D.P. Friedman and E.G. Jones. Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Cortical projections from physiologically identified neuronal groups within the thalamic ventrobasal complex (VPLc and VPM) were studied using the autoradiographic method. In each experiment the areas of the thalamus receiving somatic sensory input were mapped using standard microelectrode recording techniques. A 1 µl Hamilton syringe was guided into VB according to these maps. The final position of the injection was selected by recording from a microelectrode which had been cemented to the barrel of the syringe so that the tip of the electrode was less than 500 µ from the bevel of the syringe barrel. This pair was placed into the brain so that the electrode was immediately posterior to the opening in the bevel. 10-50 nl of tritiated leucine and proline (50 µci/µl, New England Nuclear) was expelled after determining the response properties of the nearby neurons. Such injections commonly produced a heavily labelled central core of less than 1 mm^3. Virtually all of this zone was posterior and lateral to the syringe barrel, thus enveloping the recording site.

Injected clusters responding to stimulation of deeper tissues were always most dorsally placed within VB, though sometimes at its anterior border with VPLo. Injections made into clusters of neurons responding to light tactile stimuli were more ventrally placed within VB.

The pattern of terminal labelling on the cortex was studied using series of 20 µ thionin counterstained autoradiographic sections cut in either sagittal or horizontal planes. Following injections into clusters responding to light tactile stimuli, labelling was confined to area 3b. Such labelling was seen in vertical columns or bands within layers IIIb and IV. An individual column 250-400µ wide was separated from an adjoining column by an equivalent sized gap. Within 3b columns located on adjacent sections were often arranged in register so as to form a pattern of repeating strips or bands of variable orientation with respect to the axes of the postcentral gyrus. The more dorsal injection sites,placed where units responded to stimulation of deeper tissues, produced labelling mainly in areas 1 and 2. Within those areas labelled terminals appeared in elongated bands completely within layer III. Because the labelling in these areas was extremely light a finer structure could not be clearly resolved.

2388 SOMATOSENSORY FUNCTION FOLLOWING LESIONS IN MIDBRAIN LEMNISCAL PATHWAYS.
Gabriel P. Frommer. Dept. Psychology, Indiana University, Bloomington, IN 47405

Although the consequences of lesions in somatosensory pathways of the spinal cord and in their projections in the forebrain have been investigated extensively, few data are available on the effects of lesions in the somatosensory afferent pathways in medial lemniscus and related midbrain structures. The present experiments investigated the effects of such lesions placed at sites from which brief, short-latency, contralaterally originating somatosensory evoked potentials could be recorded. The primary behavioral measure was performance on a series of roughness discriminations. Cats were required to press the rougher (or smoother) of two pedals to obtain food reinforcement. Rats had to choose the arm of a T-maze that had the rougher (or smoother) aluminum floor. Terminally, evoked potentials elicited by foreleg stimulation were recorded under barbiturate anesthesia from somatosensory cortical projections. Additional electrophysiological data were obtained from other cats prepared with electrodes chronically implanted at various sites in the somatosensory afferent pathways before and after midbrain lesions were made.

All five cats were capable of making the tactile roughness discriminations after anatomically verified major damage to lemniscal pathways in the midbrain. All four that survived long enough reached or exceeded preoperative levels of discrimination performance after extended testing. However, the terminal cortical evoked potentials were similar in amplitude, latency, and configuration to ones recorded from unoperated control animals. Evoked potential data from the chronically prepared cats showed that more extensive midbrain damage extending beyond the anatomically defined boundaries of lemniscal pathways were required to attenuate markedly the cortical somatosensory evoked potentials. Only one of six experiments comparing rats with midbrain lemniscal lesions to control rats demonstrated statistically reliable disruption of performance on roughness discriminations. Rats with lemniscal lesions relearned preoperatively mastered discriminations more slowly than did control animals. Rats also showed little if any effect of midbrain lesions on cortical somatosensory evoked responses. Lesions in the rat's medial lemnicus also produced a transient syndrome of hyperreactivity to tactile and auditory stimuli, postural and gait abnormalities, and aphagia which was apparently secondary to the motor deficits and hyperreactivity. Supported by NIH grants MH 10852 and 29204.

2389 PHYSIOLOGICAL SPECIALIZATION OF TRIGEMINAL NUCLEI? A COMPARISON OF STIMULUS-RESPONSE RELATIONSHIPS IN VIBRISSA-ACTIVATED NEURONS OF NUCLEI INTERPOLARIS AND ORALIS OF RAT. John M.Gibson, James D. Woodburn* and Wally I. Welker. Department of Neurophysiology, University of Wisconsin, Madison, Wisconsin 53706, USA.

The nuclei of the trigeminal complex exhibit cytoarchitectonic and projectional differences which suggest the possibility of differential processing of mechanosensory information. Physiological studies have, however, produced highly contradictory results regarding the issue of trigeminal nuclear specialization. We are exploring this issue through a broad-based methodology using an extensive battery of precisely-controlled stimuli in conjunction with a variety of quantitative analytic procedures.

Single-unit action potentials are recorded extracellularly with tungsten microelectrodes in the trigeminal complex of the barbiturate-anesthetized albino rat. Stimuli consist of quantitatively controlled deflections of single mystacial vibrissae. Data are collected and analyzed by means of digital computers.

The responses of units of nuclei interpolaris and oralis are qualitatively similar. (1) About half the receptive fields include more than one vibrissa. (2) Angular displacement and velocity thresholds range over three orders of magnitude. (3) Adaptation rates vary widely and are highly dependent on stimulus amplitude.

Quantitative methods, however, reveal several differences. (1) Receptive fields of interpolaris units tend to be smaller than those of oralis. The upper quartile receptive field size of interpolaris neurons is 4 vibrissae, compared with 6 for oralis. About 1/3 as many interpolaris neurons as oralis neurons have receptive fields which include more than 10 vibrissae or a patch of common fur. (2) Angular displacement and velocity threshold distributions of interpolaris neurons lie above those of oralis, although below those of first-order neurons. (3) Interpolaris neurons tend to adapt more rapidly than those of oralis. The adaptation index (defined for a step deflection of about 7^{o} as the ratio of firing rate during the third 100-msec. period of stimulation to that during the first 100-msec. period) was approximately zero (i.e., "rapidly adapting") for almost 2/3 of interpolaris neurons, compared with about half those of oralis. The upper quartile value of the adaptation index of interpolaris neurons was about 2/3 that of oralis neurons.

Although stimulus-response relationships in nuclei interpolaris and oralis are qualitatively similar, quantitative differences suggest physiological specialization for differential processing of mechanosensory information by these nuclei.

2390 INTERACTION OF ACTIVITY IN FROG SKIN AFFERENT UNITS.
M.D. Goldfinger and Y. Fukami. Dept. of Physiology & Biophysics, Washington University, St. Louis, MO, 63110.

Single axonal discharges in response to mechanical stimulation of two innervated spots of a dorsomedial skin 'touch' receptive field are recorded with a suction electrode from cutaneous nerve in decapitate spinally pithed frogs. The preparation is immersed in Ringer solution (pH=7.1, T=~21°C); the in situ orientation of skin to underlying tissues is maintained. Each mechanical stimulator consists of a 0.3 mm OD rounded tip glass rod glued to the cone of speaker driven over a range of voltages which yields proportional mechanical output. Unit identification criteria include: 1) no resting discharge; 2) rapid adaptation to a long (>50 msec) constant displacement to either spot; and 3) the single impulse evoked by a just threshold amplitude, 1 msec duration mechanical stimulus to one spot is abolished when preceded at >50 msec by a single impulse similarly evoked from the other spot, but can reobtain at the same interval with a suprathreshold amplitude stimulation. Interspot distances are >1500 µm.

The recovery cycle- tested 1/2-3 sec at one spot by conditioning with 1 impulse elicited from the other spot- declines continuously to the unconditioned threshold level in ~200 msec. However in other units, early (5-20 msec) and later (80-150 msec) discontinuities occur. Significantly, the same mechanical conditioning applied to an uninnervated region between the spots did not alter the threshold for mechanical impulse initiation at the test spot.

In other experiments, trains of 1 msec mechanical pulses are delivered 2-4/sec to one spot recurrently and to the other for ~3 sec periods randomly with respect to the recurrent train; each spot tested separately drives the parent axon 1:1. During simultaneous dual spot stimulation, the resultant impulse train resembles the combined sequential stimulus train, except for shorter interstimulus intervals corresponding to earlier periods of the recovery cycle.

These results illustrate two modes of activity interaction within the neural substrate of the receptive field: (1) RESET of threshold for impulse initiation from one spot by an antidromically elicited recovery cycle, and (2) MIXING of activity evoked from different peripheral sites.

2391 THE RELATIONSHIP BETWEEN THE PATTERN OF COMMISSURAL TERMINATIONS AND THE MAPS OF SOMATOSENSORY CORTEX (Sm I and Sm II) IN THE GREY SQUIRREL. H. J. Gould, III. Dept. Anat., Univ. Cincinnati College of Medicine, Cincinnati, Ohio 45267.

Interhemispheric somesthetic connections were studied in the grey squirrel using the Fink-Heimer technique for degeneration. The total pattern of connections was correlated with the electrophysiological maps of Sm I and Sm II. In six squirrels the corpus callosum was sectioned through the medial wall of one hemisphere six days prior to mapping the contralateral somatosensory cortex. At the end of each recording session small reference lesions were made at known points within each map. The animals were then perfused and the tissue was flattened and sectioned parallel to the surface for analysis according to the technique of Welker and Woolsey ('74, J. Comp. Neur., 158: 437).

The densest degeneration is observed along the margins and in special zones within Sm I. This degeneration is related to the midline representations of the body including representations of the upper and lower lips, neck, trunk, genitalia and tail, while the representations of distal body parts including the vibrissae, corner of the mouth, forepaw and foot demonstrate little if any degeneration. Moderate degeneration is often seen related to representations of the proximal limbs. These data corroborate the observations of others that only midline and proximal limb structures are connected through the corpus callosum. In addition, dense degeneration is observed within the special unresponsive zone (UZ) of Sm I. This supports the prediction of Sur et al., ('78, J. Comp. Neur., 179: 425) that UZ is a major commissural recipient zone. In Sm II moderate degeneration is found to be related to both midline and distal body parts within the erect representation of the body (Nelson et al., '79, J. Comp. Neur., 184: 473). The central portion of Sm II is relatively free of degeneration. These results support recent physiological studies in the cat that suggest the existence of interhemispheric connections between representations of distal limbs in Sm II (Innocenti et al., '74, Exp. Brain Res., 19: 447; Robinson, '73, Exp. Brain Res., 18: 131).

It is therefore possible that callosal connections serve different functions in Sm I and Sm II since the dense interhemispheric connections in Sm I are related specifically to midline structures and the connections in Sm II are related to all body parts. It may be that the connections in primary sensory cortex, Sm I, are essential for midline fusion of the two halves of the body within the cortex while the connections in secondary sensory areas, Sm II, are more important in the processing of complex sensory discrimination. (Supported by National Science Foundation Grant BNS-81824).

2392 THE PYTHON AND THE RATTLESNAKE: A COMPARISON OF INFRARED TRIGEMINO-TECTAL PATHWAYS USING HORSERADISH PEROXIDASE AND CHOLINESTERASE TECHNIQUES. Edward R. Gruberg*, Eric A. Newman*, and Peter H. Hartline. (SPON: Daniel Kurtz). Eye Research Institute of Retina Foundation, Boston Ma. 02114 and Massachusetts Institute of Technology, Cambridge Ma. 02139.

Infrared receptors of pit viper and boid snakes project to a specialized primary trigeminal nucleus, the nucleus of the lateral descending trigeminal tract (LTTD). Previously, using horseradish peroxidase (HRP) techniques, we showed that the LTTD of the rattlesnake projects to the contralateral optic tectum via an intermediate nucleus in the ipsilateral ventro-lateral medulla, the nucleus reticularis caloris (RC). Now, using HRP, we have traced the LTTD projection to the tectum in the python (P. reticulatus). Following HRP injection into the intermediate layers of the tectum, the Mesulam benzidine blue method revealed large (35-70 μm in diameter) multipolar cells scattered throughout the main body of the contralateral LTTD. The smaller, more numerous LTTD cells were not stained. This demonstrates that, in contrast to the case in rattlesnakes, a direct LTTD to tectum connection exists in the python and shows that only the large LTTD cells project to the tectum. We stained python and rattlesnake (Crotalus viridis) brains for acetylcholinesterase by a two step cupric sulfate-ferricyanide method. In python, the large LTTD cells stained heavily for cholinesterase. The rattlesnake LTTD lacks cells over 25 μm in diameter. However, the cells of the rattlesnake RC showed heavy cholinesterase activity; these cells (25-45 μm in diameter) have a similar multipolar appearance as the large cells of the python LTTD. In both species, the large cells project to the contralateral tectum. We suggest that these large cells serve a similar function in the infrared systems of the two groups of snakes and may have a common origin. They differ in that they form a distinct nucleus in the rattlesnake but not in the python. Supported by NIH grants R01-EY01539, T32-EY07028, T01-EY00090, and by the Bell Telephone Laboratories.

2393 COLLATERAL BRANCHING OF ASCENDING SPINAL NEURONS IN MACAQUES. Nancy L. Hayes* and Aldo Rustioni, Depts. of Anatomy and Physiology and The Neurobiology Program, UNC, Chapel Hill, NC, 27514.

A double-labeling strategy has been employed in primates a) to identify simultaneously cells of origin of ascending spinal projections to the dorsal column nuclei (DCN) and to the thalamus, and b) to answer the question of whether at least some of these spinal neurons have axons which, by way of collateral branching, reach both targets. In adult monkeys (M. fascicularis) 10 μl of 30% HRP were injected unilaterally in the ventrobasal complex, and 0.5-1.0 μl (10-30 μCi) of tritiated, enzymatically inactive HRP (^{3}H-apo-HRP, New England Nuclear) were injected in the contralateral dorsal medulla. After 2 or 3 days animals were perfused with mixed aldehydes. 1-2 mm thick slabs through selected spinal segments were reacted in Hanker-Yates substrate for histochemical visualization of HRP, embedded in paraffin, sectioned at 15 μm, and processed for autoradiographic demonstration of ^{3}H-apo-HRP (Hayes and Rustioni, 1978).

Spino-thalamic neurons, labeled by HRP-positive granules, are found mainly in lamina I and in the lateral portions of laminae IV-VI throughout the side of the cord contralateral to the thalamic injection. Spino-DCN neurons are most numerous ipsilateral to the medullary injection, in medial portions of laminae IV-VI throughout cervical levels, but laterally, in the same laminae, in lumbar segments. At lumbar levels, spino-thalamic and spino-DCN neurons are also found along the lateral border of the ventral horn. Neurons in this location, labeled by either the thalamic or the DCN injection, are large (40-65 μm) and are indistinguishable from the spinal border cells described by Cooper and Sherrington (1940) as the source of the ventral spino-cerebellar tract in cats and monkeys. At lumbar levels, but not at cervical levels, some large dorsal horn neurons are labeled by both cytoplasmic HRP-positive granules and by reduced silver grains in the overlying emulsion. These double-labeled neurons are interpreted as having an axon which gives origin, presumably at spinal cord levels (Cajal, 1909), to collaterals ascending to both the ipsilateral DCN and the contralateral thalamus. Elucidation of whether and to what extent other ascending pathways to various supraspinal targets originate from common spinal neurons may provide new insights into the functional mechanisms of ascending spinal systems.

Supported by USPHS grants NS 12440 and MH 14277 and in part by the Alfred P. Sloan Foundation.

2394 TOPOGRAPHIC ORGANIZATION OF THALAMIC NEURONS RESPONSIVE TO TEMPERATURE STIMULATION OF ORAL AND PERIORAL REGIONS OF THE CAT. H. Hirata, E.L. Auen, D.A. Poulos, and J.T. Molt, Dept. of Anatomy and Div. of Neurosurgery, Albany Med. Coll., Albany, N.Y. 12208.

The organization of thalamic neurons receiving trigeminal input arising from cutaneous mechanoreceptors has been the subject of many investigations. There have been fewer attempts to describe the organization of thalamic neurons responsive to cutaneous temperature stimulation. This report describes the spatiotopic organization within a zone of the cat thalamic nucleus ventroposterior medialis (VPM) that receives thermosensitive input from oral and perioral regions. The anatomic data reported here were acquired as part of an electrophysiological study of the response characteristics of single thalamic thermoreceptive neurons (see Poulos et al., this volume). Microelectrodes were stereotaxically placed into the thalamus of urethane-anesthetized cats and the responses of electrophysiologically isolated neurons considered to be thermosensitive were studied in detail. The size and shape of thermosensitive peripheral receptive fields were determined and electrolytic lesions were made to verify electrode placement. Cats were perfused with saline followed by 10% formol-saline, the brains were removed, blocked, frozen-sectioned at 25μ, and stained with either cresyl violet or thionin. Histological data are based on experiments completed in 14 adult cats. Reconstruction of histological sections combined with maps of thermoreceptive neuron depth within an electrode puncture, lesion sites, and neuronal peripheral receptive field size and location revealed a spatiotopic organization of thermoreceptive neurons within the dorsomedial zone of VPM. Neurons in the more rostral portions of this dorsomedial zone of VPM had small thermosensitive receptive fields (1-2mm^2) located on the ipsilateral lips, tip of the tongue, and nose. As the electrode was moved caudally within this zone the peripheral thermoreceptive fields appeared progressively larger (10mm^2), and were located on the more caudal portions of ipsilateral tongue. The medial to lateral spatiotopic organization within this zone was not as clearly defined as the rostral to caudal organization. The more lateral regions had ipsilateral receptive fields on the lateral edge of the tongue and lips and ventral surface of the tongue. The medial regions had ipsilateral receptive fields near the midline of the tongue and lips. A small area in the rostral medial border within the dorsomedial zone had small thermoreceptive fields located on the contralateral side of the tongue. A definitive spatiotopic organization was not found in the dorsal to ventral plane within the zone. While the trigeminal thermoreceptor organization in cat thalamus is not yet as well defined as that of mechanoreceptor input, it is clear that a spatiotopic organization does exist. Supported by NIH grant NS11384.

2395 ANATOMICAL DEMONSTRATION OF TRIGEMINAL AND SPINAL PROJECTIONS TO THE CAUDAL MEDULLA. Susan Hockfield and Stephen Gobel. Neurobiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

The grey matter of the caudal medulla (CM) between the obex and the spinal cord is made up of dorsal and ventral horns which are laminated much like the grey matter of the spinal cord. Our earlier work has shown that layers I, V and VI of the CM contain trigeminothalamic projection neurons that are likely to be involved in trigeminal pain pathways. Responses of layer I, V and VI neurons to noxious stimuli can be modulated by electrical stimulation of several CNS sites. In the present study, neurons that project to the CM from the cervical spinal cord and from the trigeminal nuclei are demonstrated by use of the retrograde transport of horseradish peroxidase (HRP). Unilateral injections of HRP were made in either the dorsal or dorsal and ventral horns of the CM of adult cats. Camera lucida drawings were made to determine the morphology and precise laminar or nuclear location of labeled neurons.

In the spinal cord, segments C6-C8 contain neurons that project to the CM ipsilaterally from layers I, IV and V and contralaterally from layers I and V. In C1-C3, neurons project ipsilaterally from all layers except layer II and contralaterally predominantly from layers I and V-VIII. Few labeled neurons are found in C4 and C5. Throughout the cervical spinal cord, layer II (the substantia gelatinosa layer) contains almost no propriospinal neurons.

In the CM, many labeled neurons are found contralaterally in layers I, IV, V, VII and VIII. Many labeled neurons in layers III and IV have apical dendrites that ascend into layers I and II. In layer VII, labeled neurons are found medially within the intermediate nucleus and laterally within the nucleus retroambiguous.

Most of the ipsilateral descending intratrigeminal projection neurons are found in trigeminal nucleus oralis. The other trigeminal nuclei contain far fewer labeled neurons and these lie in the medial part of the main sensory nucleus and in the dorsal part of trigeminal nucleus interpolaris.

This study shows that some ascending propriospinal neurons to the CM arise from layers which previously have been shown to contain long distance projection neurons, i.e., layers I, V and VI, suggesting that a single neuron may function as both a short intersegmental and as a long distance projection neuron. Trigeminal nucleus oralis is the major source of descending intratrigeminal neurons to the CM which is an important criterion for distinguishing it from the main sensory nucleus and nucleus interpolaris. The propriospinal and intratrigeminal projections demonstrated in this study must constitute an important source of axonal endings in the CM which may modulate the activity of trigeminothalamic projection neurons.

2396 SOMATOTOPIC ORGANIZATION OF DORSAL HORN PROJECTIONS OF CUTANEOUS NERVE TWIGS. H. Richard Koerber , and Paul B. Brown, Dept. of Physiology and Biophysics, West Virginia University Medical Center, Morgantown, WV 26506.

Brown and Fuchs (1975) proposed that the presynaptic cutaneous neuropil of the dorsal horn is somatotopically organized. We have examined projections of small cutaneous nerve twigs to cat dorsal horn. Peripheral cutaneous nerve twigs were cut and their proximal stumps were soaked in distilled water for 10 minutes. Then they were immobilized in plastic cuffs which had been sealed at one end and half-filled with 10% HRP, and the nerves were sealed in place by filling the rest of the cuffs with agar-saline. The cuffs were sutured to underlying muscle and the wounds were closed. After survival times of 2-5 days, the cats were perfused and the cords were processed according to the tetramethyl benzidine method of Mesulam (1978). The nerve twigs tested were: (1) a branch of the posterior femoral cutaneous nerve ($PFCN_3$) and (2) the lateral branch of the sural nerve (LSN). Cutaneous fields of these nerves were mapped before cutting and loading with HRP.

Central projections of these cutaneous nerves were consistent with the somatotopic organization of the dorsal horn. The $PFCN_3$ projects to L_6, L_7 and S_1, to a lateral position in the dorsal horn corresponding to the somatotopic representation of its innervation field (posterior aspect of distal thigh and calf), skirting more medial areas representing more distal skin. The LSN projects to L_7, nesting in a zone just medial to the $PFCN_3$, corresponding to the somatotopic representation of its innervation field (lateral foot, just distal to the $PFCN_3$ innervation). No other projections from these nerves were seen. All projections were to lamina I - dorsal lamina V.

2397 HINDLIMB DERMATOMES OF CAT USING AVERAGING METHODS. David H. Kukulinsky* and Paul B. Brown. Department of Physiology and Biophysics, West Virginia University Medical Center, Morgantown, WV 26506.

Previous reports of cat hindlimb dermatomes are so contradictory that they cannot be used with any precision. For proper mapping of dermatomes, the following criteria must be met: (1) Stimuli must consistently activate cutaneous nerves but not nerves innervating deep receptors; (2) The dorsal root recording method must be sensitive enough to detect activity in small numbers of fibers, but insensitive to activity in other dorsal roots; (3) A means of quantifying the response must be used; (4) Mapping of response magnitudes must use a consistent means of representation. Previous studies have generally failed to meet these criteria.

Seventy standard loci on the hindlimb were tested, in five adult cats, using mechanical pulses (3 msec rise and fall times) applied to the mat of clipped fur. An amplitude of 20 μm was used, since this was demonstrated in single unit studies to activate hair and SAI afferents, but not deep receptors. Stimuli over 25 μm can activate deep receptors. Averages were obtained from dorsal roots L_4-S_1, sampling at 10,000/sec (each root) and averaging over 100 trials (each root) at each stimulus point. Baseline dc offset, $\bar{e}_{dc}$, was computed from a pre-response period of 25 msec.

$$\bar{e}_{dc} = \frac{1}{250} \sum_{i=1}^{250} \underline{s}_i ,$$

where $\underline{s}_i$ is the i^{th} sample point. The absolute-value noise level, $\bar{e}_N$, was computed from the same sample points:

$$\left| \bar{e}_N \right| = \frac{1}{250} \sum_{i=1}^{250} \left| \underline{s}_i - \bar{e}_{dc} \right| .$$

The response magnitude, $\bar{e}_R$, was computed from the next 250 sample points, which included the neural response:

$$\left| \bar{e}_R \right| = \frac{1}{250} \left[\left(\sum_{i=251}^{500} \left| \underline{s}_i - \bar{e}_{dc} \right| \right) - \left| \bar{e}_N \right| \right] .$$

Dermatomes were plotted as contour maps of response magnitudes on the hindleg, using three standard views for each dermatome. General locations agree with earlier reports, although individual reported dermatomes differ markedly from our results. There was little inter-animal variation.

This research was supported by grants from the West Virginia University Medical Center, and USPHS Grant NS12061.

2398 ATTENUATION OF POST-CENTRAL RESPONSES TO PERIPHERAL INPUTS DURING ACTIVE MOVEMENT IN MONKEY. Y. Lamour*, H. Solis*, V. A. Jennings* and E. V. Evarts. Lab. Neurophysiol., NIMH, Bethesda, MD 20205.

Precentral motor cortex responses to peripheral stimuli are attenuated when stimuli are delivered during large active movements (Evarts, E.V. and Fromm, C., Neurosci. Lett. 5: 267-272, 1977). One of the structures which might be involved in this attenuation is the post-central sensory cortex, a region reciprocally connected to motor cortex by cortico-cortical fibers. This hypothesis was examined by recording post-central neuron responses to stimuli delivered at various phases of active movement.

Monkeys (Macaca mulatta) pronated or supinated a handle in order to maintain accurate positioning of the handle in a target zone defined by a visual display. Movements were similar in magnitude (20°) and in velocity (150°/sec) to the "ballistic" movements studied by Evarts and Fromm, but were different in that they were accurately terminated by the monkey rather than by an external "stop." Stimuli superimposed on these large active movements were changes in handle position (position pulses, 50 msec, 8-10°) delivered at different phases of the task: 100 msec after the visual cue triggering the active movements (but before any active displacement), during active movement, and during the holding period between active movements. In addition, we compared neuronal activity during unperturbed active movements with neuronal activity occurring during comparable passive movements induced by ramp displacements of the handle (150 msec, 20°).

Of 150 post-central neurons found to be sensitive to passive arm displacements, 30% showed a decreased response to position pulses delivered during large active movements (as compared to the responses to position pulses delivered during the holding period). For some neurons, responses to position pulses delivered immediately prior to onset of active movements were also decreased. Discharge during unperturbed active movements commonly differed from discharge during passive movements of similar extent and velocity. Usually the responses differed only quantitatively in amplitude and/or time course, but in some cases opposite sorts of responses were observed (e.g., excitation during active movement and no response or inhibition for the same direction of passive movement).

These results provide evidence for modulation of the responsiveness of post-central cortex neurons during active movement, and while not excluding modulation of peripheral input at subcortical levels, raise the possibility that post-central cortex is responsible, in part at least, for the modulation of peripheral inputs to motor cortex during active movement.

2399 CHANGES IN THE SENSITIVITY OF CUTANEOUS MECHANORECEPTION DURING DEVELOPMENT AND AGEING. J. Leon* and A. J. McComas. Dept. of Neurosciences, McMaster Univ. Med. Ctr., Hamilton, Ontario, Canada. L8S 4J9

The sensitivity of type I slowly adapting cutaneous mechanoreceptors, 'touch domes', changes over the course of development. This change is mediated by two mechanisms. The first is a reduction in the density of touch domes per unit skin area during growth. The number of marked touch domes in the skin of groups of rats of different ages and in the skin of individual rats during their development was counted. Touch dome density is significantly lower in rats after weaning and continues to decrease with increasing age. From repeated observations on the number of touch domes within a given nerve field during development it appears that the observed changes in touch dome density can be accounted for entirely by growth of the skin receptive field of the nerve with the maintenance of a constant number of touch domes.

In addition to their density in the skin touch domes appear to alter their sensitivity to pressure as they age. The second mechanism involves an increase in threshold to mechanical stimulation as the animal reaches old age. The threshold of the touch domes was tested using a mechanical prodder which was monitored on line with a photoelectric cell that was previously calibrated to detect prodder movement. Responses were recorded from the third lumbar dorsal cutaneous nerve. The touch domes of juvenile rats (30-45 days old) are most sensitive to mechanical stimulation. The threshold of the touch domes increases with increasing age. The threshold of touch domes in aged rats (over 6 months old) is significantly higher than the threshold of touch domes in adult rats (45 days to six months old). With decreasing density and increasing threshold, the rat progressively loses tactile sensitivity through these receptors over the course of its life.

2400 COINCIDENCE OF FUNCTIONALLY, ARCHITECTURALLY, AND CONNECTIONALLY DEFINED BOUNDARIES IN S-II/r OF MACAQUES. P. R. Loe, B. L. Whitsel, and A. Rustioni, Depts. Physiol. and Anat., U. of N. C., Chapel Hill, N. Car. 27514.

Mountcastle and Powell's demonstration that a systematic relationship exists between structure and function in somatic sensory cerebral cortical organization has been confirmed repeatedly by other workers investigating the organization of the postcentral cortex in primates. Prominent cytoarchitectonic boundaries also exist within the parietal cortex occupying the superior bank of the Sylvian sulcus in macaque monkeys (Macaca mulatta and Macaca fascicularis), but their functional significance is uncertain. The objectives of the present study were (i) to establish criteria for identification of certain prominent transitions in cytoarchitecture within the rostral part of the second somatic sensory cortical projection field (S-II/r), and (ii) to obtain neurophysiological data that would provide information about the functional meaning of these transitions. In neurophysiological mapping experiments, we determined the receptive field locations and response properties of single neurons isolated during microelectrode penetrations that crossed the boundaries of interest. The information obtained was plotted along the electrode tracks identified in serial sections from each experimental brain. The boundaries between the hand representation and the neighboring representations of proximal body regions (arm and face) in S-II/r coincide with clearly visible cyto- and myeloarchitectonic boundaries. (In most oblique or coronal sections through S-II/r, there are at least two such boundaries, corresponding to the superior and inferior boundaries of the hand representation.) To obtain additional support for the existence of transitions in cortical architecture at the boundaries of the hand representation in S-II/r, the cortico-cortical connections of the regions in question were studied. Contralateral connections were identified by injections of HRP into functionally characterized (by single-neuron recordings) regions of the contralateral S-I and S-II/r; ipsilateral connections were identified by HRP injections placed in functionally identified regions of the ipsilateral S-I. The tissues were processed using the Hanker-Yates procedure. Analyses of the distribution of labelled cells revealed that (i) while neurons within the hand area of S-II/r do not send axons to the opposite S-I or S-II/r, many neurons in this area send axons to the ipsilateral S-I hand representation; and (ii) the boundaries of the acallosal S-II/r area determined by retrograde labelling correspond precisely with the boundaries of the hand area as determined neurophysiologically. 2401 LOCALIZATION OF LARYNGEAL AFFERENTS IN THE CAT NODOSE AND CERVICAL SYMPATHETIC GANGLIA AS DETERMINED BY HRP AND FLUORESCENT DYE TRACER TECHNIQUES. G.E. Lucier and J.O. Dostrovsky. Faculties of Dentistry and Medicine, University of Toronto, Toronto, Canada M5G 1G6.

Previous electrophysiological studies (Mei, N. Exp. Brain Res. 11: 465, 1970; Sessle, B.J. Brain Res. 53: 333, 1973) have suggested that the superior laryngeal nerve (SLN) cell bodies are mainly concentrated in the region of the entrance of the SLN to the nodose ganglion. In order to determine anatomically whether there is a specific localization within the ganglion of SLN cell bodies axonal transport techniques employing fluorescent dyes and horseradish peroxidase (HRP) were used. In adult cats anesthetized with ketamine approximately 1 µl of 2.5% 4', 6-Diamidino-2-phenyl indol·2HCl (DAPI) - 10% Primuline in saline was injected into the right SLN, the nerve crushed at the injection site, and the animals allowed to recover. Four to five days later the animals were perfused with 10% buffered formalin and the nodose and superior cervical ganglia (SCG) removed. Frozen sections of the ganglia were cut at 30 µ and mounted on untreated slides. Sections were observed under a fluorescent microscope using a 360 nm excitation wavelength (van der Kooy, D. et al. Brain Res. 158: 189, 1978). Cell bodies containing DAPI-Primuline could be easily distinguished from the dark background by their blue fluorescence. Labelled cells were maximally concentrated at the rostral end of the nodose ganglion and extended caudally along the border of the SLN entrance region. In the extreme rostral end single and small groups of labelled cells were seen surrounded by axons of the vagus nerve. Fluorescent cells were also present in the SCG and although more sparse and scattered tended to be localized unilaterally along the periphery of the ganglion. Injection of HRP into the laryngeal wall resulted in a similar distribution of HRP-labelled cell bodies in the nodose ganglion. These studies indicate that the cell bodies of SLN are localized within specific regions of the nodose and cervical sympathetic ganglia.

2402 SOMATOTOPIC ORGANIZATION OF TRIGEMINAL SENSORY NUCLEI. Carl F. Marfurt* (SPON: Louis Misantone). Department of Anatomy, Temple University, Philadelphia, Pennsylvania 19140.

Central connections of sensory trigeminal nerve branches were identified in the cat trigeminal brainstem complex (main sensory and spinal trigeminal nuclei). In separate animals, the frontal, infraorbital, or mental nerve was cleanly transected and anchored in HRP-filled microtubing (50%, Boehringer-Mannheim). Forty-eight to ninety-six hours postoperatively, the animals were perfused according to the methods of Rosene and Mesulam (JHC, 1978). The tissue was reacted with tetramethylbenzidine (TMB), mounted on slides, and viewed, unstained, under darkfield microscopy for the presence of HRP reaction product.

Retrograde transport of HRP in transected fibers of the frontal, infraorbital, and mental nerves, respectively, labeled parent cell bodies in the anteromedial, intermediate, and posterolateral regions of the ipsilateral trigeminal ganglion. Transperikaryonal transport of HRP was detected within the central processes of these primary trigeminal neurons and was used to trace their terminations in the trigeminal brainstem complex. These central processes terminated somatotopically in the main sensory and spinal nuclei, with the mental nerve fibers terminating most dorsally, frontal fibers most ventrally, and infraorbital fibers primarily in an area between the latter two. The infraorbital nerve fibers were present in greater numbers and projected in modest amounts to the dorsal and ventral areas of the main sensory and spinal nuclei.

Labeled fibers from all three nerves terminated throughout the rostrocaudal extent of the trigeminal brainstem complex. However, fibers terminated in greater numbers in the main sensory nucleus and the rostral part of pars caudalis. Labeled processes or terminals could be found in the marginal, substantia gelatinosa, and magnocellular layers of pars caudalis but were most numerous in the magnocellular layer. Few labeled fibers could be identified below the first cervical segment.

Individual fibers entering the trigeminal sensory nuclei were occasionally observed coursing within intranuclear fiber bundles. However, the majority of entering fibers were seen in relation to, and presumably terminating in, areas containing nerve cell bodies. No labeled fibers were seen passing to the contralateral trigeminal complex.

Central connections of other branches of the trigeminal nerve are currently under investigation in this laboratory in an effort to refine our knowledge of somatotopic organization in the trigeminal brainstem complex. (Supported by Biomedical Research Grant RR054)

2403 FUNCTIONAL PLASTICITY IN THE CAT SOMATIC SENSORY-MOTOR CORTEX (SmI) DURING REVERSIBLE EPIDURAL ANESTHETIC BLOCKS. Jacqueline Metzler, Philip S. Marks* and Joel Ira Franck*[1]. Dept. Neurosurgery, Yale Univ. Sch. Med., New Haven, CT 06510.

The extracellular responses of single units in SmI of 4 awake, paralyzed, adult cats under N_2O analgesia were examined before, during and after short-term, reversible epidural anesthetic (bupivacaine) blocks of the L4-L5 dorsal roots. Chronic recording chambers were implanted over the left SmI and units were isolated in the rostral-medial region, the region receiving afferent projections from the contralateral upper hind limb. The somatotopic representation and response properties of the 213 units sampled in the control preparations were similar for all 4 cats and in general agreement with the results of other studies.

The 106 units studied during the subsequent blocking experiments all had receptive fields (RF's) on the upper right hind limb. Of these, 59 (56%) failed to respond to any mechanical peripheral stimulation while the epidural anesthetic was in effect. Most of these latter units were activated by cutaneous stimulation (hair movement or light touch) before and after the blocks. The remaining 47 units (44%) continued to respond during the anesthetic blocks, but with new RF's and, sometimes, to different subclasses of stimulation. These new RF's usually appeared on the abdomen or foot within 15 to 20 min after the injection of the anesthetic. Three cells had double RF's with separate excitatory fields on the foot and abdomen. The pre-block characteristics of each unit returned within 2 to 4 hrs as the epidural anesthetic wore off. Mechanical stimulation of the area of the new RF did not influence the cell's activity before and after the blocks were in effect. The response properties of the cells driven by stimulation of new body regions during the blocks differed from the pre- and post-block characteristics in several ways: (i) the responses frequently habituated to repetitive (>1/sec) stimulation; (ii) modality specificity was not always preserved; i.e., units initially classified as "cutaneous" sometimes became "deep", requiring strong mechanical stimulation to drive them; and (iii) RF sizes and shapes were not as stable and uniform.

The immediacy and reversibility of the observed effects rule out sprouting or other growth processes as an explanation. They do suggest that afferents from adjacent body areas exist in close proximity to a particular cell but that only some of these afferents are functionally effective in the unblocked state. An analogous explanation has been offered for similar effects observed in the spinal cord and dorsal column nuclei (Wall, 1977).

2404 FUNCTIONAL CHARACTERISTICS OF NEURONS IN THE TRIGEMINAL NUCLEUS CAUDALIS-CERVICAL DORSAL HORN TRANSITION ZONE. S.G. Nord and D.E. Rolince*. Dept. of Neurology, Upstate Med. Ctr./SUNY, Syracuse, N.Y. 13210.

We demonstrated previously in the cat that afferents from the three trigeminal divisions and from the C_2 and C_3 dermatomes project to a single population of neurons in the dorsolateral gray matter of the medullary-spinal cord transition zone (Nord, S.G. et al , Neurosci. Abstr., 1978, 4: 556). The present experiments were undertaken to extend these findings. A region of the zone extending from 5.1-8.5 mm caudal to the obex was explored in the monkey for neurons which responded to mechanical stimulation of the face and body. In general, microelectrode penetrations were made at, or just rostral to, levels at which the C_2 dorsal roots could be seen entering the spinal cord. The locations of selected cells were marked electrolytically. The great majority of the neurons were localized histologically in laminae IV-VI. Although some responded only to noxious stimulation and others to light touch, more (63%) were of the "wide dynamic range" type, responding differentially to variations in stimulus intensity. The majority of the neurons (62%) had receptive fields which lay entirely within the NV distribution although the proportion of such units decreased with distance from the obex. These fields were innervated predominantly (89%) by afferents from the ophthalmicand maxillary divisions and all but one were restricted to the intermediate and peripheral zones of the classical onion-skin facial pattern. An additional 29% of the neurons had fields which consisted of contiguous trigeminal and cervical areas. These usually consisted of either ophthalmic division-dorsal C_2 or mandibular division-ventral C_2/C_3 combinations. A relatively small proportion of cells (9%), which increased with distance from the obex, had exclusively segmental fields. These typically were comprised of portions of the C_2 and/or C_3 dermatomes. No sharply defined modality or somatotopic organization was observed within the region explored. Our results reveal that a substantial, loosely organized pool of neurons in the monkey nucleus caudalis-cervical dorsal horn transition zone receives projections from both upper cervical and (predominantly) posterior trigeminal regions. They also confirm our previous findings in the cat and they support our proposal that this neuronal pool mediates an overlap of trigeminal and cervical sensation which is seen clinically in man and which has been demonstrated experimentally in the monkey.

Supported by NINCDS grant 10814.

2405 THALAMO-CORTICAL INTERCONNECTIONS OF THE SOMATIC FIELD OF THE PROSIMIAN, GALAGO SENEGALENSIS. G.R.Penny* and R.S.Nowakowski* (SPON: I.T. Diamond). Dept. Psychol., Duke Univ., Durham, NC 27706.

The neocortex of Galago can be divided into three sensory fields, visual, auditory and somatic (Diamond, 1979), each of which can be subdivided into several cytoarchitectonic areas. The somatic field consists of Brodmann's area 4, a premotor area, a koniocortical area, and a belt between area 4 and the koniocortex. We have studied the thalamocortical and corticothalamic projections of single subdivisions of the somatic field by making small iontophoretic injections of horseradish peroxidase (HRP) or a mixture of tritiated leucine and proline.

The principal finding is that the labeled cells or terminals in the thalamus are distributed in bands which cross nuclear borders. The shape and position of the bands are a function of the cortical area injected. Each pattern involves at least one of the traditional relay nuclei (ventral lateral or ventral posterior) and extends into one or more of the intralaminar nuclei (central medial, central intralaminar, central lateral, centre median, paracentral or parafascicular). In many cases the band extends rostrally into ventral anterior and/or caudally into the posterior group. For example, injection of HRP into the face area of koniocortex leads to a band of labeled cells beginning rostrally in VPi and VPM and continuing dorsocaudally through VPM and VPs into CIN and Po. One branch extends from the main band medially through VM into Pc and Ce. A similarly placed amino acid injection shows that the thalamocortical and corticothalamic projections are reciprocal. Injection of HRP into area 4 labels a band of cells beginning rostrally in VL and extending caudally into rostral VPL and the intralaminar nuclei. One branch extends medially along the ventral surface of the ventral group into the zona incerta. The banding pattern produced by injection of tritiated amino acids into area 4 is remarkably similar, except that the band contains areas of heavy label in VL and CIN which are connected by thinner regions of lighter label. HRP injections confined to either the superficial or deep layers of somatic cortex and injections of HRP or tritiated amino acids into the thalamus show that different nuclei in the somatic thalamus receive from and project to different layers of the cortex. For example, VP receives fibers from layer VI and projects to layer IV, whereas CM receives fibers from layer V and projects to the layers superficial to IV.

These results confirm the generalization, which has emerged from similar studies of the auditory and visual fields, that each cortical area receives fibers from and projects to several thalamic nuclei and that the layer of origin of the corticothalamic projection and the layer of termination of the thalamocortical projection are distinct for different thalamic nuclei.

2406 RESPONSE OF THALAMIC NEURONS TO THERMAL STIMULATION OF ORAL-FACIAL REGIONS IN THE CAT. D.A. Poulos, E.L. Auen, H. Hirata and J.T. Molt, Dept. of Anatomy and Div. of Neurosurgery, Albany Medical College, Albany, N.Y. 12208.

Recordings of extracellular discharges in response to cooling of trigeminal peripheral receptive fields (PRFs) were obtained from neurons located within the thalamic nucleus ventroposterior medialis (VPM) in urethane-anesthetized cats. Two types of thermally responsive neurons were encountered. One type (T units) had thermal response characteristics identical to those of "typical" specific cold units identified in peripheral nerve and in our earlier studies of the marginal zone in the cat spinal trigeminal nucleus. T units, (1) displayed ongoing temperature dependent activity over a wide range of temperatures held constant (45-9°C), (2) responded to each of a series of rapid cooling steps below 35°C with a dynamic increase in rate of firing, (3) responded to step-like changes in the warming direction with a transient decrease in activity and (4) were insensitive to mechanical deformation of their PRFs. The second neuronal type (T+M units) had thermal response characteristics that were indistinguishable from those of specific cold units but displayed in addition, a responsiveness to mechanical deformation of their PRFs. The mechanical sensitivity of T+M units varied from those requiring only light brushing of their PRFs (which were contiguous with their thermal fields) to those requiring firm pressure or stretch. While over 100 thermally sensitive cells were identified, 39 units (25 T, and 14 T+M) were held for sufficient time to allow detailed study. 80% of the cells within the zone of VPM explored had ipsilateral PRFs. Most PRFs were small (1-2mm^2) with the exception of those located on the proximal surface of the tongue which measured up to 3 x 10mm. Response latencies to percutaneously applied electrical stimuli averaged 16.6 msec consistent with an A delta fiber input. Two results obtained in the present study differ from our observations made within the marginal zone of spinal V. First, the thalamic T units all had "typical" response profiles whereas 3 types of specific T units were seen in medulla e.g., typical units, primarily static, and primarily phasic units. It is possible that the primarily static and primarily phasic medullary unit types project either to a region of thalamus not explored and/or to other CNS structures. Secondly, the T+M units described here were not observed in medulla. They may be located within a medullary region not explored or alternatively, thalamic T+M units may represent a convergence of specific thermal and specific mechanical inputs at the thalamic level. The thalamic neurons described in the present study appear capable of providing precise and specific information about the extent and location of facial skin cooling. Supported by NIH grant NS11384.

2407 EFFECTS OF MECHANICAL STIMULUS FORCE ON DISCHARGE OF RACCOON GLABROUS SKIN SLOWLY ADAPTING CUTANEOUS MECHANORECEPTORS. Benjamin H. Pubols Jr., Christine H. Maliniak*, and Ann F. Corson*. Department of Anatomy, College of Medicine, Pennsylvania State University, Hershey, Penna.

When a mechanical stimulus produces a constant displacement of raccoon glabrous skin, concommitant reactive force reaches its peak just as the controlled static displacement is achieved, and then declines rapidly to approach a steady level after 20-40 sec. In contrast, when a constant force is applied, skin displacement may continue to increase over a period of several minutes. Upon stimulus retraction, several minutes are also required for the skin to return to its original resting position. Skin displacement is adequately described as a power function of applied force, with exponents < 1.0, over the force range 1-20 g, both initially and 20 sec after static force onset. Within this force range, displacements of 50 to more than 2000 μ are generated.

To study the role of force in determining slowly adapting (SA) mechanoreceptive afferent fiber discharge, individual median nerve fibers were isolated by microdissection in 10 sodium pentobarbital anesthetized raccoons.

The median absolute force threshold was 560 mg (range = 70-1270mg), while the median absolute displacement threshold was 20 μ (range = 5-185 μ). Absolute force and displacement thresholds were positively correlated (N = 27; P < .01).

For most moderately slowly adapting (MSA) and very slowly adapting (VSA) units (see Pubols, B., and Pubols, L., J. Neurophysiol., 1976, 39, 773-787), the decline in discharge rate over time (adaptation) is less with constant static forces than with constant static displacements.

Static forces of 1-20 g were applied at a constant rate of 10 mg/msec, and discharge rate was analyzed during the measurement period 100-500 msec following static force onset. Linear, logarithmic, and power functions were fit to the stimulus-response data of 10 MSA and 6 VSA units. For a majority of MSA units a power function (exponents between 0.62 and 1.23) provided the best fit (highest r), while for a majority of VSA units, a logarithmic function provided the best fit.

Results of the present investigation indicate that static discharge of glabrous skin slowly adapting cutaneous mechanoreceptors is in part dependent upon the viscoelastic properties of skin, and suggest that force may be a more potent variable than displacement in determining the behavior of such receptors. (Supported in part by research grant NS-13418, USPHS).

2408 SYMPATHETIC MODULATION OF SENSITIVITY IN CAT CUTANEOUS MECHANORECEPTORS. William J. Roberts and Joseph P. Pierce*. Neurological Sciences Institute, Good Samaritan Hospital & Medical Center, Portland, Oregon 97209.

Sympathetic efferent control of afferent activity has been studied in two classes of cutaneous mechanoreceptors in anesthetized cats; "type II" receptors and G hair receptors. Single units were functionally identified and then stimulated mechanically with a solenoid-driven probe to establish a baseline response. During this mechanical stimulation the sympathetic trunk was stimulated electrically and any sympathetic influence recorded either as a change in activity unrelated to a constant stimulus amplitude or as a change in stimulus intensity required to maintain a constant level of activity.

Type II receptors most commonly showed a marked increase in tonic discharge but no change in sensitivity to mechanical stimuli. This increased activity was often maintained throughout 3 min of sympathetic stimulation, although some variation was seen between units. Sympathetic-induced changes in the sensitivity of G hair receptors were related to the velocity sensitivity of individual units. The most rapidly-adapting (G_1) were generally desensitized, while the least rapidly-adapting (G_2) were sensitized. Intermediate units (G_I) were least affected. The measured changes in sensitivity of affected units were commonly on the order of 10-30% of the unconditioned threshold, although some were much larger. Sympathetic activity thus appears to result in a shift in the sensibility of G hair receptors, enhancing the detection of slower hair deflections relative to rapid deflections. As with most of the "special" senses previously tested, cutaneous sensibility in mammals is now demonstrated to be subject to efferent control.

2409 DIENCEPHALIC PROJECTIONS OF THE PONTINE RETICULAR FORMATION. Richard T. Robertson. Department of Anatomy, College of Medicine, University of California, Irvine, CA., 92717.

Ascending projections of the pontine reticular formation were studied in the cat with autoradiographic techniques. Small injections of ^{3}H-leucine were placed in either the rostral (n. reticularis pontis oralis) or caudal (n. reticularis pontis caudalis) divisions of the large celled pontine reticular formation. Pathways of ascending fibers and patterns of termination were studied in sections cut in the transverse or sagittal planes.

Efferent projections from both rostral and caudal pontine regions ascend to the caudal diencephalon and appear to bifurcate into two branches, as has been described previously. A dorsal branch terminates in the intralaminar nuclei of the dorsal thalamus, and a ventral branch terminates in the subthalamic region. The relative densities of these two general regions of termination, however, vary with the injection site. Fibers from the rostral pons project primarily beneath the dorsal thalamus, and terminate throughout the zona incerta, the fields of Forel, and in the ventral part of the thalamic reticular complex. Substantially fewer labelled fibers appear to terminate in the dorsal thalamus, but terminal sites include the centre median, parafascicular, paracentral, central medial and central lateral nuclei. Termination is prominant along the dorsal border between the dorsal medial and central lateral nuclei; the terminal field includes both nuclei.

Projections ascending from caudal pons, in contrast, terminate relatively heavily in the dorsal thalamus and sparsely in the subthalamic region. Termination sites in the dorsal thalamus include the centre median, central lateral, paracentral, and central medial nuclei. Most prominant termination occurs in the dorsal border zone of the dorsal medial and central lateral nuclei. Relatively few fibers project beneath the dorsal thalamus, but light termination is seen in the zona incerta, fields of Forel, and the ventral part of the thalamic reticular complex.

These data demonstrate that both rostral and caudal pontine reticular nuclei project to the thalamic intralaminar nuclei and the subthalamic region, but the relative densities of termination in each of these regions differ. Thus, these data suggest that the classical dorsal and ventral branches of the ascending reticular projections have largely separate origins.

Supported by NIH grants 12233 and 14267.

2410 ULTRASTRUCTURAL CHARACTERIZATION OF NORADRENERGIC AXONAL ENDINGS IN LAYERS I AND II OF THE DORSAL HORN OF THE MEDULLA. M.A. Ruda, B. Allen* and S. Gobel. NAB, NIDR, NIH, Bethesda, MD 20205.

Recent studies have drawn attention to the role of monoamines in the modulation of the response of nociceptive neurons in the dorsal horn. Previous experiments in our lab have characterized serotonergic (5HT) axonal endings in layers I and II of the dorsal horn of the medulla (DHM). The purpose of the present experiments was to similarly identify noradrenergic endings. Our approach accesses the ability of neurons which use NE as a neurotransmitter, to take up tritiated norepinephrine ([^{3}H] NE) at their axonal endings. Adult cats, pretreated with a monoamine oxidase inhibitor, were anesthetized with sodium pentobarbital and [^{3}H] NE (10^{-5}M) topically applied onto the DHM for 1 hr. In one experiment, 2 hrs prior to the [^{3}H] NE application, a serotonin neurotoxin (10^{-5}M 5,6 dihydroxytryptamine (5,6 DHT)) was topically applied for 1 hr. 5,6 DHT causes degeneration of 5HT axonal endings. Thirty min after application of the [^{3}H] NE, the cats were perfused and the DHM processed for autoradiography. Analysis of light microscopic autoradiographs demonstrated an accumulation of [^{3}H] NE in layers I and II. In EM autoradiographs, two categories of labeled axonal endings were identified: dome-shaped endings which form synapses on a single postsynaptic structure and scalloped endings which form synapses on several postsynaptic structures. These categories were further divided into five types based on morphological criteria. The same five types of labeled endings were observed in the experiment combining 5,6 DHT and [^{3}H] NE and in the experiment in which only [^{3}H] NE was used as a marker. Three types of dome-shaped endings were found in both layers I and II and were distinguished by the presence of either pleomorphic, small oval or large oval agranular vesicles. They formed mainly asymmetrical synapses on dendritic spines and shafts and occasional axosomatic synapses. In several cases, the same dendrite received synapses from both a degenerating 5HT ending and an [^{3}H] NE labeled ending. One type of scalloped ending was found both in layers I and II and contained large oval agranular vesicles while a second type was found only in the deeper part of layer II and contained small oval agranular vesicles. Both scalloped endings formed asymmetrical synapses on dendritic shafts and spines. The presence of [^{3}H] NE labeled axonal endings in layers I and II of the DHM suggests that NE afferents have access to both the projection neurons in layer I and the interneurons in layer II. The observation of both 5HT and NE endings synapsing on the same dendrite further suggests that both monoaminergic systems modulate the output of layer I projection neurons through similar mechanisms.

2411 COLLATERAL BRANCHING OF CORTICAL NEURONS TO SPINAL CORD AND MEDULLA IN CAT AND RAT. Aldo Rustioni and Nancy L. Hayes, Depts. of Anat. and Physiol., and The Neurobiology Program, UNC, Chapel Hill, NC, 27514. (Spon: R.A. King)

Collateral branching of cortical neurons projecting to the dorsal column nuclei (DCN) and spinal cord has been investigated with a double-labeling technique, using HRP and ^{3}H-apo-HRP as distinguishable retrograde tracers (Hayes and Rustioni, 1978). In cats and rats, one tracer was injected in the brachial enlargement of the spinal cord, and the other tracer was injected in the ipsilateral dorsal medulla. In rats, cervical spinal injections through the dorsal columns, in which the corticospinal tract travels, presumably allowed retrograde labeling of corticospinal neurons projecting to both cervical and lumbar levels, while in the cat the same injection avoids damage to corticospinal fibers descending to lower levels in the dorsal part of the lateral funiculus. Therefore, in one cat the spinal injection was made in the lumbar enlargement. All animals were sacrificed by perfusion with mixed aldehydes after 48 hours. One mm thick slabs through the sensorimotor cortex were processed with Hanker-Yates substrate for histochemical visualization of HRP, embedded in paraffin, sectioned at 15 um, and processed for autoradiographic demonstration of ^{3}H-apo-HRP.

In the rat, corticospinal neurons were concentrated in layer V in a band which extended approximately 7 mm along the dorsomedial aspect of the contralateral hemisphere (areas 3,4,6 and 7 of Krieg). Neurons labeled by injections in the dorsal column and trigeminal nuclei were found throughout layer V along a similar rostro-caudal extent and were most numerous in more lateral parts of the hemisphere. While the locations of the cells of origin of these two descending pathways were, for the most part, segregated (in part due to the large face representation in the lateral hemisphere of the rodent), many neurons double-labeled by both injections were consistently found intermingled with corticospinal neurons throughout their extent. That is, in regions where corticospinal and corticomedullary neurons are intermixed, the majority of corticomedullary neurons also project to the spinal cord by way of collateral branching.

In the cat, neurons labeled by the medullary and spinal injections were layer V pyramids located throughout all cytoarchitectonic subdivisions of the somatosensory cortex, with a completely overlapping distribution. However, neurons with collateral projections to both spinal cord and medulla were relatively sparse and were observed only in areas 3 and 4.

2412 CHANGES IN MOTOR-SENSORY CEREBRAL CORTEX CELLS FOLLOWING SYSTEMIC NALOXONE INJECTION. M.Y. Spiegelstein* and C.F. Tyner, Dept. Medical Neurosciences, Walter Reed Army Inst. Res., Wash DC 20012.

We studied single neurons extracellularly in forepaw postcruciate (4ℊ) cortex in chloralose-anesthetized cats and held blood gases normal. Cells were hunted in some cats with 30 mA, 1/sec shocks alternating between the central footpads of the forelimbs, and in others with innocuous mechanical forelimb stimuli. Cells were classed as S (small, contralateral forelimb [CF] receptive fields), M (whole-body fields), or I (responsive to body areas away from the CF topographic focus but either unresponsive to all CF stimuli or responsive to weak but not strong CF stimuli [Tyner and Miller, 1977. Neurosci. Abstr. 3:72]). S/M/I ratios in a reference sample of 650 cells were 9/8/3.

In a new cell sample of 90, S/M/I ratios of 1/17/2 were found after i.v. naloxone injection; 11 cells were studied before and after naloxone injection, and the remainder hunted and classified after injection. Within 0.5-2.0 min. of injection, electrically-determined CF thresholds of S neurons began to decrease, up to 50%, and responses to electrical or innocuous stimulation of other limbs began to emerge. S cells thus changed to "M" were held for up to 1.5 hrs. without reverting to the small-field configuration. I cells initially responsive to weak but not strong CF stimuli acquired responsiveness to strong CF stimuli after naloxone, becoming indistinguishable from M cells; when hunting in cats previously given naloxone, these I cells were not found. I cells initially unresponsive to all CF stimuli remained so after naloxone injection, but the powerful inhibition of other inputs to these cells, evoked by CF stimuli, was greatly reduced in amplitude and duration. We have used naloxone doses of 0.4-1.0 mg/kg principally, but have seen effects, including S to "M" conversion, with doses as low as 0.1 mg/kg.

After correcting for microelectrode sampling bias (Towe and Harding, 1970. Exp. Neurol. 29:366), a pericruciate 4ℊ cell sample contains mostly S neurons; we conclude that most 4ℊ S cells probably receive sensory input from the entire body surface. The mechanism for our result may be similar to that for the finding of Satterthwaite et al (1978. Exp. Neurol. 60:603) that 70% of pericruciate S cells receive some type of subthreshold influence from the rest of the body. We are unsure whether naloxone-induced S to "M" conversions will occur in post-dimple SI where those authors found subthreshold influences on only 25% of S cells. It is also unclear whether the unmasking of wide-field input by naloxone should be interpreted in the context of pain/stress and the antagonism of endorphins, or whether it must be regarded as a less specific release from inhibition, perhaps reflecting an interaction with chloralose.

2413 MAGNIFICATION, RECEPTIVE FIELD AREA AND "HYPERCOLUMN" SIZE IN SOMATOSENSORY CORTEX OF THE OWL MONKEY. M. Sur*, M.M. Merzenich*, and J.H. Kaas. Departments of Psychology and Anatomy, Vanderbilt University, Nashville, Tennessee and Coleman Memorial Laboratory, *University of California, San Francisco, California.*

Several features of the two complete and separate body surface representations within Areas 3b and 1 of owl monkeys (Merzenich et al., J. Comp. Neur., 181: 41, '78) have been quantified. First, magnification factors have been calculated for the two representations. The magnification factors for the same body part in both representations are similar, with somewhat greater magnifications for most body parts in Area 3b. Within each representation, cortical magnification varies greatly across different body regions. For example, both the glabrous hand and foot representations occupy nearly 100 times more cortical tissue per unit of body surface area than either the trunk or upper arm representations in both Areas 3b and 1. Within the representations of the hand digits inverse magnification is linearly related to distance from the digit tip. By interpreting the magnification function for the digits as the Jacobian of the mapping of the digits on cortex, an equation describing the mapping is derived. Second, receptive field size has been shown to be inversely related to magnification factor. Thus, mean receptive field sizes are nearly 100 times larger for the trunk than for the glabrous hand, and receptive fields are generally larger for the same body part for Area 1 than for Area 3b. Specifically, within the hand representations in Areas 3b and 1, receptive field areas over the digit phalanges vary linearly with inverse magnification. Thirdly, receptive field overlap has been related to cortical distance between recording sites. Measurements of the percentage of overlap of pairs of receptive fields and the surface distance between cortical recording sites were made for the glabrous hand and foot, the arm and the trunk. Amount of overlap of receptive fields is linearly related to cortical distance; receptive fields for recording sites more than 500-600 microns apart fail to overlap, regardless of position on the body surface. The independence of the receptive field overlap and cortical distance relation from body part is a consequence of the inverse relation between cortical magnification factor and receptive field size. Since receptive field overlap for neurons must be considered in all cortical directions, it follows that a surface area of cortex approximately 1-1.5mm in diameter would contain all neurons with receptive fields overlapping a particular receptive field any place on the body surface. It may be useful to consider such an area of tissue as a basic processing unit for somatosensory cortex, much like the "hypercolumn" proposed for primary visual cortex (Hubel and Wiesel, J. Comp. Neur., 158: 267, '74).

2414 VISCOELASTIC PROPERTIES OF SKIN AND THE ADAPTATION OF THE TYPE I MECHANORECEPTOR IN THE CAT. Daniel N. Tapper, Thomas K. Baumann* and Leonard M. Smithline*. Sections of Physiology and of Neurobiology and Behavior, Division of Biological *Science and College of Veterinary* Medicine, Cornell University, Ithaca, N.Y. 14853.

The static and dynamic mechanical behavior of the Haarscheibe (Hs), the epithelial structure containing the Type I slowly adapting mechanoreceptor of hairy skin, and of the skin alone was studied in 14 anesthetized adult cats by recording the reactive force generated by the tissue in response to indentations by a stylus of a mechanical stimulator. A new mechanical stimulator with force monitoring, based on a galvanometer scanner and a highly sensitive force-measuring system, was built for this study. By use of this device the reactive forces of the tissues to the mechanical stimuli could be monitored, thus gaining a better estimate than previously available of the actual stimuli applied to the receptor. The Hs and the adjacent skin were found to have similar mechanical characteristics. They both displayed load relaxation, a property typical of viscoelastic materials, and a nonlinear load-deformation relationship including a hysteresis. The mechanical response of the tissue was found to depend on the previous history of loading. This appears to be a long lasting effort of the order of minutes. An attempt was made to relate the properties of the Hs, acting as a mechanical filter, to the characteristics of the neural discharge of the Type I receptor. Mechanical factors appear to contribute significantly to the adaptation of the Type I receptor. (Supported by USPHS Grant 07505).

2415 REINNERVATION OF GLABROUS SKIN IN THE HAND SUBSEQUENT TO NERVE TRANSECTION AND REPAIR. J.K. Terzis and R.W. Dykes. Microsurgical Research Laboratories, Royal Victoria Hospital, McGill University, Montreal, Quebec.

The left ulnar nerve was cut at the level of the wrist in five female baboons (Papio anubis). Using sterile surgical techniques the transected nerve was repaired under magnification and using microsurgical techniques. The contralateral unoperated ulnar nerve served as the control. The animals were allowed to survive from one to five months. At monthly intervals the functional properties of the regenerating mechanoreceptive afferent fibers reinnervation the glabrous skin on the ulnar side of the previously denervated hand were investigated. The data were compared to results from normal skin and from skin subsequent to nerve crush. The electrophysiological techniques employed in this study included electrical stimulation of the ulnar nerve at the wrist, and single fiber dissection of the ulnar nerve at the mid-arm level. This arrangement allowed rapid isolation and identification of a large number of single fibers. Once the latency of the afferent fiber was recorded, the hand was searched for its receptive field. Once identified, the receptive field was demarcated under magnification and drawn on enlarged photographs of the hand. Areas of highest sensitivity were outlined. Over 600 single fibers were isolated from the repaired ulnar nerve. The results demonstrated that on the side of the nerve transection, (i) conduction velocities of the nerve fibers were significantly slower than the controls, (ii) receptive field size and shape, and areas of highest sensitivity were abnormal and this was maintained throughout the study period (contrary to findings after nerve crush), (iii) multiple receptive fields subserved by a single axon were a more common finding after nerve cut than after nerve crush, (iv) the response threshold and stimulus-response relation were altered, (v) there was a slow progression of reinnervation with time occuring in a proximo-distal direction. Contrary to findings in the study of crush injuries, there was no measureable reinnervation of glabrous skin at one month following nerve cut and repair.

These results provide insight into the basic processes underlying cutaneous reinnervation in the hand and contribute to an explanation of our clinical observations of altered sensibility subsequent to nerve injury and repair.

2416 VISION AND RECOVERY FROM DORSAL COLUMN NUCLEI LESION. T.A. Tran,* D.E. Teodoru,* and A.J. Berman. Department of Neurosurgery, V.A. Hospital, Bronx, N.Y. 10468.

Gilman and Denny-Brown (1966) reported that after dorsal column medial lemniscal system (DCMLS) interruption, blindfolded monkeys would no longer reach into extrapersonal space. Reaching movements made when vision was unobstructed were viewed as visual in origin and not indicative of somatosensory recovery. Many authors have challenged this view.

Four monkeys were trained to perform a variety of tasks involving reaching and manipulating objects and grasping small morsels of food while blindfolded. All the monkeys were overtrained. Two monkeys were kept in total darkness throughout overtraining and postoperative survival. Two were not light deprived. After DCN lesion, all monkeys were retested for 30 sessions. The dark-maintained monkeys achieved preoperative performance within 15 sessions. The monkeys maintained in light, on the other hand, failed to perform on any of these tests until placed in total darkness for 3 weeks and then retested. They then exhibited the same pattern of recovery as the dark-maintained monkeys.

The pattern of recovery in both groups followed the sequence: (1) reaching forward, grasping, and retraction of the hand to the mouth, irrespective of whether or not the hand had contacted the food; (2) reaching, followed by groping and palpation until the target was touched, followed by retraction of the hand to the mouth, regardless of whether food had entered the hand or not; (3) reaching, followed by manipulation of the food until it was successfully grasped, followed by retraction of the hand to the mouth, even if the food had meanwhile been dropped; and (4) reaching and retrieval of the food, with palpatory searching by the hand if the food was dropped before reaching the mouth. We interpret this recovery sequence to consist of the gradual introduction of tactile feedback into a preprogrammed movement.

We propose that after DCN lesion the informative quality of the residual somatosensory input is degraded. The brain therefore blocks this input's access to higher centers and depends on other modalities, e.g., vision, to guide movement. Thus, when the monkeys which were permitted vision were tested, they were incapable of using residual somatosensory feedback. Chronic blockage of vision postoperatively may force the brain to relearn the informative qualities of residual somatosensory feedback. This would explain why the dark-maintained monkeys reached into extrapersonal space whereas the light maintained animals failed to do so as was the case in the study reported by Gilman and Denny-Brown.

2417 PATTERNS OF REINNERVATION FOLLOWING REPLANTATION OF THE RABBIT EAR. B.G. Turnbull* and J.K. Terzis. Microsurgical Research Laboratory, McGill University, Montreal, Quebec.

Refinements in microsurgical techniques over the past decade have improved the surgical management of peripheral nerve lesions and have permitted replantation of free composite tissues. However, cutaneous reinnervation following replantation or nerve injury and repair often remains abnormal. The aim of this work was to replant composite tissue and to study the characteristics of the reinnervated mechanoreceptors physiologically at successive time intervals. The rabbit ear was chosen because the size of the supplying neurovascular bundle is comparable to nerves supplying the digits in man.

The right ears of 30 New Zealand white rabbits were replanted with microsurgical anastomoses of the central artery, vein and the greater auricular nerve. At various post-operative periods ranging from two weeks to eight months, the greater auricular nerve was re-exposed proximal to the nerve repair. Single fibres were isolated by dissection and their signals were studied using standard electrophysiological equipment. Once a single active unit was isolated, the ear was searched for the receptive field (RF). The size, shape and relative proportions of the several types of RF's were studied as a function of innervation age. The number of active areas within each RF was recorded as were details of its response characteristics. Finally, the conduction latencies of the fibres were obtained by percutaneous electrical stimulation.

Reinnervated RF's differed from normal fields by (i) being smaller and more irregular in contour, (ii) having fewer hairs innervated by a single nerve fibre, (iii) exhibiting changes in the relative population of guard hair units versus down hair units and by displaying multiple skin areas served by one fibre. Although both the size of the RF's, and the number of hairs capable of activating the fibre increased with time, reinnervated RF's seldom achieved normal dimensions, and irregularities in shape and high thresholds persisted. The mean conduction velocity (CV) of the regenerated nerve fibres also approached, but did not attain normal value up to the end of the study period.

Despite these differences from normal fibres it was observed that (i) submodalities of the reinnervated mechanoreceptors (down hair units v.s. guard hair units) were recognized even at early stages of reinnervation, when RF's were small and threshold high and, (ii) the relative populations of hair units approached normal values with time.

2418 VISUAL INPUT TO NEURONS IN THE CAT'S POSTCRUCIATE CORTEX. Tom O. Videen* (SPON: A. L. Towe). Depts. of Psychology and Physiology/Biophysics, Univ. of Washington, Seattle, WA 98195.

The sensitivity of neurons in the lateral postcruciate gyrus (contralateral forepaw focus of motor cortex) of chloralose anesthetized cats to visual and somatic stimuli was compared. Excitable cells were located using electrical stimulation of either the contralateral forepaw or the medial lemniscus, alternately with brief flashes of light (strobe lamp subtending approximately 23° in the central visual field, average luminance 2.5 log cd/m^2, background about -1 log cd/m^2, 3 mm diam. pupils).

Previous studies have claimed that only about one-fifth of the lateral postcruciate neurons respond to visual stimulation; most of the pericruciate visual neurons are reported to be concentrated more medially and rostrally. Of 114 excitable neurons in this study, 59% responded to light-flashes. All but one also fired to somatic stimulation. Mean latency to light-flashes was 43 msec. When the flash intensity was reduced, the response latency increased and the probability of firing decreased, falling to zero when an opaque filter was used.

When neurons were classified according to the size of their excitatory receptive fields, only 13% of those neurons excited (response probability, P≥0.3) by a single paw with no excitation (P=0) from other paws (*sa* neurons, n=24) were also excited by light-flashes, whereas 92% of those cells excited by all four paws (*m* neurons, n=38) also fired to light-flashes. Most cells excited by 2 or 3 paws (n=11) also fired to light-flashes. Some cells excited by medial lemniscus stimulation did not fire to any paw (n=5); these cells had small receptive fields on the contralateral forearm and none were excited by light.

When neurons were tested for subthreshold interactions, a facilitatory input from other paws was revealed in 6 of 15 *sa* neurons and from light in 6 of 16 nonvisual neurons. When completely tested neurons were reclassified using sub- and suprathreshold excitatory input, 94% of *m* neurons (n=48) and 33% of *sa* neurons (n=9) had excitatory visual input. All cells excited by 2 or 3 paws (n=14) were excited by light-flashes.

While the majority of neurons with excitatory visual input have large excitatory receptive fields, usually including all four paws, some visual cells have small somatic receptive fields. Two of these cells that had natural receptive fields limited to parts of the contralateral forepaw had short latency suppression from all other paws. Another cell that fired to light was suppressed by all 4 paws and by an auditory click. It is conceivable that the visual input to *sa* cells differs from that to *m* cells in some way that would be apparent with more specific visual stimuli.

2419 LOCALIZATION OF TOUCH ON GLABROUS SKIN FOLLOWING DORSAL COLUMN LESION IN A PRIMATE. Charles J. Vierck, Jr.[1] and Ruth Rand*. Dept. Physiol., Sch. Med., Univ. North Carolina, Chapel Hill, N.C. 27514.

Two Macaca nemestrina monkeys have been trained to identify the location of a tactile stimulus delivered to the glabrous skin of either foot. The monkeys initiate trials by pressing a lever and holding until a pulsatile tactile stimulus (10Hz) begins. Release of the lever within 1.5 sec of stimulus onset starts a response period in which a press of one of 6 buttons on a panel produces liquid reinforcement. On the panel surface facing the animal is an artist's rendering of the glabrous surfaces of a monkey's feet. One of several panels is selected for a daily session; the panels differ in the location of the six response buttons. Panel A, presented during preoperative training and early postoperative testing, has 3 buttons on each foot, located over the distal phalanx of the 4th toes, the middle of the soles and the heels. During blocks of 100 trials within sessions, three stimulus probes (1.5 mm diameter) are positioned over different combinations of locations on the feet that are represented by buttons on the panel, and the correct button response on each trial is defined by the location of the stimulator driven. For the combinations used with panel A, 2 monkeys have performed preoperatively at better than 95% correct button responses, and a left dorsal column (DC) lesion in one animal has deteriorated performance slightly at only one of the points (85% correct responses to stimulation of the ipsilateral mid-sole location). In addition, bar release latencies and button response latencies are unchanged by the lesion. The lesioned monkey has been trained postoperatively, using panel B, to respond accurately to stimulation of the distal pads of toes 2 or 4 or the base of toe 4 on either foot. There is no detectable ipsilateral deficit in performance on this panel. Thus, despite severe deafferentation of the distal extremity portion of SI cortex in monkeys by DC lesions, single stimuli to the feet can be quite accurately localized following DC section. Supported by grants NS 11132 and NS 14899.

2420 ACETYLCHOLINESTERASE STAINING OF BARRELS IN SOMATOSENSORY CORTEX: VIBRISSEAL COAGULATION AND COMPARISONS BETWEEN RAT AND MOUSE. Jacqueline V. Waldman* and Donald A. Kristt. Dept. Path., Johns Hopkins Univ. Sch. Med., Baltimore, Md. 21205.

There are unique neuronal clusters in primary somatosensory cortex (SmI) of rodent that receive the specific thalamocortical projection from the ventral basal complex. In previous work (Neurosci. Lett. 12, '79), it was shown that the barrel neuropil of postnatal rat (< 21 DPN) stained deeply for AchE. This staining consists of a "blush" presumed to be AchE positive fibers, which disappeared following cortical undercutting. In the present series of studies, answers to the following questions were sought. First, is this staining pattern present in the mouse (where the barrel centers are relatively cell sparse in contrast to the rat)? Using an AchE method described previously (J. Comp. Neurol. 1979), we noted conspicuous central staining of the barrels in postnatal mice without staining of the septae (and possibly the walls too). However, barrel staining was first observed at 14-16 days postnatally, in contrast to the rat, where it is first detectable at 3 days DPN. It is noteworthy that in mouse, the period 14-16 DPN corresponds to the onset of functional thalamocortical synapses in the barrels. The second question was: what effect would neonatal vibrisseal coagulation have on barrel staining? Previous workers have shown that this procedure produces fusion of the neurons from the cortical row of barrels which corresponds to the coagulated row of vibrissae. We found that following coagulation of row C vibrissea unilaterally, row C in PMBSF has become an oval mass of cells in Nissl stained sections; AchE staining is also altered. The third question was: what happens to the staining in adult rodent (in rat the blush disappears between 16-21 DPN)? In contrast to younger mice, animals 21 DPN and older show marked staining of the septae with a blush occupying the top 75-100 μm of the barrel. In adult rat, barrel centers are less well stained than the septae. In conclusion, although there are differences in barrel staining between rats and mice, the observations continue to support the hypothesis that the AchE-rich projection is derived from VBC thalamus. If this hypothesis can be verified, then it seems that in mouse VBC afferents do not possess sufficient AchE until synaptogenesis begins. This, in turn, would suggest that the AchE is, at least partially, related to neurotransmission. It would also suggest that in the mouse, the AchE is not related to catecholaminergic afferents, which appear in the barrel centers by 8 days PND. (The cell bodies and their processes in locus coeruleus contain considerable AchE in addition to their usual neurotransmitter, norepinephrine).

SPINAL CORD

2421 BENEFICIAL EFFECTS OF HIGH DOSE METHYLPREDNISOLONE ON RECOVERY FROM EXPERIMENTAL SPINAL CORD COMPRESSION. Douglas K. Anderson, Eugene D. Means, & Thomas R. Waters*. VA Hosp. & Depts. Physiol. & Neuro., Univ. Cinn., Col. Med., Cincinnati, OH. 45220

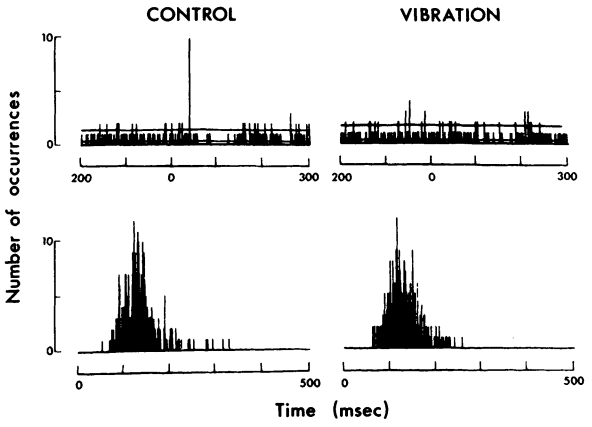
The efficacy of steroids in protecting the spinal cord (SC) from blunt trauma is problematic. Disparity in results may exist due to differences in (a) experimental animals (b) severity of injury (c) doses of steroids administered (d) techniques for evaluating neurological recovery, or (e) length of recovery period. The purpose of the present study was to determine the effectiveness of long-term, high dose methylprednisolone sodium succinate in ameloriating the effects of SC compression trauma. For this study immunized & conditioned female mongrel cats ranging in weight from 2.5 to 4.0 kg were anesthetized with pentobarbital sodium (30mg/kg ip). All cats were immobilized in a stereotoxic frame, a one-segment laminectomy performed at L2, injured & post-operatively treated as described previously. (J. Neurosurg. 44:715-722, 1976). The SC's of 23 cats were compressed with 170gms for 5 minutes. Starting 2 hrs post injury, 16 of these cats were given methylprednisolone (30mg/kg body wt) for 3 days, 15mg/kg body wt for the next 3 days & 7.5mg/kg body wt. for the final 3 days of a total 9 day regimen. The remaining 7 cats served as injured but untreated controls. Neurological function was evaluated in all cats bi-monthly for a 2 month recovery period after which they were sacrificed by intracardiac perfusion of 10% formalin & the SC's removed for histologic examination. Our neurologic evaluation procedure is based on a 16 point scale with 16 being normal. Methylprednisolone treated cats showed significantly ($p<0.001$) earlier recovery (total score: 5.9 ± 0.3 & 11.4 ± 0.3 at 2 weeks and 1 mo. respectively vs 3.7 ± 0.4 & 8.0 ± 1.0 at the same time intervals for controls) & more complete recovery (total score: 14.3 ± 0.3 at 2 mo. vs 11.1 ± 0.5 at 2 mo. for controls) than control animals. Histologically, SC's from steroid treated animals consistently showed greater tissue preservation than those from controls. Our data clearly shows that long term high dose methylprednisolone treatment is effective in protecting feline SC tissue from post injury auto-destruction. However, its potency in this regard may depend on the extent to which methylprednisolone reaches the injury site. We suggest that this is a function of the level of post injury SC blood flow which has been shown to be inversly related to the magnitude of compression (J. Neurosurg. 45:660-676, 1976). Supported in part by the VA and grants from the Paralyzed Veterans of America & the Upjohn Co.

2422 PRESYNAPTIC INHIBITION IN THE HUMAN SPINAL CORD. Peter Ashby and Molly Verrier*. Playfair Neuroscience Institute, Toronto Western Hospital, Toronto, Canada. Dept. Med., University of Toronto, Toronto, Canada.

Single, repetitively discharging, human motoneurons show a brief increase in firing probability in response to homonymous group 1 volleys. This is of appropriate latency to represent the monosynaptic Ia EPSP.

This effect of the group volleys can be blocked by continuous 60 Hz vibration of the limb even though excitability of the neuron, estimated from its mean firing rate, is unchanged.

This may be an example of presynaptic inhibition in man.



2423 DISTRIBUTION OF MET-ENKEPHALIN, SUBSTANCE-P AND SOMATOSTATIN IMMUNOREACTIVITY IN THE SPINAL CORD DORSAL HORN AFTER HEMISECTION IN THE RAT. M.S. Beattie, J.C. Bresnahan, R. Ho and F. Liuzzi*, Dept. Anat., Sch. Med., The Ohio State University, Columbus, O., 43210.

Met-enkephalin (ENK), substance-P (SP) and somatostatin (SOM) -like immunoreactivities have been described in the dorsal horn of a number of species, and a role for these peptides in the transmission and modulation of nociceptive information has been postulated. In a preliminary attempt to assess the effects of chronic disruption of the descending components of the pain modulating system, we have evaluated the effects of thoracic spinal hemisection on the distribution of these peptides in laminae I and II of the rat spinal cord dorsal horn.

The indirect immunofluorescent and modifications of the indirect PAP techniques were employed to demonstrate ENK, SP and SOM immunoreactivities on semi-adjacent sections in animals allowed to survive 1, 3, and 5 days, and 3, 5 or 20 weeks following spinal hemisection. Cross reactivity tests and absorption controls demonstrated specificity of immunostaining for each of the antisera used.

The pattern of distribution in the superficial laminae of the dorsal horn was comparable to that reported by other authors for each of the three peptides. ENK, SP, and SOM immunoreactivities were observed in varicosities and terminals within both laminae I and II. Overlap between the distributions was substantial with ENK exhibiting the deepest penetration into the dorsal horn. Although consistent assymetries were observed between the two sides of the spinal cord, these differences were not consistently related to the surgical treatment. These results suggest first, that the majority of ENK, SP, and SOM immunoreactivities in laminae I and II is related to segmental systems in the spinal cord (i.e. dorsal roots and interneurons). Secondly, the results suggest that in the rat, unilateral disruption of descending systems does not produce a reorganization of these peptidergic systems of sufficient magnitude to produce obvious changes in their distribution as revealed by these immunohistochemical techniques. A report by Naftchi et al. (Brain Res., 153: 515-528, 1978) showing fairly dramatic changes in SP distribution following spinal transection in the cat, may be indicative of a species difference in this regard. Studies are currently underway to examine this possibility. (Supported by N.I.H. Grants NS-14457 and NS-10165.)

2424 SURAL NERVE INPUT TO THE DORSAL HORN IN NORMAL AND ACUTELY HEMISECTED CATS. Gene L. Brenowitz* and Lillian M. Pubols. Department of Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Axonal sprouting of dorsal root afferents is known to occur following partial hemisection of the spinal cord (Murray and Goldberger, J. Comp. Neur. 158:19-36, 1974). Our long term goal is to examine changes in cutaneous input to the dorsal horn correlated with this type of sprouting.

This report describes the distribution of dorsal horn neurons responding to electrical stimulation of the sural nerve in normal and acutely hemisected cats. The responses of single units and unit clusters in the L7 segment to electrical stimulation of the sural nerves and to natural tactile stimulation were studied in adult cats maintained on methoxyfluorane anesthesia, using platinum iridium microelectrodes. The dorsal horn was mapped bilaterally in a transverse, 2 dimensional grid of recording loci 0.2 mm apart mediolaterally and 100 μ or 200 μ apart dorsoventrally. Some cats received right (low thoracic or high lumbar) hemisections, sparing the dorsal columns, 2 or 3 days prior to recording.

Sites yielding reliable short latency ($\leq$ 5msec) responses to electrical pulses were clustered in the lateral one half of the dorsal horn, largely in laminae IV-VI. Natural receptive fields for penetrations containing loci responsive to nerve stimulation always included some part of the region extending from the heel to the ventral foot just above the base of digit 4. The region of the dorsal horn yielding longer latency (> 5msec) responses to sural nerve stimulation overlapped with that described above but was slightly larger.

In acutely hemisected cats it was more difficult to delineate natural receptive fields on the lesioned side due to an increase in spontaneous activity in the laminae responding to tactile stimuli. Our preliminary findings indicate, however, that there are no striking changes in somatotopy or in the location and extent of the region responsive to sural nerve stimulation as a result of hemisection.

2425 ULTRASTRUCTURE OF SYNAPTIC TERMINALS IN LAMINAE I AND II OF THE CAT SPINAL CORD AFTER ANTEROGRADE LABELLING OF DORSAL LATERAL FUNICULUS AXONS WITH HRP. J.C. Bresnahan and M.S. Beattie, Dept. Anat., Sch. Med., The Ohio State University, Columbus, O., 43210.

Axons descending from the brainstem raphe nuclei and adjacent reticular formation probably participate in the modulation of neuronal activity in the marginal layer and substantia gelatinosa of the spinal cord (laminae I and II). These fibers have further been shown to travel in the dorsal lateral funiculus (DLF) of the cord in rat, cat, monkey, and opossum. We have labelled axons in the DLF using anterograde injury-filling with HRP and examined the synaptic terminals of these fibers in laminae I and II.

Adult cats were anesthetized with sodium pentobarbital and maintained as described previously (Beattie et al., Brain Res., 153: 127-134, 1978). Microinjections of HRP were made in the DLF either hydraulically or iontophoretically; the damage done by the injection pipette was sufficient to produce considerable injury filling of axons which were confined to the DLF with little or no contamination of Lissauer's tract. Alternatively, a small cut in the DLF was made and dried pellets of HRP were introduced into the cut. Tissue was processed using DAB as the reaction substrate with cobalt chloride intensification. Survival time was from 18 to 24 hours.

With the light microscope, labelled axons within the DLF could be traced for 5-10mm caudal to the injection site. Many entered laminae IV-VIII in a dense projection presumably representing cortico-spinal, rubro-spinal, and other descending systems. A smaller number of relatively fine-caliber axons could be traced to laminae I and II with many exhibiting a transverse orientation capping the dorsal horn. Terminal and en passant swellings were easily visible. With the electron microscope, both small myelinated and unmyelinated axons were labelled with HRP in laminae I and II. The majority of synaptic terminals labelled with HRP contained round vesicles and a few dense core vesicles per profile. Additionally, small terminals containing only round vesicles were observed. Synaptic contacts were usually on dendritic shafts, but contacts with vesicle-containing profiles were also seen. A small number of terminals with similar morphology were degenerating caudal to the region of HRP labelling. Both the HRP-labelled and the degenerating terminals were comparable to the types of degenerating terminals observed by Goode et al. (1977) after lesions of raphe magnus in the opossum. The relationship of these terminals to those of primary afferent origin (Beattie et al., 1978) will be discussed. (Supported by N.I.H. Grants NS-14457 and NS-10165.)

2426 THE USE OF FLUORESCENT DYES FOR STUDIES OF BRAINSTEM-SPINAL CONNECTIONS IN THE RAT. A COMPARISON WITH THE HRP METHOD AND THE POTENTIAL FOR COMBINING WITH THE GLYOXYLIC ACID METHOD. Walter R. Buck, Albert O. Humbertson, Jr. and George F. Martin, Dept. Anat., Sch. Med., The Ohio State University, Columbus, O., 43210.

HRP as a retrograde marker has done much to revolutionize the way we visualize neuronal connectivity in the central nervous system. Although extremely useful, the technique is time consuming and not easy to use in double labelling experiments (i.e., tritiated but inactivated HRP-regular HRP). Recently several authors have reported success using fluorescent dyes as retrograde markers and because of the potential use of dyes for double labelling we have tested their effectiveness on systems of interest to us. The fluorescent dye 4,6-diamino-2-phenylindole (DAPI) appears to be particularly good. Following injection of DAPI into the cord we have seen evidence for brainstem labelling which appears comparable to that present in other animals processed via the HRP method. The animals with dye injections were sacrificed two to four days after surgery and the unfixed brains were removed for cryostat sectioning. The sections were examined with a fluorescence microscope and labelled cells could be seen using a 360nm. filter system. Such cells were bright blue in color and often surrounded by similarly labelled satellite cells. Alternate sections were stained for Nissl substance for orientation. Some sections from the dye injected cases were processed by the glyoxylic acid technique before viewing with the microscope and by using the appropriate filters the examiner could determine whether or not labelled neurons contained monoamines. Other fluorescent dyes have been tried (e.g., Evans Blue, Primuline), but to date the labelling is not as crisp as that seen with DAPI. The technique will be described and the results obtained on brainstem-spinal connections using this method will be compared with those derived with the HRP technique. (Supported by U.S.P.H.S. Grant NS-07410.)

2427 FUNCTIONAL ORGANIZATION OF ELECTRICAL CONNECTIONS IN THE FROG SPINAL CORD. William F. Collins, III* and Solomon D. Erulkar. Dept. of Pharmacology, University of Pennsylvania Medical School, Philadelphia, PA 19104.

Since Grinnell[1] first described the electrical nature of the interaction between frog motoneurones, the presence of electrical connections between frog motoneuron dendrites has become widely accepted. All electrophysiological studies have involved stimulation of ventral roots usually VR_9 and VR_{10}. Since the motoneurones innervating a given muscle in the hind limb are typically spread out over more than one segment[2], these studies yield little information as to the functional organization of the electrical connections. In order to determine the functional organization of the electrical connections, the isolated, hemisected frog spinal cord (Rana pipiens) was used. The dorsal roots were sectioned and the ventral roots were left intact to the sciatic nerve. The cord was pinned down on sylgard (Dow Corning) medial side up and was perfused with cold ($14 \pm 1^{o}C$) oxygenated normal ringers. The ventral roots were led out through a greased slit to a pool of oil where the sciatic nerve (for identification of motoneurons), the muscle nerve to the Gracilis Major (knee flexor and hip extensor) and the muscle nerve to the Iliacus Internus (knee extensor and hip flexor) were each placed on bipolar platnum electrodes for stimulation. Intracellular recordings from motoneurons in the rostral part of the lumbar enlargement were made using standard techniques. To date, 93 motoneurons have been studied. Of these motoneurons, 36 responded to stimulation of the Iliacus Internus muscle nerve, 27 responded to stimulation of the Gracilis Major muscle nerve and 7 responded to both. These ventral root excitatory post synaptic potentials (VR-epsps) were virtually always subthreshold (0.5 - 2.0 mV). Current injection had no effect on the amplitude of the VR-epsps. When muscle nerve stimulation was preceeded by stimulation of the sciatic nerve (antidromic response) or a dorsal root, the size of the VR-epsp was often increased. This increase in VR-epsp amplitude was associated with an increase in the extracellular field potential indicating increased antidromic invasion of motoneurons presynaptic to the motoneuron from which recordings were made. This procedure did not reveal VR-epsps which were not present following muscle nerve stimulation alone. These results indicate functional specificity in the electrical connections of lumbar motoneurons in the frog such that motoneurons innervating synergistic muscles are much more likely to be coupled than motoneurons innervating antagonistic muscles.

2428 CYCLOBENZAPRINE: ACTION ON THE DESCENDING COERULOSPINAL NORADRENERGIC PROJECTION. John W. Commissiong†, Farouk Karoum* and Norton H. Neff. LPP and LCP, NIMH, WAW Bldg., St. Elizabeths Hospital, Washington, D.C. 20032.

The locus coeruleus (LC) provides a massive noradrenergic projection to the ventral horn (VH) of the spinal cord (Commissiong et al., 1978). Cyclobenzaprine (CBZ), a centrally-acting muscle relaxant, caused a dose-dependent depletion of norepinephrine (NE) in the VH of the lumbar spinal cord. However, noradrenergic transmission in the cord, as assessed by the production of methoxyhydroxyphenylglycol (MHPG), the major metabolite of NE, remained intact, even when NE was depleted by greater than 80%. All analyses were done by a gas chromatographic-mass fragmentographic method. CBZ (1.5 mg/kg i.v.) completely abolished muscular rigidity of the gastrocnemius-soleus muscle group in the intercollicular decerebrate rat. Muscular rigidity was assessed by an electromyographic method. However, in rats in which the LC had been lesioned bilaterally 8 days or more previously, CBZ, even at high doses (10 mg/kg i.v.) had only minimal effects on muscular rigidity. It is suggested that the clinical beneficial effects of CBZ could be mediated by an interaction with the descending coerulospinal noradrenergic inhibitory projection.

2429 SYNAPTIC COVERAGE OF THE MOTONEURONAL MEMBRANE FOLLOWING AXOTOMY. William L.R. Cruce and Bruce L. Kinney*. Neurobiology Dept., Northeastern Ohio Univs. Coll. of Medicine, Rootstown, OH 44272.

The ninth ventral root (mid-lumbar) of bullfrogs (Rana catesbiana) was transected extradurally through the intervertebral foramen thus severing axons of motoneurons but minimizing damage to dorsal root afferents. Animals were allowed to survive 5, 10, 15, 20, 25, 30, 45, and 60 days then were perfused transcardially with a mixed aldehyde fixative in cacodylate buffer, postfixed in osmium, and prepared for electron microscopy. Light microscopy of 1 μ thick epon sections was used to orient the trimming of tissue blocks around large motoneurons in the ventral horn. Three to five motoneuron somas were photographed from each side of the ninth segment of each animal and three to five animals were used for each time point. Additional cells were photographed from sham-operated and unoperated control animals. Negatives at a magnification of 4500X were projected to a final magnification of 22,500X onto a Summagraphics digitizing tablet and microprocessor where membrane lengths and lengths of membrane covered by synaptic boutons were measured and tabulated by hand or collected on-line for statistical analysis by a PDP 11/34 minicomputer. Approximately 100 μ of membrane length was sampled for each motoneuron.

Cytoplasm of the swollen chromatolytic cells showed the characteristic increase in neurofilaments and neurotubules which form channels through the aggregates of granular endoplasmic reticulum, free ribosomes, and polysomes. The motoneuron soma membrane changed from its normal smooth contour to a rough or vacuolated appearance. Numerous spaces appeared in the neuropil immediately outside the cell membrane even though nearby regions of neuropil and nearby small neurons were well fixed. Occasionally, "free boutons" making no contact to any recognizable neuronal structure were seen near the cell membrane and were surrounded by glial elements. These glial elements were usually astrocytic rather than microglial in appearance. Microglial type cells proliferated in the region near motoneurons, but rarely did they appear to surround a bouton, to be in contact with a motoneuron, or to be lodged between a bouton and a motoneuron. Preliminary measurements indicated that synaptic coverage of the motoneuron membrane dropped from 26% in controls to 20% at 5 days and to 12% at 25 days (peak of the chromatolytic reaction) following axotomy.

2430 EFFECTS OF L-DOPA ON DORSAL HORN UNIT RESPONSES TO NOXIOUS THERMAL STIMULATION. Jonathan Delatizky, Charles J. Hodge and Charles I. Woods*. Dept. of Neurosurgery, Upstate Medical Center, Syracuse, N.Y. 13210.

Descending noradrenergic pathways are believed to participate in modulation of spinal nociception. Stimulation of locus coeruleus has been reported to cause inhibition of spinal nociceptive cells, although interactions with known inhibitory serotonergic pathways may contribute to this effect. Direct iontophoretic application of noradrenaline (NA) or serotonin (5-HT) on spinal nociceptive cells is inhibitory. In contrast, nociceptive thresholds have been shown to increase following NA depletion, suggesting that NA may enhance nociception. We previously described a facilitatory role for NA on cells responding exclusively to innocuous stimuli. The contribution of NA to spinal sensory modulation is consequently uncertain.

We have investigated the effects of L-DOPA induced terminal NA overflow on responses of lumbar dorsal horn units to noxious thermal stimuli. NA actions have been separated from those of other transmitters and metabolites. Unit responses to noxious thermal stimuli were recorded extracellularly in acute spinal cats. A Peltier-effect thermode with feedback control was used to vary the skin temperature between 25 and 56°C in a standard stepped sequence. Responses to this sequence were recorded every 5 to 10 minutes at least twice before, and for at least an hour after, IV injection of L-DOPA (15 mg/Kg). Average unit activity at each temperature was determined and peristimulus time histograms were constructed by a PDP-11 computer. The following groups of acute spinal animals were used: a) no pretreatment; b) p-chlorophenylalanine (PCPA) (a 5-HT depletor); c) 6-hydroxydopamine (6-OHDA)(twice intracisternally); d) fusaric acid (FA)(dopamine B-hydroxylase inhibitor).

L-DOPA caused marked inhibition of the unit response to noxious thermal stimulation (maximum average inhibition was to 35% of the control response). This inhibition was dependent on intact 5-HT stores and was not abolished by destruction of catecholamine tracts by 6-OHDA or by blocking the conversion of dopamine to NA by fusaric acid.

The results suggest that NA alone has minimal inhibitory effect on dorsal horn nociceptive units. Most of the inhibition could be ascribed to L-DOPA triggered 5-HT release. Thus direct NA influences on segmental nociceptive mechanisms appear to be minimal, and previously reported inhibition (Anden et.al., Acta Physiol. Scand. 67:373, 1966; Pearson, Proc. Soc. Neurosci. 4:570, 1978) is possibly caused by noradrenergic interactions with serotonergic or other descending systems.

2431 SUBSTANCE-P (SP),SOMATOSTATIN (SOM) AND METHIONINE-ENKEPHALIN (ENK) IMMUNOREACTIVITY IN THE SPINAL CORD OF THE NORTH AMERICAN OPOSSUM. Frank J. DiTirro*, Raymond H. Ho and George F. Martin (SPON: D.L. Clark), Dept. Anat., Sch. Med., The Ohio State University, Columbus, O., 43210.

The rat spinal cord receives SP and SOM containing projections from the dorsal root ganglia. These projections as well as some ENK containing intrinsic elements are thought to play a role in nociception. To date, SP and SOM immunoreactivity has been identified only in selected mammals and it is premature to conclude that the results from such studies can be extended to all species. The occurrence and distribution of SP, SOM and ENK was studied in the North American opossum. Antibodies against the three peptides were raised in rabbits. The indirect immunofluorescent method of Coons was used to localize the three peptides on 10μm cryostat cut sections of spinal cords that were fixed by intracardiac perfusion with 4% paraformaldehyde in phosphate buffer. SOM immunoreactivity was undetectable in the spinal cord. Only SP immunoreactive fibers were present in the tract of Lissauer and the lateral funiculus. SP and ENK immunoreactivities were localized in the gray matter. SP immunoreactivity in terminals and fibers visible as fluorescent dots and occasional lines were present throughout the gray matter. These structures were most numerous in laminae I and II of the dorsal horn, whereas the ventral horn exhibited a very sparse staining. The distribution of ENK immunoreactive elements paralleled closely that of the SP containing structures. ENK immunoreactive elements were densest in the substantia gelatinosa and around the central canal while all other regions of the gray matter exhibited relatively sparse distribution. There were more ENK immunoreactive elements in the ventral horn than SP immunoreactive elements. The specificity of immunostaining was established in control experiments in which the primary antisera for each peptide, pretreated with an excess of the corresponding synthetic antigen failed to demonstrate the aforementioned structures on semiadjacent sections. We conclude that as in the other mammalian species reported, SP and ENK immunoreactivities are present in the opossum spinal cord. However, SOM immunoreactivity was undetectable in the spinal cord of this species. (Supported by the Snyder Fund, The Graduate School of The Ohio State University and U.S.P.H.S. Grant NS-07410.)

2432 BICUCULLINE INDUCES STEPPING IN DECEREBRATE CATS. S. H. Duenas* E. Eidelberg. Division of Neurosurgery, University of Texas Health Science Center, San Antonio, TX 78284.

It has been proposed that active inhibition has a role in the control of stepping by gating the bursts of motoneuron discharge and by modulating the overall rate of stepping. It seems likely that GABA is a major central inhibitory transmitter. We tested the possibility that GABA may be involved in stepping by injecting animals with a potent GABA agonist (muscimol) and an antagonist (bicuculline).

Bicuculline (100-300 μg/Kg,i.v.) initiated stepping in decerebrate cats, either on a treadmill or as fictive locomotion under neuromuscular block. Muscimol (1.0-2.0 mg/Kg,i.v.) abolished this stepping. Picrotoxin (0.75-1.5 mg/Kg), a putative GABA antagonist, also initiated stepping but this effect was contaminated by seizure-like discharges. The bicuculline effect could not be elicited in spinalized preparations. We conclude that these results support the hypothesis that stepping may be under GABA-mediated active inhibitory control.

This research was supported by grant NS-14546-01 of the NINCDS. Dr. Duenas is on leave from the Centro de Investigacion y Estudios Avanzados del I.P.N., Mexico 14, D.F., Mexico (Department of Neurosciences).

2433 AXON COLLATERALS OF DORSAL HORN CELLS RESPONDING TO CUTANEOUS STIMULATION. M. David Egger, Natalie C. G. Freeman* and Eric Proshansky*. Dept. Anat., CMDNJ - Rutgers Medical School, Piscataway, N.J. 08854.

Intracellular injections of horseradish peroxidase into dorsal horn cells in lumbar segments of the cat's spinal cord revealed distinctive patterns of axonal projections from cells responding to low threshold cutaneous stimulation of the hind foot. Axonal projections have been examined for 17 cells: 10 in lamina IV, 4 in lamina V, and 3 in lamina VI. In general, cells responding to stimulation of the central foot pad were located most medially, those responding to stimulation of the proximal foot and dorsal surface of the toes were most lateral.

A striking characteristic of the axonal projections of many of these dorsal horn cells was a dense arborization of collaterals in the laminar region ventral to the cell body.

In addition, all cells contributed axons to the ipsilateral white matter, many with two separate branches that either both ascended, or ascended and descended within the same white column, or entered entirely separate columns. In lamina IV, two cells that contributed axons to the dorsolateral funiculus were probably cells of the spinocervical tract. Of the other 8, the 3 most medial contributed fibers to the medial dorsal column, the 3 most lateral contributed fibers to the lateral column or to the lateral fascicles of the dorsal intracornual tract (DIT). One of these also sent an axon collateral to the dorsal portion of the dorsal column. Of the two lamina IV cells lying in an intermediate position, one sent a collateral to the medial dorsal column, the other contributed to the lateral portion of the DIT, as well as a collateral to the dorsal portion of the dorsal column. This same medial-lateral organization of axon collaterals tended to hold for the 4 cells of lamina V, but in lamina VI, all 3 cells, including two quite medially placed, sent long axon collaterals to the lateral column only.

In summary, 1) medial cells in lamina IV tended to contribute axons to the medial dorsal column, while lateral cells in lamina IV tended to send axons to the lateral column, and 2) most of the dorsal horn cells studied had, in addition to at least one long projection axon, from one to 4 collaterals arising from the main axon and distributing within the dorsal horn in approximately the same transverse level as the cell body. The pattern of distribution of these collaterals varied widely, but a prominent feature was that the collaterals were distributed ventral to the cell body, often most heavily in the lamina just ventral to the one in which the cell body was found.

(Supported by grants from NINCDS and NSF.)

2434 STEPPING, WALKING, AND INTERLIMB COORDINATION AFTER COMPLETE AND PARTIAL CORD LESIONS. E. Eidelberg, B.L. Meyer* and J. Nystel*. Research Program, Veterans Administration Hospital, and Division of Neurosurgery, University of Texas Health Science Center, S.A., TX 78284.

Midthoracic level spinal cord lesions were produced in adult cats. Their gait was studied in a treadmill; sparing of descending neurones was defined by retrograde HRP labeling from the lumbar cord. Completely transected animals stepped with their hindlimbs but did not support or propel effectively with them, and fore-hindlimb coordination was absent. Cats with incomplete lesions, even severe ones, walked albeit not normally; some interlimb coordination was clearly present even when a small fraction of cervical long propriospinal neurones had escaped section. There was no clear and consistent correlation between sparing of specific brain stem-lumbar cord pathways and residual walking ability. Ablation of the motor cortex or corticospinal tract section in the cord did not produce significant, persistent, gait deficits.

It appears possible that one of the roles of descending connections may be to facilitate the engagement of alpha motoneurones by the spinal step generators, at least in cats.

2435 CHARACTERISTICS OF INDIVIDUAL MEDIAL GASTROCNEMIUS Ia AFFERENT PROJECTIONS TO TYPE-IDENTIFIED TRICEPS SURAE MOTONEURONS. James W. Fleshman, John B. Munson, and George W. Sypert. Depts. Neurosci. & Surg., Col. Med., U. Fla.& VA Med. Ctr., Gainesville, FL. 32610

Motoneurons may be divided into more or less discrete motor unit groups based on the properties of the muscle fibers they innervate. Burke and colleagues (see J. Neurophysiol. 39: 447, 1976) have shown that several input pathways to cat triceps surae motoneurons (TSMs) exert differential effects as a function of motor unit type. We are studying the projection frequency of individual Ia afferent fibers and the characteristics of single fiber Ia EPSPs in type-identified TSMs using the spike-triggered averaging technique.

TSM intracellular potentials, obtained by conventional techniques, are led to a signal analyzer, which is triggered by action potentials in a single medial gastrocnemius Ia fiber. The EPSP generated from a single fiber's terminals is accumulated by the analyzer. Intracellular current pulses are then injected to generated specific discharge patterns in the TSM. Resulting single and repetitive muscle unit contractions are measured with a strain gauge. Motor units are classified as FF, FR, or S based on the shape of an unfused tetanus tension envelope and fatigue resistance, using Burke's criteria.

To date, EPSPs have been studied in 45 type-identified TSMs in 4 cats. Although the sample size makes statistical evaluation inappropriate, these preliminary data show a trend toward higher projection frequency and larger single-fiber EPSPs in FR units than FF. More detailed comparisons will require a considerable increase in sample size. Characteristics of the single fiber projection will be discussed in relation to data obtained with whole nerve stimulation.

2436 ANTEROGRADE TRANSPORT OF HORSERADISH PEROXIDASE IN THE FROG SPINAL CORD. Fe Glanzman*, Patricia L. Mensah, Dennis Glanzman and Richard F. Thompson. Department of Psychology, Arizona State University, Tempe, AZ, Department of Anatomy, School of Medicine, University of Southern California, Los Angeles, CA, and Department of Psychobiology, University of California, Irvine, CA.

Twenty adult frogs (Rana catesbeiana) measuring three to four inches in length were used in this study. Horseradish peroxidase (Sigma type VI) was injected into caudal medulla or cervical, thoracic and lumbar spinal cord. Large injections were accomplished under MS 222 (Tricaine) anesthesia by delivering 0.4 to 0.6 microliters of a 20% solution of HRP dissolved in distilled water. After a survival period of one to four days at room temperature, the animals were perfused intracardially with a fixative containing 1% paraformaldehyde and 1.25% glutaraldehyde in 0.1M phosphate buffer. The brain and spinal cord were then removed, post-fixed in the same fixative for 2 to 3 hours, stored in 0.1M phosphate buffer and 5% sucrose for 3 days, and sectioned at 40 micra. Sections were washed in buffer and processed for the blue reaction product according to the technique described by Mesulam (J. Histochem. Cytochem., 24: 1273, 1976). Sections were counterstained with 1% neutral red. Significant amounts of anterograde transport occurred at all times examined. After caudal medulla injections, spinal projecting fibers were seen in the lateral funiculus and in the area of the ventral funiculus occupied by the vestibulospinal system. These fibers entered the central gray and established terminal fields as described previously in lesioned Fink-Heimer stained material by Mensah and Thompson (J. Anat., 125:1, 1978) for the lateral column fibers and by Corvaja and Grofova (Prog. Brain Res., 37:297, 1972) for the vestibulospinal system. Extensive pericellular networks were common and bouton-like enlargements were seen along the course of individual axons. These results indicate that anterograde transport did occur over long distances. In addition, this study suggests that HRP histochemistry may be a reliable method for marking the terminal endings of individual afferent fiber systems. (Supported by NIMH grant number MH-25127 to R.F.T.).

2437 ENKEPHALIN PERIKARYA IN THE MARGINAL LAYER AND SACRAL AUTONOMIC NUCLEUS OF THE CAT SPINAL CORD. Ellyn J. Glazer AND Allan I. Basbaum. Dept. Anat., Sch. Med., UCSF, San Francisco, Ca. 94143.

Although several studies have reported the CNS distribution of immunoreactive leucine-enkephalin, there are no detailed descriptions of the location and morphology of enkephalin somata. In the present study, enkephalin-containing perikarya of the cat spinal cord were studied by immunocytochemistry. The cats were administered either an intraventricular (100ug in 5 ul) or an intraspinal (10ug in 1ul) injection of colchicine. Forty-eight hours after colchicine administration, the cats were perfused with 4% paraformaldehyde. Spinal segments were embedded in paraffin, sectioned at 20u and processed by PAP immunocytochemistry.

The majority of enkephalin-containing perikarya were concentrated in the marginal layer (Lamina 1) of the superficial dorsal horn. Surprisingly few enkephalin cell bodies were observed in the substantia gelatinosa. The marginal neurons, when viewed in transverse sections, varied in size and included a population of large, bipolar, fusiform neurons. The dendritic processes of these neurons extended along the outer curvature of the dorsal grey. Sections taken tangential to the marginal zone revealed a class of enkephalin-containing Lamina 1 neurons with a dendritic morphology reminiscient of the layer 1 pyramidal neurons described by Gobel in Golgi stained material (J. Comp. Neurol. 180: 375, 1978). Large enkephalin neurons were also observed more ventrally in Lamina 4/5 of the dorsal horn and medially, near the central canal. The prescence of numerous enkephalin neurons in the marginal zone raises the possibility that both local and projection neurons of the superficial dorsal horn contain enkephalin.

Of particular interest, was the presence of numerous enkephalin-containing cell bodies in the second sacral segment of the spinal cord. These cells were clustered around the lateral edge of the intermediate and ventral grey and continued dorsomedially in a narrow band towards the central canal. The distribution of these neurons corresponds to that of sacral parasympathetic preganglionic nuclei demonstrated by retrograde transport of HRP (de Groat et al; Neuroscience Letters 10: 103, 1978). Ligation of the S2 ventral root in noncolchicine-treated cats produced a comparable distribution of enkephalin perikarya in S2 and a "damming" of enkephalin-immunoreactivity in the ventral root proximal to the ligature. These results indicate that parasympathetic preganglionic neurons in the cat synthesize and transport enkephalin or enkephalin-like material to the periphery.

2438 PRIMARY AFFERENT TERMINAL DEFECT IN CATS WITH ACRYLAMIDE NEUROPATHY. Barry D. Goldstein and Herbert E. Lowndes. Dept. of Pharmacology, CMDNJ, N.J. Medical School, Newark, N.J. 07103.

Major clinical manifestations of toxic axonopathies include ataxia and loss of deep tendon reflexes. A defect in the unconditioned spinal monosynaptic reflex (MSR) of cats intoxicated with acrylamide occurs (Goldstein and Lowndes, Neurotoxicol. 1: 75, 1979) and may contribute to the neurological signs of the neuropathy. This defect could result from alterations in primary afferent terminal (PAT) function, changes in the post-synaptic membrane, or both. Spinal monosynaptic input-output characteristics and PAT function were determined in soleus (SOL) and medial gastrocnemious (MG) monosynaptic motoneuron pools in normal cats and cats with subclinical, moderate, and severe degrees of acrylamide neuropathy (total administered doses of 75, 150, and 300 mg/kg, respectively). The primary afferent discharge relative to maximal afferent input necessary to produce a liminal monosynaptic response in the ventral roots (critical input) was 29.7% in normal SOL PAT and 23.5% in normal MG PAT. The critical input increased to 52.7%-57.2% in SOL PAT and to 43.7%-49.7% in MG PAT after the administration of acrylamide. Repetitive stimulation of the MSR at low frequencies (2-10 Hz) causes a rundown to a plateau (homosynaptic depression). The plateau attained following the rundown was lower in response to all stimulating frequencies in cats treated with acrylamide. The plateau was reduced by 22%-62% in the SOL MSR and by 5%-65% in the MG MSR as a function of dose of acrylamide. Analysis of the apparent transmitter turnover parameters determined from homosynaptic depression (Capek and Esplin, J. Neurophysiol. 40: 95, 1977) indicated that the constant fraction of neurotransmitter released (P) was unchanged in either SOL or MG PAT regardless of the dose of acrylamide. However, the rate of replenishment of neurotransmitter (R) decreased in the SOL PAT by 12%-46% as a function of dose of acrylamide. In the MG PAT, R was depressed by 60% but only at the highest dose of acrylamide. It appears that fewer PAT are functional in cats with acrylamide neuropathy, even at doses which produce no clinical symptoms (75 mg/kg). Also, reduced rate of neurotransmitter replenishment and enhanced homosynaptic depression in cats with acrylamide neuropathy suggest a defect in the mobilization process of neurotransmitter to the ready releasable pool in the PAT. Further, SOL and MG appear to be differentially sensitive to the neurotoxic actions of acrylamide.

2439 LOCALIZATION AND CHARACTERIZATION OF PHRENIC MOTONEURONES IN THE SPINAL CORD OF THE ADULT RAT. Harry G. Goshgarian and Jose A. Rafols. Dept. Anat., Sch. Med., Wayne State Univ., Detroit, MI 48201

The motoneurones which innervate the diaphragm of the adult rat were localized and morphologically characterized in the spinal cord by using the method for the retrograde transport of horseradish peroxidase and the zinc chromate modification of the Golgi technique. In order to distinguish between those motoneurones which innervate most of the diaphragm and those which give rise to the accessory phrenic nerve, peroxidase was applied to crushed phrenic axons either in the neck (rostral to the union of the accessory phrenic and phrenic nerves) or within the thorax (after both nerves have joined into a single trunk). Peroxidase labelled cells were studied in frontal and sagittal sections of cervical spinal cord. In sagittal sections pinholes were inserted perpendicularly to the long axis of the cord through the center of the C3-C7 dorsal roots to identify spinal cord levels. The spinal cord was notched at C2 to distinguish rostral from caudal ends of each section. When peroxidase was applied in the neck, labelled cells were found at the C3-C6 levels of the spinal cord. However, when the application of peroxidase included accessory phrenic fibers, labelled cells were found at the C3-C6 levels of the cord. The labelled neurons were mostly polygonal or fusiform in shape and peroxidase activity ranged from lightly labelled to heavily labelled cells. The long axes of the heavily labelled cell bodies ranged from 32-46 μm while the short axes ranged from 19-26 μm. In most cases clusters of 2-6 closely apposed cell bodies were observed, but isolated cells were occasionally found. In frontal sections, the location of peroxidase labelled cell bodies was determined from measurements along mid-sagittal and horizontal coordinates using the center of the spinal canal as a zero reference point. The greatest number of labelled cells were seen at C4. At this level labelled somata occupied a cross-sectional area of approximately 150 μm in diameter with the center of the area lying 600 μm lateral to the mid-sagittal plane and 400 μm anterior to the horizontal plane. The center of the area shifted posterolaterally at C3 and anteromedially at C5 and C6. Phrenic motoneurones were identified on Golgi impregnated sections by utilizing the above coordinate system. Examination of Golgi sections showed that phrenic neurons issued several thick dendrites which branched repeatedly and radiated in all directions. Small somata were noted at the periphery of the larger phrenic cell bodies. These small neurons displayed delicate, beaded dendrites which overlapped with the dendritic fields of the phrenic neurons. Dendritic overlap between phrenic neurons and other adjacent neurones also occurred. Supported by the Paralyzed Veterans of America and NINCDS grant NS 06925-13.

2440 SYNAPTIC STIMULATION OF FROG AFFERENT TERMINALS ACTIVATES AN ELECTROGENIC SODIUM PUMP. J.C. Hackman and R.A. Davidoff. Neurology Service, V.A. Hospital and Dept. of Neurology, University of Miami School of Medicine, Miami, Florida 33101.

The dorsal root potential (DRP) reflects changes in the membrane potential of the presynaptic terminals of primary afferent fibers. In the cat, positive DRPs--which indicate hyperpolarization of afferent terminals--have been recorded from dorsal roots (DR) following single volleys in adjacent DRs; this has not been demonstrated in the amphibian (with DC recording). Our present experiments, however, show that following repetitive activity of adjacent DRs, hyperpolarization of the terminals of afferent fibers occurs in the frog.

We used the hemisected frog spinal cord continuously superfused with HCO_3^-buffered Ringer's solution maintained at 15°C. DRPs were recorded using the sucrose gap technique.

Tetanic electrical stimulation of a lumbar DR at frequencies ranging from 5 to 1000 Hz for durations of 0.05 to 30 sec produced a sustained negative shift of the potential of fibers in an adjacent DR. Such a sustained potential was consistently succeeded by a positive potential of up to 6mV in amplitude and 5 min. in duration. A single supramaximum DR volley only evoked a negative DRP but as few as 5 DR volleys evoked a detectable positive response provided that the DR was stimulated with voltages 25x the threshold for producing a detectable negative DRP. Both the amplitude and duration of the hyperpolarization were monotonically related to the frequency and duration of stimulation. Tetanic stimulation of ventral roots elicited only a negative DRP.

The hyperpolarization of the afferent terminals was clearly dependent upon metabolic processes, since it was significantly, but reversibly, reduced by cooling (Q_{10}, 2.6) and exposure to metabolic inhibitors (DNP, $5x10^{-5}$M; NaCN, $2x10^{-3}$M).

Such metabolically dependent hyperpolarizations usually reflect active transport of ions. Since there is evidence that the negative DRP results from a selective efflux of Cl^-, afferent terminal hyperpolarization could result from activation of an inward Cl pump. But compounds known to block Cl^- transport (SITS,10^{-4}M; furosemide,10^{-3}M) did not affect the potential change.

On the other hand, a variety of procedures used to inhibit Na^+ pumps did significantly reduce the hyperpolarization. These included application of ouabain (10^{-5}M); elimination of external K^+ and partial substitution of Na^+ in the superfusate by Li^+ (57mM).

These observations show that repetitive synaptic depolarization of afferent terminals is followed by a hyperpolarizing change in membrane potential which reflects an increased rate of active Na^+ extrusion from these terminals. This Na^+ pumping may be activated by the elevated $[K^+]_e$ known to occur during tetanic DR stimulation. (Supported by V.A. Hospital Funds, MRIS 1769)

2441 GLUCOCORTICOID INTERACTIONS WITH BIOGENIC AMINE AGONISTS AND ANTAGONISTS ON CAT SPINAL REFLEXES. Edward D. Hall. Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

A short-term triamcinolone diacetate regimen (8 mg/kg i.m./7 days) has been demonstrated in acute spinal (C-1) cats to enhance excitatory spinal monosynaptic (2N) and polysynaptic reflex function (Hall et al., J. Pharmacol. Exp. Ther. 206:361, 1978; Hall and Baker, J. Pharmacol. Exp. Ther. in press). In the present work, the effects of intensive triamcinolone dosing have been examined on the 2N actions of alpha adrenergic and serotonergic agonists and antagonists. In all experiments, 1.2X supramaximal stimuli were applied to the triceps surae nerves of one leg every 5 sec. and the evoked reflex responses recorded at the ipsilateral L7 or S1 ventral root.

In one series of experiments, the 2N reflex effects of a 1 mg/kg dose of the centrally-active noradrenergic agonist methoxamine (MX) given as a 20 minute infusion was studied. As described by Vaupel and Martin (J. Pharmacol. Exp. Ther. 196:87, 1976), MX produced a progressive increase in the 2N response amplitude in untreated cats with a maximum of 34.5%. In the glucocorticoid treated animals, however, no increase by MX was seen; rather a 10-15% depression in response amplitude occurred. One hour after the MX infusion, 20 mg/kg phenoxybenzamine (PBZ) was infused over 20 minutes. In the untreated cats, alpha adrenergic receptor blockade by PBZ produced a 24.2% decrease in the 2N response while in the treated animals, PBZ caused an increase of 21.4%.

In a second series of experiments, the experimental protocol of Clineschmidt et al (J. Pharmacol. Exp. Ther. 179:312, 1971) was employed to assess glucocorticoid effects on the 2N reflex actions of serotonin manipulation. Fifty mg/kg 5-hydroxytryptophan (5-HTP) was infused over 10 min.; followed at 60 min. by 5 mg/kg amitryptyline (AMT) over 5 min.; followed 25 min. later by 1 mg/kg methysergide (MS) over 5 min. In the untreated animals, 5-HTP produced a moderate decline (20-40%) in 2N amplitude. When the serotonin reuptake inhibitor AMT was then given, an immediate elevation (40-50% above control) in the response was observed which was rapidly and completely blocked by subsequent administration of the serotonin antagonist MS. In the treated preparations, 5-HTP produced the same 2N depression, but subsequent AMT produced a 3-fold greater increase in the response that was refractory to antagonism by MS.

These data may have relevance to the pathophysiology of psychotic depression in man. For instance, in many individuals with depression, there is a significant elevation in plasma levels of the endogenous glucocorticoid cortisol (Prange et al., Life Sci. 20:1305, 1977) which could as the present results suggest, have an effect on central biogenic amine transmission. (Supported by NIMH Small Grant MH 31887-01).

2442 TERMINAL DISTRIBUTION OF IA AND GROUP II SPINDLE AFFERENT FIBERS IN THE SPINAL CORD AS REVEALED BY POSTSYNAPTIC POPULATION POTENTIALS RECORDED FROM TWO ADJACENT SPINAL SEGMENTS. Elwood Henneman, Hans-R. Lüscher*[1] and Paul Ruenzel*. Spon. R. B. Szamier). Dept. of Physiology, Harvard Medical School, Boston.

Postsynaptic population potentials (PSPPs) were elicited by stretch evoked impulses in single Ia and group II fibers from the medial and lateral gastrocnemius muscle and were recorded simultaneously from L_7 and S_1 ventral roots perfused with isotonic sucrose, as described in Neurosci. Abst. 4:568, 1978. The amplitudes of the two PSPPs were correlated with the precise entry point of the dorsal root filament containing the afferent unit and with the conduction velocity of the afferent impulse. In general, PSPPs were significantly larger when recorded from the spinal segment which the afferent fiber entered than from the neighboring segment. Only 15 exceptions to this rule were found in 165 pairs of PSPPs. Data from individual experiments were used to construct 3-dimensional plots for the two recording levels, illustrating the precise and systematic relationship between the amplitude of the PSPP, the level of entry of the afferent fiber and the conduction velocity of its impulses. These results suggest that the density of active endings given off by primary afferent fibers is highest around its entry point and diminishes with increasing distance from it.

The findings indicate that the projection which each Ia fiber sends to its pool consists not only of a diffuse component going to all homonymous motoneurons (Mendell and Henneman, J. Neurophys. 34:171, 1971) but also a localized component that is topographically organized. The latter may account for the phenomenon of "localized stretch reflexes" within a circumscribed part of a muscle reported by Cohen (J. Neurophys. 17:443, 1954).

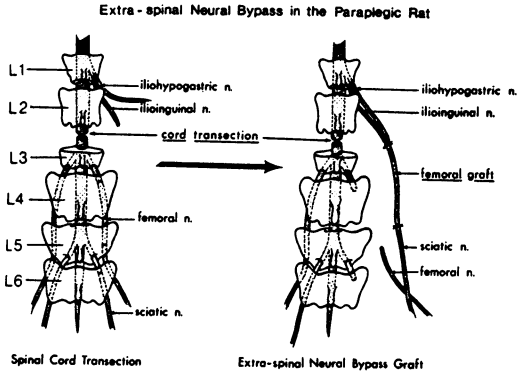
2443 FUNCTIONAL RETURN IN PARAPLEGIC RATS USING EXTRA-SPINAL NEURAL BY-PASS. Pamela K. Hill and Glenn R. Carwell.* Depts. Anatomy and Plast. Surg., East. Va. Med. Sch., Norfolk, VA 23510.

Extra spinal neural by-pass (ESNB) was performed in the right hand limb of 20 rats subjected to spinal cord transection. The ESNB utilized a graft from the right femoral nerve to connect the iliohypogastric and ilioinguinal nerves to the right sciatic nerve (see figure below). Three months post-operatively, discrete flexor movements of the toes were noted in 4 of 9 surviving animals and were synchronous with respiration. These movements were filmed for documentation. Histological examination of the nerve grafts demonstrated continuity without fibrosis through proximal and distal suture lines in 5 out of 9 animals. Collateralization of motor end-plates were present in the right gastrocnemius muscle. These neurological and morphological findings substantiate the re-establishment of communications between the cerebrum and the denervated limb.

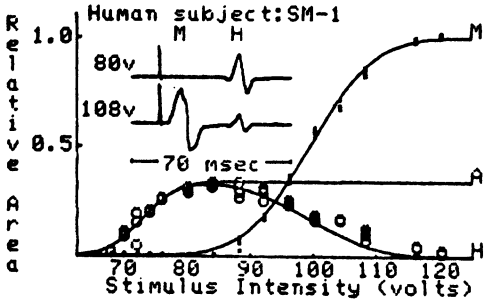


2444 A QUANTITATIVE MODEL OF THE H REFLEX. F. K. Hoehler* and A. A. Buerger. Dept. of Physical Med. & Rehab. and Physiology, Calif. Coll. of Med., UC Irvine, CA 92717.

Transcutaneous electrical stimulation of posterior tibial nerve usually elicits two separate EMG responses in gastrocnemius or soleus. The first of these responses results from the direct activation of motor axons and is termed the M response while the second is believed to be monosynaptic and is termed the Hoffmann (H) reflex. At high stimulus intensities, the H reflex is greatly reduced, presumably by collision with antidromic impulses elicited in the motor nerve. The figure below shows (a) EMG responses to two different stimulus intensities and (b) the overall effect of stimulus intensity on the size of the M response and the H reflex. If the collisions are essentially random, then the occlusion of H can be modeled by the equation

$$H = A - AM$$

where H is the size of the H reflex, A is the size of the monosynaptic reflex volley prior to collision and M is the size of the antidromic volley in motor axons (estimated by the size of the M response) with all response magnitudes expressed as proportions of the entire motoneuron pool (estimated by the size of the maximum M response). A computer program was used to generate theoretical curves which best fit the observed data and, in the majority of subjects, the fit (as shown in the figure) was quite close. "Failures" of the model resulted when subjects continued to produce H reflexes at high stimulus intensities at which complete occlusion would be predicted. Modeling of these residual H reflexes may require the assumption that, in some subjects, either (a) direct electrical stimulation of motor axons cannot activate the entire motoneuron pool or (b) antidromic impulses in motor axons may reach the motoneurons before those cells are orthodromically activated by the afferent volley.



2445 AN ANALYSIS OF MOTONEURON INTERSPIKE INTERVALS IN CATS DURING TREADMILL AND FICTIVE LOCOMOTION. Larry M. Jordan, Carol A. Pratt* and John E. Menzies*. (Spon: R.M. Jell) Dept. Physiology, Univ. of Manitoba, Winnipeg, Manitoba, Canada, R3E 0W3.

Muscle tension resulting from intracellular current injection in alpha motoneurons (MNs) was found to be substantially enhanced when the stimulus train (8-12 Hz) contained an initial doublet (interpulse interval 10msec) (Burke, et al., Brain Res., 109, 1976). It was subsequently shown that the discharge of all flexor and 86% of the extensor MNs studied during controlled treadmill locomotion (evoked by brainstem stimulation) was characterized by an initial short interspike interval (ISI) or doublet, while the intervals separating the spikes in the remainder of the burst were longer and relatively constant (Zajak and Young, In: Neural Control of Locomotion, 1976, pp.789-793). It was suggested that this discharge pattern reflected the most efficient method of maximizing tension production. Evidence is now available (R.B. Stein, personal communication) that the pattern of MN discharge which maximizes the force per impulse is one in which a short initial ISI is followed by a relatively long ISI with the remaining ISIs being of an intermediate and fairly constant duration.

The discharge of MNs which were active during controlled treadmill locomotion or fictive locomotion was analysed to determine whether the ISIs within a burst conformed to the optimal pattern which has been derived experimentally. In one series of experiments, cats were decerebrated and walked on a treadmill in response to stimulation of the mesencephalic locomotor region (MLR). Rhythmic activity in motor axons was recorded from ventral root filaments. In other experiments, decerebrate cats were paralyzed (Flaxedil, i.v.), and MNs were recorded intracellularly as well as from ventral root filaments during MLR-evoked "fictive" locomotion.

Although some MNs were found to fire during both types of locomotion according to the pattern proposed by Stein, the pattern most commonly observed consisted of a fairly regularly spaced spike train with mean ISIs in the range of 40 - 50msec, with a shorter initial ISI (mean = 24 msec) separating the first two spikes. This pattern was also observed during both types of locomotion. The mean initial ISI seen in MNs active during treadmill locomotion was much shorter and less variable(7±2 msec) than that observed during fictive locomotion (29 ± 22 msec). With one exception, MNs which produced less than 10 spikes/burst did not display an initial doublet, whereas the mean initial ISI for those with more than 10 spikes/burst was 11.2 msec. These data suggest that the details of MN firing patterns during locomotion are centrally determined.(Supported by M.R.C. of Canada)

2446 REGIONAL DISTRIBUTION OF MUSCARINIC RECEPTORS IN SPINAL CORD. S. Oguz Kayaalp* and Norton H. Neff. (SPON: D. L. Cheney). Lab. Preclin. Pharmacol., NIMH, St. Elizabeths Hosp., Washington, D.C. 20032

The distribution of muscarinic cholinergic receptors was studied in the major areas of the rat spinal cord at different levels by using the tritiated ligand [^{3}H]quinuclidinyl benzilate (QNB) as a marker. Binding sites were found in both gray and white matter. The binding capacity of the former, however, was about 3-4 times higher than the latter. The area richest in muscarinic receptors was the anterior horn, with a Bmax ranging from 62 to 122 fmol/mg protein which is significantly less than found in brain. Binding was lowest in the thoracic cord when compared with the other areas of the cord. The affinity of the binding sites for QNB seemed to be comparable at different levels with Kd values ranging from 0.06 to 0.09 nM. The binding capacity of the posterior horn was about half the anterior horn. A section of the spinal cord at the thoracic level did not change the binding parameters to a significant extent in gray or white matter. The order of potency of the cholinergic agents in inhibiting QNB binding was as follows: methscopolamine ($IC50=6x10^{-9}$ M)> atropine>oxotremorine>carbamylcholine>nicotine>hexamethonium ($IC50=3x10^{-3}$ M). The results suggest that 1) muscarinic receptor density is lower in spinal cord than in brain, 2) binding sites are quite homogenous with respect to their affinity for the ligand, 3) the binding sites in white matter may be located, at least in part, on glial cells as a section of the axons did not alter binding.

2447 SPATIAL ARRANGEMENT OF ANKLE EXTENSOR SYNERGISTIC MOTOR NUCLEI IN THE CAT LUMBAR SPINAL CORD. William D. Letbetter. Dept. Anat., Emory Univ., Atlanta, GA 30322.

Retrograde labeling with horseradish peroxidase (HRP) was used to identify all the motoneurons belonging to muscles contributing to the Achilles tendon. Medial gastrocnemius (MG), lateral gastrocnemius (LG), soleus (S), and plantaris (PL) muscles of ipsi- and contralateral hindlimbs in each preparation were injected with HRP, both singly and in various combinations, so that a detailed analysis of their spatial organization could be made from 3-dimensional serial reconstructions of the spinal cord segments containing the labeled cells. It was determined that the particular techniques employed in this study yielded quantitative results in agreement with the proposition that all motoneurons (both alpha and gamma) projecting to an injected muscle were labeled.

It was found that in the rostro-caudal dimension, MG motor nucleus is shifted by a fixed relative distance caudally to the LG nucleus with the soleus motoneurons lying in the middle of the region of overlap between the two. Furthermore, in the rostral half of the soleus motor nucleus, both the number of cells and their relative distribution are congruent with those of the rostral part of MG nucleus; likewise, in the caudal half of the soleus motor nucleus, both the number of cells and their relative distribution are congruent with those of the caudal part of LG nucleus. Although these three motor nuclei account for the vast majority of the motoneurons in their particular column (column 5 of Romanes), there are some other large neurons present which were not labeled. That they all contribute to the innervation of tibialis posterior and popliteus muscles as suggested by Romanes has yet to be determined. The number of these unlabelled cells was greatest at the rostralmost and caudalmost limits of the distribution of the ankle synergistic nuclei. The plantaris motor nucleus was found to be layered dorsal to the rostralmost portion of the distribution of the LG motor nucleus in what appeared to be the caudal part of Romanes' column 4. As the rostro-caudal overlap between LG and PL motor nuclei was not very extensive, PL motor nucleus is most aptly described as being spatially "detached" from the MG-LG-S motor nuclear complex.

This work demonstrates clearly that it is now possible to map accurately and in quantitative detail the spatial organization and interrelationships of motor nuclei in the spinal cord. It offers new hope of discovering at least the architectural, and even perhaps the functional organizational scheme of the spinal motor apparatus.

2448 SPINAL TERMINATIONS OF SUBCUTANEOUS HIGH THRESHOLD MECHANORECEPTORS. A. R. Light, S. Mense* and E. R. Perl. Dept. Physiology, Univ. North Carolina, Chapel Hill, NC 27514 and Physiologisches Institut d. Univ., 2300 Kiel, West Germany.

The spinal terminations of cutaneous receptors with fine myelinated fibers have recently been described in detail (Light and Perl, J. Comp. Neurol. 186, 1979). To compare the terminal distributions of slowly conducting afferent units originating in deep tissues, identified units innervating the tail of anesthetized cats were stained with horseradish peroxidase (HRP). After laminectomy, impulses from fibers close to the dorsal root entry zone were recorded extracellularly with a glass micropipette containing HRP solution. Once a presumed deep unit was found, the overlying skin was carefully removed and the subcutaneous tissues stimulated directly. Upon satisfactory physiological characterization of a unit, HRP was injected intraaxonally by iontophoresis. The tissue was processed histologically with diaminobenzidine.

The deep sensory receptors stained had dorsal root fibers conducting at 46.0-13.1 m/s. Most responded like cutaneous high threshold mechanosensitive (HTM) receptors, in that they required strong pressure to be activated. Their receptive fields were discontinuous and were located in muscles, tendons, joint capsules, or connective tissue of the tail. Vigorous bending of the tail was not excitatory.

The central terminals of deep HTM receptors branched extensively in the dorsal spinal gray matter. Very many en passant enlargements and terminal boutons indicative of synaptic contacts were found ipsilaterally in lamina I and in a region dorsal to the central canal; a few were in lamina II. Less numerous boutons and enlargements were also present in ipsilateral lamina V and in contralateral laminae I and V. In contrast, secondary muscle spindle fibers that conducted at velocities comparable to rapid HTM receptors terminated principally in the intermediate zone of the spinal gray matter and in the ventral horn.

These findings suggest no substantial difference between the spinal terminations of deep and cutaneous high threshold mechanoreceptors. Both end in lamina I and (to a lesser extent) in lamina V, regions implicated in nociception. The presence of numerous terminations from both deep and cutaneous nociceptors in the superficial layers of the dorsal horn underlines the importance of this region as a site for integration of afferent information.

This investigation was supported by a research grant (NS10321) and general facilities were supported by a Program Project grant (NS14899), both from the NINCDS of the USPHS. S.M. received a grant (Me 492/5) from the Deutsche Forschungsgemeinschaft.

2449 HOW THE SIZE OF MOTONEURONS DETERMINES THEIR SUSCEPTIBILITY TO DISCHARGE. Hans-R. Lüscher*[1], Paul RUENZEL* and Elwood Henneman. Dept. of Physiology, Harvard Medical School, Boston.

Volleys of Ia impulses evoke aggregate EPSPs in motoneurons (MNs), whose amplitudes correlate inversely with cell size and directly with susceptibility to discharge. The following hypothesis is proposed to explain the basis for these relationships. (1) Ia fibers approaching a MN branch more frequently and send more terminals to cells with larger surface areas; (2) the more branching there is, the greater is the possibility that impulses in these fibers will fail to invade all the terminals; (3) the percentage of synaptic knobs activated by Ia impulses is, therefor, determined by the branching pattern in the terminal arborization and by factors that influence invasion of terminals. To test this hypothesis, the sizes of aggregate EPSPs in MNs before and after post-tetanic potentiation (PTP) were related to the input resistance (IR) of the cells, which was measured by the "spike height" method. Ventral roots of L_7 and S_1 were severed to eliminate backfiring of MNs, which interferes with recordings of EPSPs. Hindlimb muscle nerves in cats were stimulated at 1/sec with shocks that set up afferent volleys in all their Ia fibers. A series of 16 monosynaptic aggregate EPSPs was recorded from the MN and averaged electronically. The muscle nerve was then tetanized with similar shocks at 500/sec for 10 sec. Thereafter another series of 16 EPSPs was recorded and averaged. As our hypothesis predicts, the smallest control EPSPs and the greatest % potentiations occurred in MNs with the lowest IRs, i.e., in the largest cells. It has generally been assumed that PTP is due to release of more transmitter from a fixed number of active endings. This theory predicts that the magnitude of PTP is independent of cell size and now appears untenable. With few exceptions PTP increased the rise-times and half widths of EPSPs, effects consistent with invasion of additional terminals. The findings suggest that invasion of Ia terminals is a graded process that is more complete in arborizations on small cells, which explains their greater susceptibility to discharge.

Supported by a grant from the National Institutes of Health.

2450 EVIDENCE FOR FOUR DIRECT BRAINSTEM PROJECTIONS TO THE INTERMEDIOLATERAL CELL COLUMN WITH NOTES ON THEIR DEVELOPMENT. George F. Martin, Dept. Anat., Sch. Med., The Ohio State University, Columbus, Ohio, 43210.

The horseradish peroxidase method was used to identify those areas of the brainstem which project to the thoracic cord and would thus be possible sources for direct projections to the intermediolateral cell column. Injections of ^{3}H-leucine were made into all of the areas identified by the HRP technique and the resulting autoradiograms show that the intermediolateral cell column is innervated by at least four areas. Injections which include the nucleus coeruleus (Coe) and closely adjacent areas elicit labelling of the ipsilateral intermediolateral cell column. Bilateral labelling of the same region is present after injections of the nucleus reticularis gigantocellularis pars ventralis (RGcv), the nucleus obscurus raphae (RaO) and the rostral part of the lateral reticular nucleus (RL). Fluorescence microscopy reveals that each of the above areas contain neurons of either the catecholamine (Coe, LR) or indolamine (RGcv, RaM, RaO) type. Since fluorescent varicosities of both types pack the intermediolateral cell column and it is known that they arise within suprasegmental centers, it seems reasonable to conclude that they take origin from the areas referred to above. Developmental studies of pouch-young opossums show that fluorescence appears in sympathetic ganglia of the peripheral nervous systems very early (11 days after conception) and that the intermediolateral cell column is one of the first targets of brainstem-spinal neurites. Supported by U.S.P.H.S. Grants NS-07410 and NS-10165.

2451 CONDUCTION STUDIES IN ISOLATED PERFUSED SPINAL CORD AND IMPLICATIONS FOR THE CAUSES OF IRREVERSIBLE SPINAL INJURY. H.F. Martin, S. Katz, and J.G. Blackburn. Department of Physiology, Medical University of South C.rolina, Charleston, South Carolina 29403.

Irreversible effects of spinal cord trauma are thought to be due to either direct damage to neural structures (i.e. membrane disruption) or to necrosis secondary to anoxia following microvascular injury. The latter hypothesis has been investigated by subjecting the spinal cord to anoxia separate from trauma. We have developed a model to investigate the former hypothesis by allowing traumatic damage without anoxia.

Excised spinal cord strips from cats or rats were placed in a chamber perfused by oxygenated Ringer's solution. Stimulating and recording electrodes were positioned to measure axonal conduction along the length of the strip. Results of these experiments have shown that conduction can be maintained for an excess of four hours provided adequately oxygenated fluid remains in contact with the tissue. Raising the cord segment into a layer of mineral oil attenuates conduction within 30 minutes, however, conduction can be restored by renewed perfusion by oxygenated Ringer's solution.

This model forms the basis for continuing investigations into the temporal sequence of changes in neural conduction following trauma. (Supported by NINDS grant #P-5P81-NS-11066).

2452 THE EFFECTS OF EXPERIMENTAL SPINAL CORD INJURY ON FIBER DENSITIES & DIAMETER DISTRIBUTION IN FELINE SPINAL CORD. Eugene D. Means & Douglas K. Anderson, Dept. Neuro. & Physiol. VA Hosp., & Univ. Cinn. Sch. Med., Cincinnati, OH. 45220

The differential effects of compression & ischemia on nerve fibers have been incompletely studied. Most data has been derived from work on the peripheral nervous system. To determine the effect of experimental spinal cord compression injury on feline spinal cord white matter, fiber densities & the fiber spectrum (diameter distribution) was computed for the dorsal column of normal & injured animals. Adult, female, mongrel cats were subjected to laminectomy at the upper lumbar area & the wound was either closed or the spinal cord was compressed using a 170gm/wt for 5 minutes. At 30, 45 & 60 days post-compression, the animals were sacrificed under pentobarbital anesthesia by intra-aortic perfusion fixation using buffered 5% gluteraldehyde. Transverse sections of SC were removed from the T_8 & C_3 levels, post-fixed in osmium & embedded in epon. Whole transverse sections of spinal cord were cut at 1 micron, stained with toluidine blue & mounted on glass slides. Using a Zeiss photomicroscope, every 6th microscopic field was systematically sampled beginning initially with any field between 0 & 9 chosen ramdomly. The photographs were enlarged to approximately 2100 x. Using a MOP-3 (Kontron) image analyzer the fiber diameter distribution was recorded from the photographic enlargements using a logarithmic mode. The dorsal columns of normal (laminectomy alone) spinal cord contained from 39,000 to 56,000 myelinated fibers/mm^2. Fiber diameters ranged from 0.5-15 micra, the majority falling in the 2-5 micron range. Injured animals showed an average fiber density in the dorsal columns of 8000 myelinated fibers mm^2. Myelinated fibers of all diameters showed a reduction in number but there was a statistically significant differential loss of fibers in the 2-4 micron range. Previous studies on peripheral nerve have shown a susceptibility of large myelinated fibers to compression injury while smaller myelinated fibers have been more susceptible to ischemia. The pathogenesis of experimental spinal cord injury is unclear but ischemia plays a significant role in the auto-destructive process following blunt trauma. Although fibers were decreased over the entire fiber spectrum, the disproportionate loss of small myelinated fibers suggests that ischemia may play a more significant role than compression in experimental spinal cord injury. Moreover, the almost total absence of degenerating fibers at the C_3 level at 60 days post-compression suggests that Wallerian degeneration was complete by this time. Supported in part by the VA & a grant from the Paralyzed Veterans of America & the Upjohn Co.

2453 A MORPHOLOGICAL STUDY OF CAT DORSAL SPINOCEREBELLAR TRACT NEURONS AFTER INTRACELLULAR INJECTION OF HORSERADISH PEROXIDASE. Vjekoslav Miletić, Mirjana Randić and Arthur D. Loewy. Dept. Vet. Physiol. & Pharmacol., Iowa State University, Ames, IA 50011 and Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110.

This work represents an attempt to elucidate structural features of electrophysiologically characterized, individual cat dorsal spinocerebellar tract (DSCT) neurons by using intracellular application of horseradish peroxidase (HRP).

The experiments were performed on thirty adult spinalized cats. After a lumbar laminectomy (L2 - L3 Level), intracellular recordings and HRP injections were made in DSCT neurons of the Clarke's column, which were identified by antidromic invasion following electrical stimulation of the ipsilateral dorsolateral funiculus. In addition, sensory inputs to DSCT neurons were determined by natural (adequate) stimuli applied to the left hind limb with intact innervation. Horseradish peroxidase was injected intracellularly into the DSCT neurons by passing a positive current of 16-18nA for 5-10 minutes through the microelectrode filled with 25% HRP (Boehringer-Mannheim) in 0.5M KCl. After a survival period of 1-6 hours the animals were perfused with a solution of 2.5% paraformaldehyde and 1% glutaraldehyde in 0.1M phosphate buffer at pH 7.4. The frozen spinal cord was cut horizontally in 100μm thick sections with a microtome and the sections processed for HRP visualization under the light microscope using the diaminobenzidine (DAB) cytochemical technique.

The morphological analysis is based on data obtained from 13 successfully labeled DSCT neurons. Ten of these units received excitatory sensory inputs from muscle receptors, while the remaining three units had either cutaneous or convergent (muscle + cutaneous) inputs. The DSCT neurons that received excitatory muscle receptor inputs are equivalent to the large Clarke cells (class C of Loewy, J. Comp. Neur., 139: 53, 1970). Their dendrites were oriented primarily in the rostrocaudal direction and generally smooth except for some branchlets. In two of these cells, the axon was traced into the lateral funiculus. There was no evidence that axonal collaterals arose from these axons during the initial trajectory through the spinal gray matter. One of the three cells that received cutaneous inputs had the morphological characteristics of a B' cell while the other two were similar in appearance to the Clarke cells.

2454 A CELLULAR SOURCE FOR SPONTANEOUS SPINAL CORD SLOW WAVES. J.T. Molt, D.A. Poulos and R.S. Bourke, Division of Neurosurgery, Albany Medical College, Albany, New York 12208.

Spontaneous, negative-going, slow waves are the characteristic components of the spontaneous spinal electrogram (SEG) as recorded from the dorsal surface of the spinal cord. It has been demonstrated that spontaneous slow waves increase in frequency of occurrence in the intact cord caudal to a site subjected to blunt trauma. The degree of change in frequency of occurrence of slow waves appears to correlate well with the extent of the lesion that results from blunt trauma. Because of this the SEG may be an important diagnostic tool in the evaluation of spinal cord injury and in the determination of effectiveness of treatment modalities. It has been shown by mapping the amplitude of slow waves as a function of depth within the cord that neurons in the dorsal gray matter may be a source of the waves. This experiment was designed to establish the cellular source of the slow potentials.

In anesthetic-free, decerebrate cats with a spinal transection at the T12 level, slow waves were recorded from a silver ball electrode on the exposed surface of the cord 2mm lateral to the midline at the L6 segment. Less than 1mm from this site a microelectrode was inserted into the cord and the spontaneous discharges of single neurons were recorded. Many neurons were sampled within a dorsal-ventral track through the gray matter, while simultaneously recording the SEG. Time intervals between successive unit firing and between successive peaks of slow potentials were measured using a PDP-12 computer. Statistical tests were performed on the time intervals.

The results show that the intervals between successive slow waves are not Poisson distributed; time interval histograms show significant bimodality. The great majority of spontaneously active cells have time intervals that show a Poisson distribution. However, in all tracks cells were encountered that showed histograms with definite bimodality. Cross correlation analyses indicate that firings in these cells correlate with the occurrence of slow waves. Cross expectation density histograms show the correlation to occur with delays of less than 10 msec regardless of whether the slow waves or the units are treated as the generating source. Electrolytic lesions placed at sites where non-Poisson unit activity was recorded show these units to be located in lamina IV of the dorsal horn.

These results suggest that a population of units in the dorsal gray matter show spontaneous activity that is reflected in a surface slow wave. That the occurrence of the slow wave can slightly precede, coincide with, or slightly follow the occurrence of unit firings indicates that the slow wave may result from summated excitatory post-synaptic potentials in these cells. Supported by NINCDS grant 13042.

2455 DEXAMETHASONE PREVENTS LOSS OF AXONAL CONDUCTION AND REFLEX ACTIVITY, AND REDUCES SPREAD OF STRUCTURAL DAMAGE IN ACUTE SPINAL CORD TRAUMA. A. C. Nacimiento, M. Bartels*, and H. D. Herrmann*. Departments of Physiology I and Neurosurgery. Saarland University, School of Medicine, 6650 Homburg (Saar) F.R.G.

A short-lasting compression of spinal L7 segment in the cat under conditions allowing quantitative monitoring of ensuing functional and structural changes (cf. Soc. f. Neurosci. Abstr., 1978, 4, 1828) was used to assess the effects of dexamethasone in CNS trauma. In control experiments a compression of 3 mm brought about immediate loss of polysynaptic reflex discharge and axonal conduction across the damaged segment. Some partial recovery of both functions took place about 2 hrs following trauma, with further decline and disappearance within the 6 hrs observation period. Main structural changes at this point were hemorrhages, edema and axonal disruption and swelling. The i.v. administration of dexamethasone (4 mg/kg) 30 min after compression brought about the following changes: a) the phase of partial recovery of polysynaptic reflex activity was prolonged throughout the 6 hrs period; b) similarly, decline and loss of axonal conduction following improvement was largely prevented; c) histopathological changes were circumscribed to the point of striking discreetness. It is suggested that dexamethasone counteracts the typically progressive tendency of functional and structural derangement following localized spinal cord trauma. Dexamethasone may exert these effects upon both functionally damaged and surrounding undamaged neuronal elements and axonal bundles in the lesioned segment. As a result improvement in synaptic transmission as well as in axonal excitability may be different expressions of a direct effect of dexamethasone on defined neuronal membrane properties.

2456 IMMUNOFLUORESCENCE STUDIES WITH GFA AND NEUROFILAMENT ANTISERA IN RATS WITH SPINAL CORD TRANSECTION. Chi Nguyen*, Doris Dahl, Bich Nguyen* and Amico Bignami. Spinal Cord Injury Service, West Roxbury Veterans Administration Medical Center and Harvard Medical School, Boston, Ma. 02132.

Antisera to neurofilament (NF) and gliofilament (GFA) proteins were used to examine with specific staining procedures the axonal and glial changes in rats with spinal cord transection. The NF antisera, raised against urea-soluble chicken brain antigen (J. Comp. Neurol. 176, 645, 1977), have recently allowed the isolation of the ∿ 70K polypeptide in bovine brain filament preparations by immunoaffinity chromatography (Trans. Am. Soc. Neurochem. 10, 141, 1979). Preliminary experiments showed the ability of the NF antiserum to stain regenerating peripheral nerve fibers by immunofluorescence. Following transection of the sciatic nerve and disappearance of the degenerated fibers, thin regenerating axons stood out prominently on a dark background in the distal stump. Transection of the posterior columns in the rat spinal cord at the low thoracic level resulted in the loss of immunofluorescence with NF antisera together with the appearance with GFA antisera of elongated hypertrophic astrocytes (isomorphic gliosis) in the fasciculus gracilis at the cervical level. With NF antisera the areas of tissue necrosis at the site of transection were characterized by the accumulation of brightly immunofluorescent round structures (axonal spheroids) often collected in clusters. With GFA antisera there was a mesh of glial fibers surrounding the areas of necrosis and diffuse astrocytic hypertrophy in the surrounding tissues. In all operated animals a few regenerating axons were seen. Although the posterior roots were not directly involved by the surgical lesion, regenerating fibers were invariably associated with cells similar to fibroblasts. In order to confirm the ability of centrally cut axons to undergo regeneration, autogenous sciatic nerve grafts and centrally connected posterior root stumps were inserted in the spinal cord. Vigorous axonal growth was observed not only in the graft but also in the surrounding spinal cord. In the spinal cord, axonal growth was associated with bundles of fibroblast-like cells. Supported by USPHS grant NS 13034 and by the Veterans Administration.

2457 THE PHRENIC NUCLEUS OF THE GUINEA PIG: SEGMENTAL LOCALIZATION OF AFFERENT AND EFFERENT CELL BODIES. E.S. Nylen*, L.S. Sigmund*, D.D. Rigamonti, C.C. Kao*. Depts. of Anat. and Neurosurg., Georgetown Med. Sch. and Veterans Admin., Washington, D.C. 20007.

Although the peripheral contributions of the phrenic nerve in the guinea pig(C4, C5, C6) have been documented by Cooper and Schiller(1975), knowledge regarding its central origin is unknown. The extensive body of information that exists for other mammals, including man, suggests that the phrenic nucleus constitutes a discrete, intermediately placed column of cells in the ventral horn. The longitudinal distribution has been observed rostrally to the third and caudally to the seventh cervical segments. Furthermore, the longitudinal placement of motor neurons does not always correspond to the ventral rami contributing to the phrenic nerve(Ullah, 1978). The ratio of afferent to efferent fibers of the phrenic nerve has not been reported in the guinea pig.

The present study exploited the HRP technique to segmentally localize the sensory and motor cell bodies giving rise to the phrenic nerve. Thoracotomies were performed aseptically on animals anesthetized with a combination of chloral hydrate and Inovar. HRP pellets were placed on crushed portions of the exposed right phrenic nerve and the enzyme isolated from the adjacent tissues by a silicone cuff. Allowing sufficient time for HRP transport, the animals were sacrificed and the cervical cord along with the right dorsal root ganglia were removed. Histological preparation follows Mesulam's technique. Longitudinal and transverse sections were made defining rostral to caudal and medial to lateral extensions of the motor cell bodies. The number of cells stained in the dorsal root ganglia were counted and segmentally defined.

Our data indicates that the longitudinal distribution of the motor cell bodies extends further rostral than the previously reported peripheral contributions would suggest. The morphological aspects of this study will be discussed in connection with data existing from other mammals. (Supported by the Veterans Administration and NIH Grant NS14413-02).

2458 SPINAL CORD AMINO ACID LEVELS IN NORMAL AND DIABETIC RATS. James T. Patrick*, David L. Felten, Michael A. Rea* and William J. McBride (SPON: Francis J. Fry). Departments of Anatomy, Psychiatry and Biochemistry and Institute of Psychiatric Research, Indiana University School of Medicine, Indianapolis, IN 46223.

Levels of the amino acids alanine (Ala), glycine (Gly), gamma-aminobutyrate (GABA), aspartate (Asp) and glutamate (Glu) were determined in thoracic spinal cord gray areas of normal and streptozotocin-induced diabetic rats. Using a dissecting microscope mounted on the outside of a specially constructed cold-box, microdisks of tissue were punched out from the dorsal gray (DG), intermediate gray (IG) and ventral gray (VG) using a modified needle (i.d. 330μm) with stylet. In the spinal cords from normal rats, an uneven distribution of amino acids was observed (Table): the level of GABA was significantly higher in the DG than in the IG and VG; the levels of Asp were significantly higher in the IG and VG than in the DG; the level of Glu was significantly higher in the IG than in the DG and VG; although there was no significant difference in the levels of glycine, there appeared to be a trend towards higher levels in the VG and IG.

Distribution of Amino Acids in Rat Thoracic Spinal Cord

Area	Ala	Gly	GABA	Asp	Glu
DG	7.4±0.9	48.7±3.8	18.1±0.8*	22.8±2.3*	85.1±6.1*
IG	6.8±0.7	67.7±8.1	12.2±1.2***	34.2±3.7	103.1±7.8***
VG	5.5±0.4	64.6±7.4	6.2±0.5**	32.4±0.9**	80.7±2.8

Levels of amino acids are expressed as nanomoles/mg protein ± SE; significance ($p<0.05$) for DG vs IG (*), DG vs VG (**) and VG vs IG (***).

In the diabetic rats, neuronal counts revealed a decrease of alpha motoneurons by 42% in the VG and a decrease of interneurons by 11% in the IG and VG (D.L. Felten, Clin. Res. 26: 67A, 1978). A comparison of the levels of the five amino acids in the DG, VG and IG of the normal and diabetic rats showed no significant difference. This suggests a nonselective diabetogenic loss of neurons. (Supported by NIH Grant P60 AM 20542 and Alfred P. Sloan Foundation Fellowship (DLF)).

2459 PHASE RELATIONSHIPS OF MOTONEURON, RENSHAW CELL AND Ia INHIBITORY INTERNEURON ACTIVITY PERIODS DURING FICTIVE LOCOMOTION IN MESENCEPHALIC CATS. Carol A. Pratt* and Larry M. Jordan, Dept. of Physiology, Univ. of Manitoba, Winnipeg, Canada, R3E OW3.

Our understanding of the neuronal circuits which comprise the spinal locomotion pattern generator in mammals has been handicapped by a lack of information on the activity patterns of identified lumbosacral interneurons (INs) during locomotion. Renshaw cells (RCs) (McCrea and Jordan, Can. Fed. Biol. Soc., 146, 1976) and Ia inhibitory interneurons (IaINs) (Feldman and Orlovsky, Brain Res., 84, 1975) have been shown to be rhythmically active during locomotion in the absence of cyclic afferent input, suggesting that they might operate as part of a central locomotion program. The role of these inhibitory INs in the control of locomotion is unknown, however. Attempts have been made in the present study to determine the function of these INs by analysing the discharge patterns of IaINs, RCs and MNs and the phase relationships of their activity periods during locomotion.

Locomotion was evoked by stimulation of the mesencephalic locomotor region (MLR) in decerebrate (precollicular-post-mammillary) cats. Rhythmic motor axon activity in an L6 ventral root filament was identified as being either flexor or extensor coupled, and then the cat was paralyzed (Flaxedil, i.v.) and artificially respired. MLR-evoked rhythmic activity in the filament provided a monitor of "fictive" locomotion. Neurons in the lumbar enlargement were recorded via glass micropipettes and identified by their responses to stimulation of various hindlimb nerves and to antidromic stimulation of cut ventral roots (L5-S1). All three cell types were recorded in the same preparation which allowed the activity of each cell to be compared to a common ventral root filament. By normalizing each step cycle, the phase relationships among cells recorded throughout an individual experiment could be determined.

RCs fired in phase with the MNs to which they were coupled with their periods of peak discharge tending to coincide with the onset of hyperpolarization of these MNs. Extensor-coupled IaINs were found to exhibit maximal firing rates in phase with the hyperpolarization of antagonist MNs. These data suggest that RCs and IaINs may function to curtail spurious MN firing by contributing to MN hyperpolarization during the appropriate phases of the step cycle. Examples were found which suggest that RC inhibition of IaINs may be a determinant of IaIN rhythmic activity during locomotion. (Supported by M.R.C. of Canada).

2460 ULTRASTRUCTURE OF SYNAPTIC TERMINATIONS OF FUNCTIONALLY IDENTIFIED FINE MYELINATED AFFERENT FIBERS. M. Réthelyi*, A. R. Light and E. R. Perl. Department of Physiology, University of North Carolina, Chapel Hill, NC 27514.

Physiologically identified axons from cutaneous high threshold (nociceptive) and "D-hair" mechanoreceptors of cat were stained intracellularly by iontophoresis of horseradish peroxidase. Histochemical reaction produced an electron-dense staining of the fibers and their terminations, traceable within the spinal dorsal horn. Ultra-thin serial sections were made of axonal branches selected with light microscopy.

Synaptic enlargements of high threshold mechanoreceptors are found principally in the ipsilateral marginal zone and the neck of the dorsal horn; boutons in the marginal zone contain round synaptic vesicles and, occasionally, dense-core vesicles (90 to 100 nm in diameter). The terminals often partially enclose dendritic profiles, greatly enlarging the contact area.

Most "D-hair" terminals are found in lamina III, with some extensions into adjacent parts of laminae II (inner substantia gelatinosa) and IV. The boutons are round, lack enclosing processes, and are filled with clear, round vesicles. Often, a bouton makes synaptic contacts with several dendritic structures. Some "D-hair" boutons are contacted by profiles containing flattened vesicles.

Thus, even though "D-hair" and high threshold mechanoreceptors have axons with overlapping (slow) conduction velocities, they differ not only in their regions of termination, but also in the morphology and ultrastructure of their central synaptic terminations.

Supported by Grants NS10321, NS14899, and NS05526 from the National Institute of Neurological and Communicative Disorders and Stroke of the United States Public Health Service; and aided by an exchange agreement with the First and Second Departments of Anatomy, Semmelweis University Medical School, Budapest, under the United States-Hungary Program of the National Science Foundation.

2461 SPINAL CORD RECONSTRUCTION: ELECTRICAL ADJUNCTIVE TECHNIQUES. D.D. Rigamonti, C.C. Kao*, R.O. Becker*, J.R. Wrathall*, M.R. Braford. Veterans Admin. Medical Centers (Syracuse and Washington, D.C.) and Depts. of Anat. and Neurosurg., Georgetown Medical School, Washington, D.C. 20007.

The delayed nerve graft technique is an experimental procedure in which viable nervous tissue is transplanted into the gap of a contused or transected spinal cord in an attempt to restore functional continuity between the injured cord stumps (Kao, 1974). This technique is routinely used in our laboratory in an attempt to restore function to paralyzed adult mammals. An adjunctive technique now under investigation is the use of electrical devices to enhance the wound healing process and subsequently promote axonal elongation into the nerve graft.

A brief description of the surgical procedure is as follows: Adult cats anesthetized with Ketamine are injured either by contusion or subpial transection and a forelimb nerve (future nerve graft) is transected in the axilla. Reconstructive surgery follows at periods varying from one to two weeks at which time "non-neuronal cells" (Wrathall, et al, 1978) are placed in the proximal and distal interface of the cord-nerve graft site. D.C. field electrodes with an output of 100 and 500 nA have been implanted during reconstructive surgery. The device, measuring 2 by 0.8 cm encapsulated in medical grade silicone, was placed between the paraspinous muscles and the spinous processes rostral to the implant site. The cathode was a 0.5 mm diameter silver wire insulated with Teflon with an exposed tip of 2.0 mm. The cathode was placed in the interface between the proximal cord stump and the nerve graft perpendicular to the long axis of the cord at a depth of 3.0 mm. The anode consisted of a loop of uninsulated silver wire with a length of 1.5 cm and a diameter of 0.5 mm. Histological reconstruction of the repaired spinal cord suggests that wound healing was improved. A second prototype is currently being constructed using platinum electrodes closely applied to the outer surface of the dura and completely encircling the cord and nerve graft. The electrode designs and significance of the histological findings will be discussed. (Supported by Veterans Administration, NIH,PCR, and NASA).

2462 VENTRAL HORN CELLS OF THE CERVICAL CORD PROJECT TO BRAINSTEM. Martine J. RoBards, Mark Stritzel,* and Richard T. Robertson. Dept. Anat., Calif. College of Med., Univ. of Calif., Irvine, Calif., 92717.

Large injections of horseradish peroxidase (HRP) into the upper brainstem and thalamus of adult opossums and hooded rats produce retrogradely labelled neurons deep in the intermediate gray zone and ventral horn of the spinal cord between C1 and C4. When the sensitive chromogen tetramethylbenzidine (TMB) is used in the HRP reaction, the fine processes of the filled neurons are visible. Several of the reactive neurons clearly show two axons; one exiting the cord in the ventral root, and another, crossing in the anterior gray commissure, ascending to the upper brainstem or thalamus.

Injections of HRP into trapezius, sternocleidomastoid, and splenius capitus muscles were used to identify the cervical ventral horn neurons projecting to neck muscles in the hooded rat. Filled cells were found throughout the ventral horns of C1 through C4, generally in a stratum deeper than that occupied by brainstem-projecting cells, but nonetheless showing spatial overlap and morphological similarity. Again, in TMB-reacted sections, cells were seen which had two axonal processes, one exiting in the ventral root and another crossing in the anterior gray commissure, the latter's destination uncertain.

Double-labelling experiments will be required to define with certainty the proportion of motor neurons in the upper cervical cord possessing both ascending and peripheral projections; and the precise loci of termination in brainstem or thalamus of these ventral horn cells remains to be disclosed.

2463 Detection of Sub-clinical Spinal Tract Sensory Dysfunction. Richard J. Schneider and Ronald Burke*. Div. Neurosurg., Dept. Surg., Univ. Md. Sch. Med., Baltimore, MD 21201.

The ability of humans and rhesus monkeys to discriminate between two somatosensory stimuli was examined in the context of signal detection theory (TSD). The subjects were seated with one leg restrained as a discrete group of hair shafts were stimulated in an oscillatory fashion. Two different frequencies of stimulation were used. The discrimination task required that the subject push a button in response to the "go" stimulus and refrain from pushing it in response to the "nogo" stimulus. Response latencies were recorded in 100 msec. time bins which formed the basis of a confidence rating scale and allowed the sensitivity of each subject to be characterized in the form of a receiver operating curve (ROC). A population of normal human subjects was compared with a population diagnosed to have multiple sclerosis. Monkeys were tested prior to and following surgically produced lesions of the spinal cord.

Normal subjects were found to generate reliable ROCs with duplicable d's regardless of response bias (β). These subjects responses indicated an ability to make the discrimination even when their subjective assessment of their performance was poor. Moreover, a varying discriminative ability, from adequate to extremely acute was shown. There was some evidence that younger subjects made the discrimination with greater facility than older ones. In comparison, the group of MS patients showed a diminished ability to make the same discrimination. Their d's were reduced, and sometimes the ROC showed that they were discriminating at random. Additionally, there appeared to be two sensory thresholds. One, seen at low frequencies and amplitudes, and another as both or either variable increased. The data from the MS population also indicated that sensory discriminative ability may diminish with repeated trials or with time.

We conclude that TSD may be utilized to produce a high-resolution, objective method for detecting spinal cord sensory injury. These results, as depicted in ROCs, clearly showed a difference between human populations. Moreover, as motor fatigue is well-documented in MS, there may be a sensory nervous system fatigue reflected by diminishing discriminative ability of the MS population as the test went on. Finally, we believe the first threshold to be related exclusively to hair-follicle stimulation and from our previous studies we think it reflects only dorsal funiculous function. We believe the second threshold is a skin or touch receptor threshold which involves other sensory pathways in addition to the dorsal funiculi.

Supported by Research Grant RG-1207-A-1 from the National Multiple Sclerosis Society.

2464 THE PHRENIC NUCLEUS OF THE DOG: SEGMENTAL LOCALIZATION OF AFFERENT AND EFFERENT CELL BODIES. L.S. Sigmund*, E. Nylen*, D.D. Rigamonti, C.C. Kao*. Depts. of Anat. and Neurosurg., Georgetown Med. Sch. and Veterans Admin., Washington, D.C. 20007.

Our earlier studies on the activation of the crossed phrenic pathway have prompted this present investigation to define the anatomical location of the phrenic nucleus in the dog and to determine the ratio of afferent to efferent nerve fibers supplying the diaphragm. Identification of the roots of origin and peripheral distribution of the phrenic nerve is well documented. However, the literature is noticeably lacking in conclusive evidence of the exact segmental location and extent of the phrenic nucleus. There appears to be almost complete agreement that the phrenic cell bodies lie in the fourth cervical segment, irrespective of species(Warwick et al.). Marinesco(1898) proposed that the distribution of these cell bodies further extended thru the fifth and sixth cervical segments in the dog. In regard to the ratio of afferent to efferent fibers, Landau, using the deafferented dog, found that efferent fibers comprised 55-65% of the fibers supplying the diaphragm.

The HRP technique was used to further define the afferent and efferent nerve supply and the segmental extent of the phrenic nucleus. The phrenic nerve was exposed in the thoracic cavity of anesthetized dogs. HRP pellets were placed on crushed portions of the phrenic nerve and subsequently isolated from surrounding tissue. Following sacrifice, the cervical spinal cord and accompanying dorsal root ganglia ipsilateral to the operated phrenic nerve were removed and histological processing was performed utilizing Mesulam's technique. Longitudinal and transverse sections were made to define both the rostral to caudal and medial to lateral extent of the nucleus. Dorsal root ganglia were also processed. The comparison of reactive dorsal root ganglia cells to phrenic nuclear cells in the corresponding spinal cord segment determined the ratio of afferent to efferent fibers. The significance of this study will be discussed as it relates to the surgical manipulations(phrenicotomy, phrenectomy, and dorsal rhizotomy) currently used to activate the latent crossed phrenic pathway. (Supported by the Veterans Administration and NIH Grant NS14413-02).

2465 RESPONSES OF EXTRACELLULAR CALCIUM ACTIVITY $[Ca^{2+}]_o$ DURING AFFERENT NERVE STIMULATION AND DURING SEIZURES IN SPINAL CORD OF CATS. G. Somjen, Dept. Physiol. Duke Univ. Med. Center, Durham, N.C. 27710.

It has been reported that $[Ca^{2+}]_o$ declines during stimulation and during seizures in cerebral and cerebellar cortex and in sympathetic ganglia[1,2,3]. I used Ca-selective microelectrodes to measure $[Ca^{2+}]_o$ in gray matter of unanesthetized decapitate spinal cords. Electric potential was recorded DC coupled from the reference barrel of the microelectrode. VRs were cut and the sciatic nerve stimulated repetitively. Changes of $[Ca^{2+}]_o$ were small and often required electronic averaging for detection. In some preparations repetitive stimulation was consistently associated with decreases of $[Ca^{2+}]_o$. Sustained potential (SP shifts of -1.5 to -6.0 mV were then associated with $\Delta[Ca^{2+}]_o$, between -10 and -50 μM. The timecourse of $\Delta[Ca^{2+}]_o$ was slower than that of the SP, and sometimes the minimum of $[Ca^{2+}]_o$ was reached only 1 or 2 sec after cessation of stimulation. In some preparations SP shifts up to-12 mV were not associated with any detectable change of $[Ca^{2+}]_o$ (limit of detection: ± 10 μM). Sometimes very prolonged repetitive stimulation evoked a very slow increase of $[Ca^{2+}]_o$ which could reach, in 35 to 45 sec, up to +120 to +150 μM, was then maintained at a plateau level, and after cessation of stimulation declined equally slowly. Responses of $[Ca^{2+}]_o$ in spinal cord are smaller than those reported for other tissues[1,2,3]. The difference cannot be explained by different total "packing density" of neural elements, for changes of $[K^+]_o$ in spinal cord are comparable to those elsewhere[4]. Opposing processes appear at work, releasing Ca^{2+} into ECF and removing it at the same time but at different rates, either by the same, or by different cellular elements. During seizures induced by i.v. injection of penicillin, decrements of $[Ca^{2+}]_o$ were also quite small and sometimes not detectable. However, in cord as in cortex[1] the decline of $[Ca^{2+}]_o$, if detectable, began before the onset of the SP shift related to a seizure. This is compatible with the concept that penicillin-induced spinal seizures are initiated by inward current in presynaptic terminals which is carried in part by Ca^{2+} (ref. 5). (Supported by NINCDS grant NS 11933)

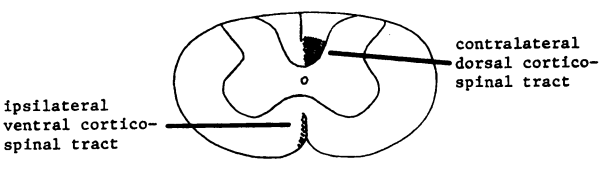
2466 EFFECT OF PRESYNAPTIC INHIBITION ON AXONAL POTENTIALS, TERMINAL POTENTIALS, FOCAL SYNAPTIC POTENTIALS AND EPSPS IN CAT SPINAL CORD. George W. Sypert, John B. Munson and James W. Fleshman. Dept. Neurosci.& Surg., Col. Med., U. Fla.& VA Med. Ctr., Gainesville, FL. 32610

Electrical test stimulation of triceps surae Ia afferents produces terminal potentials (TPs), focal synaptic potentials (FSPs) and excitatory postsynaptic potentials (EPSPs) in L_7 spinal cord laminae VI (interneuronal pool), VII (inhibitory interneuronal pool) and IX (triceps surae motoneuronal pool) and axonal potentials (APs) dorsal to these neuronal pools. Electrical conditioning stimulation (CS) of posterior biceps-semitendinosus (PBST) muscle nerve (4 shocks @ 300 Hz, max. Ia + Ib) reduces the amplitude of MG Ia EPSPs in triceps surae motoneurons (presynaptic inhibition). The present study demonstrates alterations in the latency and amplitude of MG Ia-elicited APs, TPs, FSPs, and EPSPs following CS of PBST in barbiturate-anesthetized normothermic cats. The data were averaged and digitized, using 10 μsec bin widths. In laminae VI, VII, and IX, CS reduces TP latency (20-40 μsec) and TP amplitude (15-25%) associated with reductions in FSP and EPSP amplitudes (15-25%). Similar but progressively diminishing temporal and amplitude changes in APs were observed with increasing distance of the recording microelectrode from these neuronal pools. These data suggest that CS to PBST depolarizes triceps surae Ia terminals in laminae VI, VII, and IX resulting in a shorter latency and reduced amplitude of MG Ia axonal and terminal potentials and, hence, smaller EPSPs due to reduced transmitter release (presynaptic inhibition). Supported by MRS, Veterans Administration.

2467 THE AUTORADIOGRAPHIC DEMONSTRATION OF AN UNCROSSED VENTRAL CORTICOSPINAL TRACT IN THE RAT. H. Lee Vahlsing* and Earl R. Feringa. Depts. Neuro. and Path., V.A. and Univ. of Mich. Med. Ctrs., Ann Arbor, MI 48105.

Twelve-week-old female albino rats were ether anesthetized and immobilized in a stereotactic apparatus. The skull was exposed and a 1 mm burr hole was made 2.5 mm posterior to the coronal suture and 2.5 mm lateral to the sagittal suture directly above the area of cerebral cortex containing the cell bodies that give rise to the corticospinal tract in the rat. Using a micromanipulator and a short beveled, 30-gauge needle, 50 μCi of tritiated proline in 2.5 μl lactated Ringers solution was slowly injected at a depth of 1 mm beneath the pial surface. After a 1 minute delay, the needle was withdrawn and the scalp sutured. After slow axoplasmic transport had labeled the corticospinal tract, each animal was killed by formalin perfusion and the brain and spinal cord removed. Cross sections of the brain and cord were sampled every 2 mm and 10 mm respectively. Sections were cut at 6 μm, mounted on slides, and dipped in NTB2 emulsion. They were exposed for 3 weeks in a light tight box with a CO_2 atmosphere and developed for 30 seconds in developer diluted 1:2 with water. The autoradiograms were examined by dark field microscopy.

The cross-sectional autoradiograms at the level of the injection site showed dense silver grains directly above the region of the injection site and adjacent cerebral cortex. Exiting cortical axons were labeled in the corpus callosum, the ipsilateral internal capsule and the ipsilateral ventral thalamic nucleus. At the level of the mesencephalic-metencephalic junction, only the ipsilateral corticospinal tract was labeled. In the posterior medulla oblongata, most of this tract decussated dorsally and medially to the ventral part of the dorsal white funiculus. However, roughly 10% of the tract continued uncrossed lateral to the ventral median fissure. This uncrossed tract was visible as a discrete fiber bundle in the high cervical region. It became more diffuse and contained fewer fibers in the lower cervical segments and in the thoracic spinal cord. The tract could not be traced below the mid-thoracic level.



2468 REFLEX SPECIFICITY IN THE FROG'S SPINAL CORD. M. Westerfield* and E. Frank. Dept. Neurobiology, Harvard Medical School, Boston, MA 02115.

How specific are synaptic contacts between sensory afferents and motoneurons in the bullfrog's spinal cord? We investigated this question with intracellular recordings from motoneurons innervating forelimb muscles in isolated decerebellate spinal cords. Antidromic activation by stimulation of muscle nerves identified the motoneurons.

The results suggest that the synaptic connections of sensory and motor neurons innervating the triceps muscles of bullfrogs are specific. Triceps motoneurons appear to receive short latency afferent synaptic potentials only from their own muscles. Similarly, triceps sensory neurons make strong, direct connections only with their own motoneurons.

Stimulation of the whole triceps nerve produced short latency EPSP's in motoneurons innervating triceps muscles. These EPSP's were often of sufficient size to orthodromically activate the motoneurons. Most neurons innervating the medial triceps muscle were not antidromically activated by stimulation of the other two branches of the triceps nerve. However, these motoneurons often did receive short latency EPSP's from the other two heads of triceps. Motoneurons innervating the external head of triceps almost always innervated the internal head too. Some motoneurons could be antidromically activated by stimulation of all three branches of the triceps nerve. Stimulation of other nerves in the arm produced longer latency EPSP's and IPSP's and in some cases, orthodromic activation of triceps motoneurons.

Motoneurons innervating other muscles of the front legs received short latency EPSP's from their own sensory afferents and longer latency EPSP's and IPSP's from other nerves. In many cases, single EPSP's could produce orthodromic activation of these motoneurons. Stimulation of triceps nerves produced no observable synaptic potentials in these motoneurons.

The development of this reflex specificity is being investigated.

2469 EFFECTS OF L-DOPA ON DORSAL HORN UNIT RESPONSES TO INNOCUOUS STIMULATION FOLLOWING PRETREATMENT WITH (1) 6-OHDA (2) FUSARIC ACID. Charles I. Woods*, Charles J. Hodge and Jonathan Delatizky. Dept. of Neurosurgery, Upstate Medical Center, Syracuse, NY 13210.

Studies of L-DOPA effects on sensory transmission suggest that L-DOPA modulates sensory input by releasing noradrenalin (NA) from noradrenergic nerve terminals in the spinal cord. Descending noradrenergic pathways from the locus coeruleus and other ponto-medullary reticular areas are the only source of spinal cord NA. In a previous study we demonstrated that L-DOPA increases the responsiveness of cells which respond only to innocuous stimuli, and depresses the activity of cells which respond to noxious stimuli, and showed that the inhibitory effects of L-DOPA are abolished by pretreatment with the serotonin depletor, p-chlorophenylalanine (PCPA). The present study was undertaken to determine if the effects of L-DOPA are specifically dependent on intact bulbospinal noradrenergic pathways and if these effects are due to NA rather than other metabolites of L-DOPA.

6-hydroxydopamine (6-OHDA), which causes selective degeneration of catecholamine fibers, was administered intracisternally to one group of animals (Breese & Taylor, Br. J. Pharmac. 42:88,1971), and fusaric acid, an inhibitor of dopamine-B-hydroxylase, was administered to another group (Nagatsu et.al., Biochem. Pharmac. 19:35, 1970). Cells were classified on the basis of their response characteristics, group I (cells responding to innocuous stimuli only), and group II (cells responding to noxious stimuli only or both noxious and innocuous stimuli). Cell responsiveness was evaluated using repeated identical deflection of hind limb skin or hair. The stimulus was presented at 5 sec. intervals and recorded for 15 min. prior to and at least 60 min. following I.V. injection of L-DOPA (15 mg/Kg). Average spikes per stimulus and average spontaneous activity were determined for each 5 min block.

Results following injection of L-DOPA: (1) 6-OHDA pretreatment: Most group I cells showed no change or a small decrease in responsiveness, most group II cells showed a decrease in responsiveness, (2) Fusaric acid pretreatment: (only group I cells were studied), most cells showed no change or a decrease in responsiveness.

The results suggest (1) the facilitatory effects of L-DOPA are specifically dependent on intact bulbospinal noradrenergic pathways, (2) the inhibitory effects caused by overflow of 5-HT are not mediated through noradrenergic pathways. The results of the fusaric acid experiments suggest that the facilitatory effects of L-DOPA are due to release of NA and not other L-DOPA metabolites, such as dopamine.

2470 EXPERIMENTAL TETHERED CORD. Shokei Yamada, David Zinke*, Delmar Sanders*. Dept. Neurosurg., Sch. Med., Loma Linda University, Loma Linda, CA 92350.

The syndrome "tethered cord" has been recently recognized as a neurological entity in children manifesting progessive signs, such as: incontinence and motor and sensory changes in the legs. This disorder is often associated with spinal anomalies and an elongated spinal cord. Neurosurgeons have experienced that untethering of the spinal cord often results in improvement of neurological signs.

Since neuronal cells rely absolutely on energy derived from intramitochondrial ADP phosphorylation, we postulated that oxidative metabolism of the tethered cord may be reduced below a critical level, thereby resulting in progressive neuronal injury. We applied the dual wave-length reflection spectrophotometer to the experimental tethered cord in vivo, and monitored changes in the reduction/oxidation ratio of cytochrome a,a_3, the terminal oxidase of the respiratory chain.

Twenty cats were anesthetized initially with ketamine and then with N_2O and O_2, and the lumbosacral spinal cord was exposed. Optical measurements were made at the junction of the lumbar and sacral cord. Tethering was produced by traction applied with 2-0 silk suture, one end tied around the filum terminale, the other passed over a pulley and attached to weights (1-5g). In addition, the animals were subjected to anoxic stress with 100% N_2O inhalation for 2.5 min. Spinal cord potentials were taken from its dorsal surface in response to the L6 nerve root.

Results. 1) The Traction Without Anoxic Stress. No significant changes occurred in redox level of cytochrome a,a_3 with traction 1-3g, whereas 5g traction resulted in a mild reduction. However, this reduction level is far less than the maximum reduction level obtained by anoxia.

2) Traction Under Anoxic Stress. As traction weight was increased, increases in the reduction level of cytochrome a,a_3 during anoxia became slow. Under 4 or 5g traction, changes in reduction levels failed to reach the maximum obtained with traction 0-3g; the interneuron potentials failed more rapidly under 5g traction than under 0-3g traction.

Conclusion. The experimental cord with 5g traction responds to anoxia with only minimum redox change. We believe the spinal cord under this circumstance resembles traumatized or anoxic cord with cytochromes highly reduced, probably due to vascular insufficiency. Untethering improves the oxidative metabolism of the cord, if neuronal mitochondria are not irreversibly damaged.

2471 FUNCTIONAL CHARACTERISTICS OF LARGE AND SMALL NEURONS IN SUPERFICIAL LAMINAE (I-III) OF THE CAT DORSAL HORN. Robert P. Yezierski, Dept. of Physiology and Biophysics, West Virginia University Medical Center, Morgantown, WV 26506.

Adequate stimuli and receptive field (RF) characteristics were determined for single neurons in laminae I-III of urethane anesthesized, spinal cats. Units were characterized while tracking small amplitude changes of waveforms with common functional properties using a real-time waveform recognition technique previously described (Yezierski et. al., 1978). Locations of maximum spike amplitudes were marked with ferric ions and Prussion-blue dots reconstructed using camera-lucida. Recordings were obtained from neurons across the full mediolateral extent of the gray in L6 and L7. Data from amplitude profiles were used in calculating source voltages; these voltages were used as an index to approximate size of neurons from which recordings were made. Results of this study confirm anatomical findings that neurons in these laminae constitute a heterogenous population with respect to size. Seventy-five percent of the neurons in laminae I-III had source voltages in the smallest calculated range; 30% of the neurons in deeper laminae were found in this range. Forty-two percent of the intermediate to large cells in laminae I-III were driven by light touch and noxious cutaneous stimulation; seven percent were driven only by noxious stimuli. Nineteen percent of the small neurons were driven by light touch, pressure, temperature, and noxious inputs. Very few small cells (<8%) responded exclusively to noxious stimuli. The relationships between RF characteristics (length/width ratios, RF area) and distance from toes were similar for both large and small neurons to those reported in deeper laminae (Brown et. al., 1973).

SYNAPTIC TRANSMISSION

2472 BIPHASIC IPSPS IN RAT HIPPOCAMPAL SLICE. Bradley E. Alger and Roger A. Nicoll. Depts. of Pharm. and Physiol., Sch. of Med., Univ. of Calif., San Francisco, CA 94143.

Iontophoretically applied GABA has been reported to have a biphasic (negative-positive) effect on membrane potential on certain CNS neurons. The depolarizing response has been attributed to the activation of dendritic receptors. It is not known, however, if the biphasic response can be produced synaptically, nor if the postulated dendritic site of mediation is correct.

Using the rat hippocampal slice preparation we have found that a biphasic IPSP in CA1 pyramidal cells results from orthodromic (s. radiatum) stimulation in the presence of 10^{-4} M pentobarbital. The intracellular records were obtained from CA1 cells in slices held fully submerged between two nylon meshes. We have confirmed that iontophoretic application of GABA to the soma produces a negative-positive sequence while iontophoresis in the dendritic region yields primarily a depolarization. Moreover, GABA antagonists block the electrically stimulated biphasic response, further supporting the possibility that GABA is the neurotransmitter involved in it. We found also that the dendritic depolarizing GABA response could be elicited in the presence of a low Ca/high Mg saline which blocked synaptic transmission, implying that these iontophoretic responses were not indirectly produced. These results suggested the depolarizing aspect of the electrically stimulated response was mediated by dendritic receptors. We tested this hypothesis with localized pressure injections of TTX (10^{-5}M) and found TTX could selectively abolish either hyper- or depolarization of the electrically evoked response depending on whether it was applied to the soma or dendritic regions, spectively. Blockage of the depolarizing phase occurred while was still possible to elicit full-sized somatic action potent ls with direct current pulses, indicating the TTX injections w e localized and supporting our hypothesis of a dendritic origin oi the depolarizing phase.

Both negative and positive phases of the stimulated response were associated with a large conductance increase and had inhibitory effects on action potential generation, which were similar to those found to occur with iontophoretic GABA. The depolarizing phase of the synaptic response was readily produced with orthodromic activation, but only rarely and with high stimulus intensities antidromically. This suggests the dendritic receptors may be activated preferentially as part of a feedforward inhibitory network distinct from the classical recurrent one.

2473 IMPLIED LOCUS OF HABITUATION OF THE MAUTHNER FIBER MEDIATED STARTLE REFLEX IN THE HATCHETFISH, GASTEROPELECUS. E. Aljure, J.W. Day and M.V.L. Bennett, Division of Cellular Neurobiology, Department of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Habituation of the Mauthner fiber (MF) mediated startle reflex is a common observation (J. Diamond in Fish Physiology, Vol. V, p. 265, 1971) and "fatigue" of responses of axial motoneurons (MNs) following activation of the ipsilateral MF by spinal stimulation was reported to occur at frequencies of 1/sec or less. We have confirmed EMG depression with intracellular stimulation of single MFs in uncurarized unanesthetized but restrained hatchetfish. EMGs due to activation of axial MNs were recorded from the caudal region. MF action potentials were present in the EMG record with an amplitude of about 0.1 mV, and conduction occurred at frequencies of stimulation much higher than those required for EMG depression. Recovery from depression could occur after rest periods of several seconds. During depression EMG amplitude varied, and maximal and markedly reduced responses were sometimes interspersed during stimulation at constant frequency. Since MFs activate axial motoneurons monosynaptically (cf. Diamond) and PSP amplitude at most synapses declines monotonically during depression (particularly when quantal variations are averaged over many synapses as would be expected for an EMG recording), the variability suggests a coordinated change in MN excitability (or a coordinated presynaptic inhibition or facilitation). Pectoral fin MNs participate in the startle reflex bilaterally. Either MF activates all of a group of interneurons, giant fibers (GFs), by chemical synapses and GFs activate fin MNs by electrotonic synapses. Fin movements show similar depression to axial EMGs with low frequency MF stimulation. Since MF to GF transmission remains one to one at these frequencies and electrotonic PSPs in fin MNs should be unaffected, a postsynaptic excitability change is likely to be responsible for fin MN depression and response habituation. If MF to axial MN transmission is like that from MF to GF, a postsynaptic locus would be indicated for habituation of axial movements as well. Our hypothesis is that in this system removal of a tonic excitatory input or addition of an inhibitory one causes depressed MN responsiveness which underlies behavioral habituation.

2474 A NORADRENERGIC S-IPSP IN MAMMALIAN SYMPATHETIC GANGLION, ELICITED BY A NON-MUSCARINIC ACTION OF PREGANGLIONIC VOLLEYS. John H. Ashe and B. Libet, Department of Physiology, School of Medicine, University of California, San Francisco, CA. 94143.

The atropinized superior cervical ganglion of the rabbit at 22°C exhibits a surface-positive (hyperpolarizing) potential, lasting 1-2 min, during and following a train of ganglionic spikes elicited by preganglionic nerve volleys (e.g., 5/sec for 8 sec). A considerable portion of this hyperpolarization is removed by incubation (60-90 min) with the α-blocker phenoxybenzamine (9 μM-12 μM), but not with the β-blocker sotalol (10 μM), indicating the apparent contribution of an α-adrenergic component. The remaining hyperpolarization is then "pure" posttetanic hyperpolarization (PT-HP), due to activity of the electrogenic Na-K pump (see Libet et al., Life Sci. 20: 1863-1870, 1977). PT-HP recorded at non-synaptic postganglionic axons is not affected by phenoxybenzamine.

The apparently adrenergic component of the hyperpolarization can also be eliminated by incubation with methacholine. This loss is presumably due to cholinergic action on an intraganglionic presynaptic store of catecholamine resulting in excessive release and depletion; subsequent incubation with NE or DA can in fact restore the hyperpolarization, with NE more effective. This contrasts with muscarinic depletion of SIF cells and loss of the DA-mediated s-IPSP, in which only DA is effective for restoration (Libet and Owman, J. Physiol. 237: 635-662, 1974). Conversely, incubation with the COMT inhibitor U-0521 resulted in a small but consistent increase in the amplitude and duration of ganglionic afterhyperpolarization.

These findings suggest that the phenoxybenzamine-sensitive component of hyperpolarization in the atropinized ganglion represents a second, parallel slow IPSP mediated at an "alpha" receptor by NE, and that the NE is released by a non-muscarinic action of ACh on an intraganglionic structure. Recurrent axon collaterals of ganglion cells do not appear to provide the presynaptic NE; the ganglionic hyperpolarization following a train of antidromic, postganglionic stimuli is insensitive to phenoxybenzamine. However, dendro-dendritic junctions between ganglion cells are not excluded as the synaptic mediators. (Supported by U.S.P.H.S. grant NS-00884 from NINCDS.)

2475 EVENTS UNDERLYING SYNAPTIC TRANSMISSION BETWEEN CONES AND BIPOLAR CELLS IN THE TURTLE RETINA. J.F. Ashmore* and D.R. Copenhagen* (SPON: R.H. Steinberg). Dept. Ophth., Sch. Med., UCSF, San Francisco, CA 94143.

The signal path between the cone photoreceptors and ganglion cells in the retina is formed by the bipolar cells. Two types can be distinguished by whether they depolarize or hyperpolarize to small centered spots of light. We have studied the kinetics of synaptic transmission and the voltage noise spectra from recordings in both types of bipolars in the turtle eyecup. For both cell types, the time to peak of linear range responses to flashes of light is 180-200 msec, which is slightly greater than that of the cones which drive these cells. The depolarizing bipolar cells exhibit a longer latency than the hyperpolarizing bipolar cells. In addition, the synaptic voltage gain from the cones to the depolarizing bipolar cells is greater than from cones to the hyperpolarizing bipolar cells. If it is assumed that the same transmitter is released from the photoreceptors a maximal rate in the dark and suppressed by light, then the differences in the light responses must be due to differences in postsynaptic transmitter action.

The voltage noise spectra from both types of bipolar cell has contributions from two components. Although the hyperpolarizing bipolar cells show a reduction in total noise with light (cf. Simon, Lamb, and Hodgkin, Nature 256:661, 1975), at all light levels the spectra can be fitted by the sum of a low frequency component which rolls off at 6-8Hz and a high frequency component which rolls off at 20-26Hz. The high frequency component corresponds to an event of approxmiately 20 msec in duration with an amplitude in the range 50-200 μV. It is most probable that this event is the miniature PSP whose frequency of occurrence is modulated by the dark noise fluctuations in the cones.

The depolarizing bipolar cells also have spectra which can be separated into two components. There is a low frequency component exhibiting a roll off at 6-8Hz. However the high frequency component corresponds to an event 35-40 msec in duration and is not completely suppressed by light. In both cell types, the power in the low frequency component is reduced by light, consistent with experiment data that light suppresses presynaptic voltage fluctuations. However it must be inferred that some special mechanism of transmitter action is required to explain the characteristics of the depolarizing bipolar cell response.

2476 A BIPHASIC IPSP IN PYRAMIDAL NEURONS OF HIPPOCAMPAL SLICES IN THE PRESENCE OF PENTOBARBITAL. G. F. Ayala and R. H. Thalmann*. Dept. Neur. and Cell Bio., Baylor Coll. of Med., Houston, TX 77030.

Elsewhere in this meeting we report that iontophoretic application of GABA to the somatic region of pyramidal neuron of the hippocampus produced a chloride and picrotoxin-sensitive biphasic response: a hyperpolarization followed by a depolarization. We now describe a similar biphasic response which can be elicited by synaptic rather than iontophoretic release of the inhibitory neurotransmitter if pentobarbital is present in the bathing solution. The response of CA1 pyramidal neuron to orthodromic stimulation was recorded by intrasomatic electrodes in hippocampal slices maintained at 34-35°C and bathed in CSF with a potassium concentration of 5 mM. Slices were incubated in 125 mM sodium pentobarbital for at least one hour before the experiment began. Under these conditions, low intensity stimulation elicited a hyperpolarizing IPSP which lasted from one to two seconds, and which was associated with a marked increase in membrane conductance. Increased stimulus intensities usually evoked a depolarizing component which was evident following the early hyperpolarizing peak of IPSP. A marked increase and prolongation of the membrane conductance also occurred. Topical application of a low chloride solution increased the size of the depolarizing component while shifting its reversal potential to a less negative value. Application of the GABA antagonists picrotoxin and bicucculine methiodide reduced the depolarizing component more readily than the hyperpolarizing phase. Repetitive stimulation at a rate of 1 Hz produced a summation of the depolarizing components to a plateau which could also be reduced by picrotoxin or by bicucculine. Although most responses were recorded with potassium-acetate filled electrodes, similar biphasic responses were also recorded with K-acetate and K-sulphate electrodes.

2477 **VOLTAGE CLAMP ANALYSIS OF PHENYTOIN AND PICROTOXIN ACTION IN CRAYFISH STRETCH RECEPTORS.** Floyd W. Banks and Paul R. Adams. Dept. Physiol. and Biophys. UTMB, Galveston, TX 77550.

Fast and slowly adapting abdominal stretch receptor neurones were voltage clamped using two potassium chloride filled microelectrodes and a Ringer solution containing 21 mM calcium. Inhibitory postsynaptic currents (ipscs) were set up by eliciting an axon reflex with a coarse fire polished Ringer-filled micropipette. At -100 mV and 23°C the ipsc had a rise time of ∿ 1.5 msec and an exponential decay phase with time constant (τ_{ipsc}) about 4 msec. τ_{ipsc} was somewhat increased by depolarizing the cell, the e-folding voltage being about 300 mV. The peak I-V relation was linear. In the presence of 50 μM phenytoin the ipsc decay remained a single exponential, but was about 6 times slower at all potentials. This slowing factor was proportional to phenytoin concentration in the range 10-100 μM. The ipsc amplitude was slightly increased. 10 μM picrotoxinin reduced the ipsc amplitude about 4-fold. The ipsc decay phase remained a single exponential, though slightly faster than the controls. In the presence of 50 μM phenytoin, picrotoxinin decreased the ipsc amplitude and τ_{ipsc} by about the same factor as in controls. 50 μM phenytoin shifted the log dose-conductance curve to bath applied GABA to the left, with no clear change in the maximum response. The leftward shift corresponded to a 3 to 4 fold increase in GABA potency. Formally, the results suggest that phenytoin and picrotoxinin bind to sites that control the rates of opening and closing of the GABA channel. It is not yet clear whether these sites are identical, and whether they are physically within the channel. (Supported by NIH grants NS-14920 and NS-14986).

2478 APOMORPHINE-INDUCED PHOSPHORYLATION OF A SPECIFIC SYNAPTIC MEMBRANE PROTEIN IN STRIATAL SLICES. M. Baudry* and G. Lynch Dept. of Psychobiology, Univ. of California, Irvine, CA 92717

The phosphorylation of synaptic membrane proteins has been postulated to mediate the effects of dopamine in the striatum via the stimulation of a dopamine-sensitive adenylate cyclase. However, until now, there have been no reports that dopamine or its agonists can produce a change in the phosphorylation of specific brain proteins, either in vivo or in vitro. We now report that, in rat striatal slices, apomorphine, a specific dopamine agonist, changes the phosphorylated state of a specific synaptic plasma membrane (SPM) protein. Further, this protein appears to be the same as that which has been previously reported to undergo phosphorylation after induction of long-term potentiation in the hippocampal slice preparation.

Striatal slices were incubated with or without apomorphine (100 μM) for 2 minutes, and either crude mitochondrial fraction or synaptic plasma membranes were prepared. These fractions were then assayed for endogenous phosphorylation, and the samples were then run on an exponential polyacrylamide gel system.

Apomorphine induced a marked and specific decrease in the incorporation of ^{32}P into a specific protein with a molecular weight of about 40,000 daltons (40K) in both the crude mitochondrial and the SPM fractions. This effect of apomorphine was totally reversed by incubating the striatal slices with the dopamine antagonist haloperidol (100 μM). In addition, phosphorylase B kinase (PBK), which has been shown to specifically phosphorylate the 40K protein in hippocampal SPMs, was also found to phosphorylate the 40K protein in striatal SPMs. However, this effect was smaller in SPMs prepared from apomorphine-treated slices than in SPMs from control slices.

These findings suggest the following conclusions:

1. Apomorphine, a specific dopamine agonist, increases the endogenous phosphorylation of a specific SPM protein in the striatal slice.
2. The change in the phosphorylated state of the 40K protein induced by apomorphine in striatal slices and by electrical stimulation in hippocampal slices may be mediated by phosphorylase B kinase.
3. Since dopamine agonists are known to induce long-term behavioral changes, and since repetitive electrical stimulation in the hippocampal slice induces long-term potentiation, the initial change in the 40K protein phosphorylation may well represent a common mechanism by which enduring changes in neuronal transmission are initiated.

2479 PRE-SYNAPTIC INHIBITION OF FACILITATION AT CRAYFISH NEUROMUSCULAR JUNCTIONS. Douglas A. Baxter* and George D. Bittner (Spon: Bob Grossfeld). Univ. of Texas, Austin, Tx. 78712.

The effect of pre-synaptic inhibition on facilitation was studied at the crayfish neuromuscular junction. Appropriately timed stimulation of the inhibitory motorneuron with respect to stimulation of the excitor motorneuron pre-synaptically reduced the excitatory transmitter output, presumably by decreasing the amplitude of each of the pre-synaptic action potentials in the excitor axon. When inhibitor stimulation was suddenly stopped in a train of excitor and inhibitor pulses the excitor axon at the next pulse in the train released the same amount of transmitter it would have released if only the excitor alone had previously been stimulated.

The release of excitatory transmitter was monitored via intracellular recordings of excitatory post-synaptic potentials (EPSP's) from opener muscle fibers in the cheliped of the crayfish Procambarus clarkii. A 100 Hz stimulus train having anywhere from 8 to 17 equal interval pulses was given to the excitatory axon. The train was repeated every 5 seconds and 25 successive trains were averaged with a signal-averaging computer. Then the excitatory train was repeated and the inhibitory axon was stimulated at 100 Hz at a phased angle which produced maximum pre-synaptic inhibition. After 4-14 excitatory stimuli in this second stimulus train, the inhibitor was no longer stimulated so as to release the remaining excitatory action potentials from inhibition.

In 18 of the 27 muscle fibers studied, pre-synaptic inhibition reduced the EPSP amplitude by 40-72% during the inhibited stimulus train (mean = 55%). Post-synaptic inhibition was found to have contributed only 2-9% (mean = 3.5%) of the observed reduction in EPSP amplitudes. In these fibers the amplitude for the EPSP which immediately followed the release from pre-synaptic inhibition suddenly increased to within 15% above or below the amplitude calculated for the corresponding EPSP in the non-inhibited train (mean = 8% below the EPSP amplitude observed in the non-inhibited train). The increase in EPSP amplitude following inhibition represented a far greater increase in transmitter release than is ever seen during the facilitation of transmitter release in the non-inhibited train and this increase probably resulted in part from the accumulation of facilitation during the inhibition of transmitter release.

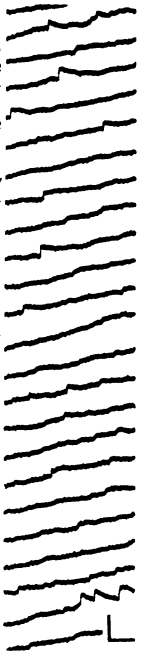
The results of this study indicates that the facilitation process can develop normally during the pre-synaptic inhibition of transmitter release. This result implies that the facilitation process is much more dependent upon the pattern than the amplitude of the pre-synaptic stimulation.

2480 PRESYNAPTIC MECHANISMS FOR CAPACITY-COMPENSATION IN A NON-IMPULSIVE NEURON. A.R.Blight and R.Llinás. Dept.Physiology and Biophysics, N.Y.Univ.Med.Ctr.,New York, N.Y.10016.

Action potentials mediate information transfer in nerve cells with low distortion from membrane capacitance,whereas graded, "analog" electrical signals are attenuated even over short distances, with much capacitative distortion. We have investigated the problem of how a non-impulsive cell is adapted nonetheless for the transmission of information, using the promotor stretch receptor fibre of the crab and its monosynaptic input to motoneurons (Blight and Llinás, Soc.Neurosci.Abst.4, 577, 1978). We have found a number of properties of the presynaptic fibre tending to compensate for the capacitative distortion of the receptor potential, conducted decrementally 12-15mm from the periphery. Injection of square current pulses into the presynaptic T-fibre revealed a graded, spike-like transient voltage response to depolarization of the membrane. The amplitude of this transient, which was previously thought to be sodium-dependent, was found relatively insensitive to TTX or replacement of external sodium, but to be directly dependent on external calcium concentration. This "graded spike", apparently based on a voltage-dependent calcium conductance with a tendency to become regenerative, increased the rate of depolarization, effectively producing a more "square" voltage response to a step current. It was found additionally to compensate lower frequency signals. Evidence was also obtained that the calcium transient induces a pulse of transmitter-release, giving a postsynaptic transient with a similar capacity-compensating effect on the motoneuron dendritic membrane, which is also non-impulsive.The form of the receptor potential itself was shown to be such that it tends to "voltage-clamp" the distant synaptic terminal, and the depletion characteristics of the synaptic transmitter store were found to be capable of re-introducing some of the "predictive", derivative properties of the receptor potential to the synaptically transmitted signal (e.g.producing a postsynaptic phase-lead in the transmission of sinusoidal signals). Though transmission in the stretch receptor is non-impulsive, it is not purely passive but rather complexly evolved to reconstruct an apparently faithful output (motor response) from an otherwise distorted input (decrementally conducted receptor potential). Similar and further mechanisms are to be expected in other "non-spiking" neurons.

2481 PROPERTIES OF SPONTANEOUS MINIATURE SYNAPTIC POTENTIALS IN HIPPOCAMPAL NEURONS. Thomas H. Brown, Robert K. S. Wong and David A. Prince. Neurology Dept., Stanford Univ. Med. Sch., Stanford, CA 94305.

The quantum hypothesis of synaptic transmission holds that neurotransmitter substances are released from nerve terminals in the form of integral numbers of multimolecular packets or quanta. In the peripheral nervous system, quanta can be liberated spontaneously (without nerve impulses) giving rise in the postsynaptic cell to the random occurrence of brief depolarizing events termed spontaneous miniature synaptic potentials. So far there has been no demonstration of spontaneous miniature potentials in the mammalian brain. We now report that miniature potentials can be recorded in guinea pig hippocampal nerve cells under conditions in which regenerative spiking activity and evokable (impulse-dependent) transmitter release have been blocked by TTX (1 µg/ml) and manganese (2 mM). This phenomenon was observed regularly in neurons of the CA3 region in the in vitro slice preparation (calibration in example at right: 5 mV and 50 msec).



The properties of these miniature potentials were analyzed in 8 cells. In each case the frequency distribution of miniature potential amplitudes was positively skewed, with the smallest events usually merging into the background noise. The mean amplitude of those events emerging above the background noise was 2.1 ± 0.3 mV. The large size of these events was not unexpected, given the high input resistance (about 40 Mohms) of these cells. The approximate net inward charge transfer associated with a miniature potential was estimated from the relation $Q = G_N \int V(t)dt$, where G_N is the input conductance measured at the soma (about 25 nS) and V(t) is the miniature potential amplitude as a function of time. For the larger events with fast rise and fall times, which presumably originate near the recording site, Q averaged 2.9 ± 1.1 pC, which is not exceptionally large. The timing of occurrence of miniature potentials in these cells suggested a random process, in that the intervals between successive events conformed approximately to an exponential probability density function $f(t) = 1/T \exp(-t/T)$, where T is the mean time interval. The mean value of T was 1.3 ± 0.9 sec.

This ability to resolve quantal events should aid our understanding of synaptic transmission between well defined neuronal populations within the hippocampus (Supported by NS 06161 & 06477).

2482 SYNAPTIC VESICLES HAVE SPECIFIC ANTIGENS, ABSENT FROM OTHER MEMBRANES. Steven S. Carlson & Regis B. Kelly. Dept. Biochem. Biophys. Univ. Calif. San Francisco, CA 94143.

The molecular constituents of synaptic vesicles may be unique or they may be shared by other cellular structures. We have examined this question immunologically by raising rabbit antibodies to cholinergic synaptic vesicles purified from the electric organs of Narcine brasiliensis. We have shown that a unique population of synaptic vesicle antigens exists. This conclusion was based upon two immunological assays; a solid phase assay and a solution assay which utilized inactivated S. aureus cells as an immuno-adsorbent. With the solid phase assay, antiserum could be shown to bind to pure synaptic vesicles which had been immobilized on a plastic microtiter well. The antibody bound was linear with antigen concentration at low antigen concentrations. To test whether the serum contained antigens which were specific for vesicles, the serum was adsorbed with a membrane fraction from the electric organ which did not contain synaptic vesicles. After extensive adsorption with non-vesicular membrane, 40% of the antigenic sites could still be recognized by the antiserum and are presumably specific to vesicles. The S. aureus radioimmune assay utilized precipitation of antibody-labeled antigen complexes with protein A coated S. aureus cells. This assay, which was linear with antigen concentration in the range of 0.05 to 1 µg of synaptic vesicle protein, could be used to detect synaptic vesicle antigen in crude homogenates of electric organ. Although the synaptic vesicle protein amounted to less than 1% of the total protein of electric organ, fractionation of crude homogenates of electric organ by differential centrifugation revealed that acetylcholine containing membranes and synaptic vesicle antigenicity co-purified. When the 100,000g membrane pellet was further fractionated on a glycerol density gradient, the antigenicity measured by both solid phase and S. aureus assays had the same density (1.20 g/cc) as vesicles detected by their acetylcholine content. No other electric organ membranes on the glycerol gradient were antigenic. Because synaptic vesicles contain specific antigens, anti-sera directed towards them will be valuable reagents in the study of nerve terminals. The vesicle-specific antigens are conserved during evolution since the anti-vesicle serum binds to nerve terminals of the frog, rat and chicken neuromuscular junction. This work supported by NIH grant NS09878 (to RBK) and a Postdoctoral fellowship from the Muscular Dystrophy Association (to SSC).

2483 EVIDENCE THAT ONE POOL OF CHOLINERGIC VESICLES IN MOUSE BRAIN CAN EMPTY AND REFILL WITH NEWLY SYNTHESIZED ACETYLCHOLINE AND ACETYLHOMOCHOLINE INDEPENDENTLY OF THE MONODISPERSE POOL OF CHOLINERGIC VESICLES. Paul T. Carroll* and Christina G. Benishin* Dept. Pharmacology, Univ. Rhode Island, Kingston, RI 02881. (SPON: J.T. McIlwain, Brown Med. School, Prov., RI 02912).

Previously we have reported that incubation of mouse forebrain minces in a lithium Krebs (L.K.) solution reduces the acetylcholine (ACh) content of a crude vesicular fraction (P_3) independently of the cytoplasm; subsequent incubation of minces in Krebs (K.) with labelled precursor, either ^{14}C choline or ^{14}C homocholine, refills the crude vesicular fraction with ^{14}C ACh or ^{14}C acetylhomocholine, respectively (Carroll & Nelson, Fed. Proc., 1979). Also, some choline o-acetyltransferase (E.C.2.3.1.6.-ChAT) cannot be solubilized from this crude vesicular fraction by high ionic strength washes (Smith & Carroll, Fed. Proc., 1979). The crude vesicular fraction contains at least two pools of cholinergic vesicles which can be separated by sucrose density gradient centrifugation, a monodisperse pool and another pool believed to be associated with neuronal membranes which sediments in a higher density of sucrose than the monodisperse pool (Barker & Whittaker, 1972). The objective of the present investigation was to determine if incubation of mouse forebrain minces in L.K. selectively reduces the ACh content of the denser vesicle fraction (D.V.F.) independently of the monodisperse vesicles (M.V.). Minces of mouse forebrain were incubated in K. or L.K. solution at 37° for 30 min, subcellular fractions prepared (Saleghmoghaddam & Collier, 1976) and the levels of ACh determined in the M.V. pellet and the D.V.F. Electron micrographs showed the presence of vesicles in both fractions. Also some non-solubilized ChAT activity was associated with the D.V.F. L.K. reduces the ACh content of the D.V.F. 86% without altering that of the M.V. with respect to K.; an acetylcholinesterase inhibitor is not required to demonstrate this reduction or maintain ACh levels in the D.V.F. Subsequent incubation of both sets of pretreated minces for 30 min in K. containing either ^{14}C choline (0.1mM) or ^{14}C homocholine (0.1mM) and paraoxon facilitates accumulation of ^{14}C choline (108%) and ^{14}C homocholine (109%) by the D.V.F. but not the M.V. of minces pre-incubated in L.K. with respect to those pre-incubated in K. The D.V.F. depleted of its ACh content by lithium pre-incubation can be refilled with either ^{14}C ACh formed from extracellular ^{14}C choline or ^{14}C acetylhomocholine formed from extracellular ^{14}C homocholine. These results suggest that a dense vesicle fraction contains non-hydrolyzable ACh which can be emptied and refilled with either newly synthesized ACh or acetylhomocholine independently of the monodisperse vesicle fraction. (Supported in part by NSF grant #BNS 78-05160).

2484 FREQUENCY DEPENDENCE OF GANGLIONIC BLOCKADE BY d-AMPHETAMINE. Daryl Christ* (SPON: D.L. Avery). Dept. of Pharmacology, Univ. of Arkansas for Medical Sciences, Little Rock, AR 72201.

The magnitude of ganglionic blockade by d-amphetamine is dependent on the frequency of preganglionic stimulation (Downing, Br. J. Pharmac. 44:71, 1972). The mechanism underlying the frequency-dependent blockade was explored in the isolated stellate ganglion of the hamster using extracellular recording techniques. d-Amphetamine reduced the compound action potential of the postganglionic nerve produced by supramaximal stimulation of the preganglionic nerve at 0.2 Hz. As the frequency of stimulation was increased, the magnitude of ganglionic blockade was decreased. 10^{-4}M d-amphetamine reduced the postganglionic potential by 86% at 0.2 Hz, and 41% at 2 Hz. The frequency-dependent block by d-amphetamine was not affected by propranolol (10^{-6}M), was slightly reduced by phentolamine (10^{-5}M), and was considerably reduced by atropine (10^{-6}M), suggesting that a muscarinic mechanism is involved.

d-Amphetamine produced spontaneous discharges in the postganglionic nerve at 10^{-3} and 10^{-4}M. This is indicative of a depolarizing action, and this depolarizing action may potentiate muscarinic transmission in the ganglion. d-Amphetamine potentiated discharges from the application of McN-A-343, a muscarinic cholinergic agonist, however this effect was not specific because discharges from the application of DMPP, a nicotinic cholinergic agonist, were also potentiated. Furthermore, the discharges by d-amphetamine and potentiation of discharges from cholinergic agonists lasted only for 10 to 20 minutes in the continuous presence of d-amphetamine. The frequency dependent effects of d-amphetamine occurred after much longer durations of exposure to d-amphetamine.

In the presence of 10^{-4}M d-amphetamine, repetitive stimulation (30 Hz, 5 sec) produced asynchronous afterdischarges. The afterdischarges were blocked by atropine, thus they were probably produced by muscarinic actions of the neurotransmitter. This indicates d-amphetamine does not depress muscarinic transmission as effectively as nicotinic transmission.

These results suggest that at low stimulation frequencies, the nicotinic blocking action of d-amphetamine will predominate and result in blockade. At high frequencies, the muscarinic actions of the neurotransmitter can potentiate the nicotinic actions of the neurotransmitter, thereby reducing the magnitude of ganglionic blockade by d-amphetamine.

2485 CHARACTERIZATION OF A POST-GANGLIONIC CATECHOLAMINE RECEPTOR IN THE RABBIT SUPERIOR CERVICAL GANGLION (RSCG), Alison E. Cole* and Patricia Shinnick-Gallagher, Univ. of Tex. Med. Br., Galveston, TX 77550.

Catecholamines (CA) have long been known to have potent inhibitory effects on ganglionic transmission (Marrazzi, 1938). Evidence indicates that a disynaptic pathway which involves a CA-releasing interneuron may mediate the inhibitory action via hyperpolarization of the post-synaptic membrane. Dopamine has been proposed as the primary neurotransmitter of this hyperpolarizing ganglionic response in the RSCG (Libet, 1970). This study will characterize the receptor involved in the inhibitory response by comparing the relative potencies of three CA's (epinephrine (EPI), norepinephrine (NE) and dopamine (DA)) in producing a hyperpolarization of the RSCG.

To examine this post-synaptic effect of CA on ganglionic transmission a concentration-response analysis was performed using an extracellular recording technique, the sucrose-gap. EPI, NE and DA in varying concentrations were administered by superfusing the ganglion.

All CA were consistently found to hyperpolarize the preparation in a clear concentration dependent relationship (N=30) with EPI>NE>>DA. DA was about ten times less potent than EPI in producing this response. The EC_{50}'s for EPI, NE and DA were 9 x 10^{-7}M, 2 x 10^{-6}M and 10^{-5}M respectively. In addition, apomorphine (10^{-3}M) had no effect on the ganglionic membrane potential (N=9), whereas clonidine (10^{-5}M), phenylephrine (10^{-4}M) and isoproterenol (10^{-3}M) produced a hyperpolarization. Phentolamine (10^{-6}M) was found to block the hyperpolarizing response of EPI, NE and DA, and shifted the concentration response curve to the right. The IC_{50} of phentolamine was 10^{-6}M. Haloperidol (10^{-6}M) was found to have no effect on the DA-induced hyperpolarization.

These results suggest that the CA induced hyperpolarizing response was due to activation of an α-adrenoceptor.

2486 FLUCTUATIONS IN LATENCY OF EPSP ONSETS: LARGE EPSPs EXHIBIT SMALLER FLUCTUATIONS THAN SMALL EPSPs. T.C. Collatos, S.G. Nelson and L.M. Mendell. Duke Med. Ctr., Durham, N.C. 27710

A recent paper from this laboratory (Collatos et al, Brain Res. 160:514, 1979) has demonstrated that EPSPs produced in a given motoneuron by a given Ia fiber exhibit fluctuating synaptic delays. The purpose of this communication is to explore the relationship between the statistical properties of the fluctuations and the resultant averaged EPSP. In cats we studied relatively large EPSPs (171-1129 μV) with brief rise times (0.3-0.6 msec, 10-90%). We have found that the variance of the latency distribution tends to be smaller at synapses which generate large EPSPs. One problem in the interpretation of these results is that large EPSPs might be easier to pick out of synaptic noise in single sweeps. This would be expected to reduce the variance of the onset latency distribution for large EPSPs artifactually. However, if this were so, it would be expected that the distributions would be skewed to the right (long latencies) since we have almost invariably observed that the population of EPSPs with short latencies at a given synapse is larger in amplitude on the average than the population with long latencies (as at the neuromuscular junction - Barrett and Stevens, J. Physiol. 227:665, 1972). In fact, about one-half the distributions were skewed, but in the opposite direction, i.e. in the direction of the larger EPSPs with shorter onset. This suggests that the variance of EPSP delays is not significantly influenced by difficulties in detection of their onsets at least for this population of relatively large EPSPs. Furthermore, since the distributions which were skewed were restricted almost entirely to synapses at which relatively large EPSPs were generated, it is unlikely that skewness was a consequence of an unfavourable signal to noise ratio. As expected from the above findings, skewed distributions tended to exhibit the smallest variances; the larger variance of some distributions was not associated with skewness. We conclude that at synapses at which large EPSPs are produced, the average time variability in the release process is less than at synapses where EPSPs are smaller. The alternative hypothesis, that the fluctuations are the result of increased variability in conduction time through the presynaptic terminals, seems unlikely since a small potential recorded from inside the motoneuron and identified as a terminal potential in the presynaptic Ia fiber (Munson and Sypert, Neuroscience Abst. 4, 1978) exhibits no latency fluctuations despite variability in onset of the subsequent synaptic potentials. It remains to be seen whether these fluctuations can be affected by stimuli which cause presynaptic inhibition at this synapse. (Supported by NIH).

2487 FAST EXCITATORY POSTSYNAPTIC CURRENTS IN SYMPATHETIC GANGLIA: ALTERATION BY PROCAINE. Elizabeth Connor*, Amy MacDermott* and Rodney L. Parsons*. (SPON: G.D. Webb). Dept. of Physiol. & Biophys., School of Med., University of Vermont, Burlington, VT 05405 and Laboratory of Preclinical Studies, NIAAA Intramural Research, Rockville, MD 20852.

Procaine and many other local anesthetics alter the decay kinetics of end-plate currents in skeletal muscle. In the presence of these drugs, end-plate currents no longer decay exponentially but have a decay time course which is the sum of at least two exponential components. The simplest kinetic scheme which accounts for this drug action is one in which drug molecules block open end-plate channels. We thought it of interest to determine whether a similar mechanism of drug action occurs at other vertebrate cholinergic synaptic membranes. Consequently, we have analyzed, with voltage clamp techniques, the alteration in fast excitatory postsynaptic currents (EPSCs) produced by procaine in bullfrog sympathetic postganglionic B cells. Synaptic currents were recorded from control and procaine treated cells from the same ganglion preparation maintained in a HEPES-buffered solution (mM: NaCl 117, KCl 1.8, $CaCl_2$ 1.8, HEPES 1.0; pH 7.3, 12-20°C). A two microelectrode voltage clamp system was used to clamp membrane voltage between +30 to -100 mV. In the absence of procaine, the EPSC rises to a peak value within a few msec and then decays exponentially with the time constant of decay having a small negative voltage dependence (A = 0.0039 ± 0.0017, M ± SD, N = 15, 14-18°C). The peak EPSC amplitude increases with hyperpolarization with the I-V relationship approximately linear in the range -30 to -100 mV. In the presence of procaine (0.2-0.5 mM), peak EPSC amplitude was markedly decreased and the I-V relationship in this voltage range became flattened so that peak amplitude did not increase substantially with hyperpolarization. In some procaine treated cells, EPSC decay no longer appeared as a single exponential function but consisted of two exponential components; an initial fast component followed by a slow component. When present, the two components of the decay time course in procaine treated cells became more obvious with hyperpolarization. In many other cells the initial component appeared absent or was too small to analyze so that the decay appeared only slowed relative to the decay time course in control cells. These results suggest that procaine produces a voltage and concentration dependent postsynaptic blockade in sympathetic ganglion cells. Supported by NIH grant NS 14552.

2488 LEPTINOTARSIN: PRELIMINARY PURIFICATION AND CHARACTERIZATION OF A PRESYNAPTIC NEUROTOXIN. Richard D. Crosland*, T.H. Hsiao*, Joseph R. Stimers*, and W.O. McClure. (SPON: B.C. Abbott). Section of Cellular Biology, University of Southern California, Los Angeles, CA 90007, and Department of Biology, Utah State University, Logan, UT 84322.

Leptinotarsin is a presynaptic neurotoxin which occurs in the hemolymph of beetles of the genus Leptinotarsa (Hsiao, T.H. and Fraenkel, G., Toxcon 7: 119, 1969). It causes a massive, biphasic release of miniature end plate potentials (mepps) from a phrenic nerve-diaphragm preparation from the rat (Satin et al., Soc. Neurosci. Abstr. 4: 584, 1978). During the first one minute phase, about 10% of the total available store of mepps is released. A second phase immediately follows the first phase and results in the release of the remaining mepps within 10-15 minutes.

Preliminary purification of L. haldemani hemolymph on a Sephadex G-150 column results in two separate peaks of activity. Each peak contains material which releases radioactivity from rat brain synaptosomal preparations previously incubated with [^{3}H]choline. The summed activity of both peaks accounts for 62% of the activity applied to the column. The material in the first peak (Peak A) is purified 4.5 fold over the hemolymph and contains 65% of the recovered activity. The material in the second peak (Peak B) is purified 2.5 fold over the hemolymph and accounts for 35% of the recovered activity. The activities in both peaks are labile, but can be partially stabilized with dithiothreitol and bovine serum albumin. Propylene glycol and EDTA are ineffective as stabilizing agents.

When applied to a phrenic nerve-diaphragm preparation from the rat , the material in both peaks causes a biphasic release of mepps similar to that caused by unfractionated hemolymph. The second phase of release caused by the material in Peak B, however, is more prolonged than the second phase of release caused by the material in Peak A. Further purification and characterization of the active components of Peaks A and B should provide useful toxins with which to elucidate the mechanism of release of acetylcholine.

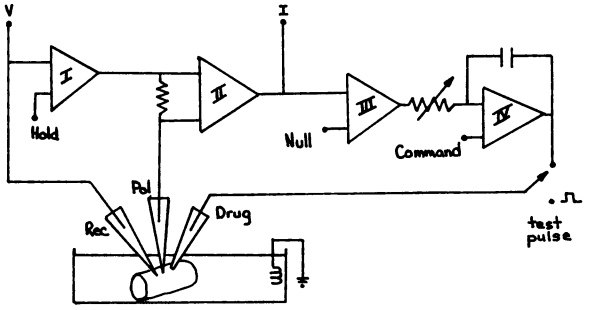
2489 SIMULTANEOUS, INDEPENDENT CLAMPING OF VOLTAGE AND AGONIST-INDUCED CURRENT ACROSS THE ENDPLATE MEMBRANE. J. del Castillo, P. Specht* and A. Auerbach*.
Lab. of Neurobiol. and Dept. Pharmacol., Sch. of Med., UPR, San Juan, PR 00901

The circuit to clamp the potential across the endplate membrane by electrophoretic drug application recently described by del Castillo and Specht (J. Physiol. 284:95-96P, 1978) has been combined with a conventional two microelectrode voltage clamp system as shown below. This allows the simultaneous and separate control of both the current required to hold the membrane potential at a fixed level, and the agonist-induced current flowing through receptor-associated channels.



Amplifier I represents the voltage clamp, with a floating current monitor in amplifier II. The membrane potential (V) is controlled by the holding potential (Hold). A signal proportional to the injected current (1 mV/nA) is applied to buffer amplifier III, where any D.C. component is manually nulled to near zero. This output goes to the drug clamp amplifier (IV). A command signal of x mV, applied to amplifier IV, will generate the outward movement of agonist necessary to maintain a drug-induced current of x nA.

This system is useful for the analysis of agonist-induced current, as it makes it feasible to maintain a steady level of receptor activity for periods longer than those possible when the agonist application is controlled manually.

Supported by USPHS Grants Nos. NS-07464, NS-14938 and RR-01802 and a MDA Postdoctoral Fellowship to A.A. (Contribution No. 89, Laboratory of Neurobiology).

2490 THE LIPIDS OF PURIFIED ELASMOBRANCH SYNAPTIC VESICLES: RELEVANCE TO THE MECHANISM OF EXOCYTOSIS. James W. Deutsch* & Regis B. Kelly. Dept Biochem. Biophys. Univ. Calif. San Francisco, CA 94143 (SPON: E. Mayeri).

A large body of evidence supports the hypothesis that the release of vesicle-contained transmitter occurs via fusion with the presynaptic membrane in the presence of Ca^{++}. Only recently has the availability of rigorously purified synaptic vesicles from Narcine brasiliensis electric organ (Carlson et al. (1978). Biochemistry 17, 1188) made it possible to address biochemically the question of how synaptic vesicles fuse. Studies of artificial liposomes reveal that Ca^{++}-mediated fusion requires negatively-charged lipid and a fluid membrane.

Purified synaptic vesicles were extracted and their lipid content analyzed. The major phospholipids are phosphatidylcholine (PC), 46 mol%; P-ethanolamine, 32%; sphingomyelin, 5%; and P-serine, which is negatively charged, 16%. The molar ratio of cholesterol to lipid phosphorus is 0.5, which is higher than that of whole electric organ (0.4) and lower than that of a non-vesicular membrane fraction which comigrates with synaptic vesicle in an early purification step (0.8). The fatty acids were analyzed by gas chromatography. The major fatty acids of synaptic vesicles are 16:0 (31 mol%), 22:6 (30%), 18:0 (13%), and 18:1 (11%). P-ethanolamine and P-serine contain high percentages of 22:6 (47% and 37%, respectively). Both whole organ and the non-vesicular membrane fraction contain significantly less 22:6 (9% and 16%, respectively).

The presence of a large amount of highly unsaturated fatty acid is consistent with the requirement from model studies that the membrane be fluid. The high concentration of cholesterol, which tends to decrease fluidity, is inconsistent, however. The amount of negatively charged lipid (P-serine) is not unusually high but it is necessary to know whether or not it is present in higher concentration on the protoplasmic surface of the vesicle membrane. This work was supported by NIH grant NS09878 (to RBK) and a NIH Postdoctoral Fellowship (to JWD).

2491 A STUDY OF SLOW POSTSYNAPTIC POTENTIALS IN SEVERAL MAMMALIAN SYMPATHETIC GANGLIA. N. J. Dun and A. G. Karczmar. Loyola Univ. Stritch School of Medicine, Maywood, Ill. 60153.

The slow postsynaptic potentials of the superior cervical ganglia (SCG) of the rabbit, rat and guinea pig were studied by means of the sucrose-gap technique. In the presence of hexamethonium (C_6,0.5 mM) which suppressed the initiation of ganglion compound action potentials, repetitive preganglionic stimulation (10-20 Hz, 1-2 sec) elicited in rabbit and rat SCG a biphasic synaptic response, an initial slow positive (P) potential followed by a late negative (LN) potential. The amplitude of P potential in the majority of these ganglia was much larger than LN potential which in several preparations was negligible. However, in guinea pig SCG superfused continuously with C_6, repetitive preganglionic stimulation evoked only a slow depolarizing response with no detectable hyperpolarization. Physostigmine (1μM) increased the amplitude of P and LN potentials in the majority of rabbit and rat SCG; in several preparations, the large increase in P masked the appearance of LN. In the SCG of guinea pigs, the amplitude of LN was first enhanced and then depressed by physostigmine, and after 15-20 min drug treatment, the LN was replaced by a hyperpolarizing potential. This effect of physostigmine was fully reversible. The effects on P and LN potentials of a number of adrenergic and dopaminergic antagonists were studied. Alpha-adrenergic blockers, phenoxybenzamine and phentolamine and beta-adrenergic blocker, propranolol, in concentrations up to 10 μM did not appreciably affect the amplitude of P and LN, whereas in higher concentrations, both P and LN were depressed by these agents. Dopaminergic blockers, haloperidol, chlorpromazine, metoclopramide and pimozide in concentrations up to 1 μM did not significantly depress the amplitude of P and LN, whereas, haloperidol (50μM) attenuated non-selectively the amplitude of P and LN in rabbit SCG. Atropine (1 μM) consistently and reversibly abolished the P and LN in all three species. These results demonstrate that muscarinic receptor is involved in the generation of P and LN potentials in mammalian sympathetic ganglia, whereas, the catecholaminergic nature of P is less certain. (Supported by NS 06455 and American Parkinson Disease Foundation).

2492 NON-VESICULAR RELEASE OF NEWLY SYNTHESIZED ACETYLCHOLINE FROM RAT CEREBRAL CORTICAL SYNAPTOSOMES. Gary E. Duncan* and Peter P. Rowell. Department of Pharmacology and Toxicology, University of Louisville School of Medicine, Louisville, KY 40232.

The release and subcellular distribution of ^{3}H-acetylcholine synthesized from ^{3}H-choline in synaptosomes were investigated in order to study the role of synaptic vesicles in acetylcholine release. Crude synaptosomal preparations were prepared from rat cerebral cortical homogenates and incubated for periods of 20 min to 2 hrs. ^{3}H-choline was shown to be transported into synaptosomes by a hemicholinium sensitive mechanism. Spontaneous release of the newly synthesized ^{3}H-acetylcholine was inhibited completely by 10mM magnesium. No detectable ^{3}H-acetylcholine was associated with particulate intrasynaptosomal contents as determined by preparative ultracentrifugation and sucrose gradient centrifugation. These results imply that synaptic vesicles are not required for acetylcholine release from synaptosomes.

2493 CORRELATIVE BIOCHEMICAL AND MORPHOLOGICAL INTEGRITY OF SYNAPTOSOMES: COMPARATIVE EFFECTS OF ISOLATION AND INCUBATION. Lynda H. Fleming*, Albertina E. Hodach*, and Norman C. Reynolds*. (SPON: D.A. Szech). Neurology Dept., Univ. of Wisconsin School of Medicine (Mt. Sinai Med. Cntr.) and Dept. of Pediatrics, Medical College of Wisconsin (Milwaukee Children's Hospital), Milwaukee, WI 53233.

Synaptosomes are often isolated in solutions with no regard to the role of pH in the production of viable nerve endings. However, isolation of viable synaptosomes which transport GABA and glutamic acid is critically dependent on the pH of the isolation solutions. (Hitzemann. J. Neurochem. 32: 669, 1979). Suboptimal isolation conditions yielding reduced numbers of metabolically active synaptosomes may also account for their relatively low levels of lactate dehydrogenase (LDH). Synaptosomes isolated in cold hypertonic sucrose solutions manifest the characteristic S-form when examined by electron microscopy. This morphology can be changed to one resembling in situ nerve endings by a brief incubation in iso-osmolar ion media. (Hajós and Csillag. Br. Res. 112: 207, 1976). Similar buffered salts solutions are often used in experiments designed to elucidate presynaptic events. Since these solutions approximate in vivo salt concentrations, it is assumed that the synaptosomes retain their integrity throughout the incubation period. However, by measuring LDH in Krebs-Ringer medium after incubation, it was shown that the addition of isotonic sucrose is essential for maintaining synaptosomal integrity. (Sperk and Baldessarini. J. Neurochem. 28: 1403, 1977).

The specific aim of this study was to provide an integrated approach to the measure of intactness of synaptosomes during isolation and incubation by using LDH activity and electron microscopy. Synaptosomes isolated on unbuffered sucrose gradients were compared with those isolated on sucrose gradients of known pH. After incubation in one of several different solutions, the synaptosomes were centrifuged and both supernant and pellet were assayed for LDH activity. In addition, effects of the incubation on synaptosomal morphology were also determined. By using this approach, we have outlined a basic technique for the optimum use of synaptosomes as a model system for the investigation of presynaptic events.

2494 APPLICATIONS FOR A MICROCOMPUTER SYSTEM IN CONVENTIONAL ELECTROPHYSIOLOGICAL EXPERIMENTS. G.H. Frederickson*, J.H. Fisher* and G.L. Ringham (SPON: H.M. Brown). Dept. of Physiology, University of Utah College of Medicine, Salt Lake City, UT 84108.

Experiments in this laboratory use conventional microelectrode stimulation and recording techniques to examine the characteristics of synaptic transmission at a synapse in the lamprey spinal cord. Recently, an inexpensive microcomputer system has been utilized in these experiments to help produce and evaluate the data. The system consists of a 4 MHz, Z80 microprocessor, multichannel digital-analog (D/A) and analog-digital (A/D) converters, dual disc drives, 32 K of memory, an external clock with a 10 MHz time base, and a teleprinter. In one application the microcomputer has been programmed to serve as a four channel, digital stimulator. In this capacity the computer delivers pulses, singly or in combination, of variable duration, delay, and frequency; it can also provide train-pulse combinations or direct voltage. The fixed amplitude pulse output of the computer itself is used to control variable voltage output amplifiers, which permit manual control of the intensity and polarity of the signal. This system is able to generate signals with an uncertainty of less than 5 μsec per cycle. A distinct advantage of this approach is that frequently used stimulation parameters can be pre-programmed into the computer and called up as needed during an experiment. Of course, any signal can be obtained when needed by simply entering the desired parameters. A second major use of the computer is for on-line analysis of the data. For example, a stimulus generated as described above can be used to produce a presynaptic action potential. This action potential and the resultant post-synaptic potential are fed to separate channels of the A/D converter of the computer, and the amplitude and time course of the potentials are measured. The computer then prints mean values for maximum amplitude and time to peak of the pre- and post-synaptic potentials produced during a given trial. Future programs will utilize the graphic capabilities of this system to produce graphs relating the pre- and post-synaptic potential changes. Experimental results obtained with this microcomputer system are presented elsewhere at these meetings.

Supported by NIH grants NS07938 and NS13884 from the U.S. Public Health Service.

2495 DENDRITIC LOCALIZATION AND DENSITY OF ACETYLCHOLINE RECEPTORS IN SINGLE CELLS IN SLICES OF GOLDFISH OPTIC TECTUM. John A. Freeman. Dept. of Anat., Vanderbilt Univ., Nashville, TN 37232.

All three major classes of retinal ganglion cells terminating in the goldfish optic tectum appear to be nicotinic-cholinergic (Schmidt and Freeman, Brain Res., in press, 1979). In order to examine the localization and density of nicotinic acetylcholine receptors (nAChE) physiologically, tissue slices 100-300 μm thick were made parasagittally through the tectum, by cooling the fish to 4° C, rapidly removing the tectum and placing it on a Peltier-effect cooled movable stage, using a methacrylate adhesive. Slices, made by rapid vertical strokes of a razor attached to a rotary solenoid, were then transferred to a coverslip which formed the bottom of a perfusion chamber, and were viewed with an inverted microscope equipped with Nomarski optics and a Zeiss fluorescence epi-illuminator. Individual cell bodies and their axonal and dendritic processes could be clearly seen (mag. 500 X), as could the 3 layers of retinal afferents. Contrast was further enhanced by supravital staining with 0.5% methylene blue (20-30 sec). Slices perfused with oxygenated Ringer's maintained their viability for 8-10 hr; normal laminar field potentials could be elicited by stimulating the retinal fiber layers, and stable intracellular resting potentials (25-65 mV) were recorded from cell bodies in the superficial and deep gray layers (diameter 7-12 μm; Z_{in} = 70-120 MΩ). The dendritic surfaces of individual tectal neurons were mapped iontophoretically for their sensitivity to ACh. ACh sensitivity was sharply localized to 3 zones, corresponding to the regions of optic nerve terminal synapses. The reversal potentialsfor ACh were near 0 mV for all 3 zones, as determined by the use of double-barrelled intracellular microelectrodes. DTAF- and TRITC-conjugated α-Btx bound selectively to these same 3 layers and abolished ACh-induced depolarization, recorded intracellularly. Individual clusters of fluorochrome labelled receptors could be discerned both on the dendrites and on many cell bodies. Assuming an area of 0.13 μm^2 for the subsynaptic membrane, a receptor density of 1,500-3,500 nAChR molecules/μm^2 was estimated at retinotectal synapses. The dynamics of acetylcholine receptors during different phases of optic nerve degeneration and regeneration are currently being investigated.

2496 IONTOPHORESIS OF ACETYLCHOLINE EVOKES A SLOW MUSCARINIC DEPOLARIZATION IN NEURONS OF DISSOCIATED RAT SUPERIOR CERVICAL GANGLION. Joseph E. Freschi* and William G. Shain (SPON: D. E. Evans). Neurobiology Dept., Armed Forces Radiobiol. Res. Inst., Bethesda, MD 20014.

Synaptic transmission within the superior cervical ganglion (SCG) has been extensively studied because it is experimentally accessible and contains a diversity of types of synaptic transmission. Further experimental simplification has been achieved using tissue culture techniques, so that the biochemical basis of neural transmission and its correlation with electrophysiology have been usefully studied. It is puzzling, therefore, that the slow synaptic potentials seen in intact animals and isolated whole organ preparations have not been discovered in primary cultures of mammalian SCG (O'Lague, P. et al., Devel. Biol. 67: 424, 1978).

We have consistently found slow depolarizing potentials in response to iontophoresis of acetylcholine (ACh) onto neurons dissociated from neonatal rat SCG. With small pulses of ACh a fast depolarizing response associated with a fall in membrane resistance (Rm) is evoked. When the fast response reaches saturation with large pulses of ACh, a long-lasting depolarization of delayed onset becomes evident. The slow ACh response increases in amplitude and duration in a dose dependent fashion, a maximal response lasting 30 to 40 sec. The Rm during the slow response either remains unchanged or increases slightly. Curare eliminates the fast ACh potential without affecting the slow response. Atropine selectively blocks the slow potential. Excitability is increased during the muscarinic action of ACh. This effect is independent of ACh induced changes in membrane potential. In some cells hyperpolarizing the membrane with steady inward current reduces the amplitude of the ACh depolarization but does not reduce the increased excitability effected by ACh. The spike afterpotential is reduced following muscarinic ACh activation, and this effect, too, occurs separately from changes in membrane potential.

The requirement of a large ACh dose to evoke the slow depolarizing potential may suggest that both nicotinic and muscarinic ACh receptors of high affinity (Heilbronn, E. and T. Bartfai, Prog. in Neurobiol. 11: 171, 1978) must be saturated before lower affinity muscarinic receptors mediating the slow response can be evoked. Our findings offer the opportunity to more easily and unambiguously study the ionic and biochemical mechanisms of muscarinic ACh action.

2497 PURIFICATION OF AN α-BUNGAROTOXIN BINDING COMPONENT FROM *DROSOPHILA MELANOGASTER*. Janice I. Gepner and Linda M. Hall. Dept. of Biology, MIT, Cambridge, MA 02139.

An α-bungarotoxin binding component was solubilized from homogenates of *Drosophila* heads as an initial step in the purification of this component. Detergents with intermediate hydrophile-lipophile balance (HLB) numbers of 13 to 14.5 were the most effective in solubilizing toxin binding activity. (HLB number reflects the relative hydrophobicity of a detergent.) Optimal solubilization was achieved with 1% Triton X-100 in 1.0 M NaCl. Under these conditions, a maximum of 50% of the binding activity was solubilized.

The solubilized α-bungarotoxin binding component was purified by passage twice through an affinity column composed of Sepharose 4B covalently linked to the α-neurotoxin from the cobra *Naja naja siamensis*. The binding component which was adsorbed to the affinity column and eluted with carbamylcholine had a molecular weight of approximately 500,000 by agarose gel chromatography and 250,000 by sucrose gradient analysis. The specific activity of the final purified α-bungarotoxin binding component was 1 μmole α-bungarotoxin binding sites/g protein, representing a 700 to 1000-fold increase over that of the solubilized extract.

Cholinergic compounds were shown to inhibit [^{125}I]α-bungarotoxin binding to the purified extract. The concentrations required for 50% inhibition are as follows: dihydro-ß-erythroidine (0.026 μM), nicotine (0.35 μM), d-tubocurarine (0.66 μM), trimethaphan (1.3 μM), gallamine (1.6 μM), acetylcholine (3.0 μM), atropine (18 μM), carbamylcholine (23 μM), dexetimide (60 μM), decamethonium (63 μM) and pilocarpine (150 μM). The relative ability of cholinergic ligands to inhibit toxin binding to the purified component is very similar to that observed with crude *Drosophila* extracts and is consistent with the suggestion that the toxin binding component is a nicotinic acetylcholine receptor.

2498 INHIBITORY POTENTIALS RECORDED FROM MAMMALIAN PARASYMPATHETIC GANGLIA. William H. Griffith, III, Joel P. Gallagher and Patricia Shinnick-Gallagher. Dept. of Pharmacol. and Toxicol. Univ. of Tex. Med. Br., Galveston, TX 77550.

The sucrose gap recording technique was used to study post-train hyperpolarizing potentials in the cat parasympathetic vesical pelvic ganglia (VPG). This is the first time this technique has been employed to record both action potentials and slow membrane potential changes from a parasympathetic ganglion.

Following nicotinic blockade of the ganglion with either hexamethonium (10^{-4}M), chlorisondamine (10^{-5}M) or nicotine (10^{-5}M) and orthodromic stimulation of 30 Hz for 1 sec, two types of hyperpolarizing potentials were observed. First, a slow inhibitory postsynaptic potential (slow i.p.s.p.) was observed with amplitude of 0.5-1.2 mV and duration of 3-9 sec. Second, a long lasting hyperpolarization that was small in amplitude (0.1 to 0.4 mV) but lasted up to 3 min. The long lasting hyperpolarization was more apparent after blockade of the slow i.p.s.p. No slow or late excitatory postsynaptic potentials were observed (N=25).

The slow i.p.s.p. could be blocked by atropine (10^{-7} - 10^{-6}M) but was not blocked by phentolamine (10^{-6}M) or propranolol (10^{-6}M). On the other hand, NE (10^{-4}M) added to the bath by superfusion depolarized the membrane; this depolarization blocked by phentolamine (10^{-6}M). The long lasting hyperpolarization was not blocked by atropine, phentolamine or propranolol. In addition, the long lasting hyperpolarization persisted in the presence of zero Ca^{++} - 1 mM EGTA. The long lasting hyperpolarization was probably not due to synaptic events, but rather resulted from the repetitive volley being conducted in axons or fibers traveling through the ganglion. The amplitude and duration of the long lasting hyperpolarization could be enhanced by increasing the frequency and duration of train stimulation.

These data suggest the presence of a slow inhibitory postsynaptic potential that is mediated via a muscarinic receptor. Hartzell et al. (1977)[1] found a similar muscarinic i.p.s.p. in parasympathetic ganglion cells that modulate heart beat of the amphibian mudpuppy.

2499 LONG-TERM PLASTICITIES ARE DIFFERENT AT DIFFERENT TERMINALS OF THE SAME PRE-SYNAPTIC NEURON IN APLYSIA. Peter B. Guthrie, Werner T. Schlapfer and Samuel H. Barondes ,Dept. of Neurosciences and Psychiatry, UCSD, La Jolla, CA 92093, and Dept. of Psychiatry, VAH, San Diego, CA 92161.

The amplitude of the EPSP evocable at R15 upon stimulation of the right connective (called RC1-R15) has been shown to exhibit prominent changes (plasticities) as a function of both its very recent and more remote history of stimulation. The pre-synaptic neuron, referred to as RC1 and presumed to be in the right pleural ganglion, has been shown to be spontaneously active (Woodson et al. Neuroscience Abstracts III (1977) #1666). The bursting pattern of RC1 allows the plasticities at RC1-R15 to be expressed such that the amplitude of RC1-R15 can vary over a several-fold range. We have now found at least twenty different neurons in the abdominal ganglion that receive direct synaptic input from RC1. The amplitude variations due to the bursting pattern of RC1 are seen at all of these synapses, suggesting that the plasticities seen at RC1-R15 are expressed by these branches of RC1.

We have examined in detail synaptic depression, frequency facilitation and post-tetanic potentiation (PTP) at the RC1 synapse onto $L9_{G1,G2}$ (tentatively identified) for comparison with RC1-R15. Identical results were obtained by stimulating RC1's processes either in the right connective or in regions of the right pedal ganglion. Although the RC1-L9 EPSP amplitude is only 30% of RC1-R15, the short-term plasticities (synaptic depression and frequency facilitation) are quantitatively similar at the two synapses. The rising phase of PTP is, however, slower ($P<.05, n=8$), PTP-amplitude is larger ($P<.001$, n=19) and the PTP-decay rate is faster ($p<.001$, n=19) at RC1-L9 than at RC1-R15. We have evidence to suggest that these differences in PTP parameters are due to functional differences in the pre-synaptic terminals and are not due to heterosynaptic influences which can accelerate PTP decay.

Since the relationships between the various parameters of the plasticities studied hold for both RC1-R15 and for RC1-L9 (e.g. PTP slope is directly correlated with PTP amplitude), we suggest that both synapses utilize the same basic mechanisms. Both the mechanisms and the biological significance, if any, of the differences in plasticities of these branches of a single neuron remain to be determined.

2500 PRE AND POST SYNAPTIC EFFECTS OF ELEVATED EXTRACELLULAR POTASSIUM UPON IN VITRO HIPPOCAMPAL SLICES. John J. Hablitz and Arvid Lundervold* Institute of Neurophysiology, University of Oslo, Oslo, Norway.

Accumulation of potassium in the extracellular space following repetitive neural activity has been repeatedly documented in the mammalian central nervous system. Subsequent changes in neuronal responsiveness during these periods have been observed. Although these changes in extracellular potassium (K+) have been shown to have particular spatial and temporal characteristics, it has not been possible to clearly delineate pre and post synaptic effects. The present study investigated the effect of manipulation of the ionic microenvironment upon extracellularly recorded indices of pre and post synaptic activity in the in vitro hippocampal slice.

Transverse slices of guinea pig hippocampus, 400-500 microns thick, were maintained in vitro. Slices were initially incubated in a medium containing 3.25 mm (K+) and KCl was subsequently added hyperosmotically to obtain (K+) levels of 6.25, 9.25, 12.25 and 15.25 mM. Low impedance glass micropipette recording electrodes were placed in stratum radiatum and the cell body layer of CA1 to record the pre synaptic fibre volley (PV), extracellular EPSP and population spike (PS) resulting from stimulation of the Schaffer collaterals. For a given constant input strength as measured by stimulus current or amplitude of PV, the population spike amplitude was directly correlated with (K+) in the range 3.25-12.25 mM. At high stimulus strengths multiple PS's were seen at (K+) concentrations of 6.25-12.25 mM and spontaneous bursts of PS's were observed in 9.25 and 12.25 mM (K+). PS's always extinguished rapidly in 15.25 mM and occasionally in 12.25 mM (K+). These effects on form and size of the PS were reversible. Elevation of (K+) also increased the size of the EPSP in response to a constant input strength in the range of (K+) from 3.25-9.25 mM. An occasional subsequent degression of EPSP amplitude was seen in 12.25 mM and again all activity was abolished in 15.25 mM.

These results suggest that raising (K+) increases excitability by effecting changes at both pre and post synaptic sites. Post synaptic changes can be attributed to a depolarizing action of (K+), while the pre synaptic EPSP changes may result from a specific effect of (K+) on the transmitter release system as described for the neuromuscular junction (Cooke & Quastel, 1973).

2501 AMINO ACIDS THAT EXCITE CEREBELLAR PURKINJE CELLS AND THEIR POTENTIAL ROLE AS CLIMBING FIBER AND PARALLEL FIBER NEUROTRANSMITTERS. J.T. Hackett, S.L. Cochran, and D.L. Brown. Dept. of Physiology, University of Virginia School of Medicine, Charlottesville, VA 22908

The climbing fiber-evoked, Purkinje cell (PC) EPSP is unitary, and its quite large amplitude easily distinguishes it from graded EPSPs evoked by parallel fiber stimulation. We have suggested that L-glutamic acid (Glu) may be the excitatory transmitter released from parallel fibers but not from climbing fibers, since the reversal potential for Glu-evoked postsynaptic potentials is similar to the reversal potential for parallel fiber EPSPs. We have examined this notion in an investigation of the Glu receptors with putative antagonists and with L-aspartic acid (Asp). Cerebella were quickly removed from anesthetized frogs and turtles. Sagittal sections (200-300 µm thick) of cerebellum were superfused with a Ringer solution from a system that permitted rapid exchange of test solutions containing known concentrations of agents. PC responses were recorded extracellularly and intracellularly with microelectrodes filled with 2 M K-citrate. We have found no distinguishing characteristics between the actions of Glu and Asp on PC responses. Thus both agents depolarize PC to the same extent, with the same time course, and over the same concentration range (0.1 to 1 mM). Several putative antagonists (methyl- and ethyl esters of glutamic acid, 2-amino-4-phosphonobutyric acid, and nuciferine) produced only excitation of PCs. These agents, at several concentrations tested (0.1 to 1 mM) did not block the PC depolarization evoked by Glu, parallel fiber, or climbing fiber stimulation. Similarly, the excitatory action of Asp was not affected by 0.2 mM D,L-α-aminoadipic acid, a putative Asp blocker--this agent also failed to block climbing fiber-PC transmission. In contrast, morphine, (in concentrations as high as 1 mM) did not cause a measureable change of PC activity evoked by stimulating parallel fibers or climbing fibers, but in the same experiments produce a 30-70% reduction in the PC excitation by Glu. Although some of these agents may have acted to depolarize presynaptic nerve terminals, Glu-evoked depolarizations were not reduced by a Ringer solution containing lowered Ca^{2+} and 2 mM Mg^{2+} which effectively blocked all synaptic transmission. In conclusion, the similar depolarizing effects of Glu, Asp and several putative antagonists suggest that they may be acting at the same receptor site. Based on a comparison of reversal potentials, the Glu site of action is more likely the subsynaptic receptors for the parallel fiber neurotransmitters than those for the climbing fiber. However, high concentrations of morphine may have acted to block nonsynaptic effects of Glu.

2502 VOLTAGE DEPENDENCE OF SYNAPTIC CURRENTS AT A CNS SYNAPSE IN THE HATCHETFISH. William D. Huse, John W. Day and Michael V.L. Bennett. Dept. Neurosci., Albert Einstein College of Medicine, Bronx, NY 10461

The Mauthner fibers form axo-axonic chemical synapses on giant fibers just beneath the floor of the IVth ventricle. Two to six giant fibers on each side arise from their cell bodies in the lateral wall of the IVth ventricle, pass medially dorsal to the near Mauthner fiber from which they receive a single synapse and then bifurcate to form anteriorly and posteriorly running branches that receive several synapses from the far Mauthner fiber (Model et al., Brain Res., 45:288, 1972). The transmitter appears to be ACh (Spira et al., J. Cell Biol., 47:199a, 1970). The two Mauthner fiber PSPs in the giant fibers can be individually evoked by graded stimuli applied to the caudal spinal cord. Iontophoresis of the dye, Fast Green, into a giant fiber had no pronounced effect on cell excitability or on MPSP rise time, decay time or amplitude, and facilitated simultaneous penetration with current and voltage electrodes. Electrodes were positioned within 50µ of one another and within 100µ of the synapse from the near Mauthner fiber. The postsynaptic region was then voltage clamped at its resting potential and stepped to various levels 15 msec before antidromic activation of the presynaptic cells. At the resting potential (c.-85 mV) postsynaptic currents rise to a peak in less than 0.1 msec; after an initial more rapid phase, decline is exponential with a time constant of c.0.60 msec. Hyperpolarization augments the peak current and slows the decline (c.0.85 msec at -160 mV). Increasing inside positivity reduces and then inverts the synaptic currents. The currents are essentially absent at reversal potentials of c.-10 mV. Reduced and inverted currents decline more rapidly (c.0.28 msec at 90 mV). Peak amplitude is linearly related to voltage. These results are consistent with data from the frog neuromuscular junction (Magleby and Stevens, J. Physiol., 223:173, 1972) in which the decline in synaptic current is more rapid at more inside positive membrane potentials. In that case the decline is determined by the rate of closing of ACh activated channels.

This investigation was supported by NIH training grant number 5T 32GM7288 from NIG MS.

2503 PRIMARY AFFERENT DEPOLARIZATION IN THE FROG OLFACTORY BULB. C.E. Jahr* and R.A. Nicoll, Depts. of Pharmacology and Physiology, UCSF, San Francisco, CA 94143.

Primary afferent depolarization in the spinal cord and brain stem is believed to be causally linked to presynaptic inhibition (Schmidt, R.F., Ergeb. Physiol. 63:20, 1971). Using the isolated olfactory bulb of the bullfrog, we have recorded by the sucrose gap method a similar, but much longer lasting, depolarization of the olfactory primary afferents following stimulation of the same or adjacent olfactory nerve (ON) fibers. The ON depolarization lasted up to 40 sec., was blocked by Co^{++} and increased in amplitude and duration with increasing stimulus strength. These results indicate that intact synaptic transmission is necessary for the ON depolarization but that firing of the same fibers is not a prerequisite. The antidromic compound action potential evoked by stimulation of the primary afferent terminal area was increased by a preceding conditioning stimulus. This excitability increase paralleled in duration the ON depolarization and was blocked by Co^{++} suggesting that the ON terminals themselves were depolarized.

The n_1 wave of the orthodromic field potential recorded in the glomerular layer with a focal extracellular electrode is the sum of the currents produced by the synaptic excitation and subsequent action potentials set up in the mitral cells by the ON terminals. Upon paired stimulation, the n_1 to the second shock was blocked at short intervals. On analogy to the crayfish neuromuscular junction (Dudel, J. and Kuffler, S.W., J. Physiol. 155:543, 1961), one would not expect an inhibitory postsynaptic conductance increase to block the synaptic current. Blockade of the n_1 is, therefore, consistent with a presynaptic mechanism. A conditioning stimulus applied to the ON can inhibit the n_1 produced by a test stimulus to adjacent but distinct ON fibers, and thus rules out the possibility that depletion of readily releasable transmitter from the ON terminals is responsible for blockade of n_1.

While the mechanism underlying the ON depolarization has not been elucidated, a picrotoxin sensitive depolarization was produced by GABA. Picrotoxin, however, does not antagonize the electrically evoked ON depolarization. Potassium sensitive electrodes are being used to determine what role fluctuations in extracellular potassium play. Both glutamate and glycine also depolarized the ON and are, therefore, candidates.

2504 ROLE OF CATECHOL-O-METHYLTRANSFERASE (COMT) IN SLOW POSTSYNAPTIC RESPONSES TO PREGANGLIONIC IMPULSES, IN MAMMALIAN SYMPATHETIC GANGLION. B. Libet and John H. Ashe, Department of Physiology, School of Medicine, University of California, San Francisco, CA. 94143.

The COMT-inhibitor U-0521 (0.3mM) produces a reversible augmentation of both the dopamine (DA)-mediated s-IPSP and the ACh-mediated s-EPSP postsynaptic responses to preganglionic nerve impulses, in rabbit superior cervical ganglia. The relative increases in both slow PSP's were larger for the weaker test responses (to a single volley), but the overall potentiations were greater and more consistently apparent for the s-EPSP.

Augmentation of s-EPSP is explained as due to potentiation of the long-lasting DA-modulatory enhancement of the s-EPSP response to ACh (acting muscarinically) (Libet and Tosaka, Proc.Nat.Acad.Sci. 67: 667-673, 1970). This implies that DA spontaneously released by the dopaminergic interneurones ("SIF" cells) can be sufficient to induce a modulatory change, when this DA is protected from inactivation by COMT. This view is further supported by finding that bromocriptine (7μM), an antagonist of DA stimulation of adenyl cyclase in brain tissue, can antagonize the augmentation of s-EPSP responses by U-0521.

The present evidence also suggests that COMT can play a significant limiting role that is analogous to that of acetylcholinesterase, in at least some neurone-to-neurone synaptic functions involving catecholamine transmitters. For DA in this ganglion, COMT-access barriers would appear to be effective primarily against the postsynaptic actions. Access to presynaptic receptors is apparently not so limited by COMT, judging from presynaptic as opposed to postsynaptic effects obtainable with DA applied exogenously. A special ability of COMT-access barriers to limit the DA-modulatory action, which can be induced by the smallest amounts of DA moving from releasing sites to possibly more distant postsynaptic receptors, could be of significance in regulating potentially related modulatory actions of catecholamines in the brain. (Supported by U.S.P.H.S. grant NS-00884 from NINCDS.)

2505 SUBSYNAPTIC LOCALIZATION OF α-BUNGAROTOXIN BINDING WHICH BLOCKS NICOTINIC TRANSMISSION AT FROG SYMPATHETIC NEURONS. Lawrence M. Marshall* (SPON: R.M. Harris-Warrick). Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

Sympathetic neurons receive primary synaptic input from cholinergic terminal boutons of preganglionic nerve fibers. The distribution of acetylcholine receptors at these synapses is not precisely known. This study shows that α-bungarotoxin, known to bind to nicotinic receptors on skeletal muscle, may also be useful for localizing nicotinic receptors on principal neurons of paravertebral sympathetic ganglia of the bullfrog.

α-Bungarotoxin (1-5 μM) produces a block of nicotinic (fast) excitatory postsynaptic potentials which is fully reversed after 5-8 hrs of washing. Nicotinic antagonists reduce the half-time of recovery from the toxin to one-third the control value, presumably by competing with the toxin for the same receptor sites. Furthermore, the response to applied carbachol is suppressed by the toxin, indicating that the block of synaptic transmission is due to reduced sensitivity of the postsynaptic membrane.

Peroxidase-labeled α-bungarotoxin is localized to small (0.2-0.5 μ diameter) patches beneath synaptic boutons. Each patch of peroxidase reaction product is restricted to those regions of the synaptic cleft just opposite the active zones of the presynaptic terminal. Additional experiments show that peroxidase-labeled antibodies against Torpedo acetylcholine receptor bind exclusively to these same subsynaptic regions; suggesting further that these patches represent the areas at which nicotinic receptors are concentrated on sympathetic neurons.

2506 RUTHENIUM RED INHIBITION OF THE CALCIUM DEPENDENT ^{3}H-GABA RELEASE DURING ONTOGENESIS IN THE MOUSE. Graciela Meza-Ruiz (SPON: Ricar do Tapia). Departamento de Neurociencias, Centro de Investigaciones en Fisiología Celular. UNAM. México.

Neuronal calcium-dependent release of GABA develops in a progressive fashion as shown in synaptosomes isolated from rat brain (Redburn et al, Brain Res. 152:511-519, 1978). On the other hand, we have shown that Ruthenium Red inhibits calcium-dependent GABA release from synaptosomes both in vitro and after intracranial injection of the dye (Brain Res. 126:160-166, 1977; Brain Res. 154:163-166, 1978).

In the present work, ^{3}H-GABA release was investigated during development in the mouse, both in the absence and in the presence of Ruthenium Red. Crude synaptosomal preparations were isolated from 5, 10, 15-day old and adult mice. They were loaded with ^{3}H-GABA (0.5 uM; 0.8 uCi) for 10 minutes at 37°C in Krebs-bicarbonate buffer, pH 7.4. ^{3}H-GABA release was performed in 4 parallel superfusion chambers at 37°C as previously described (Brain Res. 126:160,166, 1977). Calcium-dependent release was studied either by depolarization with 48 mM potassium in the presence of calcium or by calcium-stimulation in synaptosomes previously depolarized by 48 mM potassium in the absence of calcium. The effect of Ruthenium Red was studied only in the latter, in synaptosomes whose loading was performed in the presence of 40 uM Ruthenium Red in a calcium-free medium.

The release of ^{3}H-GABA was stimulated by high potassium 64, 89, 161 and 193 percent over the spontaneous baseline in 5, 10, 15-day old and adult mice, respectively. Spontaneous efflux was the same regardless of age. Stimulation by calcium was of 59, 110, 157 and 148 percent over the baseline for the same age periods. In the presence of Ruthenium Red, this stimulation was inhibited by 30, 55, 60 and 58 percent for 5, 10, 15-day and adult animals, respectively.

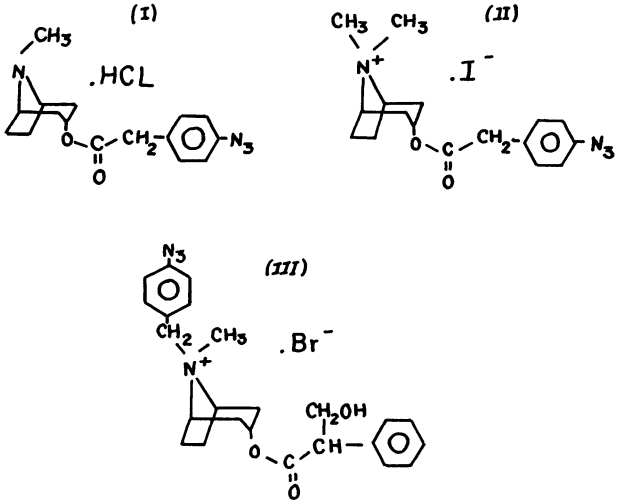
These results show that although spontaneous efflux of GABA does not change throughout development of the brain, the calcium-dependent, depolarization-induced release, sensitive to Ruthenium Red, seems to increase during ontogenesis.

The collaboration of Mrs. Consuelo Hernández and Miss Lilia Reynoso in some of the experiments is acknowledged.

2507 PHOTOAFFINITY LABELING OF SPECIFIC ^{3}H-QNB-BINDING SITES IN BRAIN MEMBRANES. Jose Moreno-Yanes* (SPON: Ruth S. Gurd). Chemistry Dept., Indiana University, Bloomington, IN 47405

The specific [^{3}H]-quinuclidinyl benzylate (QNB) binding sites of several membrane fractions from rat brain have been irreversibly inactivated by photoaffinity labeling with two azido-phenyl acetate esters of 3-tropanol (I and II) and N(p-azidobenzyl) methyl atropine (III). Without photolysis, the three compounds bind to the [^{3}H]-QNB binding sites with apparent dissociation constants of 3.7×10^{-6} M, 9×10^{-7} M and 4.2×10^{-8} M, respectively. Subsequent irradiation of these probes bound to these membrane sites converts their azido function to the highly reactive nitrene and results in an irreversible loss of the capability of the preparation to interact with [^{3}H]-QNB.

Atropine and oxotremorine, but not d-tubocurarine, afford protection against this irreversible photoinsertion of the probes. These findings suggest that the compounds may prove useful as specific photoaffinity labels for muscarinic receptors. (Supported by Research Grant NS 08309 from the NIH)



2508 A PROLONGED VOLTAGE-SENSITIVE INHIBITORY SYNAPTIC POTENTIAL IN MITRAL CELLS OF THE ISOLATED TURTLE OLFACTORY BULB. Kensaku Mori* and Gordon M. Shepherd. Section of Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510.

We have continued an intracellular analysis of synaptic potentials in the isolated turtle olfactory bulb preparation (Nowycky, Waldow and Shepherd, Neurosci. Absts. 4:583, 1978). Single olfactory nerve volleys induce a complex sequence of synaptic potentials in mitral cells. There is an early period which includes the EPSPs in the terminal tufts of mitral cell dendrites in the olfactory glomeruli, and a later period consisting of a slow hyperpolarizing IPSP. The IPSP can be divided into two phases, early and late. The early phase covers the first several hundred msec of the response, whereas the later phase lasts for very long periods; in some cases the hyperpolarization persists as long as 4 secs following a single volley. When the membrane potential was held at different levels by injected current, the early IPSP was found to have a reversal potential of -70 to -80 mV. In this respect it resembled IPSPs in motoneurons and other central neurons. Some degree of overlap with the initial EPSP may be present during this early phase. In contrast, the late IPSP did not reverse; it decreased in amplitude as the membrane was depolarized, and also when it was hyperpolarized. This is similar to the behavior of voltage-sensitive IPSPs previously demonstrated in piriform cortex neurons (Mori, Satou and Takagi, Proc. Jap. Acad. 54:484, 1978) and in parasympathetic ganglion cells (Hartzell, Kuffler, Stickgold and Yoshikami, J. Physiol. 271:817, 1978). Tests with brief injected current pulses indicated that membrane conductance was increased during the early phase. The results suggest at least two different types of synaptic receptors or receptor mechanisms for inhibition of mitral cells.

2509 TWO MORPHOLOGICALLY AND STRUCTURALLY DISTINCT POPULATIONS OF NEUROSECRETORY GRANULES PURIFIED FROM RAT NEUROHYPOPHYSIS. S.J. Morris and J.J. Nordmann*, Max Planck Inst. for Biophys. Chem., D-3400 Goettingen, FRG and INSERM U176, F-33077 Bordeaux Cedex, France.

The neurohormones vasopressin and oxytocin are synthesized and packaged as pro-hormones in cell bodies in the hypothalamus and transported down axons to nerve terminals, which together with axonal "swellings" and glia form the neurohypophysis, from which both hormones are released by exocytosis[1].

Subcellular fractionation of the granules on sucrose/Metrizamide gradients which were isoosmotic at 360 mOsm(=0.30 M sucrose)[2]produced 2 populations of granules:one with a density of ∿1.13 containing granules of 172 ±2(SEM) nm dia. and a second with a density of ∿1.11 and dia. of 197 ±9 nm. Both populations contained oxytocin, vasopressin and neurophysins. The denser granules were insensitive to osmotic change while the less dense particles behaved like perfect osmometers. When compared to the tissue homogenate, these fractions were purified 4-5 fold in relation to mitochondria and 7 fold compared to lysosomes. Chromatography of the gradient fractions on CPG 10-3000 porous glass produced further purification.

These structural differences do not reflect the cleavage of the precursor into neurophysin and hormone since virtually no precursor is found in the neural lobe[3]. Newly synthesized granules seem to move first into the nerve terminals and only then, if not released, into the "swellings"[4]. Our results suggest that the granules are transported as osmotically inert structures and that conversion of the pro-hormones to active oligopeptides and neurophysins would not greatly alter the osmotic activity of the core. We postulate that a subsequent aging process (probably exopeptidase activity) occurs in the neural lobe which renders the granule core osmotically active. Thus the osmotically inert granules fraction would represent those newly arrived while the granules sensitive to osmotic pressure would represent the older granules. In support of this, the osmotically sensitive granules have diameters similar to that of granules found in the swellings after fixation of the gland (188 ± 2 nm) whereas the non-osmotically active granules have diameters like those found in the nerve terminals (173 ± 3 nm). Thus the fractionation seems to produce granules from two anatomically different areas of the terminals of the neural lobe. The aging process might be of importance for the subsequent destruction and/or lysosomal digestion of the unused neurosecretory granules.

A complete account of this work is in press[5].

2510 DIRECT ELECTRICAL SYNAPTIC CONNECTION IS MEDIATED BY AN INTERNEURON. Kenneth J. Muller and Sheryl A. Scott. Dept. of Embryology, Carnegie Institution of Washington, Baltimore, Md. 21210.

Touch sensory neurons (T-cells) in segmental ganglia of the medicinal leech make excitatory electrical synaptic connections upon the S-interneuron, whose axon is the "giant fiber" of each segment. Positive current but not negative current can flow from T-cells to S-cells, so that S-cells do not excite T-cells. Morphological and physiological measurements suggest that excitatory currents leave the T-cell at several points within the ganglion. For example, the amplitude of excitatory synaptic potentials recorded in the S-cell is diminished when T-cell impulses, propagating into the ganglia from anterior or posterior receptive fields, fail at central branch points and activate only a portion of the T-cell's presynaptic terminals. This branch-point failure occurs in response to natural stimuli, and by modulating synaptic transmission can affect integration within the ganglion.

Intracellular injection of the marker horseradish peroxidase (HRP) reveals that ventral and lateral T-cells do not make direct contact with the S-cell; therefore, another neuron must mediate the electrical connection between them. Intracellular injection of the S-cell with fluorescent dye of low molecular weight, such as Lucifer Yellow (Stewart, Cell 14: 741, 1978) or 6-carboxyfluorescein, which can cross between electrically coupled cells in the leech, stains with nearly uniform intensity the S-cell and two small interneurons in each ganglion, designated as Stewart cells. Positive currents can pass from Stewart cells to S-cells and vice versa. HRP injections show that Stewart cells provide the necessary link between T- and S-cells and can account for the spatially distributed connection between them. When Stewart cells are selectively eliminated from the ganglion with intracellular injection of protease, which does not measurably affect cells that are electrically coupled to the injected cell, the synaptic connection between T- and S-cells is selectively abolished. We conclude that Stewart cells mediate the distributed electrical connections between ventral and lateral T-cells and the S-cell in each ganglion, connections that by physiological criteria seem monosynaptic.

2511 RELEASE OF β-ADRENERGIC AGONIST FROM SYMPATHETIC NEURONS IN CO-CULTURE WITH PINEAL CELLS. Andrew Parfitt* and William Shain (SPON: L. M. Masukawa). Dept. of Neurobiology, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Co-cultures of pineal cells and sympathetic neurons were prepared from dissociated pineal glands and superior cervical ganglia dissected from 2-day-old rats. Routinely 300,000 pineal cells were plated with 30,000 neurons. Cultures were maintained in Ham's F12 containing 10% fetal calf serum at 36.5°C in an atmosphere of 4% CO_2:96% air. Medium was changed every third day. Experiments were done 5 to 8 days post-culture preparation. Test compounds were incubated with the cultures for 6 hours. In order to monitor spontaneous release of β-agonist, co-cultures were incubated with compounds that block the reuptake of norepinephrine by nerve endings. Both desmethylimipramine (DMI) (10^{-5} M) and cocaine (10^{-6} to 10^{-4} M) caused an increase in acetyl CoA:serotonin N-acetyltransferase (NAT, EC 2.3.1.5) activity in the pineal cells. Neither DMI nor cocaine affected basal or isoproterenol(ISO)-stimulated NAT activity in pineal cells cultured alone. The DMI- or cocaine-stimulated increase in NAT activity in co-cultures was not affected by simultaneous treatment with tetrodotoxin (TTX) (10^{-7} M). This concentration of TTX was sufficient to block electrically initiated action potentials in the cultured neurons. The increase in NAT activity following treatment with DMI and cocaine varied between preparations, probably as a result of variations in the numbers of neurons in the cultures prepared on different days. This increase in NAT activity was never less than 50% and frequently approached 80% of the activity elicited by a maximally effective concentration of ISO (10^{-8} M). In order to monitor evoked release from neurons, co-cultures were incubated with batrachatoxin (BTX, 10^{-7} M), which is reported to stabilize voltage-dependent sodium channels in the open configuration, thus depolarizing the neurons. BTX treatment elicited an increase in NAT activity, which was blocked by simultaneous application of TTX, but was only slightly diminished by treatment with $4x10^{-2}$ M $MgCl_2$. Cobalt was tested but was found to kill both the neurons and the pineal cells. Neither TTX nor BTX had an effect on basal or ISO-stimulated NAT activity in pineal cells. Culture medium taken from the BTX- or DMI-treated co-cultures initiated an increase in NAT activity when added to cultures of pineal cells alone. This enabled us to bioassay β-adrenergic agonist released by the neurons in co-culture. Calculations on data from a representative experiment indicated that an amount of β-agonist equivalent to $6.7x10^{-12}$ moles of norepinephrine was released from each neuron during a 6-hour treatment with BTX.

2512 EFFICIENCY OF UTILIZATION OF QUANTAL ACETYLCHOLINE. P. Pennefather* and D. M. J. Quastel. Dept. of Pharmacology, The University of British Columbia, Vancouver, B. C., V6T 1W5, Canada.

Miniature end-plate currents (m.e.p.c.s) recorded at vertebrate neuromuscular junctions are produced by the release of quanta of acetylcholine (ACh); this gives rise to localized transient high concentrations of transmitter in the synaptic cleft. The m.e.p.c. height will be dependent on the relative likelihood of ACh interacting with receptor rather than it being lost through hydrolysis or diffusion. As a result, d-tubocurarine (d-TC) is less effective at reducing m.e.p.c. height after inhibition of acetylcholinesterase (AChE) and is more effective after partial receptor inactivation by myasthenic immunoglobulin G or α-bungarotoxin. With a few assumptions, a simple equation can be derived which relates the apparent potency of d-TC under varying conditions to the m.e.p.c. height in the absence of d-TC. This provides a basis whereby one can estimate the m.e.p.c. height that would have been achieved if all of the ACh in a quantum became bound to receptor, and the ratio of m.e.p.c. height to this maximum gives an indication of the fraction of ACh in a quantum that has become bound to receptor at the peak of the m.e.p.c. Although the equation ignores a number of complicating factors, it accurately describes the behavior of a variety of mathematical models of the synapse which include such complications. Experimental data from mouse diaphragm indicate that normally about 75% of ACh released as a quantum binds to receptor; after inhibition of AChE about 90% binds. Thus, m.e.p.c. height is little altered by inhibition of AChE. Katz and Miledi (J. Physiol. 231, 549, 1973) have pointed out that d-TC increases m.e.p.c. decay rate after inhibition of AChE, evidently by increasing the fraction of ACh that is not bound to receptor and is therefore free to diffuse from the cleft. This phenomenon can be used to estimate the fraction of ACh bound to receptor during the decay phase. We find that at e^{-1} of the peak of the m.e.p.c. only about 45% of ACh in the cleft is bound to receptor as opposed to 90% at the peak. This difference presumably arises from cooperativity in ACh binding. At e^{-1} of the peak, the concentration of ACh in the cleft has become relatively low and binding seldom proceeds beyond unstable intermediate forms. Further support for this interpretation comes from the observation that the m.e.p.c. decay rate is relatively slow early in its decay phase and progressively increases.

2513 INTRACELLULAR RECORDING FROM NEURONS IN THE LOCUS COERULEUS AND MESENCEPHALIC NUCLEUS OF THE TRIGEMINAL NERVE (MNV) IN VITRO. Christine M. Pepper* and Graeme Henderson* (SPON: A. G. Karczmar) Department of Pharmacology, Loyola University Stritch School of Medicine, Maywood, Illinois 60153.

Intracellular recordings were made in vitro from slices (350μm thick) of guinea-pig pons. Locus coeruleus neurons had a resting membrane potential of -52.7 ±2.7 mV (mean ± SEM) (n=20), an input resistance of 58.0 ± 7.6 MΩ (n=21) and a membrane time constant of 7.3 ± 1.0 ms (n=21). Only 6 of 31 cells were spontaneously active. Focal stimulation either directly activated the cell soma to fire an overshooting action potential or elicited an excitatory post-synaptic potential (e.p.s.p.); e.p.s.ps of sufficient amplitude gave rise to action potentials. E.p.s.ps were graded with stimulus intensity and were abolished in calcium free solutions. action potentials recorded in locus coeruleus neurons were 1.38 ± 0.15 ms (n=21) in duration and were followed by an after-hyperpolarization. MNV neurons had a resting membrane potential of -51.9 ± 3.6 mV (n=13), an input resistance of 15.0 ± 1.8 MΩ (n=18) and a membrane time constant of 1.4 ± 0.2 ms (n=17). These cells showed time dependent anomalous rectification to injected hyperpolarizing current pulses and accommodation to depolarizing pulses. Focal stimulation gave rise to action potentials or to low amplitude (<10 mV) short duration (<5 ms) depolarizing potentials. The electrical properties of MNV cells are similar to those previously described for sensory ganglion cells.

2514 THE EFFECTS OF VARYING Ca^{++} CONCENTRATION ON SYNAPTIC TRANSFER AT A SYNAPSE IN THE LAMPREY SPINAL CORD. G.L. Ringham. Dept. Physiology, University of Utah College of Medicine, Salt Lake City, Utah, 84108.

The synaptic transfer curve relating pre- and post-synaptic potential changes at a synapse between a Müller axon (the presynaptic element) and a large interneuron (the post-synaptic element) in the spinal cord of the lamprey has been described previously (Martin & Ringham, J. Physiol. 251, 409-426, 1975). In the tetrodotoxin-blocked preparation superfused with normal solution containing 3 mM Ca^{++}, the transfer curve saturates at presynaptic depolarizations on the order of 90-100 mV. Among the factors which could contribute to development of this plateau is a decreased inward driving force on Ca^{++} at these larger presynaptic depolarizations. This possibility can be tested directly by obtaining transfer curves at several different Ca^{++} concentrations. Those curves obtained at higher Ca^{++} concentrations should be shifted along the abscissa (toward lower levels of presynaptic depolarization) and have larger peak values.

Preliminary experiments have compared the synaptic transfer curves obtained in 3.0, 6.0 and 9.0 mM Ca^{++} solutions (prepared by isotonic substitution of $CaCl_2$ and NaCl). The curves obtained in the high Ca^{++} solutions are indeed shifted along the abscissa to the left, with a slight decrease in the apparent presynaptic "threshold" depolarization required for production of a detectable post-synaptic potential (PSP). The effects are somewhat greater in the 9.0 mM Ca^{++} solution than in 6.0 mM Ca^{++}. However, these curves often saturate at PSP values very similar to those observed in normal Ca^{++} solutions, and there is little difference in this effect between the 6.0 and 9.0 mM Ca^{++} solutions. Thus, it would appear that a decreased driving force on Ca^{++} is not the only factor determining the saturation level of these transfer curves. Perhaps this inconsistency in effect of the high Ca^{++} solutions on maximum PSP amplitude is related to transmitter depletion at those synapses with larger PSP's. Interestingly, the high Ca^{++} concentrations do not seem to depress the sensitivity of the post-synaptic membrane, because the amplitudes of spontaneously occurring miniature synaptic potentials (from numerous sources) recorded from the interneuron are essentially unchanged in these solutions.

2515 MEMBRANE POTENTIAL OF OLFACTORY BULB SYNAPTOSOMES MONITORED WITH THE LIPOPHILIC CATION TETRAPHENYLPHOSPHONIUM. S. Rochel* and F. L. Margolis (SPON: R. Wurzburger). Dept. Phys. Chem. & Pharm., Roche Institute of Molecular Biology, Nutley, NJ 07110.

Measurement of changes in synaptosomal membrane potential associated with transmitter uptake and release cannot be performed by traditional electrophysiological techniques. Recently the utility of the lipophilic cation [^{3}H]tetraphenylphosphonium (TPP^+) to study neuronal membrane potential has been demonstrated (Lichtshtein, Kaback & Blume, PNAS 76:650-654 [1979]). Since [^{3}H]TPP^+ distributes across a membrane in proportion to the transmembrane potential it can be used to measure that potential according to the Nernst equation:

$$\Delta\Psi = \frac{-RT}{ZF} \ln [TPP^+]_{in}/[TPP^+]_{out}.$$

Two crude synaptosomal fractions were prepared from rat olfactory bulb: P_1-the pellet after centrifugation at 1000 g for 10 min containing multisynaptosomal particles and P_2-the pellet after centrifugation at 14,500 g for 20 min, which is a traditional mitochondrial-synaptosomal fraction. The internal volume of P_1 was 4.5 μl/mg protein and of P_2 was 6.5 μl/mg protein as measured by ^3H-H_2O and [^{14}C]inulin distribution. Using these volumes, the concentration of TPP^+ was calculated as nmoles TPP^+ per synaptosomal volume. [^{3}H]TPP^+ accumulation into P_1 and P_2 forms a concentration gradient which is four-fold higher at low external K^+ (4.5 mM) than at high external K^+ (122 mM), indicating the dependence of resting membrane potential on the potassium diffusion gradient (in→out). Assuming that the K^+ diffusion gradient is the major component of synaptosomal ΔΨ, a resting membrane potential of 100 ± 5 mV can be calculated. Veratridine, a neurotoxic alkaloid which causes depolarization of the synaptosomes by allowing electrogenic Na^+ influx, diminished [^{3}H]TPP^+ accumulation in high Na^+ medium. This effect of veratridine was not observed when Na^+ ions were omitted from the medium. The protonophore carbonylcyanide-m-chlorophenylhydrazone, which collapses membrane potential, abolished [^{3}H]TPP^+ accumulation in our synaptosomal preparations. Interestingly, the cardiac glycoside ouabain which inhibits the Na^+/K^+ ATPase caused a 30% decrease in [^{3}H]TPP^+ accumulation within 1 min and nearly abolished the accumulation at longer times, indicating the dependence of synaptosomal ΔΨ on pump activity. These results indicate that the accumulation of [^{3}H]TPP^+ can be used to monitor the transmembrane potential of olfactory bulb synaptosomal fractions. The influence of various neuroeffectors on this phenomenon is currently under investigation.

2516 USE OF DOPAMINE β-HYDROXYLASE ANTIBODIES IN THE STUDY OF VESICLE DYNAMICS. Robert A. Rush*, Thomas J. Millar*, Laurence B. Geffen*, Centre for Neuroscience, School of Medicine, Flinders University, Bedford Park, S.A. 5042, Australia. (SPON: R. Porter, Department of Physiology, Monash University, Clayton, Vic. 3168, Australia.)

Systemically administered antibodies to dopamine β-hydroxylase are taken up into noradrenergic nerve terminals by binding to membrane bound dopamine β-hydroxylase molecules which become exposed on the external surface of the neurone during exocytosis. In the presence of complement this antigen-antibody reaction leads to a lysis of the plasma membrane, resulting in the degeneration of the whole axon terminal. When lysis is prevented by the use of an Fab_2' fragment of the antibody or in the absence of complement, the binding of antibody to DBH results in the inhibition of enzyme activity. The inhibition of enzyme activity may be used to study the turnover of DBH in nerve terminals. With the use of an appropriate label, the bound antibody may also be visualised at both the light and electron microscope level. When DBH is coupled to horseradish peroxidase (HRP) and administered either systemically or locally into the anterior chamber of the eye, the DBH-HRP complex can be localised in membranous structures within axon terminals. In this way, the fate of vesicles which have participated in the release process can be studied.

Twenty-four hours after systemic injection, the sympathetic nerve terminals of the iris contain many densely labelled small vesicles. In addition, label was also clearly visible within large membranous organelles and cylindrical cisternae. Little staining was visible on the plasma membrane of axon terminals suggesting that, following exocytosis, the vesicle membrane is rapidly retrieved. This novel approach to the ultrastructural localization of DBH within neurones overcomes many of the difficulties associated with *in vitro* immunohistochemistry and moreover provides a method for studying the fate of synaptic vesicles after they have undergone exocytosis.

2517 SYNAPTIC VESICLE MORPHOLOGY IN THE RAT NEUROMUSCULAR JUNCTION FOLLOWING APPLICATION OF LEPTINOTARSIN. A.A. Sadun, A.K. Crews*, T.H. Hsiao*, J.R. Stimers*, W.O. McClure. Neuro. Res. Lab., Huntington Inst. of Appl. Med. Res., Pasadena, CA 91105; Dept. of Biological Sciences, Univ. of S. California, Los Angeles, CA 90007 and Dept. of Biology, Utah State Univ., Logan, UT 84322.

Satin et al (Soc. Neuros. Abs. 4, 1873,1978) described a biphasic response of miniature end plate potentials (mepps) following application of leptinotarsin (LPT), a toxic protein found in the hemolymph of the beetle Leptinotarsa haldemani. We confirmed that when LPT is added to a rat phrenic nerve-diaphragm preparation, intracellular recordings show a biphasic release of mepps. Shortly after application of LPT there is a burst of mepps reaching about 900 Hz and lasting about one minute. There follows, about six minutes later, a second cascade of activity peaking to about 400 Hz and lasting about 12 minutes before the frequency of mepps falls to zero.

In control preparations, normal ultrastructural features of the neuromuscular junction were noted. The axon terminals are uniformly filled with small round vesicles and the junctional folds demonstrate a repeating precise architecture.

Preparations to which LPT was applied were then examined. Tissue which was fixed immediately after the first burst of mepps activity does not markedly differ in ultrastructure from control preparations. The terminals are filled with spherical vesicles. Mitochondria and junctional folds appear nearly normal.

In a third preparation, the tissue was quickly fixed after the second response, at the time the frequency of mepps fell to zero. Numerous morphological distinctions were noted. Significantly, the terminals contain vesicles many of which are collapsed. Mitochondria in the terminals contain swollen cisternae while mitochondria in the muscle cells look normal. The post-synaptic junctional folds show morphological variation.

Suszkiw (Soc. Neuros. Abs. 4, 1876,1978) has shown that a discrepancy may exist between the vesicular content of ACh and the number of vesicles seen. This fact, the present study, and other recent investigations suggest that vesicles may be conserved in the face of massive neurotransmitter release. These experiments provide evidence for ultrastructural changes in axon terminals secondary to the pulsed release of neurotransmitter. Some of the remaining vesicles have a distinctive morphology which may provide a clue to alternate modalities for neurotransmitter release or vesicle formation.

We thank Huntington Institute of Applied Medical Research for use of their facilities. This study was also supported by NSF, (BNS 76-80657).

2518 RELEASE OF ENDOGENOUS CATECHOLAMINES IN THE CAUDATE NUCLEUS AND PREOPTIC AREA OF THE ANTERIOR HYPOTHALAMUS OF FREELY MOVING RATS. Steven K. Salzman*, and Matej Stepita-Klauco (SPON: T. Stanton). Dept. Biobehavioral Sci., Univ. of Connecticut, Storrs, Ct. 06268

The release of endogenous catecholamines (CA), norepinephrine, dopamine and epinephrine, was studied in vivo, using a push-pull perfusion technique followed by high pressure liquid chromatography with electrochemical detection (Bioanalytical Systems). Push-pull cannulae were constructed from stainless steel hubs (David Kopf) and tubing (24g for pull, 32g for push, Small Parts) and machine screws (Small Parts). Cannulae were implanted stereotaxically, under chloral hydrate anesthesia (350mg/kg), in either the caudate nucleus or the preoptic area of the anterior hypothalamus of rats. Both the push and pull ends of the cannulae were connected, via silastic tubing (Sil-Med) to the output and input ends respectively of miniature electrically pulsed pumps (Valcor), mounted directly on a mercury commutator, thus allowing the rat free movement during the perfusion session. The pumps were pulsed remotely through the commutator by a timer with variable settings (Harvard Apparatus). Artificial cerebrospinal fluid, 0.1 micron filtered and warmed to 37°C, was perfused at a constant rate of 30µl/min. Samples were collected at 5-50 min. intervals into vials containing 50-100pg of an internal standard (dihydroxybenzylamine, Aldrich) in 75-750µl of ultrapure perchloric acid (Baker). After extracting the CA on alumina, 20µl aliquots of the alumina eluates were valve loaded (Rheodyne) onto the column (Vydac, strong cation exchange) and separated under 400 psi pressure. The mobile phase was a degassed phosphate-citrate buffer. The column was maintained at 28°C by means of a water jacket. The glassy carbon working electrode in the thin layer electrochemical cell was preset at a potential of +720 mV against a Ag/AgCl reference electrode. The current resulting from the oxidation of the CA was monitored on a pen recorder (Houston Inst.). A release profile was determined under basal conditions during waking and sleep (behavioral criteria). The optimal perfusion time for the sensitivity of the assay was also determined. Specificity of release was determined by an increase in CA output after an i.p. injection of amphetamine (5mg/kg) at the end of the session. Results are discussed in terms of the validity of the in vivo approach and its possible utility for studying transmitter release during different behavioral states. Preliminary results indicate that the concentrations of DA in the perfusate from the caudate and NE in the perfusate from the hypothalamus are in the nanomolar range.

Supported by NIMH Grant MH07212-02.

2519 HABITUATION: CELLULAR MECHANISMS IN MAMMALIAN HIPPOCAMPUS. Linda K. Simmons and R. J. W. Mansfield. Psychology Department, Harvard University, Cambridge, Mass. 02138.

Habituation, the response decrement due to repetitive stimulation, is a simple yet ubiquitous form of non-associative learning that is observed across a wide phylogenetic range. We have utilized the in vitro rat hippocampal slice, a reduced preparation that produces evoked responses manisfesting 8 of the parametric criteria characterizing behavioral habituation (T. J. Teyler and B. E. Alger, Brain Res., 115, 413, 1976), to study the cellular mechanisms underlying this form of synaptic plasticity.

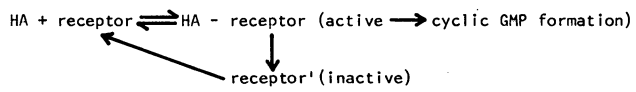
After surgery the 400 micra hippocampal slices were maintained in perfusion chambers that enabled the quick (within 30 seconds) and complete transfer of various perfusates. Stimulating electrodes were placed in the perforant pathway and recording electrodes were placed in the granule cell or molecular layer to obtain monosynaptic population spikes or EPSP's, respectively, from the dentate gyrus region of the hippocampal formation.

Studies with other preparations such as the Aplysia suggested that certain cyclic nucleotides can modulate synaptic plasticity by manipulating the voltage-dependent Ca^{2+} influx which controls levels of transmitter release (M. Klein and E. R. Kandel, P.N.A.S. (USA), 75, 3512, 1978). In the hippocampal slice both theophylline, a phosphodiesterase inhibitor, and N^6,O^2-dibutyryl adenosine 3'-5' cyclic monophosphate (Bu_2cAMP), a more membrane-permeable form of the nucleotide, significantly and reversibly attenuated the relative habituation of the evoked population spikes and EPSP's when compared to controls. Preliminary studies indicated that N^2,O^2'-dibutyryl guanosine 3'-5' cyclic monophosphate (Bu_2cGMP) has no effect upon the habituation observed at this group of synapses. This depression of relative habituation was invariably accompanied by an increase in the absolute amplitudes of the evoked responses. Since habituation is inversely related to the stimulus intensity, the decreased relative habituation displayed in the drugged solutions may be caused by the observed increase in synaptic efficacy. Control studies performed to determine the locus of the drug-induced synaptic change indicated that the effect of the experimental solutions is not due to either a change in the afferent volley size or the gross postsynaptic membrane impedance. The above results suggest that cAMP levels indirectly decrease relative habituation by enhancing transmitter release (presumably by increasing the voltage-dependent Ca^{2+} influx) for a given stimulus intensity. Whether cAMP levels initiate habituation by manipulating the Ca^{2+} current has to be determined.

(Supported in part by NSF Grant BNS75-08437).

2520 HISTAMINE H_1 RECEPTORS ON NEUROBLASTOMA CELLS: SHORT- AND LONG-TERM REGULATION OF SENSITIVITY. J.E. Taylor* and E. Richelson (SPON: R.M. Weinshilboum) Depts. of Psychiatry and Pharmacology, Mayo Foundation, Rochester, MN 55901

Mouse neuroblastoma cells (clone N1E-115) responded to histamine H_1 receptor-agonists with a large and transient increase in the intracellular levels of guanosine 3',5'-cyclic phosphate (cyclic GMP). Short-term ($\leq$ 30 min) pre-incubation of intact cells with histamine (HA) resulted in a receptor-specific, time- and concentration-dependent decrease in responsiveness to HA (desensitization). The rate at which desensitization developed was dependent on the concentration of HA used to desensitize (at 50 µM, $t_{1/2}$ = 5 min; at 100 µM, $t_{1/2}$ = 2 min). When the cells were washed free of HA, normal sensitivity to HA rapidly returned and the rate of resensitization was independent of the concentration of histamine used to desensitize (half-time ≈ 8 min). Data from the dose-response curves using cells partially desensitized with HA suggested a loss of agonist binding sites. However, binding studies with the H_1 receptor antagonist, [^{3}H]pyrilamine, to whole cells showed that there was no significant change in the number of antagonist binding sites associated with short-term desensitization. These data for short-term desensitization fit the following cyclic model as described by Gosselin[1]:



The nature of the inactive receptor for short-term desensitization is not certain, but could result from a reversible change in receptor conformation which only affects agonist binding. Long-term exposure (> 4 hrs) to HA resulted in a desensitization that was only slowly and partially reversible. Furthermore, this long-term desensitization was accompanied by a marked decrease in the number of specific [^{3}H]pyrilamine binding sites on intact cells. These results suggest that different mechanisms are involved in the short-term and in the long-term desensitization of histamine H_1 receptors. (Supported by Mayo Foundation and USPHS Grants MH 27692, MH 07925 and DA 1490.)

2521 BIPHASIC RESPONSE OF PYRAMIDAL NEURONS TO GABA IONTOPHORESIS IN HIPPOCAMPAL SLICES. R. H. Thalmann*, E. J. Peck and G. F. Ayala. Dept. Neur. and Cell Bio., Baylor Coll. Med., Houston, TX 77030.

Changes of membrane potential during iontophoresis of GABA were studied in CA1 pyramidal cells of hippocampal slices maintained at 34-35°C and bathed in synthetic CSF with a K^+ concentration of 3.5 mM. As others have reported, iontophoresis of GABA in the pyramidal cell layer produced a suppression of action potentials when recorded extracellularly. However, intracellular recording revealed that the changes in membrane potential during GABA iontophoresis near the soma may be biphasic: an early hyperpolarization followed by a depolarization. The hyperpolarization had properties similar to those of the IPSP; an increased membrane conductance, the same reversal potential as the IPSP, and sensitivity to picrotoxin. The depolarizing phase was accompanied by an increase of membrane conductance, it was reversed by transmembrane injection of outward currents, and it was abolished by picrotoxin. Topical application of a low Cl^- solution reversably decreased the size of the hyperpolarization and shifted the equilibrium potential of the depolarizing phase toward a more positive level. Application of Co^{++} at a concentration sufficient to block synaptic transmission did not change the amplitude of the biphasic response to GABA iontophoresis near the soma. The response was different if the GABA iontophoresis was near the apical dendrites. A depolarizing phase was observed which was not preceded by a hyperpolarization as in the case of somatic application. These results were obtained either by monopolar or bipolar iontophoresis and with K-acetate and K_2SO_4 microelectrodes (50-80 Mohms). Our present working hypothesis is that both components of the biphasic response are chloride dependent. Elsewhere in the meeting, we report that when the conductances during the IPSP are enhanced by sodium pentobarbital, a biphasic response to endogenous transmitter release can be evoked which has similar properties to the response elicited by iontophoresis of GABA.

2522 METHYLTRANSFERASES ARE INVOLVED IN NEUROTRANSMISSION. Jeffrey M. Thompson, Peter K. Chiang,* Robert R. Ruffolo, Jr.*, Giulio L. Cantoni* and Marshall Nirenberg. Lab of Neurosciences, Natl Inst on Aging, Baltimore, Md. 21224; Lab of Gen and Comparative Biochem, NIMH and Lab of Biochem Genetics, Natl Heart, Lung, and Blood Inst, NIH, Bethesda, Md. 20205.

Methyltransferases can be inhibited by S-adenosyl homocysteine (AdoHcy) or by analogues of this compound. Analogues which either increase levels of AdoHcy or inhibit methyltransferases directly include 3-deazaadenosine(DZA), adenosine-2', 3'-diazido-5'-carboxamide (744-99), 5'-deoxy-5'-isobutylthioadenosine(SIBA) and 5'-deoxy-5'-isobutylthio-3-deazaadenosine(DZ-SIBA). (Chiang, Richards and Cantoni, 1977, Mol. Pharmacol. 13:939-947; Chiang et al., 1978, Biochem. Biophys. Res. Commun. 82:417-423.) Neurons from 8-day chick embryo retina grown in culture with rat striated muscle cells for 24 hr formed synapses. Synapses were detected by recording spontaneous depolarizing synaptic muscle responses with intracellular microelectrodes (Puro and Nirenberg, 1976, Proc. Natl. Acad. Sci., USA, 73:3544-3548; Ruffolo et al., 1978, Proc. Natl. Acad. Sci. USA, 75:2281-2285). These synapses were investigated with the above probes to discover whether methylation reactions occur during synapse formation or neurotransmission. After treating the cultures for 2 hr with one of the AdoHcy analogues, the number of muscle responses/min in these synapses was inhibited up to 95% by DZ-SIBA (ED_{50} = 1. 5 x 10^{-6}M), SIBA (ED_{50} = 3 x 10^{-5}M), DZA (ED_{50} = 1.5 x 10^{-5}M) and 744-99 (ED_{50} = 1 x 10^{-4}M). Homocysteine thiolactone, 5'-deoxyadenosine and tubercidin, which do not increase levels of AdoHcy or inhibit methyltransferases, had no effect. DZ-SIBA inhibited the muscle responses with a half-time of 3.5 min. No inhibition of the number of synapses formed was seen. Inhibition of the number of muscle responses/min by DZA was reversed within 2 hr after removal of the compound. Further, homocysteine thiolactone potentiated the inhibition by DZA by 6-fold when the two compounds were added together. These results strongly suggest that a methyltransferase mediated reaction occurs during neurotransmission.

2523 PROPERTIES OF STORAGE OF DOPAMINE AND ACETYLCHOLINE IN GRANULES OF PC12, A CLONAL PHEOCHROMOCYTOMA CELL LINE. Lawrence Toll*, William P. Melega*, Robert V. Rebois*, Elwood E. Reynolds* and Bruce D. Howard. Biol. Chem. Dept., Sch. Med., UCLA, Los Angeles, CA 90024

PC12, a clonal line of rat pheochromocytoma, synthesizes acetylcholine and catecholamines, stores each in different granules, and exhibits a spontaneous and depolarization-induced, Ca^{2+}-sensitive secretion of each. These properties allow us to compare the mechanism of transmitter storage in two different types of storage granules produced by the same cell. The mechanism of storage of dopamine in PC12 granules is similar to that for catecholamines in storage granules from adrenal medulla and brain. Transport of catecholamines into these granules is driven by a transmembrane pH gradient (inside acidic), which also causes the retention of catecholamines within the granules. The pH gradient is established by the activity of a proton-translocating Mg^{2+}-ATPase present in the membrane of the catecholamine-containing storage granules. Transport of dopamine into PC12 granules is stimulated by ATP and inhibited either by proton ionophores that dissipate transmembrane pH gradients or by agents that inhibit the associated Mg^{2+}-ATPase. The proton ionophores cause dopamine, but not acetylcholine, to efflux from the granules. These effects can be demonstrated with isolated PC12 granules or with granules in intact cells. Other results suggest that the system involved in the loading of newly synthesized acetylcholine into granules operates relatively slowly and can be saturated. PC12 cells take up dopamine, tyrosine and choline and quickly convert the choline to acetylcholine and the tyrosine to dopamine. The newly accumulated or synthesized dopamine enters storage granules more readily than does newly synthesized acetylcholine. Incubation with the cholinesterase inhibitor eserine causes an increase in the cytosol level of newly synthesized acetylcholine but does not cause a corresponding increase in the amount of newly synthesized acetylcholine that is loaded into granules or that is released upon stimulation of the cells. Our studies indicate that PC12 will have much utility for examining the metabolism of dopamine and acetylcholine in secretory cells.

2524 STIMULATION-INDUCED RELEASE OF ^{3}H-NOREPINEPHRINE FROM EXPLANTS OF THE RAT SUPERIOR CERVICAL GANGLION: EFFECT OF ALPHA-ADRENERGIC AGENTS. N.D. Vu* and N.B. Thoa* (SPON: R.W. Colburn). Howard Univ., Washington DC 20059 and NIMH, Bethesda, MD 20205.

Alpha-adrenergic receptors have been identified in the rat superior cervical ganglion (SCG) (Kafka and Thoa, Biochem. Pharmacol. In Press). In culture, SCG cells were found to develop axonal sprouts with physiological and pharmacological properties of adrenergic nerve endings (Silberstein: in Neurosci.Res. 5:1-34, 1973). A calcium-dependent release of ^{3}H-Norepinephrine (^{3}H-NE) could be elicited in the cultured SCG with electrical field stimulation (Vu, Thoa and West, The Pharmacologist, 1979). In this study, the effect of alpha-adrenergic agents on release of ^{3}H-NE elicited by field stimulation (stimulated release) was examined. Rat SCG were cultured for 48 hours and labeled with 0.2μM of dl-^{3}H-NE in presence of 30μM corticosterone (CX) to inhibit uptake of catecholamines into extraneuronal structures. The explants were then perfused with a modified Krebs solution. After 60 min., electrical field stimulation (3Hz, 20 volts, 5 msec. duration) was applied for 1 min., and 4 min. samples were collected prior to and immediately following stimulation. ^{3}H-NE and its deaminated metabolites ^{3}H-DOMA and ^{3}H-DOPEG were assayed. Perfusates collected in the pre-stimulation period contain mostly ^{3}H-DOPEG (51%) and smaller amounts of ^{3}H-NE (26%) and ^{3}H-DOMA (23%). Field stimulation primarily increases ^{3}H-NE release (200%) and induced smaller increases of both ^{3}H-DOMA (100%) and ^{3}H-DOPEG (50%). Cocaine ($7x10^{-5}$M) blocks ^{3}H-NE uptake by 85% but does not affect spontaneous release of either ^{3}H-NE or of the two metabolites. It however potentiates stimulated release of ^{3}H-NE and completely blocks stimulated release of ^{3}H-DOPEG. The alpha-adrenergic antagonists phenoxybenzamine, phentolamine and piperoxane all increase spontaneous release of ^{3}H-NE in a dose-dependent manner with the following order of potency: phenoxybenzamine > phentolamine > piperoxane. In cocaine-treated preparations, stimulated release of ^{3}H-NE is inhibited by alpha-adrenergic agonists. This effect is stereospecific, l-epinephrine (l-EPI) being more potent than d-epinephrine. The order of potency of alpha-agonists is l-EPI > alpha methyl NE ≫ l-NE and resembled that observed at presynaptic alpha2 receptors sites (Berthelsen and Pettinger, Life sci. 21:595-606, 1977). Clonidine and dopamine are as potent as l-NE at lower doses but the former increases stimulated release of ^{3}H-NE at higher doses and the effect of the latter never reaches levels comparable with those of l-EPI or l-NE. Thus there seems to be a presynaptic feed back control of NE release (Langer, Biochem. Pharmac. 23:1793-1800, 1974) at newly formed sympathetic terminals of the rat SCG when this organ is maintained in culture.

2525 TRANSMITTER RELEASE STUDIES WITH DIAMIDE AT FROG NEUROMUSCULAR JUNCTION AND IN BRAIN SLICES. Patricia D. Wade*, Lawrence C. Fritz* and P. Siekevitz. Rockefeller University, New York, N. Y. 10021

Diamide, a sulfhydryl oxidizing agent, is known to dramatically increase the frequency of miniature endplate potentials at the frog neuromuscular junction in a Ca^{++}-independent manner (Werman, R. et al., Nature New Biology 233:120, 1971) similarly to a toxin from the black widow spider (α-latrotoxin) (Frontali, N. et al., J. Cell Biol.58:462,1972). Diamide also parallels α-latrotoxin in that following the waning of a maximal response further attempts to activate the terminal are unsuccessful. For example, upon electrical stimulation the endplate potential is blocked. Since toxin-treated terminals are empty of vesicles (Clark, A. W. et al., J. Cell Biol. 52:1, 1972), it is of interest to know how diamide-treated ones appear in the EM. Although not always entirely normal in appearance, diamide-treated terminals typically do contain vesicles, even though the terminal cannot be activated electrically nor even by the addition of α-latrotoxin. It might be that in the presence of diamide α-latrotoxin cannot interact with the terminal. However, we find that the toxin is still capable of resulting in a large decrease in the number of vesicles in the terminal as seen in EM.

Since α-latrotoxin releases every kind of transmitter from vertebrate neurons where the phenomenon has been studied (cf., Tzeng et al., PNAS 75:4016, 1978), and since the possibility exists that diamide may act on a general release mechanism as well, the effect of diamide on γ-aminobutyric acid (GABA) release from slices of rat cerebral cortex was studied. Diamide does not cause GABA release under conditions where high K^+ or α-latrotoxin does. The specificity or generality of the release mechanism of different transmitters as demonstrated by diamide action is being studied for acetylcholine and norepinephrine in brain.

2526 SPIKE AFTER HYPERPOLARIZATION AND TRANSMITTER RELEASE IN INTERNEURON L_{10} OF APLYSIA. Rafiq Waziri. Dept. of Psychiatry, Univ. of Iowa College of Medicine, Iowa City, IA 52242.

In Aplysia neurons, spike configuration in the soma may not always be representative of spikes occurring near the terminal where transmitter is released. Transmitter release by interneuron L_{10} can be modulated by the polarization of another neuron (L_{20}) which is electrically coupled to L_{10} (Waziri, Science, 195:790-792, 1977). The biphasic electrotonic potentials produced in L_{20} under experimental conditions may provide a "window" on some aspects of spike configuration that are important in the release of transmitter. Hyperpolarization of L_{10} terminal branches, by passing hyperpolarizing currents into L_{20}, diminishes transmitter release as evidenced by changes in the chemical postsynaptic potentials observed in other cells. The electrotonic potentials in L_{20}, produced by action potentials of L_{10}, show that the hyperpolarizing phase of electrotonic potentials is diminished or abolished depending on the level of induced hyperpolarization. Hyperpolarization of L_{10} which diminish transmitter release, also diminish the spike after hyperpolarization in L_{10} and the hyperpolarizing phase of the electrotonic potential. Tetraethyl ammonium ions which increase spike duration and transmitter release, also increase the amplitude of the spike after hyperpolarization. Lowering of extracellular calcium concentration does not decrease the amplitude of spike after hyperpolarization. These observations indicate that in this cell inward calcium movement which is essential for transmitter release is enhanced by outward movement of K^+ during the spike after hyperpolarization.

2527 ARE PRESYNAPTIC ALPHA-RECEPTORS INHIBITORY? G.J. Whiting*, D.A. McAfee, J.P. Horn, and N. Wenger*. Div. of Neurosciences, City of Hope National Medical Center, Duarte, CA 91010.

Synaptic transmission is dependent upon Ca^{++} in most preparations. Recently, Horn & McAfee (Science, in press) demonstrated that activation of postsynaptic α-receptors inhibits Ca^{++} current in postganglionic neurons. Activation of presynaptic α-receptors can inhibit synaptic transmission at low frequencies of preganglionic stimulation (Christ & Nishi, J. Physiol. 213, 107, 1971). We have tested the hypothesis that presynaptic α-receptors act to control presynaptic Ca^{++} influx by studying synaptic depression. Synaptic depression is thought to be due to depletion of readily releasable transmitter. We propose that activation of presynaptic α-receptors reduces Ca^{++} influx, slightly inhibiting low-frequency transmission, but profoundly facilitating high-frequency transmission.

Superior cervical sympathetic ganglia were isolated from mature rats and maintained in vitro at 24° C. Suction electrodes were used to apply stimulus trains (5-40 Hz for 1 sec.) to the preganglionic (cervical sympathetic) nerve and to record compound action potentials from the postganglionic internal carotid nerve. At frequencies above 10 Hz, the amplitude of the compound action potential progressively decreased, reaching a plateau about 1 sec. after the start of the train. At 17 Hz, the action potential was reproducibly depressed to 50% of control (EF_{50} = 17 Hz). Depression was directly proportional to extracellular Ca^{++}. Increasing extracellular Ca^{++} from a control level (2.2 mM) to 8.0 mM reduced the EF_{50} for depression about 40%, and decreasing extracellular Ca^{++} to 1.0 mM increased the EF_{50} by 40% over control values. Catecholamines had similar effects to low Ca^{++}. They reduced depression during trains at concentrations which had little effect on single responses. In the presence of norepinephrine (30 μM), the EF_{50} for depression was 25 Hz. At low frequencies (10 Hz) of stimulation, α-agonists actually facilitated synaptic responses. The order of potency was epinephrine (EC_{50} = 10^{-7} M), norepinephrine, dopamine, and isoproterenol. The effect of epinephrine and norepinephrine on depression was antagonized by the α-adrenergic blocker, phentolamine (10 μM), but not by the β-antagonists, propranolol (1 μM) or MJ-1999 (5 μM).

Our results support the above hypothesis inasmuch as the effect of low Ca^{++} was mimicked by α-agonists. We demonstrated that the α-agonists can actually promote synaptic responsiveness during repetitive activity. Intracellular studies are in progress to determine the relative contributions of postsynaptic mechanisms to synaptic depression. (Supported by NS-05820)

2528 RELATIONSHIP OF HIGH ENERGY PHOSPHATES AND pHi TO SYNAPTIC TRANSMISSION FAILURE DURING HYPOXIA IN THE IN VITRO HIPPOCAMPAL SLICE. Tim S. Whittingham* and Peter Lipton. Dept. Physiology, Sch. Med., Univ. of Wisconsin, Madison, Wis. 53706.

In vivo brain function fails rapidly during hypoxia. Transverse slices (.5mm) of guinea pig hippocampus are incubated in bicarbonate buffer containing 4mM glucose and aerated with O_2:CO_2 or N_2:CO_2 to study hypoxic transmission failure in vitro. Field potentials are recorded from the dentate granule cell region following stimulation of the perforant path. 75" after changing from O_2:CO_2 to N_2:CO_2 there is approximately a 25% decrease in the evoked response, while complete transmission failure occurs in ∿ 3'.

Increased extracellular potassium ($[K^+]_e$) and other depolarizing conditions all accelerate the rate of transmission failure during hypoxia, indicating that depolarization of neurons is leading to the hypoxic transmission failure.

Two means by which this hypoxic depolarization could occur are: 1) inhibition of the Na-K pump, and/or 2) an increase in cell membrane permeability. In either case it is important to establish whether decreased levels of ATP are responsible for the alteration in function.

Thus, experiments were done to determine if the cellular [ATP] falls rapidly enough during hypoxia to account for the decay in the evoked response. The slices were dissected such that the portion of tissue analyzed for ATP and phosphocreatine (PCr) was predominantly composed of the dentate gyral region in which transmission failure was monitored. In normal 4.4mM K^+ superfusate, the first noticeable decrease of the post-synaptic response occurred in ∿ 2'15". At this time [PCr] had fallen ∿ 37% (from 42± 3 (SEM) to 27±2 µmoles/mg protein), while ATP had decreased ∿ 15% (from 19±1 to 16±1µmoles/mg protein.) When these same experiments are done at 13.4 mM K^+, the first noticeable decrease occurs at ∿30". At this time the decrease in PCr is only 13% (from 40±2to ∿35 µmoles/mg protein) and the [ATP] remains unchanged (16± 1 µmoles/mg protein compared to ∿15.5 µmoles/mg protein in control slices). The failure of [ATP] to decrease prior to the first decrement in the post-synaptic response in 13.4 mM K^+ superfusate indicates that a decrease in [ATP] may well not be leading to the decay in the evoked response during hypoxia.

Intracellular pH has been observed to decrease during hypoxia. This fall could result in Na pump inhibition or changes in membrane permeability, resulting in neuronal depolarization. Experiments correlating pHi with the evoked response during hypoxia are currently being done and will be described.

2529 SLOW SYNAPTIC MODULATION OF EXCITABILITY MEDIATED BY INACTIVATION OF CALCIUM-DEPENDENT POTASSIUM CONDUCTANCE IN MYENTERIC NEURONS OF GUINEA-PIG SMALL INTESTINE. J.D. Wood, P. Grafe* and C.J. Mayer*. Physiol. Dept., Univ. Kansas Med. Ctr., Kansas City, KS 66103 and Physiologisches Institut der Universität München, 8 Munich 2, GFR

5-Hydroxytryptamine (5-HT) is the putative neurotransmitter for slow synaptic modulation of a particular kind of neuron (tonic-type) within the myenteric plexus (J. Neurophysiol. 42:582, 1979). Low excitability within these neurons is associated with a relatively low input resistance of the cell soma and long lasting hyperpolarizing after-potentials, both of which appear to be reflections of increased gK. Electrical stimulation of presynaptic fibers or iontophoresis of 5-HT produce a prolonged increase in excitability (slow EPSP) which is characterized by membrane depolarization, increased input resistance, repetitive spike discharge and reduction of postspike hyperpolarizing potentials in these neurons. We now report that the calcium antagonists Mg^{++} and Mn^{++} mimic all of the characteristics of the slow EPSP. When the neurons were superfused with solutions containing either 16 mM $MgCl_2$ and 1 mM $CaCl_2$ or 2 mM $MnCl_2$ and 2.5 mM $CaCl_2$, the input resistance increased, the membrane depolarized, hyperpolarizing after-potentials were abolished and repetitive spike discharge occurred. The organic calcium antagonists verapamil and D-600 did not produce these effects. The effects of elevated Mg^{++} and Mn^{++} were reversible, and were observed only in tonic-type neurons. We also studied the effects of elevated Mg^{++} and Mn^{++} on the relationship between external potassium concentration and the resting membrane potential in these cells. The results, when plotted on a logarithmic scale, showed a close fit to the Goldman equation and the slopes of the plots were significantly reduced when either 16 mM Mg^{++} or 1 mM Mn^{++} was present. These effects did not occur in other types of myenteric neurons and putative glial cells. We used intracellular current injection to control membrane potential, and estimated the reversal potential for the slow EPSP to be -73 mV. The results are consistent with the hypothesis that low resting excitability in these neurons is related to two different calcium-dependent gK systems within the membranes. One calcium-dependent increase in gK is triggered by calcium entry during the spike and results in prolonged hyperpolarizing after-potentials. The second calcium-dependent gK is associated with a high resting gK that is reflected by high membrane potential, low input resistance and low excitability. The calcium antagonists and 5-HT appear to produce augmented excitability by suppressing the two calcium-dependent gK systems. Therefore, our results suggest that the slow synaptic modulation of excitability in the tonic-type myenteric neurons involves a mechanism in which the primary action of the neurotransmitter is to interfer with the availability of calcium for the calcium-dependent gK systems.

2530 A SECOND NOVEL PRESYNAPTIC TOXIN PRESENT IN THE GENUS LEPTINOTARSA. J.E. Yoshino*, D. Baxter*, T.H. Hsiao*, and W.O. McClure. Section of Cellular Biology, University of Southern California, Los Angeles, CA 90007, and Department of Biology, Utah State University, Logan, UT 84322.

Previously we reported the ability of leptinotarsin, a neurotoxin found in the hemolymph of Leptinotarsa haldemani (LPT-H), to stimulate the release of acetylcholine (ACh) from synaptosomes and to increase spontaneously the frequency of miniature end plate potentials (mepps) at the rat neuromuscular junction (nmj) (Satin et al, Soc. for Neuroscience Abs., Vol. 4, p. 584, 1978; Yoshino et al, loc. cit., p. 586). In this study we have examined the neurochemical properties of leptinotarsin from a related species, L. decemlineata (LPT-D). LPT-D stimulated the preferential release of [^{3}H]ACh from rat brain synaptosomal preparations previously incubated with [^{3}H]choline. The releasing activity present in LPT-D was also partially dependent upon the presence of Ca^{++} in the perfusing medium and was heat labile, similar to those results found with LPT-H. Other preliminary studies with the partially purified toxin suggest, however, that LPT-D and LPT-H are not identical. The curve which relates releasing activity to increasing concentration of LPT-D is sigmoid, with a Hill coefficient equal to 1.8. In contrast, the corresponding curve for LPT-H does not exhibit any sigmoid character. Whereas the release of radioactivity by LPT-H can be well characterized by first order kinetics, the activity of LPT-D is more complex. Since the ability to stimulate release of ACh was similar to that of black widow gland extracts (BWGE), we examined the immunological similarity of LPT-D and LPT-H to BWGE by incubating the two toxins with commercial antivenin to BWGE (Lyovac). The ability of LPT-D to stimulate release was reduced 35% ($p \leq 0.05$) by treatment with 300 units of antibody/ml. Under similar conditions, the activity of LPT-H was not impaired.

We have begun the purification of LPT-D from the lyophilized hemolymph. After passage over Sephadex G-100 and gradient elution from DEAE Sephadex A50 we find an increase in the specific activity of the toxin of about 30 fold. These procedures partially separate two proteins, each of which appears to stimulate the release of radioactivity from synaptosomes. Preliminary observations indicate that the hemolymph of LPT-D stimulates an increase in the frequency of mepps at the rat nmj. When LPT-D and LPT-H are purified to homogeneity, they may be useful as mechanistic probes in examining the processes underlying the release of neurotransmitters.

2531 MORPHOLOGICAL AND ELECTROPHYSIOLOGICAL CHARACTERIZATION OF A DISCRETE CLASS OF STATOACOUSTICAL INTERNEURONS IN A VERTEBRATE BRAIN. Steven J. Zottoli and Donald S. Faber. Div. of Neurobiology, Dept. of Physiol., SUNY at Buffalo, Buffalo, NY 14214 and NYS Research Institute on Alcoholism, 1021 Main Street, Buffalo, NY 14203.

Interneurons of the goldfish medulla which are inhibitory to the Mauthner cell (M-cell) are electrophysiologically identifiable by the presence of a passive hyperpolarizing potential (PHP) coincident with the M-cell's antidromic impulse (Korn and Faber, J. Neurophysiol., 38:452, 1975). We have studied the physiological and morphological properties of one class of these neurons which are excited by eighth nerve inputs.

The majority (>90%) exhibited graded short latency depolarizations (SLDs) to subthreshold stimulation of the ipsilateral eighth nerve. SLDs were occasionally followed by mono- or polysynaptically mediated PSPs. The short latency of the SLD (430 ± 100 µsec; mean ± SD, n=92) and its amplitude independence of membrane potential suggest these PSPs are electrotonically mediated. As stimulus strength was increased, SLDs could bring the PHP neurons to threshold. Stronger stimuli evoked a shorter latency impulse (340 ± 60 µsec; n=84); collision tests and membrane hyperpolarizations did not reveal an underlying EPSP. These findings and the latency difference between this spike and the SLDs (103 ± 80 µsec; n=77) suggested the former were antidromically activated and that the neurons might be efferents (Zottoli and Faber, Soc. Neurosci., 2:1063, 1976). However no efferent process could be identified after intracellular iontophoresis of either Procion yellow or cobalt acetate (n=77). Their morphology rather suggests that they are interneurons and that the short latency spike may be generated by an electrotonic input at a more distant locus than that which mediates the SLD.

The somata of the statoacoustic interneurons were clustered dorsolateral and posterior to the M-cell soma. The apparent axon could be traced to a contralateral tract that projects caudally and lies lateral to the VIIth cranial nerve. Its ramifications project bilaterally to the vicinity of other statoacoustical neurons, large and small reticular neurons and the M-cells. Their widespread medullary projections (see also Triller and Korn, C.R. Acad. Sci., D, (Paris), 286:89, 1978) suggest that these commissural interneurons not only mediate afferent inhibition of both M-cells but of many other brainstem areas as well. (Supported by PHS Grant No. NS 12132 to D. Faber and Postdoctoral Fellowship F 32 NS5282 to S. Zottoli.)

TISSUE CULTURE

2532 NEURITE PROMOTION IN CILIARY GANGLIONIC CULTURES. Ruben Adler and Silvio Varon. Dept. Biol., Sch. Med., UCSD, La Jolla, CA 92093.

We have previously reported that chick embryo ciliary ganglionic (CG) neurons will survive in monolayer cultures if supplied with either chick embryo extracts or medium previously conditioned over chick heart cell cultures (HCM), in addition to serum. The two supplements, however, differed in their neurite-promoting effects, as embryo extracts elicited neurite growth only on collagen and HCM did so only on polyornithine (PORN) substrata (Varon et al, Brain Res., 1979, in press). We report here that HCM contains two distinct and separable agents. One is a trophic agent (HCM-CNTF), which supports the survival of CG neurons on either substratum. This agent does not seem to adsorb to either substratum, and may act directly on the cells. Its relationship to the CNTF which we have obtained from intraocular target tissues (Adler et al, Science, 1979, in press; Manthorpe et al, Trans. Am. Soc. Neurochem. 10: 76, 1979) has not yet been investigated. The CG culture assay previously developed for the eye-CNTF indicates that our HCM contains 10-20 trophic units/ml. The second agent (HCM-NPF), first described by Collins (Proc. Natl. Acad. Sci. USA 75: 5210-5213, 1978), is presumably an acidic material which adsorbs to PORN but not to collagen surfaces, and confers to the substratum a neurite-promoting activity for CG neurons that are supported by CNTF (from either HCM or embryonic extracts). Pre-exposure of PORN-coated dishes to serially diluted HCM, followed by seeding of CG neurons in the presence of HCM-CNTF, allows to assign to the original HCM an NPF activity of 3-6 unit/ml.

Neurite-promoting activity can be imparted to a PORN surface also by other means. Ciliary ganglia, explanted either on untreated PORN or on PORN precoated with HCM-NPF, display no neuritic outgrowth unless CNTF is also provided. On the pretreated PORN, CNTF-supported neuritic outgrowth is radial and unrestricted. On untreated PORN, CNTF-supported neuritic outgrowth also occurs, but it extends only within the visible confines of some substratum-attached material (SAM), which originates within the explant and coats the surrounding PORN in widening circles. Thus, it appears that both the tissue of origin (ganglion) and potential target tissue (muscle) are capable of providing supportive terrains for the trophic-driven elongation of a neurite. (Supported by NINCDS grant NS-07606).

2533 COLD-INSOLUBLE GLOBULIN ENHANCES NEURITE OUTGROWTH FROM CULTURED NEURAL RETINA AGGREGATES. Rebecca M. Akers, Deane F. Mosher* and Jack E. Lilien*. Depts. of Zoology and Medicine, University of Wisconsin, Madison, WI 53706.

Aggregates of embryonic chick neural retina extend few neurites on plastic tissue culture dishes. However, pre-incubation of culture dishes with human plasma cold-insoluble globulin (CIG) dramatically increases both the number and length of outgrowing neurites. Within 24 hours of plating on CIG-treated dishes, retinal aggregates elaborate straight, sparsely-branched processes which extend radially over the culture surface for several hundred microns. Enhancement of neurite outgrowth is evident on culture dishes treated with as little as 2.5 µg CIG (in 1 ml of medium); maximal effects are observed after pre-incubation of dishes with 25 µg CIG. Treatment of dishes with equivalent amounts of other serum proteins (BSA or fetuin) has no apparent effect on neurite outgrowth. CIG-treated dishes incubated with affinity-purified anti-CIG antibodies no longer support neurite outgrowth; aggregates plated on such dishes resemble those cultured on untreated plastic surfaces.

Neurites growing on CIG-treated substrata have a different morphology than neurites grown on poly-lysine (PLYS)-treated dishes. Like CIG, PLYS enhances neurite outgrowth from retinal aggregates. However, these neurites do not extend radially from the aggregate. Rather, they grow concentrically around the aggregate, enveloping it in a network of fine, multiply-branched processes. In addition, neurites adhere differentially to CIG- and PLYS-treated dishes. Neurites growing on PLYS adhere to the substratum along their entire length, whereas on CIG adhesion of the neurite occurs solely at the growth cone. Although CIG and PLYS both provide favorable substrata for retinal neurite outgrowth, the interactions of neurites with these two substrata appear to be different.

2534 HORMONAL REGULATION OF GLIAL RELEASED PROTEIN IN CELL CULTURE. Alaric T. Arenander* and Jean de Vellis. Department of Anatomy and the Laboratory of Nuclear Medicine and Radiation Biology, UCLA, Los Angeles, CA 90024.

Glial cells synthesize and release a variety of macromolecular factors including glycosaminoglycans, proteins (e.g., Nerve Growth Factor), glycoproteins and polypeptides, some of which are capable of influencing the morphological and/or biochemical differentiation of various neuronal populations. There has been little analysis of the range of potential protein factors or of the control mechanisms which modulate their production and release.

We report here that monolayers of rat clonal and primary glial cells release into the culture medium a reproducible, broad spectrum of soluble macromolecules. Furthermore, a number of these glial-released proteins (GRPs) are shown to be regulated in a specific manner by a variety of hormonal agents. Conditioned medium was collected from C6 glioma cell monolayers after being incubated for 24 hr in serum-free medium and labelled during the last 6 hr with either [^{3}H] or [^{14}C]leucine. SDS-polyacrylamide slab gel electrophoresis of soluble GRPs revealed 20 major peaks of labelled protein distributed over a molecular weight (MW) range of 10,000 to 300,000. Gel radio-labelled patterns were reproducible both within and between experiments based on visual examination of plots, $^{3}H/^{14}C$ isotope ratios and label reversal. Exposure of the cells to hydrocortisone (HC, 1-2 µM) for 24 hr altered the pattern of GRP in a selective and specific manner. Six major GRP peaks were consistently observed to either increase or decrease based on plots of isotope ratios. The effect could be observed at 0.02 µg/ml (5.4×10^{-8} M) but not at 0.002 µg/ml. Treatment of cells with 17-β-estradiol (2 µM) gave no observable change in pattern of GRP. Dibutyryl cyclic AMP (1 mM) and isoproterenol (10 µM) were also capable of selectively influencing the GRP patterns but in a manner different from HC. A number of the GRP peaks are glycoproteins based on metabolic labelling with [^{14}C]glucosamine. Pure primary cultures of astroglia and oligodendroglia obtained from newborn rats generated a spectrum of GRP closely resembling that of C6, differing mainly in the high MW region. HC treatment also influenced the GRP pattern from mixed glial cultures. Thus, both clonal and primary glial cultures released a wide MW range of proteins (GRP) that were under specific hormonal control. The origin and possible role in neuronal-glial coupling of GRPs is being investigated. Supported by DOE and USPHS.

2535 RECIPROCAL REGULATION OF ACETYLCHOLINE RECEPTOR AND MYOSIN IN CHICK MYOTUBES BY A PHOSPHODIESTERASE INHIBITOR AND CYCLIC NUCLEOTIDE ANALOGUES. James C. Blosser and Stanley H. Appel. Dept. Neurology, Baylor College of Med., Houston, TX 77030.

Acetylcholine receptor (AChR) and myosin are reciprocally regulated under a number of conditions. Denervation increases AChR and decreases myosin. In primary cultured muscle cells tetrodotoxin also increases AChR and decreases myosin while electrical stimulation decreases AChR synthesis and increases myosin synthesis. We have observed a similar effect with a phosphodiesterase inhibitor. A number of phosphodiesterase inhibitors were found to elevate AChR levels in primary cultures of chick 11 day embryonic muscle. Using ^{125}I-α-bungarotoxin binding to surface receptors as an index of AChR content, caffeine and theophilline (10^{-3} M) were found to cause moderate increases in AChR (25-30%). Papaverine (3×10^{-5}M) increased levels by 50% while Ro20-1724 (3×10^{-4}M) elevated receptor by over two fold. The effect of Ro20-1724 appeared to be largely due to an increased rate of receptor accumulation. The apparent rate constant of accumulation (k_{acc}) increased from 32 cpm/h (^{125}I-toxin binding sites) to 55 cpm/h while half life, as measured by loss of ^{125}I-α-bungarotoxin from prevously labeled cells, was unchanged. Under these conditions myosin heavy chains were extracted and quantitated by densitometry on acrylamide gels. After 48 hours of treatment myosin content was 11.2 ± 0.9 µg/plate in control and 5.6 ± 0.9 µg/plate in the Ro20-1724 treated cells. Pulse chase experiments with ^{35}S-methionine indicated that increased degradation is primarily responsible for the decreased myosin content (control $t_{\frac{1}{2}}$ = 72 h, Ro-1724 $t_{\frac{1}{2}}$ = 22 h). No measurable differences in DNA content were observed. To gain a better understanding of the mechanism of action of Ro20-1724, several cyclicnucleotides were tested. Dibutyryl cAMP (10^{-3}M) was found to increase AChR levels by 80% while dbcGMP (10^{-3}M) had little effect. Both dbcAMP and 8BrcAMP increased k_{acc} by 50% with little if any affect on half life. In contrast dbcGMP decreased heavy chain myosin levels by over 40% after 48 h of treatment. Similar treatment with dbcAMP had little effect on myosin content. These results suggest that cAMP and cGMP each play a role in the reciprocal regulation of AChR and myosin but by different mechanisms - cAMP affecting AChR at a synthetic or insertion level and cGMP influencing myosin degradation.

2536 ACTIONS OF GLUTAMIC ACID AND KAINIC ACID ON MUSCARINIC RECEPTOR BINDING IN SPINAL CORD CELL CULTURES. Neville Brookes and David R. Burt. Dept. Pharmacol. & Exptl. Therap., Univ. of Maryland Sch. Med., Baltimore, MD 21201.

The specific binding of [^{3}H]quinuclidinyl benzilate ([^{3}H]QNB) in surface cultures of dissociated murine spinal cord (SC) cultures was previously reported to increase with maturation of the cultures in vitro (Brookes, Burt and Goldberg, Neurosci. Abstr. 4:590, 1978). To establish that this muscarinic receptor binding is neuronal, we have treated SC cultures with selectively neurotoxic amino acids and have assayed for the disappearance of [^{3}H]QNB binding. The cultures were prepared by mechanical dissociation of spinal cords (including dorsal root ganglia and meninges) from 13-day-old mouse embryos. Cell proliferation was inhibited by application of 5-fluoro-2'-deoxyuridine after about 5 days of incubation. SC cultures at 2–7 weeks of incubation were exposed to monosodium glutamate (10^{-3} M) for 3 hr. The fraction of control [^{3}H]QNB binding present immediately after exposure was 0.88 + 0.12 (mean + SEM, N=3). The fractions remaining 1, 2 and 4 days after exposure were 0.47 + 0.05 (N=6), 0.40 + 0.05 (N=7) and 0.21 + 0.02 (N=6), respectively. The mean control values of [^{3}H]QNB binding were 125–175 fmole per mg protein. The non-collagen protein content (Wallace and Partlow, Analyt. Biochem. 87:1, 1978) of the exposed cultures was 0.86 + 0.10 (N=6) of the control value (189 µg protein per culture) 4 days after exposure. The loss of binding was not increased by prolonging the glutamate exposure to 24 hr and was detectable with exposures as short as 10 min. When [^{14}C]glutamate tracer was included with cold glutamate (10^{-3} M) in the culture medium, sample counts did not change after 24 hr and the radioactivity still ran as a single peak on thin layer chromatograms using two solvent systems. The concentration-effect relationship for the action of glutamate was very steep. The mean fraction of control [^{3}H]QNB binding two days after a 3 hr exposure to glutamate (10^{-4} M) was 0.91 + 0.14 (N=5). However, the loss of binding observed at 10^{-3} M was not increased by further raising the concentration of glutamate. The fraction of [^{3}H]QNB binding remaining 4 days after a 3 hr exposure to glutamate (10^{-3} M) was dependent on the maturity of the cultures at the time of exposure. Cultures exposed at 8, 12 and 19 days of incubation yielded 59%, 21% and 18%, respectively, of control binding. Kainic acid was only moderately more potent than monosodium glutamate. When SC cultures at 2–7 weeks of incubation were assayed 2 days after a 3 hr exposure to kainic acid (10^{-4} M and 10^{-3} M) the remaining fractions of control [^{3}H]QNB binding were 0.65 + 0.09 (N=3) and 0.83 + 0.09 (N=3), respectively. The actions of glutamic and kainic acids were not influenced by the presence of 10% heat-inactivated horse serum in the culture medium. In conclusion, at least 80% of muscarinic receptor binding in mature SC cultures is associated with a sub-population of cells, presumably neurons, which is destroyed by the neurotoxic amino acids. The time course of disappearance of the receptor binding is measured in days. (Supported, in part, by USPHS Grant MH 29011.)

2537 QUANTITATIVELY DEFINED CELL CULTURES OF THE CEREBELLUM D. Neil Currie* and Gary R. Dutton. Brain Research Group, The Open University, Milton Keynes MK7 6AA, U.K.

Primary cell cultures have great potential as models for the study, particularly by biochemical methods, of many aspects of neuronal development which are currently rendered inaccessible by the complexity and heterogeneity of the intact brain. However interpretation of biochemical results must rest on clear knowledge of cellular composition in cultures based on reliable methods of cell identification.

In order to define and quantify the composition of our monolayer cultures of rodent cerebellum, we have used three types of marker: (a) Autoradiography of ^{3}H-GABA uptake using specific GABA analogues to distinguish glial uptake from uptake into putative GABAergic neurons. (b) Established immunological markers for neurons, astrocytes, oligodendrocytes, and fibroblasts. (c) New monoclonal antibodies to cell populations in culture.

Cerebellar cultures have been found to contain at 6 days in vitro (DIV): granule neurons(84% of total cells), inhibitory GABA neurons(4%, probably stellate and basket cells), astrocytes(11%), oligodendrocytes(0.5%), and fibroblasts(0.5%). Cerebellar glial cultures have also been prepared from the same starting cell suspension using a different medium: these contain at 6 DIV over 85% astrocytes and small proportions of the other cell types.

Once cell composition can be defined in this way, it is possible to adjust conditions to favour particular cell types, such as the inhibitory neurons. Cultures of greater than 95% granule neurons can now be obtained, being the purest cultures of a single neuronal type yet available.

The availability of a range of culture systems of differing and known composition provides a sound basis for biochemical studies of cellular development.

2538 IN VITRO, GROWTH, GLUTAMINE AND GLUCOSAMINE TOXICITY STUDIES OF HUNTINGTON'S CHOREA FIBROBLASTS. I.DeMartini*, J.Archer*, S. Kiel* and E.Mancall. Departments of Neurology and Pediatrics, Hahnemann Medical College, Philadelphia, PA 19102.

Tissue culture studies were performed on skin fibroblasts from 6 patients with Huntington's Disease (HD), 6 age-matched normal controls (NC) and 6 "at risk" subjects. For growth studies, cells were plated at 1x10^5 cells/60mm plate in Waymouth/McCoy medium containing 20% fetal calf serum (FCS). Three plates were counted each day for 5 days in 3 separate experiments. HD fibroblasts grew to a significantly higher maximal cell density than NC fibroblasts ($P < 0.05$ on the 5th day) as previously demonstrated (Leonardi,A., DeMartini,I., et al. N.Eng.J.Med. 298:632,1978 inter alia). One of the 6 "at risk" subjects' fibroblasts grew to a maximal cell density in the HD range (2 standard deviations (SD) above the mean of the NC cells). The other 5 "at risk" subjects could not be clearly identified in this manner; in 3 cases the maximal cell density was within 1 SD of the mean of the HD cells, and in 2 cases within 1 SD of the mean of the NC cells.

Glutamine and Glucosamine toxicity studies were then performed with the aim of obtaining a more significant and clearly-defined difference in behavior between HD, NC, and "at risk" cells in culture. When HD and NC fibroblasts were grown for 3 days in medium containing 5% FCS (partially depleted medium) growth rates for the two groups of cells were similar (P-not significant). However, the addition of glutamine (2mM) after 24 hours growth in partially depleted medium, caused a significant reduction in the growth of HD cells but not of NC cells. (day 3 vs. day 1: Δ %=-31% for HD. $P < 0.01$, Δ %=1% for NC. P not significant). When glucosamine (1mM) was added under the same conditions, the growth of both HD and NC cells was significantly reduced $P < 0.05$. Studies with "at risk" cells are in progress, as are toxicity studies using glucosamine and glutamine in a concentration range 0.5-10mM, with plating efficiency (mean colony formation) as the end point.

These preliminary findings suggest a greater toxicity of glutamine in HD cells as compared to NC cells, perhaps as an expression of partial impairment of one or more of the metabolic pathways for glutamine and glutamic acid. This formulation would be consistent with reported findings of reduced levels of GABA and glutamic acid decarboxylase in the brain of HD subjects.

2539 EXPLANT CULTURES OF ADULT RAT SUPERIOR CERVICAL GANGLIA (SCG) MAINTAINED IN CHEMICALLY DEFINED MEDIA. Anthony Dombrowski* and Frederick C. Kauffman, Dept. Pharm. Exptl. Ther., Univ. MD, Sch. Med., Balto., MD 21201.

Organotypic cultures of adult rat SCG explants have been maintained in chemically defined media for periods of at least two weeks. Desheathed ganglia from rats weighing 125–150 g were cut transversely into 300 µm sections and placed in culture on either a collagen or Millipore filter (THWOP2500) surface. Virtually no growth was obtained in a serum-free medium (Eagle's MEM, 10 mM glucose, 100 units/ml nerve growth factor and antibiotics) supplemented with 1% bovine serum albumin (BSA). Significant outgrowth occurred when the medium was further supplemented with at least one or combinations of the following: insulin (1 µg/ml), l-thyroxine (4 µg/ml), and hydrocortisone (.05 µg/ml). On the collagen surface growth observed in the presence of BSA and all three hormones was comparable to that observed with a 10% Fetal Calf Serum (FCS) supplement. Increasing the FCS concentration to 20% or adding all three hormones plus 10% FCS did not alter this.

The explant outgrowths are long neuronal-like processes containing catecholamines but no detectable DNA. After freeze-drying the culture assembly the entire explant body can be removed from either the collagen or Millipore filter leaving the outgrowth attached to the surface.

Outgrowth may be quantitated by measuring $NADP^+$-dependent dehydrogenases localized in the growing processes. Glucose-6-phosphate dehydrogenase (G6PDH) was the most active of the four major NADPH generating enzymes in SCG explants. Activities of G6PDH, isocitrate dehydrogenase, 6-phosphogluconate dehydrogenase (6PGDH), and malic enzyme were 150 + 10, 70.8 + 11.8, 34.6 + 7.7, 8.6 + 1.5 pmole NADPH/µg protein/min, respectively in FCS media at 37°. This pattern differs from that in situ where isocitrate dehydrogenase is the most active $NADP^+$-dependent enzyme. Activities of the dehydrogenases, except 6PGDH, were higher in the presence of FCS than in explants cultured with BSA and hormone supplemented media. Both G6PDH and 6PGDH showed a trend of decreasing activity in the serum-free media. Highest activity was noted in the presence of all three hormones and decreased progressively in media supplemented solely with insulin, thyroxine or hydrocortisone.

The SCG explant maintained in chemically defined media promises to be a useful system to quantitate growth and growth promoting substances in neural tissue. (Supported by USPHS Grant NS-14728.)

2540 DEVELOPMENT OF RESTING POTENTIAL IN TISSUE CULTURED SKELETAL MUSCLE: A REQUIREMENT FOR LOW [K^+] IN BATHING SOLUTIONS. J.K. Engelhardt, K. Ishikawa*, and D.K. Katase*. Dept. of Neurology, USC School of Medicine, Los Angeles, CA 90033.

The developmental increase in skeletal muscle resting potential has been a common observation in embryonic tissue (Boethius & Knutsson, J. Exp. Zool., 174: 281, 1970; Kano, J. Cell. Physiol., 86: 503, 1975) and in primary cultures (Fischbach et al., J. Cell. Physiol., 78: 289, 1971; Ritchie & Fambrough, J. gen. Physiol., 66: 327, 1975). The experiments reported here were specifically designed to test the effect of low [K^+] in the bathing solution on the ability to observe a developmental increase in resting potential.

Our tissue culture and electrophysiological methods have been described elsewhere (Engelhardt et al., Brain Research, 110: 170, 1976). Myotube resting potentials were measured using conventional glass micropipette electrodes filled with 3 M KCl. Our 2.7 mM K^+ solution had the following composition in mM: NaCl 140, KCl 2.7, $CaCl_2$ 1.8, Glucose 11.7, HEPES 16.7, pH adjusted to 7.4 with NaOH. 5.4 and 10.8 mM K^+ solutions were prepared by substituting the appropriate amount of KCl for NaCl. The experimental protocol consisted of removing a culture dish from the incubator and discarding the media. The dish was rinsed with the appropriate experimental solution, refilled and allowed to equilibrate for 10 minutes before resting potential measurements were attempted. Experiments were conducted at room temperature (20-24°C). The statistical significance of differences in average resting potential was tested using analysis of variance.

Resting potentials measured in 2.7 mM K^+ increased from 42.1 ± 8.6 mV (mean ± SD, n = 10) on day 4 to 86.1 ± 4.2 mV on day 8, while resting potentials measured in 5.4 mM K^+ did not show a statistically significant change during the same period of time (67.8 ± 4.2 vs 71.5 ± 4.0). The change in average resting potential measured in 10.8 mM K^+ was statistically significant (51.7 ± 2.4 vs 56.5 ± 2.4), but the increase was less than 5 mV during the same period of time that resting potentials measured in 2.7 mM K^+ increased an average of 44 mV.

Our tentative explanation for these observations is that low [K^+] leads to K-channel inactivation and an increased dependence of the resting potential on other ions in the system, ions that exhibit changes in their ability to penetrate developing muscle membrane.

2541 PULSATILE MOVEMENTS OF SCHWANN CELLS IN VITRO STUDIED BY TIME-LAPSE CINEMICROGRAPHY. David S. Forman, William G. Shain, Jr., David A. Fuchs* and Clarence H. Braddock*. Naval Medical Research Institute and Armed Forces Radiobiology Research Institute, NNMC, Bethesda, Maryland 20014.

Schwann cells (Pomerat, Science 130:1759 [1959]) and oligodendroglia in tissue culture display slow pulsatile movements which may be unique to these myelin-forming cells. This behavior has been reported by several laboratories but has rarely been analyzed quantitatively. We have used cinemicrography to study the movements of Schwann cells in dissociated cell cultures of sciatic nerves, vagus nerves and superior cervical ganglia from 3-day old rats. The cells were grown on glass coverslips in F12 medium containing 10% foetal calf serum and 5 µg/ml gentamycin. In most of our cultures the proliferation of fibroblasts was suppressed either by X-irradiation (1000 rad), treatment with cytosine arabinoside, or culture in N2 medium (Bottenstein and Sato, Proc. Nat. Acad Sci. USA 76:514 [1979]). The cells were observed with phase microscopy in a continually perfused Dvorak-Stottler chamber at 36°C and photographed at 6 frames/minute. Most of the Schwann cells were elongated and bipolar with small, highly refractile cell bodies. However, they often extend more than two processes, and can flatten against the substrate. The cultures were usually filmed for an hour, during which an average of 56% of the Schwann cells displayed intermittent pulsatile activity. The duration of these active periods varied from 1 to 7 minutes, with an average of 2.7 minutes. The quiescent interval between pulsatile periods also varied widely; intervals ranging from 1 to 17 minutes were measured between pulsations (average = 4.3 minutes), but there were many longer pauses which extended beyond the ends of the filming sessions. The average cell had 4.0 periods of pulsatile activity per hour. Two types of pulsatile movement were seen: single strong contractions of the cell body or a series of low amplitude contractions or side-to-side movements of the cell body. The distributions of the duration of the active periods and of the intervals between activity were closely similar for these two types of movement, suggesting that they are two forms of the same behavior. Pulsatile motility depended upon continual perfusion of the chamber; it stopped about an hour after perfusion was discontinued and began again when perfusion was restored. Pharmacological, ionic, and developmental factors which control the pulsatile behavior are being studied. Preliminary results are that serotonin (10^{-4}M) and dibutyryl cyclic AMP (10^{-3}M) reduce the frequency of the pulsations. Raising the K^+ in the medium to 20 or 40 mM had no obvious effect upon the pulsation. The function of Schwann pulsations is unknown, but one hypothesis is that it forms a mechanism for the peristaltic pumping of materials through the long, attenuated cytoplasmic processes in myelin.

2542 ANALYSIS OF THE MECHANISM OF NEURITE TRANSECTION IN CULTURE WITH PULSED UV LASER MICROBEAM IRRADIATION. Guenter W. Gross*, M. Louise Higgins*, Marilyn N. Smith*. Dept. of Biology, Texas Woman's University, Denton, TX 76204. (SPON: J.F. Hines)

To develop a reliable and convenient method for the micromanipulation of cultured neurons and their processes in closed chambers we are investigating the effects of UV laser microbeam cell surgery on mouse neuroblastoma cells with light, scanning electron and transmission electron microscopy. It has been determined that highly localized transections can be achieved with three basic techniques: (a) direct transection due to vaporization of tissue in the laser focus; (b) indirect transection due to shock waves caused by vaporization of minute quantities of substrate below the neurite; and (c) slow coagulation of cytoplasm due to irradiation with power densities below the threshold for immediate physical damage (approx 10^9 W/cm^2). Contrary to impressions gained from preliminary data (Rieske, Gross and Kreutzberg, Laser und Elektro-Optik 2,44, 1977; Rieske and Kreutzberg, Brain Res. 148, 478, 1978; Gross, Higgins and Smith, Neurosci. Abs. 4, 590, 1978), transections are usually not direct but result from shock waves and associated physical phenomena due to vaporizing substrate. These transections are not as accurate as previously believed and often show neurite separation at sites 3 to 5 µm distal or proximal from the laser impact area along the process. Scanning electron microscopy also reveals occasional residual processes below the resolution of LM at laser impact sites. Although accuracy and reproducibility are best with technique (a) it has the disadvantages of higher levels of scattered UV and a higher risk of widespread damage if the laser focus is accidentally located in the substrate. Techniques (a) and (b) must be carried out with single shots because structural alterations in substrate cause higher absorption with successive shots and larger shock waves of unpredictable magnitudes. Despite these problems laser cell surgery allows manipulations with unprecedented accuracy and ease. Remarkably little cell damage can be demonstrated on the ultrastructural level. (Supported by NIH grant NS15167-01 and Texas Woman's University Institutional Grant 0958).

The laser microbeam system was constructed by BTG Biotechnic, Munich and consists of a nitrogen laser coupled to a Leitz microscope; max. power densities 10^{11} W/cm^2, min. focus 0.8 µm; pulse length 10 nanoseconds; frequency 337 nanometers. A HeNe laser is used to mark the target and aid in focusing the UV laser.

2543 ACETYLCHOLINE SENSITIVITY IN XENOPUS NERVE-MUSCLE CELL CULTURES DURING SYNAPTOGENESIS. Raphael Gruener and Yoshiaki Kidokoro. Dept. Physiol., Univ. Arizona Col. Med., Tucson, AZ 85724 and Salk Institute, La Jolla, CA. 92112.

We recently showed (1) that in combined cultures of Xenopus nerve and muscle cells, miniature endplate potential (mepp) amplitude and frequency increase in parallel with the nerve-induced accumulation of acetylcholine receptors (2) at the area of contact between the neurite and muscle cell. These findings are consistent with the well-described changes in acetylcholine receptor (AChR) redistribution which occurs during in-situ synaptogenesis of the neuromuscular junction.

We examined the sensitivity of muscle cells to iontophoretic application of ACh to ascertain if ACh sensitivity, at the developing contacts, may be correlated with mepp properties and to determine the sensitivity of non-contact areas on the muscle cells during development of functional interactions between nerve and muscle cells in-culture. ACh sensitivity was measured by the slope method (3) on muscle cells grown alone or with nerve-cord cells.

Application of ACh anywhere on the surface of cells grown alone produced depolarizations. In addition, small spots were randomly encountered with much higher sensitivity to ACh ("hot spots"). Muscle cells grown with neurons but without visible neurite contacts were similarly sensitive to ACh. In cells with neurite contacts and from which mepps could be recorded, more than four-fold increase in ACh sensitivity at the site of contact with the nerve correlated well with the incremental mean mepp amplitudes. The ACh sensitivity outside the contact areas, however, was not significantly different from that found in non-innervated cells.

We conclude that the increase in mepp amplitude during synaptogenesis, in this system, may be accounted for solely by the post-synaptic accumulation of receptors at the site of nerve-muscle contact.

2544 BIOSYNTHETIC REQUIREMENTS FOR NEURITE OUTGROWTH IN GOLDFISH RETINA EXPLANTS. Anne M. Heacock. Neuroscience Laboratory, University of Michigan, Ann Arbor, MI 48109

Our previous studies of goldfish retina explants have documented the dependence of the neuritic outgrowth on prior optic nerve crush and have demonstrated that the retinal ganglion cells are the cells of origin of these neurites. This preparation then serves as an in vitro model for investigations of many aspects of optic nerve regeneration and nerve growth and maintenance in general. In the experiments described here, we examined the biosynthetic requirements for neurite outgrowth, making use of inhibitors which are known to interfere with specific metabolic events. Those agents include an inhibitor of protein synthesis (cycloheximide, CXM), of cholesterol synthesis (diazacholesterol, DAC) and of glycoprotein biosynthesis (tunicamycin). Neurite outgrowth was quantitated using a morphological nerve growth index.

As might be expected, prevention of protein synthesis by addition of CXM (100 μg/ml), either at the time of explantation or at subsequent times, completely inhibits neurite outgrowth. However, maintenance of existing neuritic outgrowth is not so drastically affected by the continued presence of CXM. The neurites remain intact and appear normal for several days following inhibition of protein synthesis, then gradually deteriorate. This result implies that newly synthesized protein is not necessary for the maintenance of the axon over this interval and is in contrast to the relatively rapid degeneration within 24 h of a neurite fascicle which has been cut off from its parent explant.

Another treatment which was found to cause intact neurites to degenerate within 24 h was incubation with the cholesterol synthesis inhibitor DAC (10^{-4}M). A lower concentration of DAC (10^{-5}M) did not cause degeneration of intact neurites but did inhibit neurite outgrowth by 70-80%. This inhibition was not overcome either by the presence in the medium of fetal calf serum (which contains cholesterol) or by supplementation with added cholesterol (2.6×10^{-5}M). The DAC inhibition was however reversed by the addition of mevalonic acid (1 mg/ml), the product of a rate-limiting enzyme in cholesterol biosynthesis, HMGCoA reductase. The reversal by mevalonic acid and not by cholesterol suggests that DAC may have, either directly or indirectly, an inhibitory effect on HMGCoA reductase.

Mevalonate is the precursor not only of cholesterol but of all terpenoids, including the dolichols, long-chain isoprenoid alcohols which function as glycosyl carriers in the biosynthesis of glycoproteins. A role for the polyprenol-linked sugars in goldfish retina explant glycoprotein synthesis was investigated by examining the effect on neurite outgrowth of an inhibitor of this pathway, tunicamycin. The latter, when present continuously in the culture medium (at 5 μg/ml), resulted in a 70% inhibition of outgrowth after 5 days in vitro and greater than 90% inhibition at 12 days. These results indicate that the functioning of the dolichol sugar pathway is necessary for neurite outgrowth.

2545 EXPLANT CULTURES OF FETAL RAT BRAIN: CHARACTERIZATION BY IMMUNOFLUORESCENCE AND NEUROTRANSMITTER CONTENT. Robert J. Milner*, Quentin J. Pittman, William J. Shoemaker, Alejandro Bayon and Floyd E. Bloom. Salk Inst., La Jolla, CA 92037.

Explants of fetal rat cerebellum (CB), locus coeruleus (LC), substantia nigra (SN), caudate nucleus (CN) and arcuate nucleus including median eminence (A-ME) can be maintained in culture for several weeks. To characterize the cell types obtained in these cultures we have used immunofluorescence techniques that distinguish neurons, astrocytes and oligodendrocytes (oligos). Neurons were further characterized by assay of peptide or catecholamine neurotransmitters. Specific regions were dissected out of the brain of ED19 rats, teased into small pieces and cultured for several weeks in DMEM containing 10% horse serum. Neurons were labelled by sequential treatment with tetanus toxin and horse anti-toxin; oligos were labelled with rabbit anti-galactocerebroside; and astrocytes were labelled with rabbit anti-glial fibrillary acidic protein. The cells were visualized by reaction with rhodamine or fluorescein labelled goat anti-rabbit or horse IgG. Enkephalins and β-endorphin were measured by specific RIA and catecholamines by a radio-enzyme assay. The staining techniques were shown by double labelling to be specific for each cell type and could account for the majority of cells present in cultures of all brain regions. Neurons and astrocytes were the predominant cell types while oligos were comparatively infrequent. In cultures of CB the majority of neurons were small, with interconnecting networks of neurites. Some larger cells, possibly Purkinje cells, were also found. Cultures of LC and SN contained large neurons with extensive processes; some cells also exhibited positive catecholamine fluorescence. Both large and small neurons were found in CN cultures. Oligos were seen most frequently in cultures of CB, LC, and SN and rarely in CN. This cell type was usually found singly, although oligos were seen associated with nerve fascicles in LC and SN cultures. In all cultures large flat astrocytes formed a monolayer over the dish surface but in explant outgrowth regions astrocytes formed long fibrous processes. Only LC and SN cultures possessed measurable amounts of norepinephrine and dopamine. Enkephalins and β-endorphin were found only in A-ME cultures. Although enkephalins were undetectable by RIA in CN cultures, some CN neurons stained for enkephalin using an immunoperoxidase technique. Characterization of neuronal and non-neuronal cell types in these cultures is essential for monitoring their development under different culture conditions and for electrophysiological recording.

2546 ULTRASTRUCTURAL AND CYTOCHEMICAL CHARACTERIZATION OF SCHWANN CELLS CULTURED FROM RAT PERIPHERAL NERVE. Ward F. Odenwald*, Valerie Askanas, W. King Engel, Linda S. Carter*, Jane V. Lawrence,* NIH, Bethesda, MD 20205

Schwann cells were cultured from 3 day old rat sciatic nerves with techniques established in this laboratory for human nerve cultures. Six 1 mm^3 nerve explants were placed on collagen-coated 35 mm petri dishes, and subsequent reexplantations were performed until almost all non-schwann cells were eliminated. Cultures were fed with media as described (Neurology 25:58-67, 1975). After satisfactory growth was obtained the cultures were processed for cytochemical reactions or routine electron-microscopy (EM). EM studies were performed on areas of cultured schwann cells (CSC) preselected by light microscopy as described (Stain Technology 52: 249-254, 1977). CSC of peripheral nerve possessed similar ultrastructural characteristics to schwann cells of adult rat sciatic nerve (ASC); those were: large ovoid nucleus, numerous free and rosetted form ribosomes, narrow RER, mitochondria, golgi apparatus, ~7nm microfilaments, and ~18nm microtubules. CSC were surrounded by a well-defined plasma membrane (PM) ~9nm thick. The majority of CSC had characteristic membrane surface invaginations, ~25nm deep. Major differences between CSC and ASC were lack of a basement membrane and the presence of polarly orientated bundles of helical filaments in single and double helix configuration (helix periodicity ~56nm) in the cytoplasm of the CSC.

Positive peroxidase-post-coupled DAB staining of concanavalin A (100 μg/ml) binding revealed the presence of α-D-glucoside and/or α-D-mannoside groups on the PM of CSC. Staining with a low concentration (10μg/ml) of ConA revealed possibly stronger affinity of the invaginations toward ConA, suggesting an increased density of receptors there. Omitting the ConA from the incubating medium or pretreatment with α-methyl-glucoside resulted in lack of characteristic staining.

Horseradish peroxidase (HRP), employed as a cytochemical tracer, was added to the medium of the living cultures. After two hours, high HRP activity was observed within lysosomal-like (LL) structures in the CSC cytoplasm. HRP activity was also located at distinct sites along the PM. Uptake of HRP was much more prominent in the CSC than in the non-schwann cells. When cultures were examined for endogenous peroxidase activity, almost no activity was observed with the exception of a few grains of oxidized DAB within a small number of the LL structures.

The knowledge of ultrastructural and cytochemical characteristics of normal CSC is needed to study the influence on them of different substances suspected to cause dyschwannian neuropathies in humans.

2547 ACETYLCHOLINESTERASE, OTHER MUSCLE PROTEINS, AND DNA OF FIBROBLAST-FREE IRRADIATED MUSCLE CULTURES. W.R. Randall*, P.A. Nieberg*, and B.W. Wilson. Dept. Avian Sci., UCD, Davis, CA 95616.

Experiments that compare properties of muscle cultures from different genetic backgrounds and involve treatments that may alter distributions of cells are complicated by the presence of fibroblasts and other cell types in mixed cultures. Chemical treatments are often used to suppress dividing cells. X-ray irradiation has also been reported to destroy fibroblasts without affecting fusion of myoblasts into myotubes (Friedlander et al.; Dev. Biol., 66, 457, 1978). The experiments presented here examine the differentiation of some muscle-specific properties in such fibroblast-free cultures.

Pectoral muscle cultures from 11 day embryos were irradiated one day after plating and examined for up to 2 weeks in vitro. There was maximum elimination of fibroblasts and minimum loss of myoblasts at approximately 4000 rads. Fusion and gross development proceeded normally; 5 day old cultures contracted spontaneously and 8 day old cultures appeared morphologically normal with the electron microscope.

A sample experiment is shown below. Accumulation of ACHE (cell and medium) for cultures 10-13 days in vitro was little changed by irradiation of New Hampshire (N.H.) or White Leghorn (W.L.) lines. However, ACHE per DNA and per protein increased greatly due to loss of fibroblasts.

	ACHE	ACHE/DNA	ACHE/Protein
N.H.	5.98±0.43	0.27±0.04	7.47± 1.22
N.H. X-ray	5.34±0.86	2.35±0.93	36.1 ±13.7
W.L.	9.69±1.89	0.50±0.15	12.4 ± 2.6
W.L. X-ray	11.6 ±1.18	2.06±0.46	32.7 ± 4.3

ACHE in umoles substrate hydrolyzed/min/dish; DNA in ug/dish; protein in mg/dish. Means ± SD (N=4)

DNA content of irradiated cultures was reduced 3 fold (W.L.) and 9 fold (N.H.). Non-collagen protein was 3 fold less (both lines) than in non-irradiated controls. Similar results were obtained when activities were expressed on a protein basis. Reinoculation of the cultures with fibroblasts did not alter the properties of the myotubes. Determinations of acetylcholine receptor, myosin, creatine kinase and lactic dehydrogenase and studies of normal and dystrophic chick lines are in progress.

The results show that differentiation of physiological, biochemical and histological properties of multinucleated myotubes proceed normally after irradiation, producing cultures virtually free of fibroblasts for periods up to two weeks in vitro. (Supported by the MDA and NIH ES00202)

2548 AN α-NEUROTOXIN THAT INDUCES THE RAPID INTERNALIZATION OF FLUORESCENT α-BUNGAROTOXIN BOUND TO AUTONOMIC NEURONS. Peter Ravdin*, Ralph Nitkin, and Darwin Berg. Dept. of Biology, UCSD, La Jolla, CA 92093.

Chick ciliary ganglion neurons and sympathetic neurons both have a high affinity binding site for α-bungarotoxin (Bgt 2.2), but the toxin does not block acetylcholine (ACh) sensitivity on the neurons. We have previously shown that another α-toxin (Bgt 3.1) from the same snake venom does block ACh sensitivity on the neurons. We now report that Bgt 3.1 causes the rapid internalization of fluorescent Bgt 2.2 bound to the cells. Blockade of ACh sensitivity by Bgt 3.1, however, does not appear to depend on the internalization revealed with fluorescent Bgt 2.2.

Dissociated neurons prepared from 8-12 day embryonic chick ciliary and sympathetic ganglia were grown in cell culture for 1-3 weeks with skeletal myotubes. High affinity Bgt 2.2 binding sites on the neurons were fluorescently labeled by incubating the cultures in 4 x 10^{-8} M tetramethyl rhodamine-conjugated Bgt 2.2 (R-2.2) for 1 hr at 37°. Subsequent incubation with 10^{-7} M Bgt 3.1 at 37° led to nearly complete loss of surface fluorescence within 0.5 hr with the concomitant appearance of numerous small foci of intense fluorescence throughout the interior of the neurons. This apparent internalization of bound R-2.2 was blocked by low temperature (4°) or by preincubation of the labeled neurons with 0.1 mg/ml concanavalin A. It was not blocked by 50 μM colchicine or 200 μM cytochalasin B; it did not occur spontaneously and was not induced by Bgt 2.2.

Two observations suggest that the induced internalization may be confined to Bgt 2.2 sites. First, neurons remained electrically excitable after Bgt 3.1 treatment, indicating that they retained membrane components necessary for action potentials. Second, sympathetic neurons bound fluorescent nerve growth factor (R-NGF) in addition to R-2.2, but Bgt 3.1 did not induce rapid internalization of the bound R-NGF.

Blockade of neuronal ACh sensitivity by Bgt 3.1 can be separated from the internalization revealed with R-2.2. When R-2.2 labeled neurons were incubated with 10^{-7} M Bgt 2.2 or D. viridis 4.7.3. toxin before and during challenge with Bgt 3.1, internalization of the bound R-2.2 was blocked. Under these conditions Bgt 3.1 still produced complete inhibition of iontophoretically measured ACh sensitivity.

These data indicate that Bgt 3.1 causes two separate events: inhibition of neuronal ACh receptors and internalization of bound R-2.2. The Bgt 3.1 binding site that produces receptor inhibition apparently is not blocked by Bgt 2.2 or D. viridis toxin. (Supported by USPHS grant #12601, The Muscular Dystrophy Association, & the American Heart Association.)

2549 HUMAN SKIN FIBROBLASTS EXHIBIT HIGH-AFFINITY CHOLINE ACCUMULATION IN CELL CULTURE. Donald Kay Riker, Robert H. Roth and Xandra O. Breakefield. Depts. Pharmacology, Psychiatry, & Human Genetics, Yale Univ. Sch. Med., New Haven, Ct. 06510.

^{3}H-choline can be transported across cell membranes by high-affinity (K_T < 4μM) and low-affinity (K_T>> 4μM) systems. High-affinity choline accumulation (HACA) has been demonstrated in synaptosomes made from cholinergic brain regions, such as the hippocampus and caudate-putamen; thus, regional choline accumulation is coextensive with afferent cholinergic nerve terminals. HACA has been shown to be a function of impulse flow in central cholinergic neurons and may be the rate-limiting step in acetylcholine synthesis in the septal-hippocampal tract. In cell culture HACA has been demonstrated in avian telencephalon and spinal cord, glia, neuroblastoma, and glioma cells. Recently, Barald & Berg (Dev. Biol. 65:90, 1978) reported HACA in fibroblasts cultured from avian muscle. HACA in these fibroblasts had a K_T and V_{max} similar to that observed in dissociated spinal cord cells in culture.

We examined ^{3}H-choline accumulation in normal human fibroblasts cultured from skin biopsy. ^{3}H-choline accumulation was temperature dependent and linear with incubation time up to 6 min at 0.125 μM choline. Isoosmotic replacement of Na^+ with Li^+ (137mM) or sucrose (274 mM) severely reduced ^{3}H-choline accumulation (by 70-90%). Preincubation with ouabain (10μM) or 2,4-dinitrophenol (10μM), or replacement of Ca^{++} with Mg^{++} had little or no effect on subsequent ^{3}H-choline accumulation. ^{3}H-choline accumulation was hemicholinium-3 (HC-3) sensitive with pre-incubation in HC-3 at 37°C for 10 min. The IC_{50} at 0.125 μM choline was 3-4 μM. The K_T for ^{3}H-choline was about 4 μM, which compares favorably to that observed in brain synaptosomes and avian fibroblasts. The HC-3 sensitivity, Na^+-dependence, and low K_T suggest that human skin fibroblasts have a high-affinity transport system for choline. Presently, we are investigating HACA in fibroblasts of patients with inherited neurologic disorders which may have a cholinergic etiology. (Supported by grants to D.K.R., R.H.R. & X.O.B. from the Dystonia Medical Research Foundation).

2550 ANTINEURONAL IN VITRO ACTIVITY OF SERA FROM PATIENTS WITH AMYOTROPHIC LATERAL SCLEROSIS. F. J. Roisen*, H. Bartfeld*, H. Donnenfeld* and J. Baxter*, (Spon: A. Hess), Dept. of Anatomy, CMDNJ-Rutgers Medical School, Piscataway, NJ 08854, and the Amyotrophic Lateral Sclerosis Research Center of St. Vincent's Hospital and Medical Center, NY, NY 10011.

Amyotrophic lateral sclerosis (ALS) is a fatal, adult-onset, neurological disorder of unknown etiology which is characterized pathologically by degeneration of the anterior horn motor neurons as well as neurons in the motor nuclei of the lower cranial nerves. Wolfgram and Myers reported a high proportion of sera from patients with ALS was toxic to cultured anterior horn neurons (1, 2). Conflicting reports have been published (3, 4).

Blood samples from 18 patients were randomly selected from a total pool of 73 ALS patients. Age and sex matched sera were also obtained from 27 patients with neurological diseases (cerebral infarction, Parkinsonism, senile dementia, CNS trauma and tumors), as well as 5 from normal controls. The sera were incorporated into the media, applied to long-term monolayer cultures and assayed for a neuron-specific cytotoxic effect on developing neonatal anterior horn segments. The criteria for cytotoxicity included a reduction in neuritic processes, increased cytoplasmic granularity and vacuolarization, loss of characteristic neuronal shape, and eventually the extrusion of the nuclei.

These blind studies between our laboratories have shown that ALS sera when incorporated into the culture media have a significantly greater degree of antineuronal toxicity ($p<0.01$) than sera from patients with other neurological diseases or normal controls. Dialysis of previously tested positive sera against balanced salt solution did not reduce the antineuronal activity. The cytotoxicity appears highly specific since known positive sera did not affect embryonic sensory or sympathetic ganglia, S20 neuroblastoma, RN22 schwannoma, L-929 fibroblasts or primary dissociated embryonic muscle cultures. At present the relationship between the factor and the disease remains unclear since studies to date have shown no correlation between the course or severity of the disease and the degree of cytotoxic activity.

2551 CELL SURFACE ACETYLCHOLINESTERASE ON CULTURED CHICK EMBRYO MUSCLE CELLS. Richard L. Rotundo and Douglas M. Fambrough. Carnegie Institution of Washington, Dept. of Embryology, Baltimore, Maryland, 21210.

Chick embryo muscle cells grown in tissue culture contain two major molecular forms of acetylcholinesterase (AChE) having sedimentation coefficients of 11.5S and 7.1S. In order to study the cellular distribution of AChE forms in culture we have modified the Johnson and Russel AChE assay so that it can distinguish AChE molecules located on the surface membrane from those located inside the cell (to be described). We can demonstrate that approximately 30-40% of the total cells' contents of AChE is located external to the plasma membrane. This cell surface AChE is not removed by treatment with 1M NaCl or by competition with various sugars; however, this enzyme is easily solubilized using the detergent Triton X-100.

To determine which molecular forms of AChE are located on the cell surface, cultures were pre-treated with BW284c51, a reversible water soluble inhibitor which in this experiment regime blocks only the surface enzyme, followed by treatment with DFP, an irreversible esterase inhibitor which does penetrate the cells to inactivate the intracellular enzyme. Analysis by velocity sedimentation of the forms protected from DFP by BW284c51 indicates that both the 11.5S and 7.1S forms of AChE are located on the muscle cell surface.

Using DFP to irreversibly inhibit all AChE at different stages of muscle cell development in culture we can demonstrate that: 1) the cells synthesize the surface AChE forms in vitro, 2) the rate of surface AChE deposition increases during the time of cell differentiation in culture, 3) following treatment with DFP there is a partial recovery of the cell surface AChE in mature cultures, and 4) the surface AChE molecules have a half-life which is several times longer than that of another well-defined muscle cell surface protein, the acetylcholine receptor. During recovery from DFP treatment muscle cells in culture synthesize both the 11.5S and 7.1S AChE forms which are initially located inside the cells, and later give rise to the surface membrane fraction as well as to the secreted forms. In these studies we have not observed any apparent precursor/product relationship between the 7.1S and 11.5S molecular forms. A model depicting the synthesis, transport, and turnover of these membrane bound AChE forms will be presented.

2552 DEXAMETHASONE INDUCES BIOCHEMICAL DIFFERENTIATION IN CULTURED MURINE NEUROBLASTOMA. Dean Sandquist*, Larry Williams*, Asa C. Black, Jr., Shail Sahu*, and Terence H. Williams. Dept. of Anatomy, University of Iowa, Iowa City, Iowa 52242.

It has been observed previously that dexamethasone has a dose-dependent effect on morphological differentiation and growth inhibition of murine neuroblastoma (clone NBP_2) in vitro. We now report that dexamethasone also induces biochemical differentiation (as determined by increased dopamine content and tyrosine hydroxylase activity), and morphological differentiation (as determined by glyoxylic acid-induced histofluorescence microscopy). Dopamine content was determined by the method of Schmidt and Bhatnagar (Brain Res., in press), while tyrosine hydroxylase was assayed according to Waymire et al. (Proc. Natl. Acad. Sci., 69:2241).

Cells treated for seven days with 25 µM dexamethasone in ethanol have more intense and uniform greenish-yellow catecholamine fluorescence than solvent-treated or untreated controls. Dopamine content increased from 3.7 ± 0.6 µg. per mg. protein (untreated controls) or 5.1 ± 0.5 (solvent-treated controls) to 11.2 ± 1.2 µg. per mg. protein after dexamethasone treatment. Tyrosine hydroxylase activity increased from 0.015 ± 0.003 nanomoles $^{14}CO_2$ per hour per mg. protein (untreated controls) or 0.10 ± 0.02 (solvent-treated controls) to 0.30 ± 0.01 nanomoles $^{14}CO_2$ per hour per mg. protein. Tyrosine hydroxylase activity rose to a maximum of 0.82 ± 0.10 nanomoles $^{14}CO_2$ per hour per mg. protein after five days of treatment with 125 µM dexamethasone. 200 µg/ml Ro 20-1724 (an inhibitor of cyclic AMP phosphodiesterase) increased tyrosine hydroxylase activity to a similar extent. The increases produced by 25 µM dexamethasone in tyrosine hydroxylase activity and dopamine content were significantly different from both untreated and solvent-treated controls ($P<0.001$; Student's "t" test).

Thus dexamethasone appears to induce both morphological and biochemical differentiation in cultured murine neuroblastoma. Since agents which increase cyclic AMP levels (such as Ro 20-1724) are known to produce the same effects on differentiation as dexamethasone, and since dexamethasone does not elevate cyclic AMP levels in these cells (as measured by radioimmunoassay) we are currently determining whether dexamethasone and cyclic AMP-increasing agents have interacting or synergistic mechanisms for producing differentiation. We are also determining the characteristics of the glucocorticoid receptor in murine neuroblastoma. (Supported by NIH grants CA 24241-02 to DS and NS 11650 to THW).

2553 EFFECT OF CULTURE DURATION ON THE ELECTRIC MEMBRANE PROPERTIES OF ADULT MOUSE NEURONS. B.S. Scott and B.A.V. Edwards*. Surrey Place Centre, 2 Surrey Place, Toronto, Canada M5S 2C2.

Dorsal root ganglia (DRG) were dissected from adult mice (6 to 9 months), softened with collagenase, dissociated and plated on collagen-coated coverslips using 10% fetal calf serum in CMRL-1415 as medium (Scott, J. Neurobiol. 8: 417-427, 1977). After a various number of days in culture (DIV) the following electric membrane properties were determined 1. resting membrane potential (Vm) 2. specific membrane resistance (Rm) 3. membrane time constant (τ) 4. specific membrane capacitance (Cm) 5. duration of the action potential (DT) 6. absolute refractory period (ARP) 7. rheobasic threshold depolarization (ΔV).

Neurons had action potentials either with a simple monophasic falling phase (M type) or a more complex biphasic or triphasic falling phase (B type). M and B types had small but significant differences in their EMP and relative frequency (RF) of occurrence. Since the EMP of both types varied similarly with DIV, the data was pooled and mean values were obtained by analysis of variance with cell size and type as covariates.

	Days in Culture							
	0	1	2	4	6	12	24	40
RF	81.3	79.1	59.6	49.2	50.8	39.7	44.3	20.8
Vm	60.2	59.4	58.4	59.1	60.0	57.4	53.9	49.7
Rm	399	354	380	475	463	557	636	832
τ	1.15	1.17	1.32	1.37	1.63	1.61	2.20	2.80
Cm	3.22	4.63	3.68	3.15	3.83	3.19	3.99	3.91
DT	1.87	1.92	1.53	2.00	2.22	2.27	2.45	2.65
ARP	1.75	1.75	1.88	2.23	2.26	2.18	2.30	2.67
ΔV	24.4	21.0	21.5	24.6	19.5	14.8	9.50	7.74

Regression analysis indicated that all variables except Cm varied linearly with days in culture ($p<.001$). Since neuron survival was relatively constant for the first 6 days and even after 40 days was 60%, it seems unlikely that significant selection of neuronal types occurred. Thus, the observed changes in EMP reflect modifications in membrane functions of individual neurons. Since similar changes in EMP (decreased Vm and ΔV, and increased Rm) have been observed for denervated muscle in situ (Nicholls, J. Physiol. 131: 1-12, 1956), in vitro (Engelhardt et al., Brain Res. 126: 172-175, 1977) and embryonic chick DRG in culture (Handa, Tohoku J. exp. Med. 121: 13-25, 1977), it seems likely that these modifications are due to the isolation in culture of the DRG neurons from their usual central and peripheral connections.

2554 CYTOSINE ARABINOSIDE EFFECTS ON DEVELOPING CEREBELLUM IN TISSUE CULTURE. Fredrick J. Seil, Arnold L. Leiman*, Nathan K. Blank*, and William R. Woodward. Research Service, V.A. Med. Ctr. and Dept. Neurology, Univ. Oregon Health Sci. Ctr., Portland, OR 97201 and Dept. Psychology, Univ. California, Berkeley, CA.

Cerebellar explants prepared from newborn mice were exposed to 1-10 µg/cc cytosine arabinoside (Ara-C), an inhibitor of DNA synthesis, for the first 5-9 days in vitro, after which they were maintained in normal nutrient medium. Observations are reported from such cultures after 14-23 days in vitro. The cortices of explants exposed to Ara-C contained numerous closely packed large neurons with a paucity of intervening elements. Normal cortical lamination including layers of granule cells was not evident. In Golgi-Cox preparations, the surviving large neurons appeared to be Golgi II neurons and Purkinje cells, the latter with persistent dendritic spines. A marked increase in density of intracortical and subcortical neurites was apparent in silver stains, and proved to be Purkinje cell axons and axon collaterals by fiber tracing. In spite of the relative increase in axonal elements, myelin did not form in Ara-C treated cultures. Ultrastructural examination of cortical regions revealed an increase of Purkinje cell recurrent axon collateral terminals forming numerous synapses on Purkinje cell somata and dendrites. Both spontaneous electrical activity and stimulus elicited responses were recorded electrophysiologically. An increase in cortical discharges was induced by addition of picrotoxin, a GABA antagonist. Stimulation of cortex and subcortical fibers evoked both excitatory and inhibitory responses. These responses were interpreted as consistent with a cortical reorganization in which Purkinje cell axon collaterals were the dominant inhibitory elements.

2555 SERUM-FREE CULTURE MEDIUM MAINTAINS DIFFERENTIATED PROPERTIES OF NEURONS IN FETAL RAT BRAIN EXPLANTS. Wm.J.Shoemaker, J.E.Bottenstein, R.J.Milner*, B.R.Clark* and F.E.Bloom. The Salk Inst. and Dept. Biology, UCSD, La Jolla, CA 92037.

Explant cultures from fetal rat brain can be maintained for several weeks using a completely defined medium (N_1) without the use of serum. The following substances were added to DME medium: insulin 5µg/ml, transferrin 5µg/ml, progestrone 20nM, putrescine 100µM, and selenium 30nM; (P.N.A.S.76:514,1979). Explants of different brain regions were cultured in order to assess the effect of serum-free conditions on a variety of cell types and neurons: locus coeruleus (LC), substantia nigra (SN), cerebellum, caudate nucleus, and hypothalamus. Although attachment of the explants to either collagen or poly-D-lysine coated dishes was better in medium containing medium than in N_1 medium, addition of fibronectin aided attachment of explants under serum-free conditions. Attachment could also be enhanced by incubating in serum for the first 4-5 days in vitro and then switching to N_1 medium. The outgrowth pattern and morphological appearance of cultures maintained in N_1 for up to 8 weeks differed in several respects from identical brain regions grown in serum-supplemented medium. Regardless of the initial attachment conditions, cultures grown in N_1 had fewer background cells and less flattening of the explant. The morphology of the neurons and their processes in phase optics appeared healthy, similar to neurons grown in serum. To distinguish different cell types neurons were labelled with tetanus toxin and horse anti-toxin, oligodendrocytes were labelled with rabbit anti-galactocerebroside, and astrocytes with rabbit anti-glial fibrillary acidic protein. Comparison of cultures grown in the presence of serum or in N_1 medium revealed that in N_1 the neurons appeared to have shorter processes and that cells having a similar morphological appearance by phase optics did not all stain positively with tetanus toxin. Although there is a reduced number of non-neuronal cells in N_1 medium, large numbers of oligodendrocytes were observed. Astrocytes, however, were somewhat fewer in number in N_1 media and displayed very few processes. A major criterion for completely defined medium would be the ability of neurons cultured in its presence to maintain neurotransmitter synthesis. We assessed the ability of LC and SN cultures to synthesize and store catecholamine transmitters by a sensitive radio-enzyme assay and by fluoresence microscopy. Both assessments indicated that the number of catecholamine-containing neurons and the amine content did not differ in the two media. The later findings imply that catecholamine-containing neurons of the CNS do not require NGF or other serum factors in agreement with our previous results.

2556 CHRONOTROPIC RESPONSES MEDIATED BY ALPHA- AND BETA-ADRENERGIC RECEPTORS ON CULTURED CARDIAC MUSCLE CELLS. Christopher Nelson Sinback, Jr. Laboratory of Cell Biology, National Cancer Institute, NIH, Bethesda, MD. 20014.

Action potential rate, duration, and amplitude, maximum diastolic potential, etc, were recorded with intracellular microelectrodes from embryonic hamster cardiac muscle cells in primary cell culture. Noradrenaline, isoproterenol, and acetylcholine were delivered by iontophoresis.

Noradrenaline, and not isoproterenol, elicited positive chronotropic responses (increased action potential rate and hence increased beat rate) by activation of alpha-adrenergic receptors. Alpha-adrenergic responses were due to a fast, latency less than 500 msec, brief, 5-10 sec, depolarization which was abolished when external sodium was replaced with choline. Alpha-adrenergic responses desensitized rapidly.

Isproterenol, and not noradrenaline, elicited positive chronotropic responses by activation of beta-adrenergic receptors. Beta-adrenergic responses were characterized by a slow, latency longer than 3 sec, sustained, 20 sec - 2 min, interval of increased action potential frequency due to increased slope of the pacemaker potential. Beta-adrenergic responses did not desensitize. Beta-adrenergic responses were abolished by propranolol. During beta-adrenergic responses maximum diastolic potential and action potential overshoot generally decreased, but in some cells maximum diastolic potential increased.

2557 Intracellular Transport of Acetylcholinesterase and Acetylcholine Receptor. H. Smilowitz. Univ. Conn. Health Center, Farmington, Connecticut 06032

Most of the acetylcholinesterase (ACHE) that is synthesized by cultured chick embryo pectoral muscle cells is secreted into the culture medium by a process that is rapidly and reversibly inhibited by the monovalent ionophores (Smilowitz, H. Molecular Pharmacol. July 1979). The secretion of other continuously released glycoproteins such as collagen and fibronectin are similarly inhibited by the monovalent ionophores (Uchida, N., H. Smilowitz & M. Tanzer P.N.A.S. 76: 1868 (1979).

IN contrast, we have shown that the rate of appearance of new acetylcholine receptors (ACHR) at α-bungarotoxin (α-BGT) accessible sites, the turnover of ACHR, the total number of ACHR (total α-BGT accessible sites) and the size of the intracellular pool are nearly the same in both control and monovalent ionophore treated cells. Since the monovalent ionophores reportedly block the flow of membranes out of the golgi (Tartakoff, A. & Vassalli, P. J. Cell Biol. 79:694 (1978)) our data suggests that there are at least two types of membrane vesicles or carriers derived from the golgi- one whose formation is inhibited by the monovalent ionophores(normally transporting secretory proteins such as ACHE) and one whose formation is unaffected by the ionophores (normally transporting integral membrane proteins such as the ACHR).

Detailed histochemical and electron microscopic analysis of the ACHE secretory process show that in control myotubes, ACHE is found in the golgi, the nuclear membrane and in the sarcotubular system. After cycloheximide treatment (100 ug/ml for 2-3 hours) ACHE reaction product can no longer be found in the golgi; after monovalent ionphore treatment, two classes of ACHE containnng membrane vesicles appear. One class is perinuclear and is not accessible to externally applied ferritin; one class is cytoplasmic and is accessible to externally applied ferritin. The perinuclear vesicles derive from the golgi within two hours after the addition of 4×10^{-8} M nigericin. The cytoplasmic vesicles appear to be ampulae of the t-system. Upon removing nigericin, the golgi derived vesicles break up into smaller vesicles which resemble the t-system in appearance. We propose that the ACHE resides in the golgi following synthesis and is then transported by vesicle to cytoplasmic channels or the t-system of muscle. Once in the t-system, the enzyme is in communication with the external bathing medium. Experiments are now in progress to visualize the route of ACHR transport. (Supported by NS 13860)

2558 IMMUNOCHEMICAL CHARACTERIZATION OF ISOLATED OLIGODENDROCYTES MAINTAINED IN LONG TERM CULTURE. Kari Stefansson*, Raymond P. Roos*, Robert L. Wollmann*, Barry G. W. Arnason, Sara Szuchet*, Dept. Neur., The Pritzker Sch. of Med., Univ. of Chicago, Chicago IL 60637.

Oligodendrocytes have been isolated from lamb brains employing the procedure developed in our laboratory (Szuchet, et al., Biophys. J., 21, 51, 1978). Immediately after isolation cells are suspended in Dulbecco's modified Eagle's medium supplemented with 10% horse serum, plated at a density of 2.5×10^5 cells/cm^2 and kept in an incubator with 5% CO_2 and humidity at saturation. Freshly isolated cells exhibit surface staining, as viewed by indirect immunofluorescence, with anti-galactocerebroside (a generous gift of Dr. M. Rapport) and anti-sheep myelin basic protein antisera (a gift from Dr. A. Noronha). The pattern of staining with both antisera is patchy but the patches appear larger and more bulky with antimyelin basic protein than with antigalactocerebroside. The positive staining for myelin basic protein is consistent with the notion that components of myelin remained attached to the cells during the process of isolation. Galactocerebroside, on the other hand, is a normal constituent of the oligodendrocytic membrane (Raff, et al., Nature, 274, 813, 1978). Cell kept in culture for 21 days possess morphological characteristics which have been ascribed to oligodendrocytes (Wolfgram and Rose, J. Neuropath. and Experim. Neurol., 16, 514 (1957). Cells stick to the surface and emit processes. The majority of cells are bipolar, but multipolar cells and cells with aborted processes are also seen. Bead-like swellings which stain dark blue with Giemsa are often present either along processes or close to the cell body, these are reminiscent of "gliosomos". Some cells do not emit processes but surround themselves with extensive membranous sheets. Cells in culture exhibit positive surface staining with anti-galactocerebroside but not with antimyelin basic protein. The cells also stain with anti-oligodendrocytes antiserum obtained by immunization of guinea pigs with freshly isolated cells. Thus, cells kept in culture for an extended period retain similar surface characteristics as freshly isolated cells. This fact attest to their oligodendrocytic character. These results support our contention that oligodendrocytes can be maintained in culture for an extended period and retain their characteristic properties.

Supported by Grants # RG 1223-A-2 (S.S.) and # RG 1130-B-15 (BGWA) from the National Multiple Sclerosis Society.

2559 IMMUNOCYTOCHEMICAL LOCALIZATION OF GLIAL FIBRILLARY ACIDIC PROTEIN AND FIBRONECTIN IN PRIMARY ASTROGLIAL CULTURES. P.E. Stieg*, H.K. Kimelberg*, J.E. Mazurkiewicz*, and G.A. Banker*, Albany Medical College, Albany, N.Y. (Spon: A.J. Popp).

The development of primary astroglial cell cultures promises to provide a valuable means for studying their specific properties under a variety of conditions. We have studied the types of cells present in such cultures using immunocytochemical methods employing antisera prepared against glial fibrillary acidic protein (GFAP), a specific marker for astrocytes, and against rat plasma cold-insoluble globulin (CIg). The latter antiserum cross-reacts with cell surface fibronectin. Meninges were removed from the brains of 1-3 day old rats and dissociated-cell cultures were prepared from the cerebral hemispheres essentially by the method of Booher and Sensenbrenner (Neurobiol. 2:97,.1972).

Two major types of cells were observed in cultures which had been maintained for 4 to 28 days. Cells of the first type, which are predominant, stain positively with antiserum against GFAP but do not stain for fibronectin when both antigens are localized simultaneously. GFAP-positive cells comprise 70-90% of the total number of cells found in such cultures. Such cells are typically broad, flat, and polygonal in shape and in confluent cultures are mainly present in large patches. Some of these cells undergo a morphologic transformation when exposed to 0.1mM norepinephrine, developing numerous radially-oriented processes and closely resemble astrocytes as seen in vivo; 95% of such processing-forming cells stain intensely for GFAP. However, 75% of the cells which show no morphologic response to norepinephrine also stain for GFAP.

Cells of the second type do not stain for GFAP but show surface staining for fibronectin. In confluent cultures these cells are typically spindle-shaped and are present in densely-packed "colonies" which appear as "sheaves of wheat". Cultures prepared from meninges, or cultured neurons prepared from the rat hippocampus, showed no staining for GFAP. Cells derived from the meninges do show intense surface staining for fibronectin.

These results indicate that astrocytes, as identified by the presence of GFAP, are the predominant cell type in these cultures and that such cells do not contain detectable fibronectin. A smaller number of other cells which do not contain detectable GFAP but which do contain fibronectin are also present. Techniques to reduce or eliminate the fibronectin-positive cell population are currently under study. Supported by NINCDS grant NS13042, NIH SO7-RR05394 and by a grant from the Sinsheimer Fund.

2560 ELECTRICAL PROPERTIES OF ANEURALLY CULTURED ADULT HUMAN MUSCLE
Albert J. Tahmoush, Gregory K. Bergey,* Valeria Askanas, Phillip G. Nelson and W. King Engel. NIH, Bethesda, MD 20205

Histochemical, ultrastructural and biochemical studies of aneurally cultured diseased human muscle have proved useful in elucidating the pathogenesis of neuromuscular disorders. Electrophysiological study of cultured diseased human muscle may also prove useful for investigating neuromuscular disorders characterized by electrical abnormalities. In order to define the electrical properties of the cultured adult muscle fibers and to compare their properties to normal innervated adult human muscle, six biopsies from five patients were cultured according to our established techniques (Neurol. 25:58-67, 1975). The individual cultures were examined daily by phase contrast microscopy. When the muscle fibers became well-differentiated and cross-striated, after 21-28 days of growth, they were selected for study. Spontaneous, slow, tonic-like contractions were visible in only one culture.

For electrophysiological studies, the cultures were placed in a perspex chamber mounted on the stage of an inverted phase contrast microscope. They were maintained at 37°C in a water-saturated 95% air 5% CO_2 atmosphere. Recording and stimulating electrodes were inserted intracellularly. The grouped values (Mean ± S.D.) for 34 fibers from all 6 cultures were: a) Resting membrane potential (Vm) of 52.4 ± 6.6 mV. This was approximately 30 mV lower than the mean reported from several studies of adult innervated human skeletal muscle. b) Input resistance of 5.5 ± 3.4 MΩ. This value was much higher than those reported for adult muscle fibers. c) Only two of 34 fibers were electrically excitable at Vm. These fibers were present in the only culture in which spontaneous contractions were visible. d) When the fibers were hyperpolarized to 80 mV, an action potential could always be elicited. The threshold for excitation was 22.6 ± 8.7 mV and the action potential amplitude was 83.4 ± 28.9 mV.

These data indicate that aneurally cultured adult human muscle fibers are electrically excitable. The membrane characteristics are different from those of innervated adult human muscle in vivo. These studies demonstrate that the electrophysiological investigation of cultured adult human muscle may prove useful in analyzing the influence of neural factors on the electrical characteristics of normal muscle as well as the electrical characteristics of diseased muscle.

2561 EFFECT OF NERVE GROWTH FACTOR ON UPTAKE OF ^{3}H-DOPAMINE AND SENSITIVITY TO 6-HYDROXYDOPAMINE TOXICITY IN A HUMAN NEUROBLASTOMA CELL LINE.
Evelyn Tiffany-Castiglioni* and J. Regino Perez-Polo. Dept. Human Biological Chemistry and Genetics, University of Texas Medical Branch, Galveston, TX 77550.

The dopamine (DA) analogue 6-hydroxydopamine (6OHDA) is selectively toxic to cells of sympathetic neuronal origin as well as to certain non-neuronal cell lines. Cytotoxicity has been linked to higher uptake of catecholamines by sensitive cells than by resistant cells. Nerve growth factor (NGF) protects cells from 6OHDA toxicity both in vivo and in vitro by an unknown mechanism. There appear to be two mechanisms by which cells accumulate and bind DA: a low capacity system requiring DA concentrations of 10^{-8}M; and a high capacity system requiring 10^{-4}M DA. The high capacity system involves non-specific diffusion and binding of DA oxidation products within the cell. Since 6OHDA exerts its cytotoxic effect only at high concentrations, it is presumed that most of its incorporation occurs via the high capacity mechanism. However, cocaine, which blocks dopamine uptake, confers a small degree of protection from toxicity on human neuroblastoma cells in culture. The mechanism blocked probably corresponds to the low capacity system. We tested the hypothesis that NGF, which also protects the cells to a slight extent, acts in part by inhibiting the low capacity uptake system.

We studied the neuroblastoma clonal cell line SK-N-SH-SY5Y (SY5Y) which is very sensitive to 6OHDA toxicity, and which becomes less sensitive when treated with NGF. Uptake of ^{3}H-dopamine (^{3}H-DA) in untreated SY5Y cells was compared to that of cells treated with NGF or cocaine, as well as to ^{3}H-DA accumulation by a fibroblast-like cell line A_1B_1, which is more resistant to 6OHDA. Line A_1B_1 was cloned from the human glioma line U-251-MG. Uptake was measured by liquid scintillation counting of solubilized cells. ^{3}H-DA was added to cultures in serum-free F-12 medium, containing 20µg/ml ascorbic acid, at a concentration of 1µCi/ml (4 x 10^{-8}M), of which only 0.2 - 0.4% was taken up by the cells. The level of uptake plateaued within 30 minutes. Cocaine (9 x 10^{-6}M) blocked 23% of the total uptake in SY5Y cells indicating that most of the uptake is non-specific. Furthermore, A_1B_1 cells accumulated twice as much ^{3}H-DA as SY5Y cells. NGF was observed to increase the level of ^{3}H-DA uptake in SY5Y cells by 30%. We conclude that low capacity dopamine uptake is not a factor in the sensitivity of SY5Y cells to 6OHDA toxicity.

2562 MYELINATION IN ROTATION-MEDIATED AGGREGATING CELL CULTURES.
Bruce D. Trapp*, Laurence J. McIntyre*, Henry deF. Webster and Margaret R. Murray. NINCDS, NIH, Bethesda, MD 20205.

Myelination was studied in aggregating cell cultures of mechanically dissociated 15-16-day fetal rat brain utilizing ultrastructural, biochemical and immunocytochemical methods. Myelination began at or shortly before 15 days in vitro. As in vivo, the first evidence of myelination was the appearance of myelin basic protein (MBP) in oligodendroglia. At 15 days in vitro, MBP antiserum stained oligodendrocyte cytoplasm and a few cells extended stained processes which occasionally surrounded axons. Oligodendrocytes and axons surrounded by few myelin lamellae were identified ultrastructurally in 15-day aggregates. As the cells within the aggregates continued to differentiate the number of oligodendrocytes stained by MBP antiserum increased. By 25 days in vitro oligodendrocytes had extended numerous stained processes which were continuous with stained myelin sheaths. Ultrastructurally mature oligodendrocytes and myelinated axons were present. The periodicity of the myelin lamellae was similar to that found in vivo. Myelin can be isolated in sufficient quantities for biochemical analysis. The yield of myelin protein from 30-day aggregates was 0.9% of the protein in the initial homogenate. The specific activity of the myelin associated enzyme, CNP, was 1,095 in the 30-day aggregate myelin. Myelin proteins from 30-day aggregates were compared to those from normal rat brain on 12.5% SDS slab gels. All the major myelin proteins were present in aggregate myelin. Although the amount of myelin synthesized in aggregating cell cultures was less than that found in vivo, the biochemical composition of this myelin (thus far analyzed) was similar to its in vivo counterpart. In summary, aggregating cell cultures provide a useful model system for multidisciplinary investigation of myelination in vitro.

2563 TISSUE CULTURE OF NORMAL ASTROCYTES FROM RAT OPTIC NERVE.
P.A. Trimmer*, P.J. Reier and T.H. Oh. Dept. of Anat., Sch. Med., Univ. of Maryland, Balto.,MD 21201

Previous studies of gliogenesis in the rat optic nerve have shown that most astrocytes are generated within the first week. Since it has also been reported that a preferential production of this cell can be induced by denervation during this time, the present study was undertaken to determine whether immature optic nerves could provide a favorable source of cells for the establishment of homotypic populations of astrocytes in tissue culture. Optic nerves were excised from 5-day-old, Sprague-Dawley rats. Following removal of the meningeal sheath, the nerves were incubated in collagenase. Subsequent mechanical dispersion yielded a low-density suspension of cells (1.0-4.0 X 10^5 cells/ml) which was plated on collagen-coated culture dishes. The cells were maintained in a solution of Dulbecco's Modified Eagle's Medium, horse serum and embryo extract in a humidified CO_2/air environment. During the first 5 days in vitro (DIV) two types of cells could be distinguished by phase contrast microscopy: (1) a population of small cells having a few attenuated processes emerging from their perikarya and (2) many flattened, polygonal cells with a light cytoplasmic matrix. Between 7-14 DIV two basic cellular profiles could be identified in addition to the flattened cells which were still present. The first (Type I) was characterized by a pyramidal or bipolar perikaryon from which two or more processes emerged and extended radially for considerable distances. The second (Type II) cell exhibited a small, round perikaryon with numerous processes which terminated near the cell soma. By 20-40 DIV Type I cells represented 60%-80% of the culture population, and the processes of this cell formed a complex meshwork over the collagen surface. Examination of these cultures with the electron microscope showed that the Type I cell and its processes contained numerous fibrillar bundles, characteristic of astrocytes. A few, mature oligodendrocytes (probably represented by the Type II cell) were also distributed randomly within the culture. As seen in vivo, several gap junctions were established between overlapping astrocytic processes and glial growth cone profiles were also apparent. It has thus been possible to establish from immature optic nerves an enriched population of well-developed, viable astrocytes which can be maintained as a primary culture for extensive periods. Since astrocytes represent a major reactive component following axonal injury within the CNS, development of a suitable culture system can permit more direct study of the influence of this cell on neuritic elongation.

2564 PURIFIED NEURONAL CULTURES FROM GANGLIONIC AND CENTRAL NERVOUS TISSUES OF SEVERAL SPECIES BY USE OF A DEFINED, SERUM-FREE MEDIUM. Silvio Varon, Stephen D. Skaper*, Ruben Adler, Jane Bottenstein and Gordon Sato*. Dept. Biol., Sch. Med., UCSD, La Jolla, CA 92093.

Cultivation of neural cells in synthetic media routinely requires serum supplementation and, sometimes, trophic factors. The addition of serum results in several problems, not the least of which is proliferation of nonneuronal cells. The eventual formation of a confluent monolayer of nonneurons in these cultures limits their usefulness in neurobiological studies. Also, simplification of medium composition to recognizably essential elements would eliminate the complex and relatively undefined nature of serum. A mixture of defined ingredients (insulin, transferrin, progesterone, putrescine and selenium) has recently been formulated which supports proliferative growth of rat neuroblastoma clonal cells in serum-free medium (J.E. Bottenstein and G. Sato, Proc. Natl. Acad. Sci. 76: 514, 1979).

In the present studies, dissociated embryonic chick dorsal root ganglionic cells were plated on collagen-coated culture dishes in medium containing 10% fetal calf serum. After allowing 48 hr for adequate cell attachment, the cultures received fresh medium supplemented with 10% serum or serum-free defined medium (N_1), which comprised insulin, transferrin, progesterone, putrescine and selenium. Nerve Growth Factor was also required in both media. The N_1 medium selectively maintained the neurons and did not support proliferation or even survival of nearly all nonneuronal elements. Survival of neurons in N_1 was initially as good and eventually better than in serum-containing medium. After 6 days in N_1 the cultures consisted almost entirely of neurons (>95%).

The N_1 medium was also used to culture cells from a variety of chick embryo central nervous system tissues (optic lobe, neural retina, spinal cord, telencephalon), and fetal or neonatal rodent. As with the chick sensory neurons, N_1 supported the survival of fiber-bearing cells (features typical of cultured neurons), while proliferation and in large part survival of flat cells were always suppressed. This, then, may provide a general way to obtain purified subpopulations of process-bearing, neuronal-like cells. (Supported by NINCDS grants NS-07606 and NS-12893).

2565 A FACTOR, DISTINCT FROM NERVE GROWTH FACTOR, THAT, LIKE NERVE GROWTH FACTOR, INDUCES INCREASED ADHESIVENESS AND MORPHOLOGICAL DIFFERENTIATION IN ANAPLASTIC GLIOMA AND PHEOCHROMOCYTOMA CELLS. Stanley A. Vinores* and Gordon Guroff. NIH, Bethesda, MD. 20205.

Nerve growth factor (NGF) induced increased cell-to-plastic and cell-to-cell adhesivesness in F98 rat anaplastic glioma cells. Increased adhesiveness could be observed at NGF concentrations as low as 1 ng/ml. Since malignancy is often associated with a decrease in cellular adhesiveness, this could explain, at least in part, the decreased tumor growth rate observed in anaplastic glioma-bearing rats treated with NGF (S. Vinores and A. Koestner, J. Neuropath. Exp. Neurol., 37: 704, 1978; Fed. Proc. 38: 1269, 1979). Conditioned medium from the NGF-secreting tumor cells, C-6 rat glioma and S-180 mouse sarcoma, also increased the adhesiveness of these cells, but this response was unaffected by anti-NGF IgG. Conditioned medium also induced adhesiveness in PC12 rat pheochromocytoma cells, and this was reduced by anti-NGF IgG. Conditioned medium collected from C-6 cells that were pretreated with 17β-estradiol, which stimulates increased NGF secretion, induced the highest degree of adhesiveness observed in both F98 and PC12 cells and this was unaffected by anti-NGF IgG. Insulin, epidermal growth factor, anti-NGF IgG, cytochrome-C, bovine serum albumin, dibutyryl-cAMP, and conditioned media from PC12 and IMR-32 human neuroblastoma cells did not increase adhesiveness. The factor inducing these effects is non-dialyzable, heat sensitive, and ammonium sulfate precipitable, and its secretion appears to be stimulated by 17β-estradiol. Supplementing conditioned medium with control medium produced an even greater increase in adhesiveness than did 100% conditioned medium, suggesting that factors depleted from control medium by growing cells also are necessary for maximum adhesiveness. As little as 1% conditioned medium had some effect on adhesiveness.

The processes induced by NGF in PC12 cells in vitro were longer and more filamentous than those induced by conditioned media. PC12 cells treated with conditioned medium also appeared flatter than NGF-treated cells. In F98 cells, the processes induced by NGF take longer to appear than those induced by conditioned media. None of the in vitro morphological responses to conditioned media in PC12 or F98 cells were neutralized by anti-NGF IgG. The data indicate that both NGF and certain conditioned media increase adhesiveness and induce morphological differentiation in F98 anaplastic glioma and PC12 pheochromocytoma, and that factors in addition to and other than NGF are active in the conditioned media.

2566 ION DEPENDENCY OF NERVE GROWTH FACTOR ACTION ON DORSAL ROOT GANGLIA. Norman R. West and Robert W. Stach. Depts. Anat. and Biochem., SUNY Upstate Med. Ctr., Syracuse, NY 13210.

Embryonic sensory neurons from 8 to 10 day chick embryos have an absolute requirement for the nerve growth factor (NGF) to survive and grow fibers in culture. We have shown that the inorganic cations magnesium and potassium are also necessary for the survival of these cells. On the other hand, calcium is not needed for the survival of these neurons, but is needed for these neurons to grow fibers. Our culture medium is simply Gey's balanced salts solution (GBS), (Amer. J. Cancer 27, 45-76, 1936) with various concentrations of NGF, 0.1 to 300 ng/ml, added. Therefore, it is an easy matter to remove a particular cation from the medium and determine what effect that cation has on the biological activity of NGF. When ganglia are cultured in potassium free GBS with various concentrations of NGF for 24 hours, there is no fiber outgrowth and 57% of the ganglia are floating. If normal GBS, containing the same concentrations of NGF, is now readded to the cultures and incubation is continued for an additional 48 hours, there is still no fiber growth and 71% of the ganglia are floating. Using the same paradigm, after 24 hours of incubation in magnesium free GBS containing various concentrations of NGF, there is no fiber growth and 49% of the ganglia are floating. With readdition of normal GBS and an additional 48 hours of incubation, there is no fiber growth and 67% of the ganglia are floating. Using floating ganglia and no fiber outgrowth as criteria for dead cells, our results show that potassium and magnesium are necessary for sensory neurons to survive. When calcium free GBS (CFGBS) is used as the culture medium, there is no fiber growth after 24 hours of incubation with various concentrations of NGF. However, only 5% of the ganglia are floating which is equivalent to control GBS cultures. Also, upon readdition of GBS, containing various concentrations of NGF, there is a normal fiber outgrowth at the normal concentration of NGF and again only control numbers (12%) of ganglia are floating. In GBS the biological activity of NGF is 6.9 ± 3.6 ng/ml. Upon readdition of GBS to the CFGBS cultures and an additional 48 hours of incubation, the biological activity of NGF is 4.6 ± 1.4 ng/ml. These results show that calcium ions are not needed for sensory neurons to survive but are needed for the neurons to grow fibers. The results obtained for the CFGBS can not be explained by low levels of calcium being present since the concentration of free calcium ions is below 5×10^{-11} M.

TROPHIC FUNCTION

2567 LONG-TERM ALTERATIONS OF ELECTROTONIC SYNAPSES, Anderson, T.E., Bittner, G.D. and Ballinger, M.L.*, Dept. of Zoology, University of Texas, Austin, TX 78712.

Adjacent single lateral giant axon segments (SLGA) in the crayfish (Procambarus clarkii) CNS are coupled by septate electrotonic junctions in the abdominal ganlia. Following injury to an SLGA (cutting the segment in the connective rostral to the ganglion) the resistance across the septum in the posterior ganglion increased more than seven-fold, while input resistances for both intact and lesioned axonal segments remained at normal levels (Asada & Bennett, J. Cell Biol. 49:159). Ultrastructural studies revealed a complete absence of previously abundant gap junctions in these septa (Pappas, Asada & Bennett, J.Cell Biol. 49:173). However, these studies examined only short-term (1-6 hr) changes in lesioned segments in contact with their original cell body.

The distal portion of an SLGA is capable of surviving for up to one year, with no discernible hypertrophy of surrounding glia (Bittner et al, J. Exp. Zool. 180:13). However, if an SLGA is double cut, the segment survives less than 7 days, again with no glial hypertrophy (Meyer & Bittner, Br. Research 143:195). It thus appears that septal connections are important for long-term survival of axonal segments of SLGA's separated from their cell bodies, raising the possibility that the initial separation and loss of gap junctions might reverse over time to allow direct passage of trophic substances through pore-like structures found at the junctions. We have found that gap junctions made with the distal SLGA segment, anterior to the cut, disappear shortly after cutting the axon, and further, that they are essentially absent even 100 days post-operatively. Clear vesicles 400-800 A^0 in diameter remain abundant however. Associated with ultrastructural absence of gap junctions there is a maintained increase in the septal resistance, although the input resistance for both intact and severed SLGA are within normal limits. Resistance changes are observed at septa both anterior and posterior to the cut initially, but resistance posterior returns to normal within 10 days. Following nerve cord ligation, increased resistance is found only at the anterior septum. Thus, in spite of apparent transfer of trophic substances from intact to isolated SLGA, electrotonic connections are not re-established. The most likely hypothesis for long-term survival of severed SLGA segments is an exocytotic-pinocytotic transfer involving the clear vesicles.

2568 ACCELERATED DEGRADATION OF JUNCTIONAL α-BUNGAROTOXIN-ACETYLCHOLINE RECEPTOR COMPLEXES IN DENERVATED RAT DIAPHRAGM. R.S. Brett and S.G. Younkin (SPON: L.H. Younkin). Dept. of Pharmacol., Case Western Reserve Univ. Sch. of Med., Cleveland, Ohio 44106.

The AChR in innervated and 5-day denervated left hemidiaphragms were labelled in vivo by injecting 1.0 μg of ^{125}I-αBT into the thoracic cavity of 250-350 g male Wister rats and maintaining them in a vertical position overnight. Virtually all animals survived this procedure which labelled about 35% of the AChR in the left hemidiaphragm. Toxin binding was measured 5 days after labelling. Because of the rapid degradation of extrajunctional toxin-receptor complexes essentially all of the toxin remaining bound to muscle 5 days after labelling is associated with the more slowly degraded junctional AChR. Denervation had a dramatic effect on junctional toxin-receptor complexes; the toxin bound to denervated hemidiaphragms was only 21% of that bound to innervated hemidiaphragms ($p < 0.0005$ by Student's t test). The result of this experiment could be partially or completely due to a denervation-induced increase in the rate of degradation of junctional AChR. We therefore measured toxin-receptor complexes in innervated and 5-day denervated left hemidiaphragms 1, 3, 5 and 8 days after the labelling procedure (i.e., 6, 8, 10 and 13 days after denervation). The loss of toxin from the endplate-containing area of innervated hemidiaphragms occurred with an apparent half-time of 11 days. The loss of toxin from the endplate-containing area of 5-day-denervated hemidiaphragms was much more rapid, occurring with an apparent half-time of 2 days ($p < 0.005$ by Student's t test). This result indicates that the normal metabolic stability of junctional toxin-receptor complexes is reduced during the period between 6 and 13 days after denervation. Because of the uncertainty inherent in the estimation of receptor half-life in vivo we cannot establish whether the increased rate of degradation accounts entirely for the decrease in toxin binding seen 5 days after labelling. The influence of nerve stump length on the denervation-induced change in junctional toxin-receptor complexes was examined. The toxin-binding to areas of muscle near the point of nerve entry (short stump) and areas far from the point of nerve entry (long stump) were compared in innervated and 2-, 5- and 8-day denervated hemidiaphragms. Animals were sacrificed 5 days after the labelling procedure (i.e., at 7, 10 and 13 days after denervation) when virtually all of the extrajunctional toxin-receptor complexes had been degraded. The decrease in ^{125}I-αBT bound to denervated hemidiaphragms occurred earlier in proximal (short stump) segments of the muscle. The fact that the denervation-induced alteration of junctional toxin-receptor complexes is influenced by nerve-stump length indicates that it is at least partly independent of the loss of muscle activity associated with denervation.

2569 PROPERTIES OF SOLEUS MUSCLE AND OF INDIVIDUAL SOLEUS MUSCLE UNITS AFTER CROSS-INNERVATION BY FDL MOTONEURONS. R. E. Burke, R. P. Dum, M. J. O'Donovan*, J. Toop*, and P. Tsairis. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205 and Dept. of Neurology, Cornell U. Med. Sch., New York, NY 10021.

We studied the histochemical and physiological properties of homogeneous "slow" soleus (SOL) muscles in adult female cats 9 - 10 months after re-innervation by heterogeneous, mainly "fast" flexor digitorum longus (FDL) motoneurons. Individual motor units were isolated with intracellular methods, enabling precise identification of motoneurons as originally FDL. Data from cross-innervated (XIN) muscles/motor units were compared with results from self-innervated (SI) SOL and from size-matched normal cats (NL SOL; Burke et al. J. Physiol. 238:503, 1974). XIN SOL muscles were close to normal in size, weight, force output and gross appearance when the FDL to SOL nerve anastomosis was mechanically intact, in contrast to XIN FDL (see Dum et al., this meeting). In all XIN SOL, over 90% of fibers had histochemical profiles identical to NL SOL fibers (type I); the minority fiber type was IIA (NL SOL can contain up to 4-5% type IIA fibers). However, the whole XIN SOL twitch times ranged from 55 to 65 msec (mean 61 msec; N = 4), versus 106 - 150 msec (mean 119; N = 4) for SI SOL and 99 - 186 msec (mean 140 msec; N = 14) for NL SOL. In one case, both SOL and FDL axons reinnervated a SOL muscle, giving a twitch time of 61 msec when FDL axons were stimulated versus 108 msec with SOL axons (tension deficit with simultaneous tetanization was only 18%, suggesting little dual fiber innervation). There was no detectable histochemical mosaic in ATPase staining at any pH, although the FDL-innervated fibers appeared to have lower neutral fat content (inferred since 1 unit glycogen-depleted from an FDL motoneuron had low fat in Oil Red O stain). We sampled a total of 17 SOL muscle units innervated by identified FDL motoneurons (4 were also studied histochemically by glycogen depletion). All 17 were type S and resembled NL SOL muscle units except for faster twitch contraction times. Range and mean (paren.) values for relevant properties of NL SOL muscle units and NL FDL motoneurons are given below (PTD = post-tetanic depression of twitch). The heterogeneous FDL motoneurons appear to reinnervate SOL muscle readily to produce typical type S muscle units with faster contraction times and less PTD than normal SOL units.

MOTOR UNITS IN:	NL SOL (S)	XIN SOL (S)	NL FDL (all)
Tw time (msec)	64 - 131 (97)	37 - 80 (53)	
Tw/ Tet.	0.16 - 0.41 (0.26)	0.05 - 0.44 (0.18)	
PTD incidence	10/26	1/16	
C. V. (m/sec)		64 - 111 (83)	72 - 111 (97)
AHP (msec)		42 - 71 (58)	32 - 68 (45)

2570 NERVE DEGENERATION CONTRIBUTES WITH INACTIVITY TO THE CHANGES OCCURRING IN MUSCLE AFTER DENERVATION. A. Cangiano and L. Lutzemberger*. Istituto di Fisiologia, Università di Pisa, Italy.

Overwhelming evidence indicates that factors different from nerve impulses are involved, together with inactivity, in the development of the membrane modifications occurring in muscle after denervation. One line of evidence shows, for instance, that pure muscle inactivity is less effective than denervation in producing spike resistance to tetrodotoxin and fibrillation or extrajunctional acetylcholine receptors. Lack of a hypothetical "neurotrophic" factor could be involved, although an alternative possibility is represented by the release of products of nerve degeneration between the muscle fibres. We have now obtained data in support of the latter interpretation with experiments of partial denervation of rat EDL and soleus muscles whose nerves were in addition subjected to impulse conduction block with tetrodotoxin containing cuffs for 2-3 days. We found that junctional and extrajunctional spike resistance to tetrodotoxin (TTX) as well as extrajunctional sensitivity to acetylcholine (ACh) developed virtually to the same extent in the denervated and in the adjacent innervated, but impulse-blocked fibres. This was in striking contrast with the behaviour of impulse-blocked fibres of control muscles not containing denervated fibres which, at this early time, showed little or no membrane changes. These results appear difficult to reconcile with the hypothesis of "neurotrophic" factors contributing with activity to the control of muscle membrane properties since such factors should not be missing from the impulse-blocked but innervated fibres of the partially denervated muscles. The results are on the other hand consistent with the interpretation that nerve degeneration consequent to denervation sets free the action of some factor that summates with inactivity in producing high values of ACh hypersensitivity and TTX resistance.

2571 MEMBRANE PROPERTIES OF THE SKELETAL MUSCLE AFTER BLOCKADE AND RECOVERY OF FAST AXONAL TRANSPORT. S. S. Deshpande*, R. J. Boegman, and E. X. Albuquerque. Dept. Pharm. & Exptl. Therap., University of MD, Sch. Med., Baltimore, MD 21201.

A single subperineural injection of batrachotoxin (BTX, 9.3 pmoles) into the peroneal nerve of rats causes immediate block of fast axonal transport and subsequent membrane depolarization of the surface fibers of the extensor digitorum longus (extensor) muscle. The onset of membrane depolarization is dependent on the site of BTX injection - the more distal the site, the earlier the onset (Neurosci. Abs. 4: 1978). BTX injection into the peroneal nerve (about 10 mm from the nerve's entrance into muscle) in female Wistar rats paralyzed the limb only for 3–4 days. The fast axonal transport in the nerve was determined by measuring migration of ^{3}H-leucine labelled proteins and showed complete recovery at day 7 at a time when the extensor muscle was still depolarized by about 14 mV. By day 22 the resting membrane potential (RMP) returned to near control levels (–76 mV vs. –79 mV). Between 4 and 14 days extrajunctional sensitivity to microiontophoretically applied acetylcholine was high (200–400 mV/nC) and spread over the entire surface of the muscle fiber. In addition, muscle action potentials were resistant to TTX (3 μM). Spontaneous miniature endplate potentials (mepps) and neurally elicited action potentials in muscle were totally absent up to day 7 but these showed gradual recovery by day 22 however, when significant recovery in RMP had occurred the mepp frequency was still lower than the control (1.27 ± 0.29 sec^{-1} vs. 2.40 ± 0.22 sec^{-1}). Muscle atrophy was prominent between day 4 and 14. Collateral sprouting was not observed after BTX injection. In addition, after degeneration of the distal stump produced by BTX, the newly grown nerve terminal reinnervated the former endplate. It is concluded that in spite of the early clinical recovery of the affected limb and its use in locomotion, the membrane properties of the extensor muscle do not return to control levels for at least 3 weeks after a single subperineural injection of BTX. The delayed recovery in RMP and of the physiological properties of the neuromuscular synapses were most likely a consequence of degenerative processes such as proliferation of Schwann cell (which is known to occur following denervation) interposed between pre- and postjunctional membrane. Apparently in spite of the recovery of the fast axoplasmic transport, the pattern of muscle recovery is similar to that seen after transection of nerve (Supported by USPHS Grants NS-12063, and funds from Muscular Dystrophy Association and the Paralyzed Veterans of America Inc..)

2572 EFFECTS OF DENERVATION AND REINNERVATION ON CHOLINERGIC ENZYMES IN SCIATIC NERVE, SLOW AND FAST MUSCLE OF RAT. Wolf-D. Dettbarn. Dept. Pharmacol., Sch. Med., Vanderbilt Univ., Nashville, TN 37232

The changes induced by loss and reestablishment of functional connections between nerve and muscle offer a suitable model for studying the mechanisms that control nerve and muscle enzymes such as acetylcholinesterase (AChE) and choline acetyltransferase (CAT). A difference in the rate of loss and recovery of these enzymes may give us insight into the mechanisms by which these enzymes are controlled in muscle. The sciatic nerve was crushed in the mid-thigh region, and 1-6 weeks following the surgery, the loss and recovery of function and the changes in activity of AChE and CAT in fast extensor digitorum longus muscle (EDL) and in the slow soleus muscle (SOL) were compared with those in sciatic nerve segments (1 cm long), one proximal (PN) and one distal (DN) adjacent to the crush. Enzyme activities were calculated as activity/muscle or unit length (cm) of nerve. Within 24 hours after nerve crush, neuromuscular transmission was blocked. Maximal loss of AChE and CAT activity was seen by the end of the second week. AChE activity in EDL, SOL and DN was reduced to 15-25% of control while the loss of AChE in PN was 50%. CAT activity was reduced to 40% in EDL, 20% in SOL, 25% in DN and to 80% of control in PN. During the third week, functional reinnervation of individual muscle fibers was observed and full innervation was reestablished by the end of the sixth week. During this period, AChE activity in SOL recovered rapidly, with maximum enzyme activity at 4 weeks after crush (200% of control) returning to control values by the end of the sixth week. AChE activity in EDL, DN and PN recovered at a much slower rate than that of SOL. None showed an increase over control activity nor was AChE activity fully restored during the observation period. By the end of the third week, CAT in PN had reached control activity, while in EDL (80%), SOL (60%) and DN (80%), CAT activity was still below the control value. The data indicate that recovery of AChE and CAT in regenerating nerve and self-reinnervated fast EDL proceed at a similar rate, indicating that the motor nerve has some regulatory function. In slow SOL, however, AChE activity recovers at a much faster rate than in the PN and DN leading to a temporary increase of AChE activity (200%) over that of the normal control muscle. The direct influence of the nerve does not seem to be the only factor controlling the recovery of AChE in reinnervating muscle. The observed difference may in part result from the difference in muscle fiber types in these two muscles.

2573 THE PROPERTIES OF WHOLE FDL MUSCLE AND OF INDIVIDUAL FDL MUSCLE UNITS AFTER CROSS-REINNERVATION BY SOLEUS MOTONEURONS IN CAT. R. P. Dum, R. E. Burke, M. J. O'Donovan* and J. Toop*. Lab. of Neural Control. NINCDS, NIH, Bethesda, MD 20205.

The properties of the heterogeneous "fast twitch" flexor digitorum longus (FDL) muscle and of individual muscle units were studied 7 to 12 months after reinnervation by motoneurons of the homogeneous "slow twitch" soleus (SOL) muscle, using adult female cats. Intracellular methods were used to isolate single motor units and to identify their motoneurons as belonging to the SOL nucleus. Data from cross-innervated (XIN) muscles were compared with contralateral FDL, self-reinnervated (SI) FDL, and with results from size-matched normal cats (NL FDL; see Dum et al., Neurosci. Abstr. 4:294, 1978). XIN FDL muscles varied between cats (3/11 were very small with atypical histochemistry but apparent functional innervation), but tetanic force/gram wet weight was normal in 7/11. Histochemical fiber compositions in XIN FDL also varied but in the "best" cases, over 95% of the muscle was type I (low ATPase) with uniformly high oxidative staining. Further studies of myosin subtypes are in progress.

WHOLE MUSCLES	WET WT.(gm)	TET. TENS. (kg)	TW TIME (msec)
Normal & SI FDL	0.8 - 1.3 (1.0)	1.5 - 2.1 (1.7)	25 - 40 (33)
XIN FDL	0.2 - 0.7 (0.5)	0.08 - 1.0 (0.6)	34 - 137 (76)

We studied 32 motor units in 11 XIN FDL muscles, some of which were also studied histochemically by glycogen depletion. All were type S by physiological criteria and resembled NL SOL units in having a high incidence of post-tetanic twitch depression (PTD). The table below shows a comparison of properties (C.V. = axonal conduction velocity; AHP = afterhyperpolarization duration) for normal (NL) FDL type S, normal SOL type S and XIN FDL (FDL muscle units innervated by SOL motoneurons) motor units. Ranges are shown, with mean values in parentheses.

MOTOR UNITS:	NL FDL (S)	XIN FDL (S)	NL SOL (S)
Tw Time (ms)	34 - 81 (56.2)	33 - 82 (56.7)	
Tw/Tet	0.2 - 0.7 (0.4)	.06 - 0.6 (0.3)	
PTD incidence	1/10	12/29	10/26
C. V. (m/sec)		63 - 85 (73)	58 - 91 (72)
AHP (msec)		69 - 105 (85)	75 - 134 (93)

Re-innervation of the FDL muscle by SOL motoneurons in adult cats produced variable results, but at best there was evidence for significant "conversion" of muscle units from the predominant normal "fast" types (FF and FR) to a slow type with similarities to the S units of normal SOL. We found no evidence for reorganization of group Ia synaptic connectivity patterns.

2574 BENEFICIAL EFFECT OF WATER-DEPRIVATION ON MUSCULAR DYSTROPHY OF THE CHICKEN. Richard K. Entrikin, Judith A. Mouritsen*, Gary T. Patterson and Barry W. Wilson. Depts. Avian Sci., Pharmacol., and Phys. Med. & Rehab., Univ. California, Davis, CA 95616.

Drugs that beneficially affect hereditary muscular dystrophy of the chicken often decrease body weights. The possibility that the dystrophy might be altered by water and food utilization was tested by depriving dystrophic chickens (UC Davis line 413) of water and/or feed for periods of up to 96 hours beginning on day 33 ex ovo. At this age dystrophic chickens exhibit decreased righting ability, abnormal electromyographic (EMG) activity, increased plasma creatine kinase (CK) levels, increased acetylcholinesterase (AChE) levels in plasma and muscles, and histopathological changes in fast-twitch muscles.

Data below are from a 72-hour study of normal control (412C), dystrophic control (413C), water-deprived dystrophic (413 -H_2O), and feed-deprived dystrophic (413 -feed) chickens at 37 days ex ovo. Values are means ± SEM (8-10 birds per group) of exhaustion scores (ES, consecutive number of times a bird can rise from the supine position during a single trial), plasma CK (mU/ml), and body weights (Wt, grams).

	ES	CK	Wt
412 C	22.5 ± 1.2	173 ± 11	534 ± 13
413 C	1.0 ± 0.4	5370 ± 525	549 ± 23
413 -H_2O	8.7 ± 2.0	466 ± 109	348 ± 23
413 -feed	0.6 ± 0.2	1399 ± 104	322 ± 14

Water-deprivation increased righting ability nearly 9-fold and decreased plasma CK levels by about 90%. Feed-deprivation reduced body weights to the same extent as water-deprivation, but had less effect on CK and no beneficial effect on righting ability. Further studies showed that water-deprivation also reduced abnormal EMG activity and AChE levels. Pectoralis major muscle fibers of water-deprived dystrophic birds had smaller diameters and less-rounded, "more normal" angular shapes. Although water-deprivation was shown previously to decrease muscle stiffness in congenital myotonia of the goat (Hegyeli and Szent-Gyorgyi, Science 133:1011, 1961), it alleviated symptoms of the avian dystrophy that are independent of myotonia. The magnitude and scope of the changes brought about by water-deprivation exceed those of any drug yet studied in the dystrophic chicken. A mechanism revealed by water-deprivation might explain the beneficial effects of chemically-dissimilar drugs such as phenytoin, methysergide, and penicillamine on the avian dystrophy. (Supported by the Muscular Dystrophy Association, Inc.)

2575 NERVE GROWTH FACTOR RECEPTORS ON CHICK SYMPATHETIC GANGLION CELLS. Earl W. Godfrey and Eric M. Shooter. Dept. Neurobiol., Stanford Univ. Sch. Med., Stanford, CA 94305.

It has previously been shown (Sutter et al., Soc. Neurosci. Abstr. 3:461, no. 1475(1977); J. Biol. Chem., in press) that sensory ganglion neurons from chick embryos have two distinct high-affinity binding sites for nerve growth factor (NGF) on their cell surfaces. One class of receptors (site I) had a K_d of about 10^{-11} M; the other (site II) had a K_d of about 10^{-9} M. Both steady-state and kinetic analyses showed these two classes of receptors did not interact in a negatively co-operative manner. The site II receptors were already present on the surface of sensory cells at day 4 of incubation, whereas the site I receptors first appeared between days 5 and 6. Several lines of evidence indicated that the neurite outgrowth response to NGF was mediated by site I receptors.

These studies were extended to the cells of the chick embryo sympathetic ganglion. The NGF receptors were measured using the specific binding of ^{125}I-βNGF as an assay. Steady-state analysis of binding to dissociated cells at 37° revealed two distinct sites with K_d's of about 10^{-11} and 10^{-9} M. The kinetics of association and dissociation of NGF and its receptor appear similar to those seen with the sensory neurons. Sites I and II were about equally sensitive to inactivation or degradation by trypsin. No evidence for negatively co-operative interactions between the two sites was found. The development of the receptors has been followed, and both sites I and II were found on sympathetic cells from day 6.5 to day 20 of incubation. There were about 10 times as many site II as site I receptors per cell (as measured by steady-state analysis at 37°); this ratio did not change significantly from day 9 to day 15 of incubation. After several days in culture, non-neuronal cells from sympathetic ganglia exhibited high levels of site II receptors, but site I receptors have not yet been detected on non-neuronal cells. The NGF receptors on chick sympathetic ganglion cells seem, in most if not all respects, to be similar to those found on chick sensory ganglion cells.

2576 EFFECTS OF SOUND DEPRIVATION ON PRIMARY AUDITORY SYNAPSES IN THE COCHLEAR NUCLEUS OF THE ADULT GUINEA PIG. R.L.Gulley,D.Mattox* and F.Ulrich*Depts. of Anat.and Surg.(Div.Otolaryng.),Univ.of Texas Health Sci.Cntr.,San Antonio,Tx. 78284

Primary auditory terminals in the rostral anteroventral coch lear nucleus were studied in thin-sectioned and freeze-fractured material from animals maintained for 24 hours in a sound-reduced environment. All animals had their external auditory canal occluded with bone wax. Some animals were maintained under ketamine and urethane anesthesia for 24 hours to minimize animal-generated noise. Awake and anesthetized control animals were kept in ambient noise for 24 hours. In thin-sections,three changes are seen in the primary auditory terminals of sound-deprived animals. 1)In anesthetized sound-deprived animals few enlarged channels of extracellular space surrounding the active zone contain glial processes. In anesthetized and awake animals in ambient noise, many of the enlarged channels contain glial processes. In awake, sound-deprived animals the number of channels containing glial processes is reduced compared to control animals; however,some channels containing processes are present. These deeply invaginate the terminal,and the glial processes are located within the channel,deeply embedded in the terminal. Frequently the sides of the channel beneath the glial process are parallel and separated by a 20-30nm gap. 2)Numerous smooth elongated or crescentric-shaped cisternae appear within the terminal after sound-deprivation. These cisternae may be transitional forms in the formation of large double membrane-bounded sacs which are also common in the primary terminals of the sound-deprived animals.These sacs, measuring about 0.2μm in diameter, are sometimes filled with vesicles which are the same size and shape as the synaptic vesicles in the terminal.The cisternae and sacs may be related to an acceleration of a generalized remodeling process in the nerve terminal,since similar structures have also been observed in frog neuromuscular junctions subjected to various regimens of stimulation (K.Lynch,personal communication). 3) There is a decrease in the number of synaptic vesicles in the terminal.In freeze-fracture preparations of awake,sound-deprived animals, the number of non-aggregate particles in non-junctional regions of the postsynaptic membrane is over 130 particles /μm^2 compared to 53 particles /μm^2 in awake animals kept in ambient noise. Thus,in the auditory system, sound-evoked activity is apparently necessary for the maintenance of the presynaptic terminal and is a factor in the trophic regulation of the organization of intramembranous particles in the postsynaptic membrane.

2577 AXONAL CHEMOTAXIS TO NERVE GROWTH FACTOR AND ITS POSSIBLE MEDIATION BY CYCLIC NUCLEOTIDES AND CALCIUM. Ross W. Gundersen* and John N. Barrett. Dept. Physiol. Biophys., Univ. Miami Sch. Med., Miami, FL 33101.

This present work reports a fast chemotactic response of dorsal root axons to β-Nerve Growth Factor (NGF) and attempts to determine the physiological events contributing to this response. A local gradient of NGF was applied, via a micro-perfusion system, to single growth cones of cultured chick dorsal root axons (8-13 days approximate emryonic age). All axons tested turned and began to grow up the NGF gradient within 9-21 min, without any detectable change in growth rate. This directed growth was observed when the micropipette source contained 2-50 biological units (BU) NGF/ml and the background level was 1 BU NGF/ml. Directed growth was not observed toward sources of fetal calf serum, bovine serum albumin, or sources duplicating the background concentration of NGF. A decrease in the number of axons turning toward a 50 BU NGF/ml source was observed when the background level of NGF was increased to 25 BU/ml. This oriented growth is not due to effects on growth rate, survival, fluid movement, or general response to any protein, but rather appears to be a chemotactic response to NGF which may involve saturable NGF receptors on the growth cone.

Dorsal root axons also turned and grew toward 1 mM sources of mono- and dibutyryl cyclic adenosine monophosphate, 1 mM cyclic guanosine monophosphate (c-GMP), phosphodiesterase inhibitors (caffeine, theophylline, Roche 20-1724), 1 mM cyclic adenosine monophosphate (c-AMP) in the presence of 10^{-7} M Roche 20-1724, and 20 mM calcium in the presence of the calcium ionophore A23187 (10^{-7} M). These results suggest that the physiological mediators of the chemotactic response to NGF may be increases in the intracellular levels of c-AMP and/or c-CMP, and free calcium. Supported by NIH grants NS 12207 and NS 07044.

2578 Neurofibromatosis: Evidence of Genetic Heterogeneity Supported by Nerve Growth Factor Alterations. WILLIAM R. KANTER*, Albany, New York, ROSWELL ELDRIDGE, and THELMA KOERBER*, Bethesda, Maryland

Neurofibromatosis is a complex hereditary syndrome which includes the common peripheral form and a central form recently documented by us. The latter is an autosomal dominant disorder whose hallmark is bilateral acoustic neuroma. There are generally mild skin changes as well consisting of 1 to 4 cafe-au-lait spots or subcutaneous neurofibromatosis.

Nerve Growth Factor (NGF) has been analysed in 9 affected with central neurofibromatosis and 22 at risk from 3 kindreds personally studied. The laboratories of Ned Boyer, Johns Hopkins and George Todaro, NCI, participated in the assays. NGF in serum was measured for antigenic activity by means of radioimmunoassay employing anti-mouse NGF antibody and for receptor binding by competition radioreceptor assay employing formalin fixed human melanoma cells. central

NGF antigenic activity was significantly elevated in those with neurofibromatosis while those at risk consisted of two groups, one whose NGF antigenic activity was normal and one whose activity was elevated. Receptor binding was normal or low. In contrast, receptor binding is reported elevated in peripheral neurofibromatosis while antigenic activity is normal or low.

On the basis of these clinical and biochemical observations, we suggest that central and peripheral forms of neurofibromatosis are closely related but distinct diseases that may be associated with separate alterations in NGF activity. These findings may help explain the "maternal effect" noted by us in central neurofibromatosis and by Miller and Hall in pheripheral neurofibromatosis. They may also lead to a method for screening individuals at risk, and suggest that mechanism responsible for the neoplastic and other changes common in this syndrome.

2579 NEUROTROPIC SUBSTANCE AS MEDIATOR FOR AXON-SHEATH CELL INTERACTION. H. Mei Liu*. (SPON. Igor Klatzo). Brown University, Providence, Rhode Island. 02906.

The present study aimed at defining the neurotropic mechanism between axon and sheath cell by in vitro and chemical methods. Cultures of sheath cells (Schwann cells) were established from sciatic nerves of chick embryos after 16 days of incubation and fed with serum-free medium for three days. The conditioned medium was subjected to bioassay with chick embryo dorsal root ganglia (DRG) and found to have nerve growth promoting activity (NGF action). Gel filtration of the conditioned medium with Sephadex G-200 revealed three major components with the NGF action. Affinity chromatography using Con-A Sepharose abolished the NGF activity in the conditioned medium while purified β NGF was not affected by the same treatment. These findings indicated that β NGF molecules secreted by sheath cells form a complex with the Con-A binding material in the conditioned medium. Chick embryo DRG placed at a distance of 2-3 mm away from explants of sheath cells showed accelerated neurite growth oriented towards the explants. Adhesion between neurites and sheath cells was observed. The cell recognition and adhesion appeared to be mediated by a Con-A binding, PAS and colloidal iron positive material on the sheath cell and axonal surfaces. The location of Con-A binding material corresponded precisely with the distribution of β NGF molecules on the cell membrane as revealed by indirect immunofluorescent technique (incubation with rabbit antiserum to β NGF followed by fluorescein conjugated goat antiserum to rabbit IgG). The above findings suggest that β NGF molecules synthesized by the sheath cells exist as a complex with glycoproteins on the cell membrane. The macromolecule, tentatively called "neurotropic substance" (NTS) is constantly shed into the microenvironment as a result of membrane turnover. This results in the presence of free NTS molecules in the conditioned medium. In the in vivo system, a diffusable gradient of NTS surrounding the sheath cells may be envisioned. The biological action of NTS appears to be twofold: one of local action and involves cell recognition and adhesion between axon and sheath cell that is mediated by the glycoprotein molecules and the other is a well known NGF action following transfer of NGF molecules from NTS to the receptor on the axonal membrane. The neurotropic substance appears to be the guiding principle in the organization of the peripheral nerve during embryogenesis and regeneration.

2580 PURIFICATION OF A SCIATIC NERVE PROTEIN HAVING TROPHIC INFLUENCES ON SKELETAL MUSCLE IN CULTURE. G. J. Markelonis* and T.H. Oh. Dept. of Anatomy, Univ. of Maryland Sch. of Med., Baltimore, Maryland 21201.

It has long been known that the spinal motor nerve exerts trophic influences on the morphologic, physiologic and metabolic properties of skeletal muscle. Evidence has been accumulated to indicate that such trophic influences are mediated in part by a neurally-derived trophic substance(s). Citrate-soluble chicken sciatic nerve protein was fractionated biochemically and added to aneural chick embryonic skeletal muscle cultures in order to identify the component(s) with neurotrophic activity. Biological activity of fractions was assessed by the ability of the fraction to enhance morphological development of muscle cells and to stimulate the incorporation of ^{14}C-leucine into muscle protein. A protein fraction expressing trophic activity was obtained by ion-exchange chromatography on diethylaminoethyl-cellulose followed by gel filtration on Sephadex G-100 superfine. This protein fraction, when added to mature, muscle cultures at 3-day intervals, maintained muscle fibers in a well-differentiated state for at least 5 weeks, a time when control cultures had degenerated completely. Characterization of the active fraction by sodium dodecyl sulfate-polyacrylamide gel electrophoresis revealed a single major protein with a molecular weight (M_R) of 84,000. At low concentrations, the protein migrated as a "doublet" when separated on standard, 7.5% polyacrylamide gels. Analytical isoelectric focusing revealed that the active protein was acidic, focusing as four species with isoelectric points (pI) of 5.74, 5.77, 5.92 and 6.15. Maximal stimulation of muscle protein synthesis was elicited by 20μg of active protein per ml. These data suggest that an acidic protein having trophic influences on muscle has been identified and purified.

Supported in part by grants from the NIH, NSF and Paralyzed Veterans of America. GJM is a MDA Post-doctoral Fellow.

2581 AROMATIZATION OF ANDROGEN TO ESTROGEN MEDIATES INCREASED ACTIVITY OF GLUCOSE 6-PHOSPHATE DEHYDROGENASE IN RAT LEVATOR ANI MUSCLE. Stephen R. Max and James F. Knudsen*. Depts. Neurology & Pediatrics, Sch. Med., Univ. Md., Baltimore, MD 21201.

The mechanism of action of androgens on striated muscle is not understood. One approach to this problem is to study the production of specific proteins in response to androgen administration. We studied glucose 6-phosphate dehydrogenase (G6PD), the rate-limiting enzyme of the oxidative pentose phosphate pathway, as a biochemical marker, in the hormone-sensitive levator ani muscle of immature male rats. Sixteen h. after one i.p. injection of testosterone propionate (2.5 mg/100 g. body weight in DMSO), G6PD specific activity increased by 58% (Table). However, other androgens, e.g., fluoxymesterone and 5α-dihydrotestosterone, were without effect. These latter substances have a common characteristic, viz., they cannot be aromatized to estrogen. On the other hand, androstenedione, a metabolite of testosterone which is a good substrate for aromatization, increased G6PD by 98%. We therefore assessed the effect of estrogens and found that estradiol-17β and diethylstilbestrol increased G6PD by 58% and 44%, respectively. The response is stereospecific since the biologically inactive isomer, estradiol-17α, produced no effect. The increase in G6PD by testosterone was blocked by the anti-estrogen, MER-25, and by 4-hydroxyandrostenedione, a potent inhibitor of "androgen aromatase".

Experiment	G6PD, % Control
Vehicle	100
Testosterone propionate	158*
Fluoxymesterone	97
5α-dihydrotestosterone	90
Androstenedione	198*
Estradiol-17β	158*
Estradiol-17α	96
Diethylstilbestrol	144*
Testosterone propionate + MER-25	112
Testosterone propionate + 4-hydroxyandrostenedione	110

*$p < 0.05$

These results demonstrate that the conversion of testosterone to estradiol mediates the increased G6PD following testosterone injection. This phenomenon represents a direct effect of estrogen which is probably distinct from the general myotrophic actions of androgens. (Supported by MDA, Inc., and by the National ALS Foundation, Inc.)

2582 HYPERSENSITIVITY TO ACh IN INNERVATED MUSCLE FIBERS. E. J. Muñoz-Martinez, Jesús Cueva* and Pedro Joseph-Nathan*. Departamentos de Neurociencias y de Ingenieria Química. CIEA del IPN. México 14, D.F.

Ingestion of the fruit of Tullidora (Karwinskia humboldtiana) produces flaccid paralysis and segmental demyelination of peripheral nerves in cats and rats. Demyelination leads to conduction block of the nerve impulses and, consequently, to functional denervation when motor axons are affected. However, it cannot be excluded that paralysis results in some cases from axonal degeneration.

We investigated whether the soleus muscles of rats treated with extracts from Tullidora showed the alterations which are found after denervation; the extracts were administered through a gastric probe. After a latent period of 3-5 weeks, rats treated with a single dose (1.5 gr/Kg) showed paralysis. The soleus muscles were then removed under anesthesia and individual muscle fibers were tested in vitro for sensitivity to ACh (iontophoresis). The end plates showed the usual sensitivity but 90% of the explored fibers (215) showed hypersensitivity outside of the end plates as in the case of denervation. However, only 30% of these fibers were functionally denervated as judged by lack of response to nerve stimulation; in one fully innervated muscle, 87% of the fibers were also hypersensitive to ACh. In contrast, fore limb muscles from the same treated rats did not show hypersensitivity. On the other hand, non-treated rats but with hindlimb paralysis after chronic transection of the spinal cord showed normal sensitivity to ACh. Therefore, hypersensitivity to ACh in soleus muscles of treated animals does not result from denervation or from direct action of Tullidora on muscle fibers. Also, muscle inactivity cannot be implicated. We propose that increased sensitivity to ACh in the animals treated with Tullidora results from lack of a trophic substance which normally controls the synthesis and distribution of ACh receptors.

The same type of experiments were repeated in rats treated with a purified poliphenolic compound isolated from the fruit of Tullidora and the results were esentially the same as those described above.

2583 CELL PROLIFERATION IN DENERVATED MOUSE MUSCLE. Marjorie A. Murray* and Norman Robbins (SPON: Vernon Rowland) Dept. Anat., Sch. Med., Case Western Reserve Univ., Cleveland, OH 44106

Nerves exert control over cell division in many target tissues. In adult skeletal muscle, cell division increases soon after nerve section, but it is unclear which cell types proliferate or whether the response is spatially related to degeneration of nerve terminals. Indeed, some authors suggest that early membrane responses to denervation are causally connected to a cellular reaction at the endplate region.

In the present study, cell division in the extensor digitorum longus muscles of young adult mice was studied by injecting ^{3}H-thymidine (^{3}H-TdR) after denervation. Scintillation counting of muscle homogenates showed that ^{3}H-TdR incorporation into DNA in the denervated muscle was higher than in the sham operated muscle for the first week after nerve section, with the peak response at 4 days. Autoradiography revealed that most of the label was in cells extrinsic to muscle fiber basal laminae, although a few satellite cells were labeled. Some of the extrinsic cells had characteristics of fibroblasts, while others appeared to be macrophages. Although several cell types incorporated label, they were not preferentially located near certain structures such as small venules or nerve terminals. The muscle was not edematous and no polymorphonuclear leukocytes were seen.

In a series of reinnervation experiments, scintillation counting during recovery showed that 90-95% of the label injected at 3 days did not remain in the muscle 6 weeks later.

Several reports indicate that the number of satellite cells increases after denervation. In this study approximately 1% of the labeled cells were satellite cells, as confirmed by electron microscopy. This small number is not surprising since these cells comprise only 2-4% of the nuclei in the tissue. Satellite cell increase may result from budding off of myonuclei rather than mitosis. Experiments to test this hypothesis are under way.

The stimulus for cell proliferation after denervation seems to be a generalized signal throughout the muscle. Since the signal is reaching cells that are not synaptically connected to the nerve, it may be a secondary message, resulting from an earlier change in muscle fibers. Alternatively, cutting the nerve may alter primary mitotic influences that are normally present.

Supported by grants from the Muscular Dystrophy Association and by NIH AG-00795.

2584 PERSISTENCE IN DEGENERATING SCIATIC NERVE OF SUBSTANCES HAVING TROPHIC INFLUENCES ON CULTURED MUSCLE. T.H. Oh, G.J. Markelonis* P. J. Reier and A.A. Zalewski. Dept. of Anatomy, Univ. of Maryland Sch. of Med., Baltimore, Md. 21201 and NIH, Bethesda, Md., 20014.

It is well known that cholinergic innervation exerts trophic influences on skeletal muscle and that such influences are mediated in part by trophic substances. Evidence for the trophic substances has been obtained from "nerve stump" experiments which suggest that there is a progressive depletion of trophic substances in the transected distal nerve stump. In the present study, we investigated whether depletion of trophic substances actually occurs in transected degenerating nerves by testing the effects of soluble protein obtained from normal and degenerating nerves on protein synthesis, maturation and maintenance of cultured muscle. When soluble protein obtained from normal or 21-d denervated chicken sciatic nerves was added to chick embryonic muscle cultures, the incorporation of ^{14}C-leucine into muscle protein was significantly greater than in control cultures. Addition of these proteins to muscle cultures markedly enhanced the rate of morphological maturation of muscle cells. By 6 d, cross-striated myotubes were present in cultures treated with normal or degenerating nerve protein, whereas control cultures showed thin immature myotubes. Under our culture conditions, control cultures began to degenerate after 2 w. By contrast, addition of normal or degenerating nerve protein to mature, muscle cultures maintained these cultures for at least 4 w. Recently, we have identified and purified a protein (MW 84,000) from normal chicken sciatic nerves which has trophic influences on cultured muscle (Proc. Nat. Acad. Sci., in press). To determine whether this protein persisted in degenerated nerves, we separated soluble proteins from normal, 3-d or 21-d denervated chicken sciatic nerves by SDS-polyacrylamide gel electrophoresis. The resulting gels showed that an 84,000 dalton protein was present in the degenerating nerves. The present study shows that soluble protein from normal or degenerating nerves was equally effective in promoting synthesis, maturation and maintenance of cultured muscle and that the electrophoretic pattern of normal and degenerating nerve proteins contained a protein which migrated in a manner identical to the trophically active, 84,000 dalton protein. We conclude that the in vivo changes in muscle following denervation are not due to the depletion of trophic substances following nerve transection. Instead, these results indicate that a trophic substance is still associated with the degenerating, distal nerve segment and possibly with non-neuronal cellular elements. Supported in part by grants from the NIH, NSF, PVA and MDA Postdoctoral Fellowship (GJM).

2585 A NERVE STUMP DEPENDENT APPEARANCE OF ACH RECEPTORS IN ORGAN CULTURE. Anthony Olek* and Norman Robbins (Spon: F. Boller). Dept. Anat. Sch. Med. Case Western Reserve Cleveland, O. 44106

The presence of a 2-3 cm. nerve stump retards changes in the numbers of acetylcholine receptors which occur after denervation (Uchitel and Robbins, Br. Res. 153.539, 1978). In order to determine whether the nerve stump effect depends on systemic influences and to develop a system for analysis of this effect, phrenic nerve-diaphragm preparations were studied in organ culture for up to 48 hrs.

Strips of rat diaphragm cultured for 42-44 hrs. after denervation demonstrated nerve stump dependent differences in the number of acetylcholine receptors (assayed by I^{125}-alphabungarotoxin binding) in endplate regions, but not in extrajunctional areas. The endplate region is defined as a 2mm. wide piece around the myelinated nerve trunk found to contain 95% of the endplates. The number of receptors specific to this region is expressed as that found after subtracting, on a weight basis, the number of receptors in far extrajunctional regions.

Paired diaphragm strips, one ("+N") with a long nerve stump, the other ("-N") with a short stump, showed no differences in receptor number until 42 hrs. of denervation in culture, at which time (-N) strips contain 2.0±.6 fm/mg more receptors than (+N) strips ($p < .002$). The receptor number specific to the endplate regions of (+N) strips at 42 hrs. of culture is not significantly different from that of fresh innervated muscle. Autoradiographic examination of the endplate region is under way to determine the locus of the increased endplate regional binding found in (-N) strips. Strips with the nerve stump present but cut close to the muscle demonstrated no difference in receptor number compared to (-N) strips. In non-endplate areas up to 48 hrs. of culture, both (+N) and (-N) strips showed increases of 3.3± 1.5 fm/mg, comparable to muscles denervated in vivo for the same time.

One interpretation of these results is that the nerve acts by some non-activity related mechanism to maintain numbers of receptors in the endplate region at the level found in innervated muscle. In vitro, this neurotrophic regulation by the nerve stump can be dissociated from effects on far extrajunctional receptors, i.e., distinct regions of the muscle may respond differentially to neural control and the regulatory mechanisms may differ.

2586 TRANSNEURONAL CHANGES IN THE ECTOMAMILLARY NUCLEUS AND VENTRAL LATERAL GENICULATE NUCLEUS FOLLOWING EYE REMOVAL IN THE NEWLY HATCHED CHICK. J. D. Peduzzi* and W. J. Crossland (SPON: J. A. Rafols). Department of Anatomy, Wayne State University, School of Medicine, Detroit, MI 48201.

Previous investigations of unilateral eye removal in newly hatched chicks have shown that the ectomamillary (EMN) contralateral to the removed eye is reduced in volume (up to 50%) when compared with the EMN contralateral to the unoperated eye. The ventral lateral geniculate nucleus (GLv) is also reduced in volume by a smaller magnitude (30%). The three most likely explanations for the observed reduction in nuclear volume are: 1) cell death, 2) reduction of neuron volume and/or 3) arrest of neuron growth. To examine these possibilities, chicks were unilaterally enucleated on the day of hatching and allowed to survive from 2 to 81 days. Since all (or nearly all) of the optic fibers cross at the chiasm, comparisons could be made between the affected and unaffected sides of the brain. Comparisons were also made with unoperated animals. The brains were embedded in paraffin and 10 µm thionin stained sections were examined. Neurons containing nucleoli were traced using a camera lucida to obtain neuron cross-sectional areas and to determine neuron number.

There was a significant cell loss in both the EMN (30%) and GLv (20%) by the end of the first post-operative week. The neuronal loss remained constant in both affected nuclei despite an additional 10 week survival time. In the GLv the cell loss was greater in the neuropil lamina (25%) than in the internal lamina (5%). Measurements of neuronal cross-sectional areas revealed a 20% reduction on the affected sides in both nuclei which was apparent by the end of the first week. Changes in cell area paralleled changes in cell number: neuronal atrophy remained constant following additional survival time and neurons in the GLv neuropil lamina were more severely reduced in area (30%) than neurons in the internal lamina (5%).

Although the EMN and GLv have different patterns of volume reduction following eye removal, the EMN and GLv neuropil lamina show marked similarities. In both sites we have demonstrated transneuronal cell atrophy as well as transneuronal cell loss. The latter observation seems particularly interesting in view of the relatively few studies of anterograde transneuronal degeneration which have quantified cell loss.

2587 TROPHIC EFFECTS OF MUSCLE ON NERVE II. ACETYLCHOLINE (ACh) SENSITIVITY AND RELEASE. Guillermo Pilar, Jeremy Tuttle*, and Ken Vaca*, Physiology Section, Biological Sciences Group, UConn, Storrs, CT 06268

During normal in vivo development, ciliary neurons do not form intraganglionic, neuron-neuron synapses. However, embryonic ganglion cells form contacts upon themselves having typical synaptic ultrastructure during the initial two weeks in culture. These anomalous interneuronal synapses are ineffective, due either to a lack of sensitivity to ACh or to the inability to release ACh at these synapses. These phenomena were further examined by: 1) testing cultures of these neurons for the release of ACh; 2) examining other culture conditions which might lead to the retention or induction of membrane sensitivity to transmitter.

1) Ciliary ganglion neurons take up the ^{3}H-choline (^{3}H-Ch) from the medium and convert up to 50% of the transported ^{3}H-Ch into ^{3}H-ACh. Also the ^{3}H-ACh synthesized is primarily derived from ^{3}H-Ch taken up by a Na^+-dependent high-affinity process. Cultures were then tested for ^{3}H-ACh release in response to high $[K^+]_o$ depolarization. In all cases, depolarization caused the release of a significant proportion of the neuronal ^{3}H-ACh into the medium. However, the ACh released by neurons cultured alone was only 50-60% Ca^{++}-dependent, with the remainder not requiring extracellular Ca^{++}. Thus, the neurons cultured under conditions which seem to favor interneuronal synaptogenesis are capable of ACh release and the synapses formed are ineffective due to a lack of sensitivity to ACh. 2) Most ciliary ganglion neurons from ST 32 embryoes lack sensitivity to iontophoretically applied ACh in the initial weeks of pure neuronal culture, but the frequency of sensitive neurons increases by 4 weeks. In addition, the neurons that respond to ACh have very restricted "spots" of higher sensitivity on the soma, with other areas showing little responsiveness. However, when we tested the effect of co-culture of ciliary ganglion neurons with striated muscle upon their ability to respond to ACh, all of the neurons tested depolarized in response to applied ACh, even if tested during the first two weeks in vitro. Furthermore, the neuronal somas displayed a relatively uniform and high sensitivity over their entire surface. As has been reported by others, the neurons in these co-cultures formed functional neuromuscular synapses. We conclude that under in vitro conditions, contact and synaptogenesis with muscle induces either the retention or more rapid restoration of neuronal ACh sensitivity. This behavior in vitro may be similar to the response to axotomy in vivo. Non-transmitting, but otherwise normal-appearing interneuronal synapses are not effective in this regard. Supported by NIH-NS10338, NS5382, and the Univ. of Conn. Research Foundation.

2588 NEURITE OUTGROWTH ACTIVITY (NOA) IN SOLUBLE EXTRACTS OF CHICK EMBRYO -- ONTOGENY, AND EMBRYONIC DAY (ED) 8 REGIONAL DISTRIBUTION. Richard J. Riopelle and Donald Cameron*. Queen's University, Kingston, Ontario, Canada, K7L 3J7.

A single cell bioassay for βNGF using 8 day chick embryo sensory ganglion neurons (Sutter, Riopelle, Harris-Warrick and Shooter, J. Biol. Chem. 1979, in press) has been used to quantitate endogenous factors in soluble extracts of chick embryo that promote neurite outgrowth.

NOA can be detected on ED1 and has increased by an order of magnitude by ED6 when expressed on a per embryo basis. When expressed on a per microgram soluble protein basis NOA rises rapidly from ED1 to 4 and begins to decline at the time of a growth spurt of the chick embryo (ED5-6).

At ED8, NOA is in highest concentration in muscle, heart, gut and sensory ganglia and is in lower concentration in structures of the neuraxis.

Only a fraction of NOA has immunological cross-reactivity with mouse βNGF when heat inactivated rabbit antibody to purified mouse βNGF is used. At concentrations of antibody that are four orders of magnitude (10^4) greater than those required to suppress βNGF neurite outgrowth by 50%, there is less than 20% suppression of extract-induced neurite outgrowth from whole embryo or from any organ.

NOA is reduced by approximately 50% following incubation at 56°C for 60 minutes, and by 40-50% when stored in a lyophilized form at -80°C for 6-8 months.

2589 GLIAL SEROTONIN TRANSPORT IN THE FROG FILUM TERMINALE: POSSIBLE MODULATION BY DESCENDING SEROTONERGIC FIBERS. T. Ritchie, S. Glusman, and B. Haber. Marine Biomed. Inst., Dept. Human Biol. Chem.&Genetics & Dept. of Neurology, UTMB, Galveston, TX 77550.

The frog filum terminale (FT) is that portion of the spinal cord (SC) extending caudally beyond the level of the last spinal root. It is morphologically different from the SC, having few neuronal elements, and can be considered as largely a glial preparation. We have previously shown that the FT contains sodium-dependent, temperature sensitive, high-affinity transport systems for the uptake of GABA and serotonin (5HT), with respective Km's of 27μM and 2μM. The high-affinity 5HT transport system is inhibited in the FT by chlorimipramine, desipramine, Lilly 110140, and a variety of indoleamine analogs to extents comparing favorably with those seen for 5HT uptake in clonal cell lines of glial origin and in brain slices and synaptosomes. The accumulation of GABA and 5HT by the glial cells of the FT was confirmed by autoradiographic studies.

The accumulation of 5HT at all levels caudal to the last spinal root is higher than in the lumbar enlargement (LE), and is maximal in the conus medullaris (CM). This correlates well with measured values of 5HT along the frog cord, highest values being in the CM. In contrast to this, the uptake of GABA, while being higher at all levels caudal to the last spinal root than in the LE, increases in a rostro-caudal direction with maximal rate of uptake in the most caudal portion of the FT. Preliminary studies show a similar rostro-caudal increase in the rate of norepinephrine uptake along these same regions.

The presence of descending serotonergic fibers in the lumbar region of the frog cord suggested to us that the higher rate of 5HT uptake by the CM may be due to the presence of descending serotonergic nerve fibers ending in the CM. To test this, lesioning was performed by transversely sectioning the cord at the level of the last spinal root, and a period of 10 days was allowed for degeneration of nerve fibers. At the end of this period a drastic decrease in the rate of 5HT uptake was observed only in the CM. Intraventricular injection of 50μg of 5,6-dihydroxytryptamine, which results in selective destruction of serotonergic terminals, and allowance of 2 weeks for the degeneration process to occur, also resulted in a decrease in 5HT uptake by the CM with little effect being seen in the more caudal portions of the FT. These observations would suggest that the presence of descending serotonergic fibers in the CM modulates glial transport of 5HT. The specificity of this modulation is under investigation.

2590 NEUROTROPHIC REGULATION OF MUSCLE GLUCOSE-6-PHOSPHATE DEHYDROGENASE IN VITRO. Norman Robbins, Dept. Anat., Case West. Res. Schl. Med., Cleveland, O. 44106

In vivo, glucose-6-phosphate dehydrogenase (G6PD) activity of rat diaphragm increases 12 hrs after denervation, but the increase is delayed if a 3 cm nerve stump is left attached to the denervated muscle (Robbins & Carlson, Br. Res., in press). In order to analyze this apparent neurotrophic regulation further, an in vitro system was devised in which 2 strips of rat diaphragm with and without a 2.5 cm nerve stump ("+N" and "-N", resp.) were organ cultured in parallel in Med. 199 at 36°. A control strip was taken from the same muscle at the beginning of culture.

In -N strips, G6PD activity increased progressively by 34% at 16½ hrs and 54% at 19 hrs in vitro, provided the culture medium was changed at 11 hrs. Without the medium change, the increase was slower, presumably because of leakage of factors from nerve terminals before they degenerate. In +N strips with medium change at 11 hrs, G6PD activity was not increased at 16½ hrs and differed significantly (34%, $p<0.001$) from paired -N strips. If the nerve was crushed or cut at the point of entry into the muscle and left in culture, no nerve stump effect was observed. The nerve stump effect persisted in paired +N and -N strips exposed continuously to curare (1.5-3ug/ml). Curarization did not alter the time course of enzyme increase. Addition of nerve extracts or effluents from stimulated nerve-muscle preparations did not affect the enzyme increase. Also, -N and +N strips cultured in the same vessel showed no mutual influence on G6PD activity. However, transfer of medium conditioned by +N strips to -N strips in the 11-16½ hr period had a small but significant effect, dimishing enzyme increase by 11% ($p<0.05$) compared to paired controls treated with -N conditioned medium.

Conclusions: The neurotrophic effect of the nerve stump on G6PD activity does not require in vivo factors such as stretch, blood flow, and circulating cells or factors. 2. The effect is independent of physiological acetylcholine action on nicotinic receptors. 3. A soluble factor, probably leaking slowly and spontaneously from nerve terminals, produces effects similar to those of a nerve stump.

2591 Physiological and anatomical consequences of sensory denervation of the cornea. B. Schimmelpfennig* and R. Beuerman, Stanford University Medical Center, Stanford, CA 94305.

A trophic action of the sensory nerves of the cornea and their target tissue, the epithelium, was first suggested by Magendie in 1824. However, convincing evidence for this type of interaction has not been obtained. The present studies show that deafferentation produces functional as well as morphological alterations in the epithelium.

Radiofrequency thermocoagulation, delivered by an electrode inserted through the soft palate, was used to produce lesions in the medial portion of the trigeminal ganglion in anesthetized albino rabbits. Although there was no behavioral response to punctate mechanical stimulation of the cornea following the lesion, normal blinking (4 to 5/hour) was retained. Nerve degeneration was confirmed by electron microscopy. Slit-lamp observations revealed that the corneal surface was free from defects. Permeability in the denervated corneas was found to be significantly greater ($p<.005$, N=11) when determined by measurement of aqueous humor fluorescence 30 min after the instillatin of 5% fluorescein. Re-epithelialization of a 4 mm centrally placed abrasion was examined in 13 animals. After 40 hr all control corneas were epithelialized, but the denervated corneas were only 72% covered. Complete counts of mitotic figures were made in 6 mm dia. central corneal buttons and stained by the orcein method. The denervated corneas contained significantly fewer mitoses ($p<.001$).

Electron microscopy of the denervated epithelium has revealed alterations in structures responsible for the maintenance of cell shape and adhesion. Transmission microscopy in 6 rabbits showed that the cytoplasmic density of the epithelial cells decreased due to a loss of tonofilaments. Both hemidesmosomes and desmosomes stained less densely; in addition a decrease in number and size of the hemidesmosomes was noted. Scanning microscopy showed an abnormal desquamation of the surface cells many of which had lost microvilli and were smooth. In conclusion, it is shown here that the sensory innervation of the corneal epithelium is important to the maintenance of its tissue properties.

2592 EFFECTS OF NICOTINE ON NEURITE OUTGROWTH IN CHICK SENSORY AND SYMPATHETIC GANGLIA: COMPARISON WITH NERVE GROWTH FACTOR. Betty F. Sisken and Jesse E. Sisken.* Wenner-Gren Research Laboratory, College of Engineering and Department of Pathology, College of Medicine, University of Kentucky, Lexington, Kentucky 40506.

To date only a few factors (NGF, conditioned medium, dibutryl cAMP, electrical stimulation) have been reported to stimulate nerve fiber outgrowth from ganglionic explants. Previous observations that nicotine stimulates microfilament function in Hela cell cleavage furrows (Vedbrat, et al 1979) led to the hypothesis that nicotine may also stimulate neurite outgrowth since the latter might be dependent upon microfilament function (Yamada et al, 1971). In this report, we present evidence that nicotine, a sympathomimetic alkaloid, can produce a substantial stimulation of neurite outgrowth in both sensory and sympathetic ganglia. Nicotine in concentration ranges of 15-500 µg/ml was tested on 8 day chick trigeminal, dorsal root and sympathetic ganglia explanted onto collagen-coated Falcon culture dishes. They were cultured in Dulbecco MEM supplemented with 10% calf and 5% fetal calf sera, glucose and penicillin-streptomycin. Nerve fiber outgrowth was evaluated after 3 days in vitro by a scoring procedure which took into account number, length, degree of branching and distribution of neurites around the explant. This outgrowth was compared to untreated control cultures and cultures treated with 200 units/ml of 2.5 S NGF (gift of R. Bradshaw, Washington University). Findings will be presented to demonstrate that significant stimulatory effects were produced by nicotine in the concentration range of 80-250 µg/ml at a pH range of 6.8-7.2. Preliminary evidence suggests that sympathetic ganglia are more responsive to nicotine than either trigeminal or dorsal root ganglia. Studies are in progress to determine the mechanisms behind this effect.

Supported in part by the University of Kentucky Tobacco and Health Research Institute, Project Number KTRB 2411.

2593 REGULATION OF SODIUM ION EXTRUSION BY NERVE GROWTH FACTOR IN RESPONSIVE NEURONS: A COMPARISON OF DIFFERENT GANGLIONIC CELL PREPARATIONS. Stephen D. Skaper* and Silvio Varon. Dept. Biol., Sch. Med., UCSD, La Jolla, CA 92093.

Nerve Growth Factor (NGF) is necessary for maintenance and growth of neurons from sympathetic and dorsal root ganglia. Traditional responses to NGF are observed only several hours following presentation of the factor. Short-latency responses, occurring within minutes, are more likely to reflect primary events involved in the mode of action of NGF.

Cell suspensions from embryonic chick dorsal root ganglia lose the ability to take up hexose (and certain other small molecules) when deprived of NGF, but recover it promptly if NGF is supplied within 6 hr. The recovery occurs over one to several minutes, depending on NGF concentration. The dependence on Na^+ gradients of these NGF-regulated uptake systems has led to the discovery that NGF controls extrusion of Na^+ (and, thus, intracellular Na^+ levels) in these ganglionic neurons. Incubation of the cell suspension with $^{22}Na^+$ for 6 hr causes accumulation of radioactivity which is 6 times greater when no NGF is present. Subsequent presentation of NGF to $^{22}Na^+$-loaded cells causes extrusion of the $^{22}Na^+$ with a speed (minutes) which is dependent on NGF dose. This "sodium response" (i.e., accumulation in the absence of NGF and extrusion on its delayed presentation) has now been examined with various ganglionic materials known to be NGF-sensitive. Qualitatively similar results are found with 1) intact as well as dissociated chick embryo dorsal root ganglia, 2) intact and dissociated chick embryo sympathetic ganglia, and 3) dissociated, but not intact dorsal root ganglia from neonatal mouse. In these last ganglia, it has been previously reported that cultured neurons do not require exogenously supplied NGF when adequately supplemented with ganglionic nonneurons (e.g., within the intact ganglion). Chick sympathetic ganglia and mouse dorsal root ganglia also allow the separation of viable neuronal subpopulations. Data to be presented will attempt to correlate the occurrence of Na^+ responses with NGF requirements for neuronal survival in culture. (Supported by NINCDS grant NS-07606).

2594 TROPHIC EFFECTS OF MUSCLE ON NERVE I. ACETYLCHOLINE (ACh) SYNTHESIS. Ken Vaca*, Jeremy Tuttle* and Guillermo Pilar (SPON: W. Chapple). Physiology Section, Biol. Sci. Gp., Univ. of Conn., Storrs, Conn. 06268.

The terminals of the ciliary nerve of the chick initially form functional synaptic contacts with iris muscle at embryonic stages 34-40. At the onset of this period the nerve terminals do not exhibit a Na^+-dependent high affinity choline (Ch) uptake system, and the very low level of ACh synthesis from ^{3}H-Ch is insensitive to removal of Na^+. At St. 36 ^{3}H-ACh synthesis gradually increases, the increment being Na^+-dependent. However, ACh synthesis in the embryonic iris is insensitive to a conditioning $[K^+]_o$ depolarization even as late as ST. 43. Prior to hatching the nerve terminals show a small response to conditioning depolarization, an augmented ACh synthesis, but by 2 days ex ovo this response has increased by an order of magnitude. Ultrastructural examination of the developing ciliary terminals reveals few synaptic vesicles and other specializations at early stages, which may underlie the rapid fatigability of immature synapses. Near hatching (St. 44) clustering of vesicles in regions of synaptic contact starts to appear, eventually attaining a closely packed morphology in the ex ovo chick. This correlation between vesicular accumulation and responsiveness to conditioning depolarization supports the suggestion that regulation of Ch transport and ACh synthesis depends primarily upon the recompartmentation of cytoplasmic ACh into vesicles.

In the absence of other cell types, dissociated ciliary neurons (St. 33) form ineffective synapses with each other in culture. Yet a few days after plating they are able to synthesize considerable amounts of ACh. 25 to 35% of the ^{3}H-Ch accumulated by these cells is via Na^+-dependent transport. This Na^+-dependent uptake is the predominant source of Ch for ACh synthesis. After a conditioning depolarization, these cells respond with a small increase in ACh synthesis (15-20%). A few days after dissociated ciliary neurons are plated onto cultured myotubes, resting levels of ACh synthesis are several-fold higher than muscle-free neuron cultures plated at the same time (on a per cell basis). Furthermore, the neurons respond to a conditioning depolarization with a large increase in ACh synthesis (100%). These cells are able to synthesize ACh at a rate comparable to that in mature parasympathetic neurons. It is suggested that cholinergic characteristics are present at a low level prior to synapse formation and then become progressively concentrated at points of synaptic contact. Full expression of the mature phenotype may require inductive interactions with appropriate target tissues. Supported by NIH-NS10338, NS5382 and the Univ. of Conn. Research Foundation.

2595 CHARACTERIZATION OF SPONTANEOUS TRANSMITTER RELEASE AND THE EFFECTS OF TEMPERATURE IN NORMAL AND DYSTROPHIC CHICKENS. S. Yeagle*, J. E. Warnick and E. X. Albuquerque (SPON: C. S. Hudson). Dept. Pharm. and Exptl. Therap., Univ. MD. Sch. Med., Baltimore, MD 21201.

Miniature endplate potentials (MEPPs) were examined in posterior latissimus dorsi (PLD) muscles of normal (line 412) and dystrophic (line 413) chickens from 6 to 12 week ex ovo. At 23° C the MEPP amplitude in surface fibers of normal PLD muscle (0.37 + 0.02 mV) was greater ($P < 0.01$) than dystrophic (0.26 + 0.02 mV) whereas the frequency of MEPPs in normal fibers (0.23 + 0.02 sec^{-1}) was similar to that seen in dystrophic fibers (0.24 + 0.02 sec^{-1}). Increasing the temperature to 40° C produced a unimodal exponential increase in MEPP frequency in both normal and dystrophic fibers with a Q_{10} between 2 and 3 and energy of activation between 30-40 kcal. The difference in MEPP amplitudes were sustained at 40° C (0.40 + 0.03 mV in normal vs. 0.29 + 0.03 mV in dystrophic; $P < 0.05$), while the MEPP frequencies remained indistinguishable (0.93 + 0.20 sec^{-1} in normal vs. 2.44 + 1.04 in dystrophic). MEPPs from fibers of both lines had similar rise times at both 23° C (3.32 + 0.16 msec in normal vs. 3.57 + 0.30 msec in dystrophic) and at 40° C (0.42 + 0.12 in normal vs. 0.65 + 0.10 in dystrophic). Half-decay times of MEPPs in both lines were also similar at 23° C (6.81 + 0.24 msec in normal vs. 7.79 + 0.59 msec in dystrophic) and at 40° C (0.79 + 0.06 msec in normal vs. 0.88 + 0.13 msec in dystrophic). At 23° C input resistance at the endplate region in normal fibers (0.44 + 0.03 MΩ) was not significantly different from dystrophic fibers (0.41 + 0.06 MΩ). Addition of neostigmine (3 μM) to the bathing medium or treatment with diisopropylphosphorofluoridate (1 mM) at 23° C produced a similar degree of potentiation of MEPP amplitude in normal and dystrophic fibers. It appears unlikely that the observed differences in the amplitudes of MEPPs in normal and dystrophic fibers can be attributed to differences in input resistance or junctional acetylcholinesterase alone. It seems probable that the decrease in MEPP amplitude in dystrophic fibers is due to either some alteration in the transmitter release process as suggested previously (Exp. Neurol. 63:135, 1979) or to a reduced access of acetylcholine to the receptor site since it has been shown that junctional acetylcholine sensitivities of normal (line 200) and dystrophic (line 304) chickens are similar (Exp. Neurol. 43:21, 1974). In addition, at temperatures from 18 to 41° C the MEPP frequency in PLD muscle fibers of both normal and dystrophic chickens fails to show the bimodal response to temperature increases seen in some other vertebrate species (J. Physiol. 132:650, 1956). (Supported in part by USPHS Grant NS-12063 and a grant from the Muscular Dystrophy Association of America.)

VISION

2596 SPATIAL AND TEMPORAL PROPERTIES OF RECEPTIVE FIELDS IN MONKEY AND CAT VISUAL CORTEX. Duane G. Albrecht, Lisa G. Thorell* and Russell L. De Valois*. Department of Psychology, University of California, Berkeley CA 94720.

The spatial and temporal variations are the two most important aspects of a visual stimulus with respect to evoking a response in a visual cortical neuron in area 17. The structure of the receptive field demands a specific spatial and temporal distribution of light. To quantify these space-time contingencies, one would like to have a method of analysis which produces a concise, accurate, general description. Use of spatial-temporal sinusoidal grating patterns, within the context of linear systems analysis, can potentially provide such a description. In this study we used such a method of analysis to measure (a) the spatial tuning, (b) the temporal tuning, and (c) the interaction between two.

With respect to the spatial tuning, the results show that most of the cells have a band pass characteristic; each cell attenuates its response to both high and low spatial frequencies. The average width of the band at half the maximum response (averaged across all of the cells) is 1.2 octaves. There is, however, a great deal of variability in this regard from cell to cell; the narrowest bandwidth was 0.5 octaves and the broadest was greater than 2.5 octaves. There is also a great deal of variability, from cell to cell, with respect to the locus of the peak of the spatial tuning function.

With respect to the temporal tuning function, while most of the cells (75%) do show both low and high frequency attenuation, the tuning is extremely broad (in comparison to the spatial tuning). There is a great deal of variability from cell to cell with respect to the width of the tuning function and the locus of the peak. The mean bandwidth for the entire sample was 3 octaves and the range extended from 2 to 6 octaves. The mean peak for the entire sample was 3 Hertz and the range extended from 0.5 Hertz to 16 Hertz. Somewhat surprisingly, there were no obvious differences in the temporal properties of simple vs complex cells. Correlation (across cells) of the peak of the spatial tuning function with the peak of the temporal tuning function revealed a very low negative correlation (-0.2).

Human psychophysical experiments have shown a clear interaction between spatial and temporal variables of a visual stimulus. Parametric examinations of these two variables for area 17 cells showed that for the vast majority of cells no such interaction exists. That is, for most cells the spatial tuning remains invariant as a function of temporal frequency. A few cells, however, showed a systematic interaction between these two variables.

2597 REGIONS WITH CONVERGENT VISUAL INPUT IN AREA 18 OF THE CAT. K.Albus and D.Sanides*. Dept. Neurobiology, MPI Biophysic. Chemistry, 3400 Goettingen, FRG.

In normal adult cats three regions with callosal projections (callosal islands) have been identified at the lateral limit of area 18 by anterograde and retrograde axonal tracing techniques. Receptive fields of single units and multiunits have been recorded in the callosal islands and were found to reach an extremely large size. Their centers lay either on the vertical meridian or 10°-20° in the contralateral hemifield. However similar as in other regions with callosal input the fields reached across the vertical meridian and often considerably into the ipsilateral hemifield. The callosal islands were wedged in between acallosal parts of lateral area 18 which represent the periphery of the contralateral visual field(periphery islands). Thalamic input to these different two parts of lateral area 18 has been identified by retrograde tracing with peroxidase. The periphery islands have been found to receive heavy input from the main part of the lateral geniculate nucleus (LGN) and light input from the medial interlaminar nucleus (MIN). In both nuclei it was restricted to portions with peripheral retinal input. The callosal islands have been found to receive peripheral visual input from the LGN, and a rather heavy projection from portions of the MIN representing the contralateral retina, the midline of the retina as well as the ipsilateral retina. It thus appears that the extremely large receptive fields in the callosal islands of lateral area 18 are produced by converging afferent fibers with widespread retinal input.

In some animals large receptive fields covering nearly the entire visual field were found also at the representation of the vertical meridian in area 18. The pattern of thalamic connections of these medial parts of area 18 resembled that of the callosal islands in lateral area 18.

The callosal regions in area 18 fulfill the criterion of a separate visual area because they contain a representation of most of the visual field. Unlike the remainder of area 18 and other visual cortical areas the representation is not or only poorly retinotopically organized.

2598 BRIEF LIGHT DEPRIVATION ALTERS NEURAL ORGANIZATION IN HUMANS. Patricia Apkarian*, Dennis M. Levi*, Ken Nakayama* and Christopher W. Tyler* (SPON: P. Bach-y-Rita). Smith-Kettlewell Institute of Visual Sciences, San Francisco, CA 94115.

We have used the steady state visual evoked potential (VEP) to study the changes in neural responsivity in the human brain following very brief periods (e.g., 10 sec) in the dark. Under our recording conditions, the synchronous response to uniform field flicker and counterphase flickering gratings reaches a maximum after about one second of stimulation. Following brief light deprivation, the buildup of neural activity elicited by the same stimulus is delayed by as much as 20 seconds, after allowing adequate time for light adaptation prior to recording.

This effect, which is clearly present after only 10 seconds in the dark, asymptotes after 1 minute. Control studies rule out pupillary responses, accommodation and convergence as the source of the effect, and the time course dissociates it from previously described neural and photochemical effects of light and dark adaptation. In addition, the effect of brief periods of darkness is different for the fundamental (f) and second harmonic (2f) of various uniform field flicker frequencies. Similar effects also occur with counterphase flickering gratings; however the profiles vary depending on the spatial and temporal frequency of the stimuli.

The high degree of specificity found in these studies does not conform with conventional light adaptation mechanisms, but indicates selective modification of different neural mechanisms resulting from brief light deprivation.

2599 SMOOTH PURSUIT EYE MOVEMENTS. A. Terry Bahill and B. Todd Troost, Biomedical Engineering, Carnegie-Mellon University, Pittsburgh, PA 15213

The easiest target to track with smooth pursuit eye movements is one that is moving sinusiodally. To track such a target humans use the saccadic system, the smooth pursuit system, and high level prediction processes. In order to limit our study and eliminate the prediction process we used nonpredictable target motions. Gaussian white noise was too confusing and induced numerous saccades. We used a waveform with a series of constant velocity ramps each of which has an unpredictable velocity and duration. The bandwidth of the target waveform was important; a bandwidth of one hertz was optimal.

The recorded eye movements consisted of a combination of smooth pursuit and saccades---dual mode tracking. We modified this record by removing all of the saccades to yield a cummulative smooth pursuit eye movement record---single mode tracking. We visually inspected these time domain records, but did all of our data analysis in the frequency domain.

Fatigued subjects, and patients with progressive supranuclear palsy had large differences between the single mode and dual mode transfer functions, particularly around one hertz. Patients with unilateral posterior hemispheric disease had smooth pursuit movements in only one direction which caused a large low frequency gain for the single mode transfer function and a very low value for the coherence function at low frequencies.

2600 RETINAL SENSITIVITY DEFECT IN THE MUTANT MOUSE PEARL. G. W. Balkema, Jr., and L. H. Pinto. Dept. of Biol. Sci., Purdue Univ., West Lafayette, IN 47907

We have previously reported the presence of two visual defects in the mutant mouse pearl. (1) Pearl does not show visually evoked nystagmus for any test luminance, but its post-rotatory nystagmus is normal. (2) In recording from tectal cells we found that at dim backgrounds a threshold stimulus had to be about 2 log units more luminous for pearl than for normal mice; at higher backgrounds pearl thresholds approach normal values. This sensitivity deficit does not seem to be caused by a defect in pearl's photoreceptors, since the neuronal mechanism responsible for the generation of the ERG is normal.

In a search for histological abnormalities we injected the eyes of pearl mice with tritiated proline and prepared the brains for autoradiography. This method did not reveal any defects in the projections to the superior colliculus or the primary visual cortex in pearl mice. Furthermore, when we examined 1 μm plastic sections that were embedded in epon/araldite and stained with toluidine blue, we could find no differences between the retinas from pearl and normal mice.

Next, we tried to narrow down possibilities for anatomical sites of pearl's sensitivity deficit by recording from the axons of single retinal ganglion cells in pearl and normal mice. Of the different types of ganglion cells we saw in both normal and pearl, we selected the ones with concentric receptive-field organization for a comparison of sensitivities. Incremental threshold measurements showed a deficit similiar to the one we observed in pearl tectal cells: with dim backgrounds (-5 to -3 log cd/m^2) pearl ganglion cells required a stimulus 1.7 log units greater in luminance than normal ($p < 0.001$); with more luminous backgrounds (0 to 2 log cd/m^2) pearl's sensitivity came close to wild type values.

Thus, we have found that the coat color mutant, pearl, has in addition to its lack of OKN, a retinal sensitivity deficit in the dark-adapted state. Furthermore, this deficit in pearl appears to lie between the site of generation of the ERG and the ganglion cells in pearl's retina.

2601 **SOMATOSENSORY AND VISUAL RECEPTIVE FIELD CHARACTERISTICS OF SINGLE UNITS IN THE NUCLEUS INTERCOLLICULARIS OF THE PIGEON.** **Gary O. Ballam* (SPON: D. M. Schroeder). Indiana University, Bloomington, Indiana 47401**

Microelectrode recordings from the Nucleus intercollicularis (ICo) of the unanesthetized pigeon indicate the presence of neurons responsive to visual and tactile stimuli. The receptive field size of units driven by tactile stimuli varies from 5% to 100% of the feathered body surface area. The units driven by tactile stimuli can be divided into 3 distinct groups according to receptive field size. The somatosensory receptive field (SRF) size of units representing these three groups peaks at areas covering 15%, 48% and 100% of the body surface. Units representing the smaller size group are more likely to demonstrate somatonsensory adaptation characteristics, receive inhibitory visual inputs from the ipsilateral eye and non-adapting visual inputs from the contralateral eye. Units representing the two larger SRF groups (those which peak at 48% and 100% of the body surface area) have similar receptive field characteristics and contain a smaller percentage of units demonstrating somatosensory adaptation. They also tend to receive either an excitatory or no visual input from the ipsilateral eye and have a much larger proportion of visual inputs from the contralateral eye which demonstrate adaptation. The visual receptive fields (VRF's) of units driven by the contralateral eye range in size from 15° to 180° of visual arc and can be divided into 2 groups according to receptive field characteristics. Units representing the group having smaller VRF's peak at 90° of visual arc and contain a larger proportion of inputs from the smaller sized SRF group. The units with smaller VRF's do not tend to demonstrate adaptation. They receive very few excitatory inputs and a relatively large proportion of inhibitory inputs from the ipsilateral eye. The second visual group, comprised of units with larger VRF's, contains a greater percentage of inputs from large SRF's and more units tend to demonstrate adaptation. The units with larger VRF's also receive a greater percentage of excitatory and a lesser percentage of inhibitory inputs originating from the ipsilateral eye. These different groups of units driven by visual and/or tactile stimuli may represent populations of neurons in the ICo associated with different behavioral responses such as orientation, focused attention or alertness.

2602 *LIMULUS* VENTRAL PHOTORECEPTORS: DO THEY SEND INFORMATION TO THE BRAIN? Ranjan Batra*, Mildred Behrens* and Steven Chamberlain*. (SPON: R. B. Barlow, Jr.). Inst. for Sensory Res., Syracuse University, Syracuse, NY 13210; and Masonic Medical Research Lab., Utica, NY 13503.

Although *Limulus* ventral photoreceptors have been extensively utilized for studies of basic photoreceptor mechanisms, little is known of their central connections or functions in the larger context of the animal's visual system. Because the ~1.5 cm long central axons do not conduct nerve impulses, it has often been suggested that ventral photoreceptors may not provide visual information to the adult animal.

We have stained single photoreceptors and their central terminations by intracellular injection of cobalt ions. We have recorded light-evoked depolarizing potentials intra-axonally at various points along the ventral optic nerve and in the brain.

The ventral optic nerve makes connections with the ganglion cell layer of the medulla along the ventral and anteromedial borders of the medullar neuropil. The axons of single cells terminate in a ramification of fine processes covering about 0.1 mm^2 of medullar surface.

Intra-axonal recordings reveal depolarizing potentials (2-15 mV) elicited by illumination of cell bodies in the distal tip of the ventral optic nerve. These depolarizing responses have been recorded both at various points along the nerve trunk and within the protocerebrum itself along the anterior margin of the medulla.

Taken together these findings support an alternate view that even in adult animals, the ventral photoreceptors of *Limulus* may make specific and functional connections with higher visual centers.

2603 Orientation Anisotropy in Striate Cortex of Awake Monkeys. Roman Bauer*, Bruce Dow and Robert Vautin* (Spon. E. Koenig) Neurobiology Division, SUNY, Buffalo, NY 14226.

In a series of penetrations through foveal striate cortex in alert behaving macaque monkeys, we noticed that the first encountered striate cell typically had a preference for lines oriented at 45° to horizontal and vertical. This was a somewhat surprising result in view of Mansfield's (1974) earlier report of an anisotropy for horizontal and vertical orientations among foveal striate cells. Review of our own data from marked penetrations in acute, anesthetized animals suggested that the horizontal/vertical anisotropy was in fact most prevalent in middle and lower layers of striate cortex.

In order to pursue this issue more systematically, we have been examining changes in orientation at 200-250 μ intervals from pial surface to white matter in penetrations at various angles to the cortical layers. The angle of our electrode is determined by the angle of the recording cylinder base with the monkey's skull. Variations in recording angle within a given hemisphere are thus primarily dependent on the contours of the cortical surface. To avoid bias in our test procedure we routinely present a series of standard orientations to every cell and use computer plotted histograms as a measure of response magnitude.

In a typical penetration through foveal striate cortex, the first encountered cells have orientation preferences within about 15° of diagonal. Subsequent cells prefer orientations close to this, with slight progressions in either a clockwise or counter-clockwise direction until the middle of layer 4, when orientation tuning becomes much broader or disappears completely. Toward the lower part of layer 4 the orientation suddenly jumps by 45° or more and then remains about the same until we enter white matter.

The most parsimonious interpretation of our data is that there are alternating horizontal and vertical orientation dominance columns in foveal striate cortex. Each column must necessarily consist of 2 subregions, one responsible for clockwise rotation, the other for counterclockwise rotation. Clockwise rotation from vertical and counterclockwise rotation from horizontal would both lead to the same limit, namely +45°, suggesting that 2 such subregions should lie adjacent to one another. Similarly, horizontal clockwise and vertical counterclockwise subregions should also be adjacent. The anisotropy for diagonal orientations in upper layer cells bears some resemblance to the binocularity of upper layer cells (Hubel & Wiesel, 1968), except that inhibitory mechanisms would appear to play a greater role in generating diagonal orientations, and two different diagonals must be generated instead of a single cyclopean eye.

2604 EFFECTS OF INFEROTEMPORAL COOLING ON PERFORMANCE OF A VISUAL RECOGNITION TASK. Richard H. Bauer, John P. Jervey* and Joaquin M. Fuster. Department of Psychiatry and Brain Research Institute, School of Medicine, University of California, Los Angeles, Calif. 90024.

Ablation studies in the monkey have implicated the inferotemporal cortex (area TE) in learning and retention of visual discriminations. Presumably lesions of this cortical region interfere with some aspect of visual memory. The present study examines the effects of reversible inferotemporal lesion on performance of delayed matching-to-sample, a behavioral task that demands short-term retention of visual stimuli. For this study the stimuli were circles of red and green light projected on a panel. A trial required from the animal two successive instrumental responses. The first occurred immediately upon presentation of one color, the sample, which initiated the trial. This response turned the sample color off and started a preset delay. The second response occurred at the end of the delay, when the two colors appeared simultaneously and the animal had to select the one that matched the sample. Correct choices were rewarded. The sample color and the position of the matching stimulus were changed randomly between trials. Cryogenic brain probes were implanted bilaterally in three monkeys trained to perform the task. The probes conformed to the convexity of the temporal lobe and were epidurally placed, covering a major portion--about 1 cm^2 --of TE cortex. Cortical temperature was controlled by implanted thermistors. Bilateral inferotemporal cooling to 20°C produced the following reversible effects: 1) An increase in the number of errors; this effect was more pronounced on trials with long delay (8, 16 or 32 sec.) than on those with short delay (1 or 4 sec.). 2) An increase in reaction time on presentation of the sample color. 3) An increase in reaction time on presentation of the two colors for delayed matching (choice reaction time). The results indicate a participation of the inferotemporal cortex in short-term retention of visual stimuli. The effects of inferotemporal cooling on reaction time, especially choice reaction time, may be secondary to the difficulty that inferotemporal lesion induced in mnemonic function.

2605 VISUAL PROJECTIONS OF THE TREE SHREW CLAUSTRUM: AN ANTEROGRADE AND RETROGRADE TRANSPORT STUDY. Mark F. Bear* and Russell G. Carey* (SPON: P. Kaufmann). Dept. Psychol., Duke Univ., Durham NC 27706.

We have previously reported that the dorsal claustrum projects to striate cortex in the tree shrew, Tupaia glis (Carey, Fitzpatrick & Diamond, Anat. Rec. 193, 1979). Further investigations have shown that injections of tritiated amino acids in striate cortex lead to autoradiographic grains concentrated over this same region of the claustrum. The present study was undertaken to examine the laminar organization of these connections by making iontophoretic injections of either tritiated amino acids or HRP into the claustrum.

Injections of amino acids in the claustrum produce a heavy accumulation of transported label in area 17 and a considerably smaller amount of label in the extrastriate regions. In striate cortex the terminal grains are primarily localized over layer IV and to a lesser degree over layers IIIb, VI and I. In extrastriate cortex, terminal grains are again mainly over layer IV with lesser activity over layers I and VI. No activity is seen in layer III outside of striate cortex. After injections of HRP in the same region of the dorsal claustrum, labeled cells are found concentrated in layer VI of striate cortex with a few scattered cells being found in the temporal visual areas. Both the claustral projection onto area 17 and the reciprocal projection back to the claustrum are found to be topographically organized. Control injections in the cortex overlying the claustrum lead to a pattern of activity or labeled cells totally different than that seen after injections of the claustrum.

Examination of the activity seen in the thalamus after these claustral injections indicates that the claustrum is reciprocally connected with the visual intralaminar nuclei that were previously shown to project to cortical layer I of striate cortex (Carey, Fitzpatrick and Diamond, Science, 203, 1979).

These results indicate that the claustrum is unique in its anatomical relationship with the visual cortex. First, it is the only nucleus outside the thalamus that receives a projection from cortical layer VI. Second, the claustrum projects heavily to striate cortex and overlaps the terminal zones of all the thalamic nuclei known to project to striate cortex. These findings lead us to speculate that the dorsal claustrum may play a significant role in modulating activity in the visual system, both at the cortical and thalamic levels.

2606 IDENTIFICATION OF RETINAL TERMINALS IN THE CAT SUPERIOR COLLICULUS: ELECTRON MICROSCOPIC AUTORADIOGRAPHY AND DEGENERATION. Mary Behan and John K. Harting. Univ. of Wisconsin, Madison, WI 53706.

We have used the EM-autoradiographic method to determine specific details regarding the terminations of retinocollicular axons in the cat. Our findings confirm and extend earlier studies which have shown that while the major portion of the contralateral projection terminates within the stratum griseum superficiale (SGSl of Kanaseki and Sprague, '74), retinal efferents also end within the more ventrally located SGS2 and SGS3. With a data tablet digitizer interfaced with a computer, we have measured the mean diameter of terminals in sublayers of the superficial grey. These data reveal that contralateral retinocollicular terminals can be grouped into two size classes, the smaller (1.40μm ± 0.33 S.D.) ending within SGSl, and the larger (1.73μm ± 0.67 S.D.) within SGS3. The mean size of terminals in SGS2 is intermediate between that of SGSl and SGS3. Furthermore, we have found that the ipsilateral retinocollicular terminals, which end primarily in the upper 100μm of SGS2, correspond in size with the larger terminals of the contralateral SGS3 (1.87 ± 0.72 S.D.). Thus, it appears that there is a gradient of retinocollicular terminal size within the superficial grey: small terminals are more dorsally located and large terminals more ventrally located. This suggests a correlation with the distribution of W and Y cell axons as established by electrophysiological methods. While we have been able to identify different sized retinocollicular terminals, we have not been able to correlate this difference with either vesicle shape or type of synaptic density. Thus, retinal terminals contain round vesicles and form asymmetric contacts and the morphology of these terminals appears consistent in all layers of the superficial grey. However, there is a correlation between the morphology of profiles postsynaptic to retinal terminals and depth: 40% of postsynaptic profiles in SGSl (W cell input?) contain round vesicles in contrast to 23% in SGS3 and 19% in ipsilateral SGS2 (Y cell input?).

Mean counts of degenerating terminals from 7 contiguous sample areas cross the medio-lateral extent of the ipsilateral colliculus indicate that 5% of retinal terminals are from the ipsilateral eye. This figure of 5% is also obtained from counts of labelled terminals. However, presumably as a result of the patchy distribution of the ipsilateral projection, the proportion of ipsilateral terminals in small areas varies considerably.

2607 THE ANATOMY OF THE OPTIC NERVE OF XENOPUS. Jerry N. Blancato, Dept. Chem. Eng., Univ. of Del., Newark, DE 19711, James E. Fulbrook, and David M. Koester, Inst. for Neurosci. and Sch. of Life and Health Sci., Univ. of Del., Newark, DE 19711.

The optic nerve of adult Xenopus laevis was studied by both light and electron microscopy. Approximately 90% of the fibers are unmyelinated. Unmyelinated fibers were all less than 1.0 micron in diameter. About 3.5 x 10^3 myelinated fibers ranging from 0.8 to 8.0 micra in diameter were counted. Total fiber counts yielded an estimated 6.0 x 10^4 axons in optic nerve of about 200 micra in diameter.

The distribution of fibers appeared to be random in cross sectional areas. Sections of the same nerve, taken several micra apart showed the larger fibers readily changing relative positions, revealing a sinuous path for many cells. Neuroglial cell distribution appears uniform throughout and accounts for approximately 10% of the total area. Previous studies (Wilson, Quart. of Exp. Physio. 56:83, 1971; Reier and Webster, Neurocytol. 3:591, 1974) show comparable findings and some discrepancies attributable to differences in animal ages.

Blood vessels of varying sizes were found exclusively outside the neuronal elements, within the pial sheath. Data dealing with vascular relationships, neuroglial cells types, and distribution and counts of neuronal fibers will be compared to other amphibian species and to reptilian data presented last year (Fulbrook, Soc. For Neurosci. Abs. 4:628, 1978).

2608 SPECTRAL ANALYSIS REVEALS SEPARATE VEP SOURCES RESPONDING TO CONTRAST MODULATION IN THE HUMAN CORTEX. I. Bodis-Wollner, J. Camisa*, and C.D. Hendley*, Mount Sinai School of Medicine, New York, N.Y. 10029.

The amplitude of the steady state visual evoked potential (VEP) to modulation of the contrast of a grating pattern depends on both mean spatial contrast and modulation depth (Bodis-Wollner, Hendley & Kulikowski, Perception 1:341, 1972). In some observers the VEP waveshape recorded near the inion is dominated by the fundamental, in others by second harmonic components (Bodis-Wollner & Hendley, Chap. 9, Visual Evoked Potentials in Man, 1977). A second harmonic contribution may be enhanced by maintaining adaptation to the same grating (Bodis-Wollner & Hendley, Soc. for Neuroscience, 1978, p. 620). Now, in 8 observers we simultaneously recorded VEP-s over the inion and from an electrode 7 centimeters higher. Temporal frequencies were 6, 7.6 and 9.4 Hertz. Spectral analysis of the VEP showed that three observers had similar spectral composition at both electrode locations, but in five others the harmonic amplitudes were unequal with respect to electrode location. Furthermore, a reversal of the ratio of the first and second harmonic amplitude occurred between the two electrodes, irrespective of the temporal frequency of modulation. We conclude that separate sources may respond to the fundamental and to the second harmonic frequency of contrast modulation. The tuning of each source is wide with respect to temporal frequency, but relatively narrow with respect to harmonic ratio. It seems that first and second harmonic components in the human VEP represent separate responses of distinct neuronal ensembles of the visual cortex in which linear or nonlinear properties predominate.

Supported by Grant No. EY01708 of the National Eye Institute.

2609 DISTRIBUTION OF ENKEPHALIN AND SUBSTANCE P IMMUNOREACTIVITY WITHIN AMACRINE CELLS OF THE RETINA. N. Brecha and H.J. Karten, Department of Psychiatry and Behavioral Science, S.U.N.Y., Stony Brook, N.Y. 11794.

The distribution of enkephalin and substance P immunoreactivity within the retina was studied with immunohistochemical techniques. Pigeons were perfused with cold 6% dextran and 4% paraformaldehyde in 0.1M phosphate buffer. The eyes were removed, postfixed in 4% paraformaldehyde 2-4 hours and stored overnight in 30% sucrose-phosphate buffer at 4°C. The retinae were sectioned at 10 μm either perpendicular to the vertical axis of the eye or tangential to the retinal surface. Retinal sections were subsequently incubated in antiserum directed against either Leu^5-enkephalin or substance P and processed according to standard immunohistochemical techniques. Specificity to the antiserum was established by absorption of the antiserum with 10 μm concentrations of synthetic peptides.

Immunohistochemical positive staining for enkephalin and substance P was observed with morphologically distinct classes of amacrine cells and their processes within the inner plexiform layer. Enkephalin-like immunoreactivity was located within diffuse amacrine cells which ramify within the most superficial (lamina 1) and deep (laminae 3-5) laminae of the inner plexiform layer. The majority of enkephalin immunoreactivity cells were located within the second and third tier of the inner nuclear layer. Enkephalin immunoreactivity was distributed throughout the retina with the greatest density of labeled cells within central retinal regions including the red field of the superior retina. In contrast substance P-like immunoreactivity was located within unstratified amacrine cells which ramify only within lamina 3 of the inner plexiform layer. The substance P immunoreactive cells were located at the border of the inner nuclear layer and inner plexiform layer and the second tier of the inner nuclear layer. Substance P immunoreactivity was distributed within inferior and superior retinal regions. There were less substance P immunoreactive cells located within the red field when compared to non-red field regions of the retina.

These observations demonstrate the existence of two distinct populations of peptidergic amacrine cells within the retina. The localization of peptides to the retina suggest they play specific roles in retinal processing.

2610 TEMPORAL ASPECTS OF CODING IN SINGLE CELLS OF MONKEY STRIATE CORTEX. Bruce Bridgeman, Dept. Psychology, U. of Ca., Santa Cruz, CA 95064.

Responses of single cells in parafoveal striate cortex of two Macaca Fascicularis monkeys were recorded while the animals performed a simultaneous brightness discrimination (B trials). Monkeys were rewarded for pressing a panel corresponding to the brighter of two projected discs. Interspersed at random with the B trials were other trials in which one choice was a simultaneous disc and ring, while the other was an identical flashed disc followed by a delayed ring at a delay previously determined to be optimal for metacontrast masking in that animal (M trials). These trials were rewarded for either behavioral choice. Response histograms were collected separately for correct and incorrect B trials, and for responses to M trials on the simultaneous or delayed side. On the basis of other work on temporal analysis in cats and humans, histograms were divided into early (0 to about 150msec post-stimulus) and late (150-400msec) components.

Early post-stimulus activity was independent of behavioral choice for both M and B trials (M, $t=0.49$, N. S.; B, $t=1.44$, N. S.), reflecting only stimulus variables. Late activity in M trials, however, was significantly greater when the monkey pressed the "simultaneous" side (and presumably experienced metacontrast masking on the other side) than when he pressed the "delayed" side ($t=3.41$, $p<.005$). Similarly, late activity in B trials was greater when the monkey responded on the correct side than on the incorrect side ($t=2.36$, $p<.04$). Pre-response changes were assessed by calculating a linear regression line through a 250msec backward-averaged pre-response histogram and testing the statistical significance of its slope. 25% of the cells showed a pre-response slope significant at $p<.05$. Differences in overall cell activity had disappeared by this late epoch (M trials, $t=1.70$, N. S.; B trials, $t=1.11$, N. S.), though the pre-response histograms summed in each trial type appeared different for correct vs. incorrect B responses, or simultaneous vs. delayed M responses. Thus the overall difference in firing level in the late post-stimulus interval was recoded to a difference in temporal pattern just before the response.

These results show that the first burst of stimulus-evoked firings in visual cortex is related only to the stimulus; at a later interval in the same cells this information is combined with data about the meaning of the stimuli in the current context, and at a still later time the same cells receive information about the organization of the behavioral response.

2611 SPATIAL RESOLUTION IN THE LGN OF KITTENS REARED WITH ARTIFICIAL STRABISMIS. James L. Burchfiel, George Mower*, Frank H. Duffy, and David Berry*. Seizure Unit & Dept. of Neurology, Children's Hospital & Harvard Med. Sch., Boston MA 02115.

A characteristic deficit in strabismic amblyopia is decreased acuity in the deviating eye. Changes of spatial resolving capacities in single cells of the lateral geniculate nucleus (LGN) may underlie this visual deficit. Here, we compare several models of strabismic amblyopia in terms of their effects on spatial resolution of single cells in the LGN.

Kittens were reared in total darkness from birth except for daily one-hour visual exposure sessions. One group was surgically esotropic. Another group wore goggles with twelve diopter prisms which optically displaced the image to one eye. Normal and monocularly deprived kittens with similar rearing histories served as controls.

Single units in the LGN were classified as "X" or "Y" and the highest spatial frequency square-wave grating which elicited a modulated response was determined. Significant differences ($P< .001$, t test) in mean spatial resolving power between the normal and treated eye were found for X cells in monocularly deprived (X=2.7 c/deg vs 1.3), esotropic (2.3 vs 1.1) and prism (2.4 vs 1.1) kittens. The differences were most marked for cells close to the area centralis. There were no differences in X cells of the normal control (2.0 vs 1.9). Y cells showed significantly lower spatial resolving power than X cells in all animals, but there were no differences between Y cells devoted to one or the other eye in any animal. Histological studies of the LGN are in progress, as are physiological comparisons of fixed and variable prismatic displacements.

We conclude that interocular differences in spatial patterns are sufficient to produce deficits in spatial resolution of LGN cells.

2612 NEURONS IN THE NUCLEUS OF THE BASAL OPTIC ROOT (ACCESSORY OPTIC SYSTEM) OF BIRDS RESPOND PREFERENTIALLY TO VERTICAL STIMULUS MOVEMENT. Sheila Burns* and Josh Wallman. Dept. of Biology, City College of the City University of New York, New York, NY 10031.

The accessory optic system, which is found in all vertebrate classes, has been implicated in the visual control of eye and head movements. In birds, the accessory optic system contains the nucleus of the basal optic root (nBOR), which is also known as the ectomamillary nucleus and is homologous with the medial terminal nucleus of mammals. The nBOR has several interesting anatomical features: (1) its principal input is from the displaced ganglion cells of the retina, a clearly identifiable collection of neurons, (2) it projects directly to the oculomotor complex, providing a short loop for visual control of eye movements and (3) it also projects to the vestibulocerebellum both directly, as mossy fibers and indirectly, via the inferior olive, as climbing fibers.

Single unit recordings were made from nBOR in chickens. Preliminary results show that individual neurons have extremely large receptive fields and respond preferentially to stimuli moving vertically at slow velocities (about 1 deg./sec.). They respond best to large stimuli and poorly, if at all, to small or stationary stimuli. Neurons with a preference for movement in the horizontal direction appear to be absent from this nucleus. The physiological properties of the neurons are, thus, strikingly consistent with the anatomical findings of Brecha and Karten (Science 203: 913, 1979; pers. comm.) which show that projections of nBOR in the oculomotor complex are to regions which control vertical eye movements. (Supported by NIH Grant EY-2937).

2613 THE MONKEY FRONTAL EYE FIELDS HAVE A NEURONAL SIGNAL THAT PRECEDES VISUALLY GUIDED SACCADES. M. C. Bushnell* and M. E. Goldberg. Lab. Sensorimotor Res., National Eye Institute, NIH; Behavioral Sciences Dept., Armed Forces Radiobiol. Res. Institute, Bethesda, MD 20014; and Dept. Neurology, Georgetown Univ., Washington DC.

Electrical stimulation of the monkey frontal eye fields (FEF) elicits conjugate contralateral saccades, yet in this area the only neurons found to be related to saccades discharge during or after the eye movements (Bizzi, 1968). Other cells in FEF respond to visual stimuli (Mohler, Goldberg, and Wurtz, 1973), and half of these neurons show an enhanced response before visually guided saccades (Wurtz and Mohler, 1976). We now show that this enhancement is specific to saccades and independent of the on-response of the neurons. Activation of these neurons could account for the eye movements evoked by stimulation of FEF.

We recorded extracellularly from over 200 neurons in rhesus monkey FEF while the monkeys performed visual tasks. The monkeys learned to fixate a spot of light and then make one of several responses to peripheral visual stimuli presented both inside and outside the receptive field of the neuron being studied: to continue to fixate the spot and ignore the peripheral stimuli, to make a saccade to one of the stimuli, or to reach out and touch a stimulus without breaking fixation on the original spot.

Nearly half of the visually responsive neurons in FEF showed more vigorous responses to the stimulus onset when the monkey was preparing to make a saccade to the receptive field stimulus. This enhancement was specific to a saccade to the receptive field; it did not occur when the monkey made a saccade outside the receptive field or when he touched the stimulus in the receptive field without making a saccade to it.

FEF neurons responded phasically to the onset of a stimulus, and then their activity habituated to a background level even if the stimulus stayed lit. We trained monkeys to make saccades to constantly illuminated visual stimuli using the disappearance of the fixation point as a cue. When the constantly lit stimulus was in the receptive field of an enhanceable neuron, the neuron gave no significant response until the cue to make the eye movement, at which time the neuron would produce a large burst of discharge that preceded the eye movement. This burst was predictive of a visually guided saccade; it did not occur when the animal made the identical movement in total darkness. Thus there is a discharge preceding visually guided eye movements that can be dissociated from the on-response of the neuron. It occurs only when the animal prepares to make a saccade to the stimulus in the neuron's receptive field.

Constant current biphasic stimulation through the microelectrode at sites of visually responsive neurons gave saccades into their receptive fields at thresholds as low as 20 uA. Microstimulation at the sites of cells that discharge during or after eye movements did not evoke saccades.

The enhanced response of FEF neurons may provide a retinal error signal that drives the brain stem to produce visually guided saccades. This activity may provide the biological signal duplicated when electrical stimulation of FEF evokes saccades.

2614 THE EFFECT OF INTEROCULAR ADAPTATION ON CONTRAST MODULATION. J. Camisa*, I. Bodis-Wollner, and C.D. Hendley*. Mount Sinai School of Medicine, New York, N.Y. 10029.

A contrast modulated grating is the sum of a steady and a counterphase flickering grating of the same spatial frequency. Adaptation to a steady grating separates the two mechanisms subserving detection of this stimulus: as a result of adaptation, the threshold of the counterphase component becomes independent of the stationary contrast (Bodis-Wollner & Hendley, J. Physiol., 1979). In addition, adaptation "enhances" the sensitivity to the counterphase component above 10% mean contrast. This paradoxical result is presumably due to some sort of "adapting out" of the steady component which at high mean contrasts normally reduces sensitivity to the counterphase component. In the present study the effect of contraocular adaptation on contrast modulation sensitivity was explored for a 6 c/deg grating modulated at 8 Hz. Contrast modulation thresholds were established both before and after adaptation for mean contrasts ranging from detection threshold to 40%. There was little and often insignificant effect of adaptation on the modulation sensitivity near detection threshold, but in the range above 10% contrast we again found a paradoxical increase in sensitivity similar to the effect of monocular adaptation. These results indicate that the interaction of the stationary and counterphase components of the 6 c/deg grating are affected by interocular adaptation, and therefore the major site of this interaction between the stationary and counterphase components must be at or beyond the point of binocular convergence.

2615 STIMULATION OF THE CAT SUPERIOR COLLICULUS EVOKES EAR MOVEMENTS WHICH PARALLEL EYE MOVEMENTS. H. Peter Clamann and Barry E. STEIN. Dept. Physio., Med. Coll. of Va., Richmond, VA 23298.

The superior colliculus is believed to be involved in orienting receptor organs to a variety of sensory cues. Yet, while the influence of the colliculus on eye movements has been studied extensively, relatively little information is available about its control of ear movements. These experiments were directed toward examining whether or not an ear movement "map" is present in the cat colliculus and, if so, what its relationship is to the eye movement map. A cylindrical steel chamber was implanted over a cranial opening in each of 10 cats 1 to 3 weeks prior to experimentation. During an experiment the animal was alert. Its head was rigidly held by a special mount attached to the cylinder, so that no wounds or pressure points were created during experimentation, and movement of the ears was not impeded. Electrical stimuli were delivered through tungsten electrodes lowered to the colliculus through visual cortex. Both eye and ear movements were evoked in most electrode penetrations, and their thresholds were usually lowest at the same depth in the colliculus. Initial ear position and the final position achieved during stimulation were photographed with three orthogonally placed cameras. Reliable, ballistic-like movements of the contralateral ear were evoked and were predictable on the basis of stimulus site. Evoked ear and eye movements paralleled each other with lateral sites in the colliculus producing downward movements and medial sites producing upward movements. Stimulation of the most rostral aspect of the colliculus evoked forward ear movements while stimulation of caudal sites evoked backward ear movements. Colliculus-evoked movements orient the ears and eyes toward the source of a natural sensory stimulus. However, the organization of ipsilateral (to site of electrical stimulation) ear movements appears to be complicated by the sound-shadowing effect of the head.

2616 PROJECTIONS OF THE LATERAL GENICULATE AND LATERAL POSTERIOR NUCLEI TO POSTERIOR NEOCORTEX OF RAT. W. J. Clerici, J. Coleman and D. Clark. Depts. Psychol. and Physiol., Univ. of South Carolina, Columbia, SC 29208.

Most mammals studied conform to the classical view that the projection from the dorsal lateral geniculate nucleus (GL) is restricted to area 17 of cortex. Using the retrograde degeneration method Lashley (J. Comp. Neurol., 1934, 60, 57) reported such a projection confined to area 17 of the rat. More recently, results using neuronal transport techniques suggest that GL also projects to extrastriate cortex in rat (Hughes, J. Comp. Neurol., 1977, 175, 311). Our goal was to study thalamic input patterns to areas of posterior cortex of albino rat by making horseradish peroxidase (HRP) injections of limited spread by using microiontophoresis. HRP injection of lateral striate cortex produced a column of labelled cells at the dorsal border of GL; injection remote from the lateral border of striate cortex produced a column of labelled cells ventrally within GL. Striate injections also labelled cells in the lateral posterior nucleus (LP). Injection in Krieg's area 18a adjacent to the caudal-lateral portion of area 17 produced not only columns of labelled cells in LP, but also diffuse labelling within GL. An HRP injection placed more laterally in 18a labelled numerous cells in LP, and in GL more sparsely. Injection of area 36 lateral to 18a produced labelled cells in caudal LP without any GL labelling. In conclusion, GL projects topographically to striate cortex of rat and in a more diffuse manner to portions of area 18a, while LP connections are distributed in a systematic manner to striate and extrastriate areas. The projection of GL outside striate cortex of rat may differ in organization and magnitude from that observed in the cat.

2617 CORTICAL TOPOGRAPHY IN SIAMESE CATS. Michael Lee Cooper and Gary G. Blasdel*. Division of Biology, California Institute of Technology, Pasadena, Ca. 91125

In Siamese cats, many ganglion cell axons from the temporal retina are misrouted in the chiasm, so that they misproject to the contralateral hemisphere. As a result, the Siamese LGN contains a representation of much of the ipsilateral visual field. Two mechanisms have been described for the way in which the Siamese visual cortex processes this aberrant visual information. In the "Midwestern" pattern, the abnormal geniculocortical inputs are suppressed, resulting in a roughly normal topography, with the border between areas 17 and 18 representing the midline of the visual field. In the "Boston" pattern, the aberrant inputs are inserted in an orderly fashion between the maps of the contralateral hemifield in areas 17 and 18, so that the 17/18 border comes to represent a point up to 20^{o} into the ipsilateral field.

We recorded from four Siamese cats; by making several electrode penetrations in each animal, we tried to map the region of the 17/18 border in at least two widely separated AP levels. By determining the receptive field positions for single units at intervals of about 100 μm along each electrode track, we obtained data concerning the extent of the ipsilateral field representation at each cortical level. In all of our animals, tracks made at coronal levels corresponding to the horizontal meridian and those made at levels representing lower visual field showed substantially different maximum excursions into the ipsilateral hemifield. Thus, penetrations crossing the 17/18 border at levels corresponding to average elevations between -7^{o} and -13^{o} resulted in maximum excursions of 14^{o} to 19^{o} into the ipsilateral field. Therefore, these tracks conformed to the "Boston" cortical pattern. However, in these same cats, more posterior tracks traversing the 17/18 border at levels representing average elevations from $+1^{o}$ to -4^{o} yielded receptive fields which were never centered more than 6^{o} into the ipsilateral hemifield. These posterior tracks thus gave maps reminiscent of the "Midwestern" modification. These differences in the extent of ipsilateral field representation were not due to any outward cyclorotation of the eyes during paralysis, as shown by photographic determinations of eye rolling made during each experiment.

The applicability of our results is not restricted solely to cats from our colony, since one of our four experimental animals was obtained from outside sources. However, it appears that not all "Boston" cats follow the pattern we describe, since Shatz and LeVay (Science, 204, 1979) found typical "Boston" topographies near the horizontal meridian in animals from their colony.

2618 ELECTROCORTICAL RESPONSES TO VISUAL SPATIAL FREQUENCY IN BEHAVING MONKEYS. Richard Coppola and Richard K. Nakamura, NIMH, Bethesda MD 20205

Cortical potentials to visual stimulation by gratings of various spatial frequencies (SF) were obtained from alert rhesus monkeys to gain some insight into the processing of visual pattern information. Stimuli consisted of vertically oriented sine wave or square wave gratings in the range 0.125 to 8.0 cycles/degree. They were presented on a computer controlled CRT screen in both pattern appearance-disappearance and pattern reversal sequences. Contrast was held constant at 0.44 and luminance was constant at 0.2 ft-L. The animals had chronically implanted electrodes of stainless steel or platinum wire with ball tips placed on the dural surface at striate (S), prestriate (PS) and inferior temporal (IT) locations. The animals were trained to attend to the screen as follows. A trial was initiated by a lever press which caused the grating to appear-disappear or reverse in contrast each 250 msec. After random time periods the screen activity stopped and the animal had to release the lever to get a water reward. 500 msec from the start of the trial the amplified electrical activity from the electrodes was digitized with correct trials saved and averaged.

The appearance response at striate consisted of a positive component at 100 msec latency whose amplitude decreased with SF and a negative component at 150 msec which was relatively flat with SF. The prestriate response had three components: positive at 90-110 msec that peaked at low SF and then declined with increasing SF; negative at 130-150 msec that peaked with SF and; positive at 190-210 msec that increased slowly with SF. The IT response had a negative component at 100-120 msec and a positive at 190-210 msec both of which were relatively flat with SF. The largest difference between sine wave and square wave gratings was for the late positive component at PS and IT, which were smaller for sine wave.

The reversal response at striate was a large positive wave at 100 msec that showed a relatively sharp peak at 2-4 c/deg. The PS response at 100 msec had a less sharp variation with SF. IT had a more variable response that seemed to show a considerable latency change with SF. Square wave reversal responses were generally larger than sine wave but showed the same form relative to SF.

These findings are similar to those for human responses to checkerboard stimulation (Jeffreys and Axford, Exp. Brain Res. 16:1-40,1972). The components of the PS response in particular seem related to the CI, CII, and CIII responses. Further, these findings are consistent with the idea that CII and CIII are of extrastriate origin.

2619 METABOLIC PATTERNS INDUCED IN MONKEY VISUAL CORTEX BY STIMULATION WITH COLORED LIGHTS. M.L.J. Crawford, J.D. Fagan*, M. Borchert*, A. Heston*, and R.E. Marc. U. of Texas Graduate School of Biomedical Sciences, Houston, Texas 77025.

The visual cortices of young monkeys stimulated monocularly by monochromatic lights show interesting patterns as revealed by the labeled 2-deoxyglucose method. In the autoradiographs from the striate cortex there are narrow bands of increased metabolic activity which extend from the cortical surface to the white matter but, unlike the orientation columns described by Hubel, Wiesel, and Stryker (J. Comp. Neurol., 1978, 177, 361-379), cortical layers I and II contain the highest density of the label. The labeled column is significantly narrower than the adjacent non-labeled space (0.367mm vs 0.529mm, N=500) suggesting that only a subpopulation of the neurons of the eye-dominance hypercolumn was activated by the colored stimulus. In tranverse sections the superficial cortical layers appear as strings of labeled spots, similar to those described for orientation columns, but bearing a close relationship to the eye-dominance hypercolumn (within row period = 0.850mm). These results are consistent with the idea that, at the striate cortex, color information is processed in a mosaic of functional columns of neurons and subsequently relayed to more specialized pre-striate areas.

In the pre-striate cortex, a complex pattern is consistently found throughout the inferior occipital sulcus (IOS). In the vault of the IOS the columns are 0.650 to 0.750mm in width with a period of 1.8mm. Crossing the IOS vault at right angles, the bands of label extend down the posterior bank to terminate at the ventrolateral edge of the striate cortex. Similarly, the broad parallel bands run down the anterior bank of the IOS to become diffuse at the ventral edge. Zeki (J. Physiol., 1978, 277, p. 233) has described aggregates of color specific neurons found in this area of pre-striate cortex.

2620 BINOCULAR INTERACTIONS ACROSS THE CORPUS CALLOSUM. Max Cynader, Allan Dobbins, Jill Gardner, Franco Leporé and Jean-Paul Guillemot. Dept. Psychol. Dalhousie Univ. Halifax, N.S. and Dept. Psych. Université de Montreal, P.Q. Canada.

We have examined the responses of cortical units to monocular and binocular visual stimulation in cats in which the optic chiasm had been surgically-sectioned. The effect of this manipulation is to interrupt the direct retina-geniculate-cortex pathway from the contralateral eye, leaving the connections from the ipsilateral eye intact. Quantitative study of over 100 cortical units located near the border between areas 17 and 18 (with receptive fields located near the vertical meridian) showed that some units were driven exclusively by stimuli presented through the ipsilateral eye. However the firing rate of more than half of the units encountered could also be influenced by stimulation through the contralateral eye. The effect of visual stimuli presented through the contralateral eye could be excitatory or inhibitory.

We tested cortical units for their sensitivity to the retinal disparity of binocularly presented stimuli (corresponding to different positions in depth) and also for sensitivity to different directions of motion in three-dimensional space. While many units did not respond differentially to visual stimuli with varied locations or trajectories in depth, a subset of the units encountered were highly sensitive to the position and/or direction of movement of stimuli in 3 dimensional space.

Units showing strong binocular interactions were clustered within what appeared to be hemicolumns in the visual cortex. Within these hemicolumns which extended from the cortical surface to the geniculate-recipient zone in layer 4, successively-recorded units were sensitive to particular characteristics of binocular stimuli. On a given penetration through the superficial cortical layers one might encounter cell after cell which responded optimally to stimuli moving toward the animal. Other penetrations yielded units which responded optimally to stimuli moving sideways at a given depth. Binocular interactions were most pronounced in units of the supragranular cortical layers and nearly absent in layer 4. In the infragranular layers the large-field complex cells were often binocularly-activated but displayed no selectivity for disparity. Some units in cortical layer 6 did however respond differentially to stimuli at different disparities.

The responses to stimulation of the contralateral eye were abolished or much reduced after inactivation of the visual cortex on the other side of the brain indicating that the major pathway mediating these responses is the corpus callosum.

2621 EFFECT OF A COMBINATION OF MONOCULAR AND DIRECTIONAL DEPRIVATION ON THE PERCENTAGE OF NON-SPECIFIC CELLS IN CAT VISUAL CORTEX. Nigel W. Daw and Michael Ariel*. Dept. Physiol., Washington Univ. Med. Sch., St. Louis, MO, 63110.

Two groups of kittens were reared with a combination of monocular and directional deprivation. Group A (3 animals) had one eye sutured shut at 2 weeks of age, with each kitten placed in a striped drum rotating continually around it in one direction for one hour per day, otherwise remaining in the dark. Group B (5 animals) was reared similarly, except that the direction of drum rotation was reversed at 5 weeks of age. These rearing conditions were continued until 12 weeks of age, then the animals remained in the dark until electrophysiological recording. Cells recorded from visual cortex were classified as unidirectional, bidirectional, and omnidirectional or "hard to drive"; according to their ocular dominance; and various other characteristics.

The percentage of omnidirectional or nonspecific cells ranged from 22% to 41% for the deprived animals, compared to 6% to 15% for normal animals. Omnidirectional cells were found in substantial numbers in all layers of the cortex in the deprived animals, interspersed with specific (unidirectional or bidirectional) cells. Very few cells were dominated by the closed eye: of those that were most were nonspecific. The results of the animals in Group A showed that the monocular deprivation had a much more powerful effect than the directional deprivation for these rearing conditions. The results, when displayed in a two dimensional array with ocular dominance along one axis and directional sensitivity along the other, suggest that these cortical cells either lose their input from one eye, or lose their directional specificity, or both.

2623 NEURONS IN THE SUPERIOR TEMPORAL SULCUS OF THE MACAQUE STILL RESPOND TO VISUAL STIMULI AFTER REMOVAL OF STRIATE CORTEX. R. Desimone*, C. Bruce* and C. G. Gross. Dept. Psychol., Princeton Univ., Princeton, N.J. 08540

Following total removal of striate cortex, monkeys (and man) retain an impressive degree of complex visually-guided behavior. Yet no cortical area has yet been found whose visual responsiveness survives striate removal or inactivation. We report on a cortical area which does retain visual responsiveness after striate removal. This area, the Superior Temporal Polysensory Area, lies in the upper bank and fundus of the anterior and middle portions of the superior temporal sulcus. Neurons in this area respond to visual, auditory and somesthetic stimuli, and usually have receptive fields encompassing virtually the entire visual field (including both half-fields). About half the units are sensitive to the direction of movement of a stimulus, usually preferring movement in depth or movement towards the fovea from any point in the periphery (or vice-versa) (Neurosci. Abs. 3, 554).

In three monkeys, striate cortex was removed unilaterally. Several weeks later the monkeys were paralyzed, anesthetized with N_2O, and single unit responses were recorded from the Superior Temporal Polysensory Area ipsilateral to the lesion. Each animal was repeatedly recorded from. Over two-thirds of the units responded to visual stimuli in the half-field contralateral to the striate lesion. In this "cortically blind" half-field, receptive fields were still very large but there was little or no sensitivity to the direction of movement. Some of the units which had no direction specificity in the contralateral field did have such specificity in the ipsilateral field. Preliminary experiments in two monkeys indicate that the superior colliculus contributes to the visual responsiveness that remains after the striate lesion.

2624 MOVEMENT-SENSITIVITIES OF VISUAL INTERNEURONES IN THE MEDULLAE OF FLIES. Robert D. DeVoe. Dept. Physiol., Sch. Med., Johns Hopkins Univ., Baltimore, MD 21205.

Intracellular recordings from the medulla (second optic ganglion) were made in intact, restrained flies that faced a hemispherical surface upon which moving patterns and spots were projected from the rear. Most cells responded to light and movement with slow-wave depolarizations or hyperpolarizations; some had spikes in addition or alone. In the distal medulla, noisy hyperpolarizing responses to light alone were characteristic of incoming axons of second-order, laminar cells. These cells responded with flicker-like oscillations to black-white alternations within moving gratings of 15°/cycle but not of 2.5°/cycle. Medullary cells penetrated nearby responded to grating movements with similar but depolarizing oscillations that were 180° out of phase with the laminar cell responses and may have been driven by the laminar cells. These simple, oscillating responses to gratings are quite likely indicative of the inputs to the motion detectors.

Most medullary cells had abrupt, maintained depolarizations in response to moving gratings. When the direction of movement was reversed, there were short, rapid, partial-repolarizations, but when movements stopped before reversals, the cells would partially-repolarize much more slowly. The depolarizations to movement were non-directional, but directionally-biased oscillations superimposed upon the depolarizations were sometimes recorded, either with increasing speed of movement or when the moving grating was restricted to within a small projected spot. A few, spontaneously-active spiking cells that were inhibited (hyperpolarized) by light were probably not purely OFF cells. Rather, these cells might have been inhibited by other, movement-excited cells, since one cell inhibited by light during movement resumed firing when movement was stopped.

Receptive fields of medullary cells were tested with small spots and were found to be simple, non-opponent and generally elliptical. It was usually possible to match a response elicited at any point in the receptive field to a response elicited by a suitable intensity at the center of the receptive field. Maximum extents of receptive fields ranged from 40° to 60° of visual field. Edges and spots elicited their largest responses when they moved across the borders of the receptive fields. These results indicate that large numbers of medullary cartridges contribute to the movement responses recorded.

2625 A DEMONSTRATION OF COMPLEX PATTERN VISION IN THE MONKEY COMPLETELY LACKING STRIATE CORTEX. John Dineen* and E. Gregory Keating. Dept. Anat., Upstate Medical Center, Syracuse, N.Y. 13210 and Neurology Service, Veterans Hospital.

We developed a series of discrimination tasks to ascertain the types of visual cues that can be used by de-striate monkeys. After long periods of shaping and postoperative training, three of our five monkeys were able to discriminate a number of patterns that were equated for luminance and luminous flux.

Our results verify that the de-striate monkey can discriminate multi-element patterns differing in spatial organization but equated for amount of contour, number of corners and number of elements. The performance of our animals on several control tasks indicated that the monkeys were not simply using specific local cues but were using the overall organization of each stimulus to distinguish between patterns.

Histological examination of one of our animals revealed complete bilateral removal of area 17. No cell clusters were present throughout the extent of both lateral geniculate nuclei.

We interpret these results as evidence that the de-striate primate can realize the overall spatial organization of light falling on its retina, i.e., pattern. Our animals were not, as previous research would have suggested, limited to merely summating the amount of various visual features (e.g., contour or corners) irrespective of their spatial distribution. These results support Schilder et al's observation of basic form vision in the de-striate monkey and further extends the capacities of the primate extrastriate pathways to also include more complex pattern discrimination. The extensive postoperative training needed for our animals, however, suggests that the geniculo-striate pathway is the primary pattern vision system in the normal monkey.

2626 SPATIO-TEMPORAL INTERACTIONS IN CAT VISUAL CORTEX AND THE RESPONSE TO MOVING STIMULI. Robert M. Douglas* and Max Cynader (SPON: G. Melvill Jones) Psychology Dept., Dalhousie University, Halifax, N.S. B3H 4J1.

Many cells in the visual cortex respond much more vigorously to stimuli moving on one direction than in the opposite. We have examined how this property may be constructed from timed interactions between parts of the receptive field.

The receptive fields of units in area 18 of the cat were mapped and divided into 7 positions. Light bars 0.5° wide and 20 msec in duration were flashed onto one or two of these regions. Stimulation of two regions sometimes evoked a response considerably different from that expected from the sum of the responses to the 2 bars delivered separately. Both increases (facilitation) and decreases (inhibition) were observed. The pattern of these interactions was studied systematically in 15 cells. The 2 bars were flashed on all combinations of the 7 positions, and the delay between onsets varied between 0 and 640 msec. The 343 (7x7x7) stimulus conditions were presented in a randomized interleaved order, and the unit's responses compared with the linear prediction. At the same time, the directional properties of the cell were examined with bars of the same width moving between 2 and 512 degrees/sec.

Both facilitation and inhibition were widespread. Particularly common was a facilitation with 640 msec. intervals. However, it was the interactions at the shorter intervals (20-80 msec) that appeared to be most responsible for the directional properties. Stimulation of 2 positions in the same order as occurs when a stimulus moves in the preferred direction produced either a facilitation or an absence of inhibition. Movement in the opposite direction evoked inhibition. In the most directional cells the interactions were large and consistent. The consistency took 2 forms. In some cells, the spatial position of the major facilitatory or inhibitory feature was independent of the position of the first bar. In other cells, the position was relative. For any position used for the first bar, the facilitation occurred 1 to 2° away in the preferred direction.

Quantitative predictions for moving stimuli were obtained by first summing the responses to the single bars, and then adding those interactions corresponding to a given direction and speed. Without any further assumptions this measure was able to predict the preferred direction, although the degree of directionality was underestimated, particularly at the low velocities. Thus the directional properties of cortical neurons appear to be due to these interactions between receptive field areas.

2627 Extrastriate Color Cells in the Awake Monkey. Bruce Dow, Roman Bauer* & Robert Vautin*, Neurobiology Division, SUNY, Buffalo, NY 14226.

We have been examining the response properties of extrastriate cells in the foveal projection pathway of alert, behaving macaque monkeys (Rhesus and Cynomolgus), and have identified substantial numbers of color-selective cells. There is a concentration of such cells in the anterior bank of the lunate sulcus, confirming Zeki's (1973) earlier report of a color area (V4) in this region. Other color cells are found in the inferior occipital sulcus. Electrolytic lesions along with receptive field properties permit us to distinguish color cells in the various subregions of extrastriate cortex.

Our major concern has been to determine the color preference of extrastriate color cells. On the basis of cone inputs and spectral response peaks, there appear to be two distinct cell populations. The first group has opponent inputs from the long and middle wavelength cones (L/M cells) and excitatory/inhibitory peaks in the vicinity of 610-640nm (red) and 480-510nm (blue-green). The second group has synergistic input from long and short wavelength cones and antagonistic input from middle wavelength cones (LS/M cells). Excitatory/inhibitory peaks for this group are at the two ends of the spectrum (red-blue, i.e., purple) and at 530-570nm (yellow-green). Neutral points for L/M cells are in the same spectral region (530-570nm) as the central peaks of LS/M cells. LS/M cells have two neutral points, one toward each end of the spectrum. Some LS/M cells with very lateral neutral points can masquerade as non-color cells because of their midspectral response peak. Others with more medial neutral points can masquerade as either S/LM cells or L/MS cells. In all such cases we find responses to extraspectral purple (matched for brightness) to be more vigorous than responses to either blue or red alone. In instances where a neutral point was not immediately evident at one or the other end of the spectrum we have been able to uncover an opponent mechanism through the use of chromatic adaptation.

The two spectral loci of the opponent response peaks of any given color cell can be used to generate a line in CIE color space. Most such lines appear to pass close to the achromatic center of CIE color space. Color axis lines of L/M and LS/M cells are generally orthogonal in color space, though there is a considerable degree of scatter in each group. The data thus suggest anisotropy in the distribution of color axis lines. We are currently collecting further data to test this hypothesis.

2628 RETINOFUGAL PROJECTIONS IN PIGMENTED, ALBINO AND ONE-EYED MICE. Ursula C. Dräger and John F. Olsen.* Dept. Neurobiol., Harvard Medical School, Boston, MA 02115.

Retinofugal projections were studied in black and albino mice, and in mice in which one eye had been removed at birth. One optic tract was cut at the level of the lateral geniculate nucleus and soaked in horseradish peroxidase. Most but not all retinal ganglion cells that projected into the tract were filled; from mouse to mouse filling varied. In the retina contralateral to the injected tract, cells were stained throughout. Ipsilateral to the injection all 3 types of mice had labelled cells mainly within a crescent-shaped area, which formed the lower and temporal margin of the retina and constituted about 20% of total retinal area. Displaced ganglion cells, located at the inner border of the inner nuclear layer, were concentrated in the peripheral retina, and were relatively much more common among ipsilaterally than among contralaterally projecting cells: for all 3 types of mice, 15.6% (sd 3.9) of the ipsilateral cells and only 0.95% (sd 0.3) of the contralateral ganglion cells were displaced.

Less ganglion cells were filled from the ipsilateral optic tract in albino than in pigmented mice: the best example from a black mouse had 978 filled cells in the ipsilateral retina, the best-filled albino retina 655 cells. The number of ipsilateral cells averaged approximately 2.8% of the total contralateral population in black mice, and 2.1% in albinos. This correlated with recordings in area 17 of albino mice: though the binocular region was normal in extent and most cells could be driven from both eyes, cells dominated by the ipsilateral eye were far less common than in black mice. Cell-area measurements in both albino and black mice showed that ganglion cells destined for the ipsilateral tract were on the average between 36 and 48% larger than contralaterally projecting ones. In unilaterally enucleated mice the number of ganglion cells projecting ipsilaterally from the remaining eye was much higher than in two-eyed mice: in the best-filled retina we counted 1592 such cells. A population of predominantly small cells filled from the ipsilateral optic tract was observed throughout the retina, outside the crescent region, in all 3 types of mice. In black mice these aberrant cells accounted for 4% of all cells in the ipsilateral retina, in albinos for 6.8% and in one-eyed mice for 14%.

The albino mutation in mice thus causes a homogeneous reduction in ipsilateral retinal projection, with much more subtle consequences for central visual pathways than described for Siamese cats. Eye enucleation at birth leads to an increase in the projection from the remaining eye to the hemisphere ipsilateral to it, in number of cells from topographically appropriate and inappropriate regions.

2629 THE LANDING REACTION (LR) OF FLIES: A MODEL REACTION FOR STUDYING THE NEURAL BASIS OF BEHAVIOUR. Hendrik E. Eckert, Dept. Animal Physiol., RUB, P.O. Box 102148, D-4630 Bochum 1, W.-GERMANY.

The landing reaction consists in flies of a simultaneous upwards throw of both foreleg tibiae obeying an 'all-or-none' rule. Employing stripes moving apart and periodic moving gratings the dependence of the LR - measured as the number of positive responses to 20 stimulus presentations - on the angular velocity, the extent and directions of pattern motion was tested for different regions of the eye. (1) Despite the 'all-or-none' rule of the behavioural reaction, the neural circuit is activated in a graded manner: the larger the extent of angular movement the higher the percentage of stimulus induced responses if ommatidia from the anterior to the posterior part of the eye (progressive motion) were stimulated; reversal of this direction of motion (regressive motion) exerts a graded inhibitory influence as can be shown by simultaneous and successive regressive and progressive motion. (2) The most effective direction of stimulus motion corresponded to progressive motion for all regions of the eye; the higher sensitivity of the frontal (binocular) region of the eyes to upwards motion is caused by binocular interactions. (3) The response to objects presented at different distances to the animal indicates a capability for depth perception. (4) The most effective angular velocity corresponded to a contrast frequency (i.e. the ratio of angular velocity and angular width of the pattern period) of 6-7 Hz, thus clearly separating the LR from the optomotor torque response whose peak lies at 1.4 Hz. The position of these peaks cannot be altered by subsequent filtering since the measured responses already represent the time-averaged outputs of the neural circuits. Thus separate neural pathways have to be postulated for mediating these two behavioural responses.

This behavioural investigation provides the means of studying the respective underlying neural circuits (e.g. depth perception, orientation of elementary movement detectors, excitation and inhibition).

2630 INCREASE IN MONOCULAR DOMINANCE IN AREA 17 OF THE CAT FOLLOWING NEONATAL SECTION OF THE POSTERIOR CORPUS CALLOSUM. Andrea J. Elberger. Dept. of Anatomy, University of Pennsylvania School of Medicine, Philadelphia, PA. 19104.

Extracellular single unit recordings in Area 17 were made in 8 adult cats that had received neonatal surgical section of the posterior corpus callosum. Callosal surgery was performed when the cats were 13-29 days of age; 2-3 years elapsed before the present experiments occurred. During the interim time period all cats had unrestricted visual experience.

Cells were examined qualitatively, using hand-held projected stimuli, and classified according to cell type (simple, complex, hypercomplex), ocular dominance (1-7, Hubel and Wiesel), receptive field size, and location from the vertical meridian. The cells were sampled across many ocular dominance columns, and were excluded from data analysis if orientation selectivity was not observed. For purposes of comparison, 3 normal adult cats were studied; in addition, reference to an additional normal population (Albus, 1975) was made. The extent of corpus callosum section was verified by subsequent histology.

There is a significant increase in monocularly driven cells (groups 1 and 7) throughout the visual region examined (receptive field centers 0.0-39.0°) following neonatal corpus callosum section. Forty-five percent of classified cells were monocularly driven, as opposed to 24% of the normal cats' cells studied. In the central region, 0.0-3.9°, the higher proportion of monocularly driven cells agrees with previous data for normals (Albus, 1975) Therefore, the observed increase in monocularly driven cells occurs mainly in cells with receptive field centers from 4.0-39.0°.

An additional comparison of the ocular dominance distribution of neonatal corpus callosum sectioned cats with adult corpus callosum sectioned cats (Payne, Elberger, Berman and Murphy, this volume) indicates that while neonatal, as well as adult, callosum sectioned cats show significant shifts in ocular dominance from normal cats, the neonatal results also differ significantly from the adult callosal results. The neonatal corpus callosum sectioned cats show a proportion of monocularly driven cells intermediate to that of normal and adult corpus callosum sectioned cats.

Cats with neonatal corpus callosum section have been shown to have a substantial loss of the extent of the binocular visual field, as well as exhibiting small, and varying, degrees of divergent strabismus (Elberger, Exp. Brain Res. 1979). The behavioral loss of the binocular visual field is reflected in the physiological loss of binocularly driven cells observed in the present study. These results suggest that the normal development of binocular vision, and binocularly driven cortical cells, depends in part on information transmitted by the corpus callosum early in life.

2631 NEURONS SENSITIVE TO BINOCULAR DEPTH IN AREAS 17 AND 18 OF THE CAT VISUAL CORTEX. David Ferster* (SPONSOR: David H. Hubel). Dept. of Neurobiology, Harvard Medical School, Boston MA, 02115.

Several studies have suggested that neurons in area 17 are sensitive to retinal disparity and may form the basis of binocular depth perception. There are also reports that area 18, at least in sheep and monkeys, contains neurons even more suited to the task. The object of the present study was to assess the relative importance of these two areas for binocular vision in the cat. For 86 cells in area 17 and 187 cells in area 18 the optimal monocular stimulus was determined. This stimulus was then presented to both eyes, while retinal disparity was varied in a direction perpendicular to the receptive field orientaion with an adjustable prism in front of one eye. Eye movements were monitored with a binocular reference cell in area 17.

Two types of disparity sensitive neuron, similar to those in areas 17 and 18 of the monkey (G.F. Poggio and B. Fischer, J. Neurophysiol. 40:1392, '78) were found in the cat visual cortex. The first type resembled the tuned excitatory cells of the monkey in having a symmetrical peak in their disparity tuning curves. The position of the peak for each cell almost invariable coincided with the point at which the cell's own two receptive fields were superimposed; at this prism setting the receptive fields of the reference cell were also superimposed. This point was therefore taken to be the point of retinal correspondence, or 0° disparity. The zero disparity cells were usually binocular. The second type of disparity sensitive neuron resembled the near and far cells of the monkey and were usually monocular. In most cases they gave their smallest response (often no response at all) at 0°. On one side of 0° the response grew linearly for up to 5° towards its maximum (usually equal to the monocular response); on the other side it remained at the minimum for up to 2° before rising.

The two types of disparity sensitive neuron were present in both area 17 and 18 and in each area they were found in the same layers (2,3, upper 4, 6). There were, however, two important differences between the two areas. 1) the relative numbers of the two types of disparity sensitive cells were quite different: area 17 - 33 zero disparity cells, 9 near and far cells; area 18 - 18 zero disparity cells, 42 near and far cells. 2) The cells in area 18 were sensitive to much larger disparities than their counterparts in area 17. In area 17, near and far cells reached their maximum response within 2° of zero while in area 18 the response could change for up to 5°. The zero disparity cells of area 18 also had much broader tuning curves. It seems therefore that both areas 17 and 18 are involved in depth vision; area 17 is capable of discriminating small disparities close to 0°, while area 18 covers a larger range, but with less acuity.

2632 EXTRAVISUAL NEURONS IN THE OPTIC TECTUM OF A SIGHTED AND AN UNSIGHTED FISH. S.E. Fish* and T.J. Voneida (SPON. C.M. Sligar). Northeastern Ohio Universities College of Medicine; St. Rt. 44; Rootstown, OH 44242.

Extracellular recordings were made from single neurons in the optic tectum of the blind cave fish (Astyanax Hubbsi) and the goldfish. Cells were tested for responses to visual, somatosensory, auditory and lateral line stimuli. Although the cave fish has a vestigial optic nerve (Voneida and Sligar, J. Comp. Neur., 165:89, 1976), only somatosensory neurons were found. About two thirds of these cells were isolated in the periventricular layer with the remainder scattered throughout more superficial laminae. The somatosensory neurons were found to be organized with the rostral to caudal body axis represented from anterior to posterior in the tectum and the dorsal to ventral body axis represented from medial to lateral.

Normal visual responses, as reported by others, were recorded from the goldfish tectum. As in the cave fish the only extravisual responses recorded were somatosensory, although many fewer were found. The topography was similar to that of the cave fish but these neurons were rarely recorded outside the periventricular layer. In the goldfish a spatial correspondence was observed between visual and somatosensory receptive fields recorded from the same general location of the tectum. In mammals this correspondence is thought to facilitate visual orienting to non-visual stimuli (e.g. Chalupa and Rhoades, J. Physiol., 270:595, 1977). The significance of the (apparently more widespread) somatosensory representation in the blind fish optic tectum is under investigation.

2633 DISTRIBUTION OF ACETYLCHOLINESTERASE IN THE LATERAL GENICULATE NUCLEUS AND STRIATE CORTEX OF GALAGO SENEGALENSIS AND AOTUS TRIVIRGATUS. D. Fitzpatrick* and I.T. Diamond (SPON: G.C. Thompson). Dept. Psychol., Duke University, Durham, NC 27706.

This inquiry began with the discovery that just two layers of the lateral geniculate nucleus (GL) of Galago contain large amounts of acetylcholinesterase as demonstrated by the method of Karnovsky and Roots (J. Histochem. Cytochem. 12,1964). These two layers (3 and 6) are similar in cell size and staining characteristics, project to the same layer in the striate cortex and are thought to be homologous to the parvocellular layers of other primates.

This hypothesis has been strengthened by examining the distribution of acetylcholinesterase in the lateral geniculate nucleus of the owl monkey, Aotus trivirgatus. In this species, the parvocellular layers (3 and 4) stain darkly for cholinesterase while the magnocellular layers (1 and 2) are only slightly stained. The interlaminar zones as well as the "S" layers of the owl monkey GL also stain for cholinesterase.

In an attempt to determine the source of this cholinesterase staining in layers 3 and 6 of Galago, we made kainic acid injections into GL in some animals and lesions of striate cortex in others. Injections of .5 µg of kainic acid into GL, followed by survival times of 2-11 days, produce severe cellular destruction in GL,yet the cholinesterase staining of these layers is undiminished. In contrast, a small lesion of striate cortex, followed by a 9-day survival period, produces conspicuous gaps in the cholinesterase staining of layers 3 and 6. These gaps are restricted in width and their relative positions define a projection column that is perpendicular to the orientation of the layers of GL. These results indicate that the cholinesterase staining of these layers is not attributable to the cells within the layers, but is dependent upon descending projections from the striate cortex.

These results turned our attention to the distribution of acetylcholinesterase in the striate cortex. In Galago, cholinesterase positive cells can be seen in layer VI of striate cortex; and in both species, striate cortex is distinguished from other cortical areas by a prominent band of cholinesterase activity which coincides mainly with the lower tier of layer IV. This band ends abruptly at the 17-18 border. The precise origin of this cholinesterase staining within layer IV of the striate cortex remains to be determined. However, the fact that layer VI pyramidal cells project to GL (Raczkowski & Diamond, Br. Res.144, 1978) and that these cells send axon collaterals to layer IV in the monkey (Lund & Booth, JCN, 1975) suggests that the cholinesterase positive cells in layer VI may be responsible for the cholinesterase activity at both thalamic and cortical sites.

2634 COMPARISON OF HEAD TILT BEHAVIOR DURING REARING IN STRIPED CYLINDERS WITH THE DEGREE OF MODIFICATION OF PREFERRED ORIENTATION IN VISUAL CORTICAL CELLS. Dorothy G. Flood*, Paul D. Coleman, and Robert C. Emerson. Dept. of Anatomy & Center for Visual Science, Univ. of Rochester, Rochester, NY 14642.

Rearing in striped cylinders has variably produced kittens whose visual cortical neurons have been modified to prefer the orientation experienced during rearing. We examined the influence of head tilt behavior during rearing on the modification of preferred orientation of cortical cells. Visual experience was limited to 100 or 300 hrs in horizontally or vertically striped cylinders, beginning at 4 wks of age. Head position was sampled by computer every second during the exposure. The cylinder light was turned off by the computer when the kitten's head tilted beyond a specified angular range. There were 3 groups of kittens with ranges specified as: continuous illumination or ±15° or 30° of erect. Kittens were then prepared for single unit recording using standard techniques of paralysis, anesthesia, and refraction. Tungsten-in-glass microelectrodes were angled to pass anteriorly down the medial bank of the lateral gyrus. A modified LINC-8 computer was used to present a square wave grating on a tangent screen (0.3 cycles/degree, moving broadside to and fro at 6°/sec) and to record in real time unit responses to the grating as a function of its orientation. Thirty-six to 91 units having a preferred orientation were recorded from 18 cats. All units that were encountered and isolated were studied, regardless of distance between units. The preferred orientation of each unit was plotted. Additionally the responses of all cells were summed at each orientation to produce the summed orientation preference of the sample of single units. Not only did some cats show a bias for the rearing orientation, while others did not show a bias, but some cats showed a bias for an orthogonal orientation. Generally, a subgroup of the inactive kittens formed the group which showed a bias toward the rearing orientation. Also restricted lighting conditions were somewhat more effective in producing biased cats. For kittens having a preferred orientation other than the rearing orientation, there is a preliminary indication that head tilt preferences during rearing were an important factor in producing a bias in the orientations of single units. 2635 DUAL RETINAL INNERVATION OF THE NUCLEUS RAPHE CENTRALIS SUPERIOR. Warren E. Foote. Dept. of Psychiatry, Harvard Med. Sch., Mass. General Hosp., Boston, MA 02114.

Prior work utilizing iontophoretic injections of horseradish peroxidase into the dorsal raphe nucleus revealed the presence of reaction product in the large "alpha" ganglion cells of the cat retina.

We now report the results of anatomical and electrophysiological experiments designed to determine if retinal afferents terminate in the nucleus raphe centralis superior. Applications of 4% horseradish peroxidase dissolved in .05m Tris-HCl buffer pH 8.6 were iontophoresed into the nucleus centralis superior in 4 cats. The animals were permitted to survive for 24 hours before being sacrificed and perfused with a 2.5% glutaraldehyde, 0.5% paraformaldehyde mixture. The brains and retinas were then removed and reacted with Hanker-Yates solution. Under oil immersion the presence of reaction product was detected in some of the large and small ganglion cells in all retinas. Ganglion cells containing reaction product were found scattered in all retinal quadrants but appeared to cluster in an area circumscribing the area centralis.

In an attempt to obtain confirmatory physiological data a series of animals were anesthetized and prepared for stimulation and unit recording. Bipolar stimulating electrodes were placed in the optic chiasm and superior colliculus and glass micropipettes were used for recording from cells in the nucleus centralis superior. Orthodromic activity was observed from both stimulation sites. The latency of activation from optic chiasm was dichotomous with one group of target neurons responding with a mean latency of 1.6 msec and another group with a mean latency of 6.6 msec. The combination of anatomical and physiological data suggest a dual retinal innervation of cells in the area of the nucleus centralis superior that appears to originate from the large "alpha" or y ganglion cells and the smaller "gamma" or w neurons.

2636 THE EFFECTS OF HEAVY METALS ON PHOTORECEPTOR FUNCTION. Donald A. Fox and Arnold J. Sillman. Dept. Animal Physiology, Univ. Calif., Davis, CA 95616.

Isolated perfused bullfrog (Rana catesbeiana) retinas, treated with sodium aspartate, were studied to determine whether or not heavy metals affect photoreceptor function. Sodium aspartate was present in the perfusing solution to suppress the PII and the proximal PIII components of the electroretinogram and to isolate the distal PIII or late receptor potential. Retinas were first perfused for 30 or 60 minutes with control Tris-Ringer and then for an equal duration with Tris-Ringer containing the chloride salt of either divalent lead (Pb), mercury (Hg) or cadmium (Cd). The concentration range of the heavy metals was 1 to 50 μM. Following each experimental perfusion the retina was again perfused with the control Tris-Ringer solution so as to compensate for any normal decay with time and to examine the reversibility of the effects. Rod and cone responses to brief light flashes were separated using previously described techniques (Sillman, Vision Res.14,1021,1974). Treatment of the retinas with either Pb, Hg or Cd resulted in decreases in the amplitude of the receptor potential of rods, but cones were never affected. The effects of Pb and Cd were reversible and concentration dependent. The effects of Hg were not reversible. On an equimolar basis Cd was two to three times more potent than Pb. Pb-treated photoreceptors exhibited a 0.7 log increase in absolute threshold. The results are consistent with reports describing scotopic vision deficits in human and non-human primates following exposure to either Pb or Hg. These observations suggest the involvement of rod photoreceptors as a primary lesion site in this deficit. The results predict that Cd exposure may produce clinical effects similar to those reported with Pb and Hg. (Supported by NIEHS ES05094 and PHS EY01839.)

2637 LINEAR FREQUENCY DOMAIN ANALYSIS OF PHOTOTRANSDUCTION IN THE FLY COMPOUND EYE REVEALS TEMPORAL RESONANCE BEHAVIOUR. Andrew S. French. Department of Physiology, University of Alberta, Canada.

The response of most photoreceptors to a brief flash of light consists of a slow graded depolarization or hyperpolarization. Although the early photochemical and biochemical stages of the process have been elucidated in several species, none of the mechanisms discovered so far can account for the time course of the response. The model originally proposed by Hodgkin and Fuortes to account for the dynamics of phototransduction in *Limulus* consists of a chain of exponential filters cascaded together. This model has been used with varying numbers of stages to describe the behaviour of several invertebrate and vertebrate photoreceptors.

We have shown previously that the frequency response function for light transduction is a useful method for testing the cascade model since the asymptotic gain and phase curves at high frequencies can be used to determine the number of stages involved. Unfortunately the signal to noise level of photoreceptors always drops progressively with ascending frequency so that it is difficult to determine the validity of the model and the number of stages with accuracy.

In the current work we have used an averaging technique to improve the signal to noise ratio at higher frequencies. Photoreceptors in the compound eye of *Phormia regina* were stimulated with repeated bursts of identical pseudo-random sequences of light fluctuations via a light emitting diode. The resultant membrane potential fluctuations recorded by microelectrodes were then averaged to reduce the inherent noise and the results processed as in normal linear systems analysis using a random input signal. This procedure resulted in significant improvement in the reliability of the frequency response function at higher frequencies, as measured by the coherence function. The frequency response function curves were fitted by the normal factorization of a polynomial into poles and zeros. All of the experimental results could be well fitted by a model which contained two second order poles and two first order poles. The presence of the second order poles indicates that there are temporal resonances occurring within the phototransduction mechanism and that the cascade model must be judged inadequate to account for the behaviour. In addition it was found that the phase portion of the frequency response function always lagged without limit as higher frequencies were approached. This strongly suggests that there is a pure delay element of several milliseconds present in the phototransduction mechanism.

2638 STRUCTURE OF GENICULATE X- AND Y-CELLS IN NORMAL AND MONOCULARLY DEPRIVED CATS. Michael J. Friedlander, C.-S. Lin, and S. M. Sherman. Dept. Physiol., Sch. Med., U. Va., Charlottesville, Va. 22908

At least 25 neurons in the dorsal lateral geniculate nucleus of normal adult cats were classified both physiologically and morphologically. To do this, we used intracellular recording and iontophoretic injection of horseradish peroxidase (HRP)[1]. Y-cells, morphologically, are Guillery's[2] class 1 cells, some are class 2, and the rest are intermediate between these morphological classes. Most X-cells, morphologically, are intermediate between Guillery's classes 2 and 3, while some are completely class 2 or 3.

Other morphological differences between X- and Y-cells were seen in our sample. 1) The X-cells have smaller somata. 2) X-cell dendrites tend to be elongated perpendicular to the lamination, while the Y-cells display no such asymmetry in their dendritic arborization. 3) Axons of most Y-cells issue collaterals within the region of the perigeniculate nucleus, while few X-cell axons have these collaterals. 4) Some X-cells issue intrageniculate axon collaterals, while none occur from Y-cell axons. 5) Dendrites of X-cells remain entirely within the lamina, while dendrites of Y-cells cross laminar boundaries.

In addition to the experiments on normal cats, preliminary data from monocularly deprived cats has been obtained. To date, only 7 cells from deprived animals have been analyzed. While soma sizes appear altered by the deprivation, the normal structure/function relationship, which relates receptive field type to dendritic morphology, appears unchanged. More detailed morphological studies of geniculate X- and Y-cells in monocularly deprived cats are in progress.

2639 **FUNCTIONAL ACTIVITY OF PIGEON OPTIC TECTUM REVEALED BY C-2-DEOXYGLUCOSE AUTORADIOGRAPHY.** **B. J. Frost and P. Ramm. Dept. Psych., Queen's Univ., Kingston, Ont., Canada, K7L 3N6.**

In the pigeon, single unit studies have shown that a majority of cells are optimally triggered by relatively small moving stimuli. Most of these same neurons however, do not respond to large textured patterns, and in fact have their response to small stimuli completely inhibited by patterns moved 'in-phase' (same direction and velocity)with test stimuli (Frost, 1978). These and other data suggest that one of the functions of the tectum is to 'notice' or respond to object motion and to ignore or veto self-induced motion produced by body, head or eye movements.

^{14}C-2-Deoxyglucose (^{14}C-2DG) autoradiography was used to reveal the relative responsiveness of tectal cells to small moving stimuli, to large textured patterns and to various combinations of these two types of stimuli. Lightly anesthetised birds were injected with 50 uci of ^{14}C-2-DG via the brachial vein. They were then rapidly inserted into a stereotaxic instrument and one eye opened to view a tangent screen upon which stimuli were projected, while the other eye was closed and occluded. One group of pigeons viewed for 45 minutes a single spot of light (<1° diameter) as it was repeatedly swept forward along the same 70° long horizontal path centered on the fovea. In other conditions birds viewed a large random dot pattern, with the same motion characteristics, and in-phase and anti-phase combinations of the test and background patterns. Autoradiographs were analysed using a computerized image processing system, so that the stimulated contralateral tectum could be compared to the ipsilateral tectum. The autoradiographs revealed no density increases in the region stimulated by the movement of the large random dot pattern, with or without the moving test spot. In contrast, forward motion of the small test spot alone produced a clearly visible and discretely localised area of increased density extending through all tectal laminae. This line of increased density ran posterior to anterior alons the tectum and was quite dorsally situated, thus suggesting that the lower visual field has a relatively larger tectal representation than the upper visual field.

2640 DISFACILITATION AND INHIBITION IN THE VERTEBRATE RETINA. Thomas E. Frumkes, Paul A. Coleman* and Nora Nicotera*. Dept. Psych., Queens Coll. of CUNY, Flushing, NY 11367.

The response properties of mudpuppy retinal neurons were examined by means of intracellular recording and current injection, and by studying receptive field properties. Most neurons with a predominantly depolarizing response show evidence of hyperpolarizing response components. For example, depolarizing bipolar cells often exhibit a small, hyperpolarizing prepotential (HPP) prior to depolarizing: in these cells, the HPP is more apparent with diffuse light stimulation than with a light flash restricted to the receptive field center. A similar HPP is also observed in the response of on-off amacrine and ganglion cells: hyperpolarizing current enhances the HPP while depolarizing current causes the HPP to diminish in amplitude. In contrast, the on and off IPSPs observed in on-off ganglion cells reverse when small amounts (less than 0.1 nA) of negative current are injected. Of interest, different amounts of current must be injected to reverse the on and off IPSPs of some on-off ganglion cells. Finally, ganglion cells can be categorized on the basis of their hyperpolarizing response components. For example, our analysis indicates the existence of three classes of off-center ganglion cells. Sustained off cells, which display a maintained hyperpolarization during photic stimulation and a small depolarization at light offset, show few obvious signs of any inhibitory input. Two classes of transient off ganglion cells respond with a phasic hyperpolarization at light onset and a depolarization-hyperpolarization sequence at light offset: in transient type I cells, the initial negative deflection is enhanced by hyperpolarizing current while the off negative deflection is reversed by hyperpolarization and appears to be a true IPSP; in transient type II cells, both on and off hyperpolarizations reverse with negative current injection and appear to be IPSPs. These results are consistent with the prior suggestions by Frumkes and Miller that different latencies of neurons in the outer nuclear layer play a major role in information processing, and that several different classes of amacrine cells supply the inhibitory input to ganglion cells.

2641 V2 IN THE MACAQUE: VISUOTOPIC ORGANIZATION AND EXTENT. Ricardo Gattass*, Julia H. Sandell* and Charles G. Gross (SPON: B. G. Hoebel). Dept. Psychol., Princeton Univ., Princeton, N. J. 08544

The visuotopic organization of V2 was investigated in Macaca fascicularis. Six monkeys were studied with multiunit electrodes while immobilized and under N_2O/O_2 in repeated recording sessions. V2 surrounds striate cortex and contains a virtually complete representation of the contralateral half field. It corresponds closely to von Bonin and Bailey's cytoarchitectonic area OB and is myeloarchitectonically distinguishable by a dense and homogeneous fiber pattern in layers IV to VI. Dorsolaterally, V2 includes most of the annectant gyri and the posterior bank of the lunate sulcus. It extends dorsomedially into the posterior bank of the parieto-occipital sulcus and ventromedially it includes the collateral sulcus, the posterior portion of the occipito-temporal sulcus and moves into inferior occipital sulcus. On the ventrolateral surface it includes the posterior bank of the inferior occipital sulcus.

The representation of the fovea in V2 is located ventrolaterally, adjacent to that of the foveal representation in V1. The representation of the vertical meridian in V2 is adjacent to that of V1 and the isoeccentricity lines in V2 are continuous with those in V1. The representation of the horizontal meridian splits and forms the anterior border of V2, laterally, medially and in the calcarine sulcus. The lower visual field is represented dorsally and dorsomedially and the upper visual field is represented ventrally and ventromedially. Thus as in the cat and owl monkey, V2 is a second order transformation of the visual field.

2642 PROJECTIONS OF THE LATERAL SUPRASYLVIAN VISUAL AREA TO THE PONTINE NUCLEUS OF CATS. Mitchell Glickstein, Janet Lee Cohen*, George Mower*, Farrel Robinson*, and Alan Gibson*. Dept. of Psych., Hunter Lab., Brown U., Providence, RI 02912

The lateral bank of the suprasylvian sulcus of cats receives a direct visual input from the dorsal lateral geniculate nucleus and contains several independent representations of the visual fields. The receptive field properties of cells in these lateral suprasylvian areas resemble those of pontine visual cells in that they are insensitive to the orientation of targets but responsive to their speed and direction. In the present study, we hoped to determine: 1) Where in the pontine nucleus fibers from lateral suprasylvian visual areas terminate. 2) Which cells in the lateral suprasylvian areas project to the pontine nuclei. 3) Whether some lateral suprasylvian cells project both to the superior colliculus and to the pontine nuclei by way of bifurcated axons.

We made lesions in the lateral suprasylvian area of three cats and mapped degenerating fibers in the pontine nuclei and superior colliculus. In two additional cats, we injected radioactive amino acids into the lateral suprasylvain area. In one case, we injected only this area. In the other, the other lateral suprasylvian cortex was injected along with visual area 18 and 19. We also injected small amounts of HRP into the pontine visual area of five cats and the superior colliculus of one cat and reacted the tissue to label corticopontine and corticotectal cells.

The lateral suprasylvian areas send a dense projection to the pontine nuclei. The projection overlaps that from other cortical visual areas but is more extensive. Nearly all of the fibers terminate in a zone which is just medial and ventral to the pyramidal tract in the rostral pons. Unlike other cortical visual areas, the lateral suprasylvian cortex also projects to the pontine nucleus on the opposite side. These contralateral projections are confined to a small medial region which also receives fibers from the ventral lateral geniculate nucleus. The cells of origin of the corticopontine tract are layer V pyramidal cells. Indirect evidence based on the shape and size of corticopontine and corticotectal cells and direct evidence from a parallel study of antidromic activation suggests that many layer V cells send an input both to the pons and to the colliculus by way of a bifurcated axon.

The research reported herein was supported in part by National Science Foundation Grant BNS77-16884, "Visual Input to the Cerebellum."

2643 THE C-WAVE OF THE ELECTRORETINOGRAM IN LIGHT AND DARK-REARED ALBINO RATS. Adrienne L. Graves*, Daniel G. Green, and Maureen K. Powers. (Spon. T.E. Robinson). Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI 48109.

The c-wave of the electroretinogram (ERG) is thought to be produced by the pigment epithelium in response to a light-induced decrease in extracellular potassium (K^+). The K^+ change is believed to be generated by the hyperpolarizing response of the photoreceptors. In view of this, the reports of failure to find a c-wave in albino rats are very surprising. Observations of our own suggested that the conditions of light-rearing might be an important confounding variable. Consequently, we recorded the ERG c-wave in 2 groups of albino rats. One group (N=14) was reared from birth in dim illumination (dark-reared) and the other group (N=20) was reared from birth in 12/12 cyclic light (light-reared). Rats were tested after birth from 22 days to about one year. In response to a one second flash (I= -1.2 log cd/m^2), all dark-reared animals showed c-wave responses ($\bar{x}$=301 μv). Rats reared in cyclic light typically showed no detectable c-wave; one young animal did show a very small (50 μv) c-wave in response to these flash conditions. Using a longer, brighter flash (5 sec, I=1.2 log cd/m^2), we were able to elicit small (<200 μv) c-waves in only 3 of the light-reared animals. This consistent difference, c-waves present in dark-reared animals but absent or severely diminished in light-reared animals, is probably not due to extensive light induced retinal damage. This could be ruled out because b-wave responses in the 2 groups of animals were indistinguishable. No differences were seen in b-wave thresholds for the 2 groups (I= -3.70 log cd/m^2 for dark-reared; I= -3.79 log cd/m^2 for light-reared). Maximum b-wave amplitudes were also comparable in the 2 groups ($\bar{x}$=994 μv for dark-reared; $\bar{x}$=987 μv for light-reared). No differences were seen in b-wave intensity-response functions in dark- and light-reared animals. Thus, we find that exposure to light can selectively interfere with the process of c-wave generation. Two possible mechanisms are: 1) light-rearing may cause photoreceptor debris to accumulate around the outer segments, so that ionic flow to the pigment epithelium is impeded; 2) light-rearing may damage the apical membrane of the pigment epithelium, so that it is unable to respond to extracellular K^+ changes. (Supported by EY00379).

2644 A PRETECTAL PROJECTION TO THE DORSAL LATERAL GENICULATE COMPLEX IN THE CAT. A.M. Graybiel, D.M. Berson*, T.P. Langer*, and C.L. Colby* (SPON: F.O. Schmitt). Dept. of Psychology, M.I.T., Cambridge, MA 02139

In the cat the pretectal region gives rise to an ascending extrageniculostriate pathway leading by way of the pulvinar-LI complex of the thalamus to parieto-occipital association cortex. This pathway is distinct from the tecto-thalamo-cortical channel leading from LPm to the lateral part of the Clare-Bishop complex. We here report that the pretectal region, like the superior colliculus, also sends a fiber projection to the dorsal lateral geniculate body (LGd). While the tectal projection is distributed mainly to the deep C-laminae, the pretectum projects mainly to the more dorsal laminae and to NIM. These observations confirm and extend earlier fiber degeneration findings described by Itoh (1977).

Pretectal efferents were studied by autoradiography in 28 adult cats. Without exception, ^{3}H-amino acid injections centered in the nucleus of the optic tract (NOT) elicited labelling of the LGd complex on the ipsilateral side. In several of the animals, labelling was dense enough to be seen at low power with dark-field optics. In the laminar LGd, labelled fibers formed a rich feltwork that was densest in layers A and A1 (including the monocular segment of A) and, variably, in lamina C. It is not clear that any labelled fibers terminated in laminae C1-C3, for labelling in these layers was weak and due at least in part to perforant fibers. Labelling of NIM was always as dense, and often denser, than that in the main LGd laminae. Extremely weak LGd labelling sometimes appeared contralaterally. It is striking that in the laminar LGd, the layers of densest labelling correspond to those richest in AchE activity and that in the LGd complex as a whole, the labelled regions correspond to those known to receive retinal Y-cell input.

In cases of thalamic or tectal injection sparing the pretectum, such a pattern of LGd labelling was absent, though in the thalamic cases labelled fibers passed through LGd in straight-line trajectories and after tectal injections a terminal field appeared in C_2/C_3. Pretectal deposits elicited labelling of LGd only when they involved NOT, save in one case (an olivary nucleus deposit with weak LGd labelling). Results in a case of HRP injection into LGd also suggest that the fiber projection arises in NOT, as most (but not all) HRP-positive cells in the pretectum were in NOT.

Since two amino acid deposits involving lateral NOT labelled mainly rostral LGd while 4 medial NOT injections labelled mainly caudal LGd, the pretecto-geniculate projection appears to have topographic order, at least along one main axis. 2645 EFFECT OF NEONATAL SECTION OF LATERAL RECTUS MUSCLE ON THE PROPERTIES OF RETINAL GANGLION CELLS OF CATS. D. I. Hamasaki* (SPON: S.H. Gruber). Bascom Palmer Eye Instit., Univ. Miami, Florida 33136.

At 10 days of age, the lateral rectus muscle was cut unilaterally in 6 kittens and bilaterally in one kitten. Experiments were conducted when the kittens were approximately 9 months old, and the properties of 468 ganglion cells were compared with the properties of 436 units recorded from normal cats.

The stimulus intensity required to elicit a firing rate of 200 spikes/sec was significantly higher for the units obtained from the experimental animals. This was found at all retinal loci tested. The maximum firing rate evoked by stimulating the receptive field center was significantly lower in the experimental animals at all retinal loci. The differences between the experimental and control animals were more marked for the units recorded in the area centralis. The correlation between the receptive field center size and conduction velocity found in normal animals was not found in the experimental animals.

These observations were made for units recorded from the operated as well as from the unoperated eye.

2646 ATTEMPTS TO MODIFY THE VESTIBULO-OCULAR REFLEX OF NORMAL AND DARK-REARED CATS. Laurence R. Harris* and Max S. Cynader (SPON: G.V. Goddard) Dalhousie University, Halifax, Nova Scotia, Canada.

We have developed a method by which the vestibulo-ocular reflex (VOR) may be modified within 1 hour in a normal adult cat and that maintains its effects for at least one hour after the adapting period. When a cat is rotated sinusoidally in the light, vestibular and optokinetic information combine to produce very accurate compensatory eye movements. If, however, an optokinetic drum is rotated continuously in one direction at a velocity equal to the peak velocity of the simultaneous sinusoidal oscillation of the cat, the visual information conflicts with the vestibular signal in one direction, while enhancing the vestibular signal in the other. The gain of the VOR is asked to double in one direction and simultaneously to decrease to zero in the other. Since it is the difference between the responses to the two directions that is of interest, any confounding effect of variation in the gain of the VOR with arousal etc... is minimized.

After one hour of this procedure in the normal cat the gain of the VOR (measured in the dark) goes to two in one direction and zero in the other. However, measurement of the VOR at different frequencies reveals that the effect of adaptation is to add a constant velocity (that of the drum) to the normal VOR. Thus, at lower frequencies (lower peak velocities), the gain increases above two in one direction and actually becomes negative in the other.

The VOR of a dark-reared cat normally has a very low gain (Harris and Cynader, ARVO, 1979). Attempts to modify the dark-reared's VOR with the same method as above revealed no modifiability, even though visual and vestibular information could combine to produce appropriate compensatory eye movements measured in the light.

Surprisingly, physical movement of the animal is not necessary for modification of the VOR in the normal cat. After one hour of drum movement, the subsequent optokinetic afternystagmus (OKAN) is sufficient by itself to explain the observed modification of the VOR. This explanation of VOR modification is supported by the observation that the dark-reared cat, whose VOR could not be modified, shows no significant OKAN.

2647 A HYPOTHALAMO-TECTAL PROJECTION IN THE CAT: EVIDENCE OF PATCH-LIKE TERMINATIONS WITHIN THE SUPERIOR COLLICULUS. John K. Harting, Michael F. Huerta, Joseph T. Weber, and G. James Royce. Dept. of Anatomy, University of Wisconsin, Madison, WI 53706.

Following an injection of tritiated proline into the dorsal part of the tuberal region of the hypothalamus, an extensive and dramatic pattern of transported protein is apparent within the ipsilateral superior colliculus. In one particular experiment the injection site of ^{3}H-proline lies primarily within the dorsal hypothalamic area (see figure). To a lesser degree the precursor spreads into the lateral hypothalamic area and the most medial tip of the zona incerta. The bulk of the label in the superior colliculus occupies the stratum griseum intermediale (SGI). Specifically, the silver grains are aggregated into: (1) a puff at the medial margin of the SGI which measures 700μ dorsoventrally and 450μ mediolaterally, (2) a tier of small clusters of label at the most dorsal boundary of the SGI, and (3) a lateral tier of label which follows the ventral border of the SGI and measures 1700μ mediolaterally and 300μ dorsoventrally. While there are other scattered areas of label in the SGI, the medial puff and the ventrolateral tier described above are continuous in the rostral-caudal extent of the colliculus. We emphasize that the SGI contains the greatest amount of transported protein (see figure). Layers ventral to the SGI contain only sparse label which is fibrous in appearance.

A second, extemely dense zone of label is located in the region of the central grey which lies immediately medial to the deepest collicular laminae. Although the distribution of transported protein does not cross the dorsal or ventral borders of the central grey, the lateral boundary is crossed by a flange of label which extends into the mesencephalic reticular formation at the horizontal level of the cerebral aqueduct.

2648 DEMONSTRATION OF OCULAR DOMINANCE COLUMNS IN NISSL STAINED SECTIONS OF MONKEY VISUAL CORTEX FOLLOWING ENUCLEATION. E. C. Haseltine*, E. J. DeBruyn*, and V. A. Casagrande. Departments of Anatomy and Psychology, Vanderbilt University, Nashville, TN 37232.

Enucleation produces trophic effects in both the lateral geniculate nucleus (LGN) and visual cortex of mammals. We studied the geniculostriate system of a monkey following long term monocular enucleation in order to determine 1) if deprived cells in the LGN maintain connections with cortex, and 2) if any deprivation related changes can be demonstrated in visual cortex. The right eye of a wild adult cynomologus macaque was removed. Following a survival time of 29 months the remaining eye was injected with 500 µCi of ^{3}H proline and both cortices were injected with 30% horseradish peroxidase (HRP). Two days later, the animal was perfused and appropriate sections were processed for autoradiography, reacted with diaminobenzidine, or stained with cresyl violet. Examination of the LGN showed that although cells in the denervated laminae were 39% to 53% smaller in area than their non-deprived counterparts, the percentage (90%-95%) of HRP labelled cells from the cortical injections was approximately equal in all layers. This demonstrates that the deafferented neurons maintain cortical connections.

Inspection of the visual cortex revealed a striking and unexpected change. In Nissl sections, layer IV of striate cortex in both hemispheres showed alternating light and dark variations in staining that were comparable in width (300µ-500µ) to ocular dominance columns previously described in this species (Hubel et. al. '68, '76, 77). Although adjacent light and dark bands were of equal widths, there were 20%-30% more neurons in the dark bands, and cells in these bands were 7%-14% smaller than those in light bands. Because of differences in the degree of overlap in the bands, we were unable to determine if individual cells in the darker bands were more heavily stained. Comparison between the two hemispheres in the monocular region of cortex indicated that the darker columns represent the enucleated eye. With regard to these results, it is noteworthy that a decrease in cell size and an increase in cell packing density have also been observed in cats following early nerve crush (Cragg, '75). Taken together, these results demonstrate that in addition to transneuronal changes in the LGN, removal of one eye of a primate can result in dramatic changes in the visual cortex, even after maturity.

2649 CELL BIRTH IN THE DORSAL LATERAL GENICULATE NUCLEUS OF THE CAT: A H^3-THYMIDINE STUDY. T.L. Hickey and N.R. Cox*. School of Optometry/The Medical Center and Department of Comparative Medicine, University of Alabama in Birmingham, Birmingham, AL 35294.

Single 'pulse' injections of H^3-thymidine have been used to define the birthdates of nerve cells in the cat dorsal lateral geniculate nucleus.

Using the following procedure dividing cells destined to form the dorsal lateral geniculate nucleus have been radioactively labeled in individual kitten fetuses of known gestational age. In order to gain access to the uterus a laparotomy is performed in each mother cat. Once the uterus has been exposed a single injection of H^3-thymidine (500 µCi in .05cc of sterile water) is made, through the uterine wall, into each conceptus. The intact uterus is then returned to its normal position in the abdomen and all surgical incisions closed. Following surgery the mother cat is housed in a metabolic cage for a period of two weeks during which time all waste products are collected and checked for radioactivity. At the end of the two weeks the mother cat is returned to her home cage and allowed to deliver her kittens normally. All kittens are reared for at least two months with either normal binocular visual experience or with the lids of one eye sutured closed. Each animal is then sacrificed and blocks of brain tissue embedded in paraffin and processed routinely for autoradiography. Since the radioactively labeled thymidine is injected directly into each conceptus it is necessary to expose the autoradiographs for only three-to-four weeks.

The results of these injections show that most dorsal lateral geniculate nucleus cells in the cat are generated during a period of rapid cell proliferation that begins during the fourth week of gestation and continues for slightly longer than one week. Although cell proliferation is most rapid between gestational days twenty-five and twenty-nine, a few dorsal lateral geniculate nucleus cells are born as late as gestational day thirty-three. Injections made at later times, including gestational days thirty-five, thirty-seven and fifty-five, have, in the animals processed to date, failed to label any cells in the dorsal lateral geniculate nucleus. However, other visual system structures do contain labeled cells with birthdates later than gestational day thirty-three.

Since, in the monocularly lid-sutured kittens, cells with the same birthdates can be found in both the deprived and non-deprived laminae of the dorsal lateral geniculate nucleus, deprivation induced changes in cell cross-sectional area can be determined for different populations of cells.

2650 LAMINAR ORIGINS OF IPSILATERAL TECTOBULBAR PATHWAYS. Virginia Holcombe and William C. Hall. Departments of Anatomy and Psychology, Duke University, Durham, N.C.

As part of an ongoing investigation of the laminar organization of the superior colliculus in the grey squirrel, Sciurus carolinensis, the ipsilateral pathways from the superior colliculus to the brainstem have been studied with the following anterograde and retrograde techniques. Buffered solutions of tritiated leucine and/or lysine were injected electrophoretically into the superior colliculus 45-50 hours before sacrifice; series of 30-40µm sections were defatted, exposed to photosensitive emulsion for 4-5 weeks, developed, and counterstained. HRP (30% in saline) was injected electrophoretically into the brainstem 24-48 hours before sacrifice; series of 40-48µm sections were processed with 3,3',5,5'-tetramethyl benzidine and counterstained for Nissl substance.

When tritiated amino acids are injected into the superior colliculus, a prominent well-defined efferent pathway can be traced laterally and ventrally through the ipsilateral brainstem. The terminal fields of this pathway include the lateral tegmentum and the dorsolateral pontine nucleus.

When HRP is injected into the dorsolateral pontine nucleus and dorsally adjacent tegmentum, peroxidase-filled cells are located in all laminae of the superior colliculus with the exception of stratum zonale. In a typical case, the majority of labeled cells are located in stratum griseum superficiale while the remaining cells are distributed throughout stratum opticum, stratum griseum intermediale, and stratum griseum profundum. In stratum griseum superficiale, the number of labeled cells increases caudally.

Injections of tritiated amino acids, as well as lesions, which are restricted to stratum griseum superficiale suggest that the tectopontine projection arises in large part from superficial collicular laminae. Thus, the cells located in the deeper laminae, which are labeled following our HRP injections, may be the source of the projection to lateral tegmentum. We are currently seeking a more refined distinction between the cells of origin of these two projections by making a series of more restricted injections of HRP.

2651 NEW PHOTOGRAPHIC METHODS FOR THE MEASUREMENT OF ACCOMMODATION AND REFRACTIVE STATE OF VERTEBRATE EYES. Howard C. Howland, Christopher Murphy* and Joanne Ballarino*; Division of Biological Sciences, 136 Langmuir Laboratory, Cornell University, Ithaca, New York 14853.

We have developed three new methods for the photographic measurement of accommodation and refractive state of vertebrate eyes. The first, applied to the great horned owl (Bubo virginianus) and the barred owl (Strix varia)involves the continuous binocular photographic measurement of degree of defocus relative to the plane of the camera, using a photorefractive method developed for single still pictures (Howland & Howland, 1974). The very large size of the owl's pupil provides enough light for continuous recording on Tri X cinematographic film. With this technique, we have been able to show that owls are normally focussed for distant vision, that the range of accommodation in the great horned and barred owls under semi-natural (tethered) conditions is no greater than 2 diopters and that their eyes are essentially non-astigmatic.

Secondly we have developed a method for the photographic determination of the axis of astigmatism in humans and the relative sign of defocus (in front of or behind) the camera. This method requires the use of simple attachment to a 35 mm camera consisting of a fiber optic light guide centered in an extension ring to photograph the pupils of the subject. The principle is the same as that of conventional photorefraction with the exception that the camera is focussed both in front of and behind the subject, and the two pictures are compared to determine the sign of defocus. Astigmatisms appear as an elliptical pupil reflex with the axes of the ellipse indicating the axes of the astigmatism.

Lastly we have developed a new photokeratometer, also an attachment to a 35 mm camera consisting of a ring of 8 light emitting diodes. The diode array is powered by a 9 volt calculator battery. The ring is used together with an extension tube set and the magnified image of the point source diodes is photographed on ASA 3000 speed recording film. By measuring the image diameters of the ring of lights it is possible to compute the corneal curvature and hence dioptric power from the known constants of the optical system in four meridia simultaneously.

2652 THE ORGANIZATION OF RETINOCOLLICULAR PATHWAYS IN MAMMALS. Michael F. Huerta, Joseph T. Weber and John K. Harting. Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706.

We have made extensive use of the anterograde autoradiographic tracing method in order to analyze the organization of retinocollicular pathways in thirty different mammals. Representatives of the following orders were studied: monotremata, marsupialia, chiroptera, edentata, rodentia, lagomorpha, artiodactyla, carnivora, and primata.

Our data reveal several important features of retinocollicular organization across mammals. In several cases, exceptions have been omitted in order to generalize.

In all mammals thus far studied, retinal axons end exclusively within tectal laminae lying dorsal to and including the stratum opticum. The contralateral projection extends throughout the rostral-caudal extent of the colliculus. Terminations are most dense within the medial portions of the stratum zonale and the dorsal part of the stratum griseum superficiale. Caudal zones of the contralateral colliculus contain more label than do rostral levels. To a slight degree in carnivores and in all primates a patch-like distribution of contralateral endings are present within the binocular region of the colliculus, whereas lower orders have continuous contralateral input.

The ipsilateral retinocollicular pathway is less extensive than the contralateral in its overall projection (i.e., rostrocaudally and mediolaterally). In some of the lower forms this pathway is reduced, consisting of only one or two small patches of label. In contrast, primates possess an extensive ipsilateral pathway. The ipsilateral projection is also restricted in its laminar distribution, usually being confined to one of the sublayers of the superficial grey. In this regard, the ipsilateral input present in higher forms terminates within regions of the stratum griseum superficiale, while in lower mammals the stratum opticum is the locus of ipsilateral endings. Finally and quite importantly, the ipsilateral pathway terminates ventral to the region of densest contralateral input and always ends in a puff-like, discontinuous manner.

Additional points of interest are that: (1) in all primates the density of label within the collicular region containing the representation of central vision is reduced (but not absent) when compared with label present within the zone containing the representation of the peripheral visual field, (2) the greatest degree of ocular segregation, as revealed anatomically in our studies, is present in several marsupials and the prosimian Galago, and (3) the only mammals that do not possess an ipsilateral pathway are the echidna, the armadillo and the tree shrew.

2653 PERCEPTUAL GROUPING AND PATTERN DISCRIMINATION IN THE DESTRIATE CAT. H. C. Hughes and J. M. Sprague. Dept.Anat.,Sch.Med.,Univ.of Pennsylvania, Phila., PA 19104.

Using a two choice discrimination apparatus, cats were tested for their capacity to polarize rectilinear arrays of pattern elements (dots or oriented line segments) into "rows" which appear oriented either at 45° or 135°. This apparent cohesion between figural elements is known as "perceptual grouping", and in this case, the association between elements is governed by their relative proximity to one another. These grouping effects are generally regarded as being importantly involved in one of the earliest stages of visual form and pattern perception, the division of the visual field into a figure-ground dichotomy.

A set of lattice-like arrays was generated through systematic variation of the spatial relationships between the pattern elements. The arrays were constructed so as to vary widely in the ease with which perceived orientation can be induced, that is, they vary in the magnitude of the proximity cue (i.e., relative spacing between elements). The patterns were then used to construct "frequency-of-seeing" curves which relate discrimination performance with the magnitude of the proximity cue. These psychometric functions were obtained before and after removal of areas 17 and 18.

In view of the large magnification factor associated with the striate and peri-striate representation of the visual field, it was hypothesized that the central representation of the spatial relationships between figural elements in these patterns would be most precisely elaborated within these areas. Accordingly, we expected that removal of areas 17-18 would impair the grouping process, especially when it was initiated by near-threshold proximity cues.

The results indicate that the formation of a linear gestalt in cats is immediate and unlearned, as judged by their near-perfect transfer of learned discriminations of obliquely oriented square-wave gratings to the rectilinear dot-patterns.

In contrast to our expectations, removal of area 17 and 18 had little effect on the grouping process, even under conditions of weak proximity cues. However, discrimination of randomly distributed arrays of similarly oriented line segments, a problem which requires a fine grain analysis of the geometry of the pattern elements, is adversely affected by the lesion.

The results thus indicate that processes which may mark the initial stages of form and pattern processing do not require the participation of striate-peristriate visual cortex, but that these cortices are important for more detailed spatial analysis, an interpretation that is consistent with parallel processing models of visual perception. (Supported by grants EY00577 and EY05130-02).

2654 Anatomical organization of layer IV in tree shrew striate cortex (area 17): evidence for two sublaminae. A.L. Humphrey & J.S. Lund, Dept. of Ophthalmology, Univ. of Washington, Seattle, WA 98195

The striate cortex of the tree shrew (Tupaia glis) does not have ocular dominance columns but it does have a highly organized orientation column system. The majority of cells in all cortical layers are binocular and/or orientation selective. As part of an investigation into the anatomical substrates for binocularity and orientation selectivity in the tree shrew striate cortex we studied the structural organization of layer IV, the site of major input to area 17 from the dorsal lateral geniculate nucleus (dLGN). Examination of the distribution of thalamic afferents to layer IV, and of the cell types within the layer, their dendritic spread and their axon trajectories outside of the layer leads us to conclude that layer IV of the tree shrew striate cortex consists of two laminar subdivisions.

Afferents to striate cortex were labeled using the method of anterograde transport of horseradish peroxidase (HRP) following injection of the enzyme into the optic radiations. Afferents from the dLGN previously have been shown to terminate in layers I, IIIB and IV in tree shrew striate cortex (Harting, Diamond & Hall, JCN, 150, '73). We examined HRP filled axons distributing in these laminae in the dorsal binocular region of area 17. Within layer IV, individual axons were seen to terminate only in the upper or lower half of the layer, with little encroachment upon the other half. The majority of the axon fields occupied from one half to all of the upper or lower subdivision of layer IV; axons with more narrow fields (≤1/3rd of a subdivision) were located adjacent to the layer IIIC-IV border. The average horizontal extent of single axon fields in both subdivisions was about 150 microns.

Examination of cells in the striate cortex stained using the Golgi rapid method further suggested a bipartite subdivision of layer IV. Three types of impregnated cells were seen in the layer: spiny stellate, non-spiny stellate, and pyramidal cells. Only stellate cells were present in the upper half of the layer; the lower half contained all three cell types. The dendritic trees of the spiny stellate cells tended to be stratified at the upper and lower boundaries of the two laminar subdivisions, while spiny stellate cells more centrally located in each subdivision had more spreading dendrites that spanned a greater thickness of the subdivision. The pyramidal cell somata and basal dendrites partially clustered at the upper border of the lower subdivision of layer IV. The apical dendrites of the pyramidal cells arborized in layer IIIB, as did the pyramidal cell recurrent axon collaterals and the axon collaterals of the spiny stellate cells of the lower division. In contrast, the collaterals of spiny stellate cells in at least the most superficial part of layer IV arborized in layer IIIC.

2655 RESPONSES OF X AND Y LATERAL GENICULATE UNITS TO STATIONARY AND MOVING STIMULI. [1]Linda S. Ide* and Robert C. Emerson. Center for Visual Science, Univ. of Rochester, Rochester, NY 14627; [1]Dept. of Pharmacolog. & Physiolog. Sci., Univ. of Chicago, 947 E. 58th Street, Chicago, IL 60637.

Responses of 72 units recorded from the dorsal laminae of the cat's dorsal lateral geniculate nucleus were examined to determine whether units classified as X versus Y on the basis of linearity of summation in the receptive field differ in their patterns of responses to stationary and moving bar and edge stimuli. Several types of "null tests" were used to evaluate whether units summed effects of simultaneous luminance increments and decrements in an essentially linear manner. Thirty-five units were classified as X (linearly-summing) and 26 as Y (non-linearly-summing). Eleven units were incompletely classified or had ambiguous response properties. Stimuli of relatively low contrast were used, with luminances ranging from 0.3 to 0.6 log units above a background of 1.2-1.4 cd/m^2. Response patterns of both X and Y units could be interpreted as reflecting the interaction of antagonistic center and surround response mechanisms. Certain properties of the response patterns of Y units, however, support the hypothesis of Hochstein and Shapley that Y units have, in addition, nonlinear subunits within their receptive fields. Presentations of stationary stimuli to X units typically elicited responses whose character shifted abruptly between center- and surround-dominance as a function of stimulus position. Comparable abrupt shifts did not occur in responses of Y units; rather, mixed center-surround responses were elicited over a significant portion of the receptive field. Center and surround response components were more transient in Y units, with generally faster rise times. Further, surround response components were more pronounced in Y units. In responses to moving stimuli the greater strength of surround response components in Y units was reflected in more pronounced responses associated with stimulation of the distal surround by moving bars and edges. Some of the differences between responses of X and Y units appeared to depend on stimulus contrast. For example, a few X units tested at slightly higher contrasts showed stronger surround responses. Differences between X and Y units along a number of receptive field parameters support the idea that the two populations subserve distinct functions.

2656 EFFECT OF PRETECTUM ABLATION ON DETECTION OF BARRIERS AND APERTURES BY FROGS. David Ingle, Brandeis University, Waltham, Massachusetts 02154.

Earlier studies in our lab demonstrated that ablation of optic tectum in frogs had no effect on the ability to negotiate barriers orapertures. Our recording studies in frog and those of Ewert in the toad revealed units in the "pretectal" region which may be called "stationary object detectors" in contrast to motion-dependent units of tectum.

The present study tested the hypothesis that barrier detection critically depends upon the integrity of the posterior thalamus or pretectal region. Eight frogs with ablation of the posterior third of the dorsal thalamus were severely or totally deficient in turning beyond the terminal edge of a hemicylindrical barrier. Control lesions in anterior or middle thalamus had no significant effect on this test. None of the lesions severely affected avoidance jumps elicited by visual threat.

Four animals who jumped randomly to the large barrier could rather consistently avoid a small (30° wide barrier) placed in a homogeneous white field. The same animals, however, also avoided a black or white aperture in a small compartment instead of jumping through to escape noxious stimuli. We conclude that a primitive mode of object vision survives some of these lesions, such that frogs can avoid a small area that is either darker or lighter than the homogeneous wide-field background, but fail to appreciate depth relationships. However, frogs which fail even the "small barrier" test can still avoid looming discs - an ability associated with the optic tectum.

Because tectum ablation in the tree-shrew can also dissociate deficits in food-localization from barrier detour capacity, we raise the possibility that mammalian pretectum mediates comparable "locomotor orientation" by mammals.

2657 CORTICAL BINOCULAR RECEPTIVE FIELDS AFTER VISUAL FIELD ROTATION IN DEVELOPING KITTENS: EFFECTS OF SUBSEQUENT NORMAL VISUAL EXPOSURE DURING ADULTHOOD. Michael R. Isley*, Kenneth R. Plummer*, and Paul G. Shinkman. Univ. North Carolina, Chapel Hill, N.C. 27514.

Previously (Shinkman, Bruce, & Isley, 1977) we showed that when kittens' early visual experience consisted of left- and right-eye visual fields optically rotated in opposite directions about the visual axes (16° of disparity between the two eyes), the distribution of interocular differences (IOD) in visual cortical cells' preferred stimulus orientations was found subsequently to be centered about the rotation experienced during early development.

The purpose of the present experiment was to assess the permanence of this effect, and its susceptibility to modification by subsequent normal visual experience during adulthood. Two kittens were reared in darkness except for two hours every day between the ages of 4 and 12 weeks, during which the kittens viewed a normal environment through goggles fitted with small prisms arranged so as to introduce a relative rotation between the visual fields in the left and right eyes, 8° counterclockwise in the left eye and 8° clockwise in the right eye. Both kittens showed good visual behavior: accurate orienting toward and pursuit of visual targets, good discrimination on a visual cliff, and so forth. Subsequently, the receptive field organization of visual cortex was studied, and the earlier results were confirmed. Except for the IOD distribution, the organization of visual cortex resembled that found in normally reared kittens, in terms of ocular dominance, orderly arrangements of orientation columns, and topographic representation of the visual field. The IOD distribution was centered about the experienced rotation ($\bar{X}$=19.7°), and the mean differed significantly from the expected value of 0° found in normally reared kittens.

The kittens were subsequently returned to the main colony without goggles where they experienced a normal visual environment for about 5 months, between the ages of 8 and 13 months. Each kitten was then retested to assess the effects of this exposure upon the physiological organization of visual cortex.

No changes were found. The pattern of results was the same as in the earlier measurements. The mean of the IOD distribution was 17.3°; this value differed significantly from 0° but not from the previously obtained mean of 19.7°. We conclude that the altered distribution of disparities between visual cortical cells' preferred stimulus orientations in the two eyes, induced by visual experience with prism goggles between the ages of 4 and 12 weeks, is permanent and not subject to modification by subsequent prolonged visual experience without the goggles during adulthood.

2658 MODE OF PARASYMPATHETIC INNERVATION OF THE INTRINSIC MUSCULATURE OF THE EYE IN THE MACAQUE MONKEY AND RABBIT. R.J. Jaeger*and L.A. Benevento, Anat. Dept., Univ. of Ill. Med. Ctr., Chicago, IL.

The pathways controlling the intrinsic musculature of the eye are not fully understood. The most general view is based upon the observations that surgical removal of the short ciliary nerves in monkeys produced chromatolysis in 97% of ciliary ganglion (CG) cells while iridectomy alone caused chromatolysis in only 3% of the cells (Warwick, J. Anat. 88: 71, 1954). More recent physiological and pharmacological studies in monkeys challenge the view that a postganglionic pathway is involved in accommodation (Westheimer & Blair, Inves. Ophthal. 12: 193,1973). In the present study we investigated the mode of innervation of the intrinsic musculature by monitoring the retrograde transport of horseradish peroxidase (HRP). In both monkeys (Macaca iris) and rabbits the sclera was punctured with the needle of a 50 µl syringe and a series of 1 to 3 µl deposits of 20% HRP were made about the ciliary body and iris. The surface of the bulb was flushed with ophthalmic solutions immediately after puncture and withdrawal to minimize external flow of HRP. As a control for any seepage of HRP on to the eye or into the orbit, HRP was applied topically as well as injected subfascially in separate animals. After 24 hrs. the animals were perfused and the ciliary ganglia and brainstems were processed with the benzidene method. In the monkey, although it was not likely that we had the entire CG due to attrition of material during dissection, HRP reaction and processing, we have estimated that 20% of the cells were labeled. This percentage may represent the effectiveness of our intraocular application of HRP. The cells found in the brainstem were scattered throughout the dorsoventral extent of the midline of the oculomotor complex along the borders that the visceral nuclei (Edinger-Westphal, E-W) have with the somatic and accessory oculomotor nuclei. The cells were distributed in such a way that it was not possible to collectively assign them to a nucleus or nuclei. The cells did not have the usual appearance of the somatic cell types, but had smaller somas with sparce and often elongated dendritic fields. Some cells were clearly of the visceral type. In the rabbit, the results in the brainstem were similar. The labeled cells were of the visceral type and were, again, found at the edge of the E-W adjacent to the somatic and accessory nuclei. These projections appear to be unilateral. In the controls no cells were found in the brainstem. Although remote, the possibility of retrograde transsynaptic transport across gap junctions in the CG might explain our results and stay in harmony with the classic view. It might also be hypothesized that a ganglionic plexus in the intrinsic musculature exists in parallel with the CG. (Supported by grant EY2940)

2659 SEARCH FOR THE ORIGIN OF REPLACEMENT TERMINALS IN THE LATERAL GENICULATE NUCLEUS, PARS DORSALIS (LGd) OF THE ANOPHTHALMIC MOUSE USING HRP AND CORTICAL LESIONS: A LIGHT AND ELECTRON MICROSCOPIC ANALYSIS. I. R. KAISERMAN-ABRAMOF. Dept. Psych., Massachusetts Institute of Technology, Cambridge, Mass. 02139 and Dept. Anat., School of Med., Case Western Reserve University, Cleveland, Ohio 44106.

Using the anophthalmic mutant mouse (ZRDCT-An) as a model of primary deafferentation of the visual system, we have previously described a surprisingly normal anatomy of the LGd, visual cortex and oculomotor nucleus. Although these centers are somewhat reduced in volume and cell number, they contain the neuronal types that characterize the normal visual centers. Experimental analysis (HRP) of the circuitry of this mutant indicated that, despite complete absence of a retina, afferent and efferent connectivity exists between the LGd and striate cortex; in addition our study demonstrated a greater input from the thalamic LP and LD to the striate cortex. This quantitative difference in connectivity may represent a plastic and/or compensatory response that occurs during the differentiation of the visual system of the anophthalmic mouse.

A single distinctive feature of the mutant LGd at the ultrastructural level is the presence of a large terminal that replaces the retinal terminal in the glomeruli. The present study was directed toward identification of these large replacement terminals. The most likely origins were considered to be the cerebral cortex, thalamic nuclei or other subcortical centers.

The participation of other thalamic nuclei in providing replacement terminals was tested by microiontophoretic injection of HRP into the LGd of anophthalmic and normal mice. No HRP labeled cells were observed in any thalamic nuclei. Only the parabigeminal nucleus which is extra-thalamic was labeled; connectivity is known to exist between this nucleus and the superior colliculus. Cortical origin was tested in experiments on 31 animals in which discrete lesions were placed in area 17 and areas 17, 18, and 18a. In addition hemidecortication was performed. These lesions were made using suction. Also thermocoagulation was used to produce lesions extending beyond the visual cortex. Survival times varied from 2.5 to 14 days to allow detection of progressive degeneration. Most cortical lesions were made on the right side; the left LGd served as a control. The expected degenerative signs appeared in the ipsilateral LGd; however the replacement terminals persisted within the glomerular structure. This investigation indicates a subcortical origin of the large axonal terminals that replace the retinal afferents in the anophthalmic mouse.

2660 DEVELOPMENT OF RETINOGENICULATE SYNAPSES IN THE DORSAL LATERAL GENICULATE NUCLEUS OF THE CAT. R.E. Kalil and G. Scott*. Department of Anatomy, University of Wisconsin, Madison, WI 53706.

Our previous light microscopical work has shown that afferents from the retina have reached the dorsal lateral geniculate nucleus (LGN) and are arrayed in an orderly laminar arrangement in the newborn kitten. It is of interest to know whether retinal axons have made synaptic connections in the LGN at the time of birth, but at present there is little information available concerning the developmental timetable for retinogeniculate synapse formation.

We have therefore used the electron microscope to study this problem in a series of cats ranging in age from newborn to adult (intermediate ages, 1, 2, 4, and 8 weeks). The animals were perfused with a mixture of paraformaldehyde and glutaraldehyde, and parasagittal slabs of the entire LGN were embedded in eponaraldite. Photographic montages were constructed from thin sections restricted to lamina A near the center of the LGN, and terminals from the retina were identified on the basis of their relatively large size, round vesicle shape and pale mitochondria (RLP classification of Guillery, '69).

In the newborn, RLP terminals make simple axodendritic synaptic contacts. The postsynaptic profiles do not contain vesicles, nor do any retinogeniculate synapses appear to be isolated from the surrounding neuropil by glial sheets. At one week, RLP terminals are somewhat more evident than in the newborn kitten, but synaptic organization remains essentially unchanged. The encapsulation of synaptic zones begins at around two weeks postnatal, but is not a prominent feature until four weeks. The end of the first month also marks a change in the complexity of retinogeniculate synaptic organization since many postsynaptic elements themselves contain synaptic vesicles. By eight weeks, synaptic complexes similar in configuration to those in the adult are common.

These results demonstrate that the morphological substrate for the relay of information from the retina through the LGN exists at birth in the cat. However, the development of mature retinogeniculate synaptic complexes does not take place until the second postnatal month, which may be related to the relatively late emergence of Y-cell responses in the LGN (Daniels et al., '78).

2661 PENTOBARBITAL ENHANCES THE ACTION OF MUSCIMOL ON DOPAMINE TURNOVER IN THE RAT RETINA. Cylia W. Kamp* and William W. Morgan. Dept. Anat., Univ. Texas Hlth. Sci. Ctr., San Antonio, TX 78284.

Pentobarbital (PB) may exert part of its anesthetic action by potentiating GABAergic mechanisms. Recently, we demonstrated a GABAergic influence on the light-induced increase in DA turnover in the rat retina (Kamp and Morgan, Fed. Proc. 38:747, 1979). Muscimol (Mu), a GABA agonist, reduced the light-mediated enhancement of DA turnover in a dose-dependent fashion while picrotoxinin (Px), a GABA antagonist, blocked the effect of Mu on DA turnover. The present experiments were designed to determine the ability of PB to potentiate this GABAergic action. Five groups of rats were dark-adapted for 15 hr, and at the end of this time, one group was sacrificed without subsequent exposure to light while the other groups were exposed to light for 60 min before sacrifice. The first group of light-exposed rats was treated with a cumulative dosage of Mu (6.6 µmole/kg, i.v.), a concentration previously shown to be ineffective in altering DA turnover. The second group received an anesthetic dosage of PB (40 mg/kg, i.v., cumulative), and the third was treated with a combination of Mu and PB. The control group received saline injections at all time points. Half of the animals in all 5 groups were injected with α methyl-p-tyrosine (αMPT 250 mg/kg, i.p.) 60 min before sacrifice. The retinas were removed and frozen immediately after sacrifice. Later, DA contents were assayed radioenzymatically, and the rate of DA turnover was estimated from the depletion of DA following αMPT administration. Once again, light significantly enhanced retinal DA turnover in dark-adapted rats. Neither PB nor the low dose of Mu alone altered the dopaminergic response to light, but the combination of PB and Mu dramatically reduced the light-induced increase in DA turnover ($p<0.005$). In a separate experiment Px (1.88 mg/kg, i.v.) blocked the reduction in retinal DA turnover produced by the combination of PB and Mu. These data provide evidence for a GABA potentiating action of PB in the retina. The reliability of this retinal DA system as an in vivo test model of drugs which modulate the GABA system in the CNS is currently being investigated. 2662 RELATIONSHIP OF NEURONAL TO K-RESPONSES IN MUDPUPPY RETINA. Chester Karwoski, Hiroshi Shimazaki* and Luis Proenza. Depts. of Psychology and Zoology, Univ. Georgia, Athens, GA 30602.

Intracellular responses of on/off-neurons (probably amacrine cells) and of Müller (glial) cells, and changes in $[K^+]_o$, were recorded in the mudpuppy eyecup. A drop of Ringers was placed in the eye to retard drying.

Within a thin layer of the distal retina, an apparent light-evoked K-increase was observed in about 20% of the penetrations. The response was usually labile and its amplitude was typically small, but on two occasions it was greater than 0.6 mM. When observed, the distal K-increase always showed strong surround antagonism, but additional data on its behavior remain limited.

In the proximal retina, the light-evoked increase in K was quantitatively compared to Müller cell responses. This K-increase had maximum amplitudes of up to 0.6-1.0 mM, which should evoke glial responses of 5-9 mV. The rise time and latency of the K-increase were generally slower than glial responses, suggesting dead space may normally degrade the recorded K-response. In a few penetrations, however, the time course of the proximal K-increase was as fast as that of glial responses, so, on fortuitous occasions, dead space effects seem negligible. In these cases the half-decay time of K and glial responses was similar: 2-3 sec. Analysis of the spatiotemporal characteristics of the K-decay suggest both active reuptake and diffusion play roles in the clearance of K from extracellular space.

Müller cell responses show surround antagonism and decreased amplitude to high intensity stimuli, as previously shown in eyecups drained of vitreous. Müller cells in undrained eyes had large, stable resting potentials, but responses were small, averaging only 1-3 mV at maximum.

All on/off-neuron responses show initial transient and later sustained components. The sustained component shows surround antagonism and decreased amplitude to high intensity stimuli, which together with other evidence suggests that on/off neurons liberate much of the K recorded in the proximal retina. On/off responses and recorded K may be related as follows: (1) on/off neurons release K in proportion to their level of depolarization, (2) K accumulates in (is integrated by) extracellular space, and (3) the accumulating K is cleared by processes that have a half-decay time of ~2.5 sec. These three events can be modelled by passing on/off responses through a low-pass filter network having appropriate rise and decay times. The resultant "smoothed" neural responses bear striking similarities to K and Müller cell responses in all aspects yet examined.

2663 EYE MOVEMENT-DEPENDENT ENHANCEMENT OF VISUAL RESPONSES IN THE PULVINAR NUCLEUS OF THE MONKEY. William Keys* and David Lee Robinson. Laboratory of Sensorimotor Research, National Eye Institute, Bethesda, MD 20014; Behavioral Sciences Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014; and Department of Neurology, Georgetown University, Washington DC.

Cells in the superior colliculus and several cortical visual areas are excited by visual stimuli and show an enhanced response to a stimulus in their receptive field when a monkey uses this stimulus as the target for an eye movement. The behavioral contexts in which enhancement takes place vary for these regions of the brain. We have recorded from the pulvinar nucleus because its subdivisions receive inputs from these structures, and we wished to determine if enhancement were present and under which behavioral conditions it was demonstrable.

We have studied over 200 neurons in three rhesus monkeys trained on several tasks. The animals learned (1) to fixate a spot of light while visual stimuli were presented passively in the periphery, (2) to execute a saccadic eye movement from the fixation spot to another target, and (3) to maintain fixation while attending to a second light in the periphery. Extracellular single unit activity and eye movements were monitored while the monkey performed these tasks.

Ten percent of the cells in the pulvinar show a 50% increase in the response to a receptive field stimulus when the monkey uses that stimulus as the target for a saccade. This enhancement is spatially nonselective; the incremented firing rate is present when the animal makes saccades away from and into the receptive field. A similar proportion of cells in striate and prestriate cortices show enhancement that is likewise spatially nonselective but is nonspecific for eye movements (Wurtz and Mohler, 1976; Baizer and Robinson, 1974). The enhanced visual responses in the pulvinar are specific for eye movements. The modulation is present when the animal makes a saccade to a peripheral stimulus and is absent when the animal attends to but makes no eye movement toward the same stimulus. Enhancement in the superior colliculus and frontal eye fields is similarly dependent on eye movements but is spatially selective (Wurtz and Mohler, 1976; Bushnell, Robinson, and Goldberg, 1978). Thus the enhancement found in the pulvinar is unique. No other area of the brain is known to combine spatial nonselectivity with eye movement specificity.

The augmented firing of pulvinar cells in the enhanced condition indicates that a visually guided saccade is about to occur; it does not appear to encode the direction or size of the impending saccade. Such signals prior to eye movements may be useful to perceptual portions of the visual system in dealing with changes in the nature of the afferent stimulation caused by each eye movement.

2664 A SPECTRAL OPPONENT MECHANISM ENCODED BY ON-TYPE GANGLION CELLS OF RANA PIPIENS. Earl Kicliter and Yuzo M. Chino*, Laboratory of Neurobiology, University of Puerto Rico, San Juan, PR 00901, Illinois College of Optometry, Chicago, IL 60616.

We have previously shown that the major spectral opponent process on which the blue preference behavior of Rana pipiens is dependent, involves an interaction between the $\lambda_{max} \cong 432$ nm pigment of the green rods and the $\lambda_{max} \cong 580$ nm pigment of the principal and/or single cones (Kay and Kicliter, ARVO, 1978). We show here that some ON-type ganglion cells terminating in the anterior thalamus of these frogs encode the same spectral opponent process. Recordings were made from the anterior thalamus of Rana pipiens in or near the neuropils of Bellonci and the corpus geniculatum thalami, using tungsten-in-glass electrodes. Single ON-type units were isolated and were stimulated in the following manner. First, the receptive field of the unit was mapped. Then a spot of light was positioned within the receptive field center. The spot was composed of beams from 2 sources combined with a beamsplitter. Beam 1 was composed of short wavelength monochromatic light (dominant wavelength 450 nm). Beam 2 could be formed of any of 10 monochromatic stimuli varying in wavelength from 430-650 nm; these 10 stimuli were adjusted for equal quantal flux with a neutral density wedge. One sec stimuli were presented and total spikes in a 2 sec interval beginning with stimulus onset were counted. Activity produced by stimulation with beam 1 alone is defined as baseline activity. When beams 1 and 2 were combined, the following results were obtained. When the dominant wavelength of beam 2 was less than 500 nm activity was increased over the baseline rate. When the dominant wavelength of beam 2 was 500-640 nm activity was reduced as compared to baseline. Not all ON-type units appeared to respond in this manner, but at least some units encode the same spectral opponent process on which the behavior is based. This strengthens the evidence that the blue preference behavior of Rana pipiens is dependent on information transmitted to the anterior thalamus by ON-type ganglion cells.

2665 RETINAL INVOLVEMENT IN THE ELONGATION OF NEONATALLY SUTURED CAT EYES. Albert W. Kirby and Harold Weiss*. Ophthalmology Dept., Kresge Eye Institute, Wayne State Univ. School of Medicine, Detroit, Mich. 48201.

Last year at this meeting we reported that the sutured eye of monocularly deprived (MD) neonatal cats and monkeys shows an increase in axial length compared to the fellow eye. In agreement with an earlier report by Wiesel & Raviola (1977) the deprived eye of a monkey is myopic. The deprived cat eyes are sometimes myopic and sometimes not. In the case of the non-myopic eyes the corneal curvature usually compensates for the increase in axial length. The amount of myopia differs considerably from that predicted on the basis of axial length differences alone, and the corneal changes, although in the right direction, are in most cases not sufficient to explain the absence of myopia in the non-myopic cats. Raviola & Wiesel (1978) further reported that dark rearing MD monkeys prevented the increase in globe length, seemingly implicating retinal absorption of light in the process. We sought to test this in cats by two methods: ablating all or part of the retina with laser photocoagulation, thereby destroying the involved retinal region and presumably preventing axial elongation; and by dark rearing MD cats.

Laser treatment alone apparently has no effect on eye growth. While we sometimes have trouble manipulating a small eye sufficiently to ablate the entire retina, we certainly ablate a large portion including the area centralis and surrounding regions. Lasered and fellow eyes develop in an identical manner. If we suture an eye which has previously been lasered, it elongates similarly to MD through suture alone, although it is certainly true that some critical retinal patch may have been missed by the laser. Finally, dark rearing seems to prevent axial elongation. While dark reared MD cats show equal axial dimensions in both eyes, their MD litter mates, reared under normal lighting conditions, show increased axial dimensions in the sutured eye.

Unfortunately we do not know the mechanism of axial elongation in MD cats or the reason the cornea sometimes compensates for the increase in axial length. It does, however, appear that some retinal absorption of light is required to provide visual feedback which somehow controls eye growth.

2666 BINOCULAR COMPETITION: ITS ENHANCEMENT BY NOREPINEPHRINE. Baruch Kuppermann* and Takuji Kasamatsu. Division of Biology, California Institute of Technology, Pasadena, CA 91125

It has previously been proposed that norepinephrine (NE) plays a role in synaptic plasticity in the cat visual cortex (Kasamatsu and Pettigrew, Science 194, 1976; Pettigrew and Kasamatsu, Nature 271, 1978). In the present study, cats given continuous local perfusions of 50 µM NE for seven days with a binocular environment were found to have a conspicuous lack of cells dominated by the ipsilateral eye, even though the ratio of binocularly:monocularly driven cells remained unchanged. This effect was not seen for periods of NE perfusion of less than three days. A slight innate contralateral bias in ocular dominance (OD) distribution has long been observed (Hubel and Wiesel, J. Physiol. 160, 1962). Therefore, NE is involved in exaggerating this natural bias in OD distribution. Several normal kittens were subjected to the same procedure, continuous local perfusion of 50 µM NE for seven days, but were simultaneously kept in the dark. The resulting OD histograms were quite normal, with none of the exaggerated contralateral skewedness observed. This suggests that the tendency for NE to induce a contralateral bias is activity-dependent. In current experiments, spontaneous retinal activity is being directly manipulated to further test this hypothesis.

2667 SUBCORTICAL PROJECTIONS TO DORSAL LGN. Thomas P. Langer* and Carol L. Colby* (SPON: J.G. Malpeli). Dept. of Psychology, MIT, Cambridge, MA 02139.

We have examined the anatomical properties of those neurons in the superficial gray of the cat superior colliculus (SC) which project to the dorsal lateral geniculate nucleus (dLGN). In particular we have looked at their size, shape and position in relation to the known afferents and efferents of the superficial gray.

Small dense electrophoretic injections of HRP were made in the C laminae of dLGN. Sections were reacted with TMB which is essential for demonstrating the very small neurons in the dLGN projection.

After injections centered in the C laminae of dLGN, labelled neurons were found in a compact group at the corresponding retinotopic position in the ipsilateral SC. They were distributed throughout the depth of the zone of horizontal cells (0-250 µm below the collicular surface) and less densely within the upper margin of the zone of vertical cells (occasionally as deep as 350 µm). This region of the SC is known to receive a heavy input from the contralateral retina, the nucleus of the optic tract(NOT) and from both parabigeminal nuclei (PB) in addition to a lighter input from areas 17, 18 and 19 in visual cortex.

The HRP-labelled neurons were among the smallest encountered in the SC (mean cross-sectional area 33.4 $\mu m^2 \pm 15.2\ \mu m^2$ S.D.). There was little dendritic filling but the location, size, shape and proximal dendrites, where present, suggested that these were the stellate granule cells found in this region in Golgi impregnated material.

The collicular projection to dLGN is but one part of a network of interconnections involving SC, PB, NOT and dLGN. Labelled neurons were also found bilaterally in the parabigeminal nuclei, the NOT and in the parabrachial mesencephalic reticular formation along with the adjacent central gray ventral to the inferior colliculus. Ipsilateral neurons were more numerous in all these regions and the NOT group of labelled cells was almost entirely ipsilateral. The cells were of a variety of sizes but tended to be smaller than the average within each region. The labelled cells in PB were among the smallest neurons in that nucleus.

The collicular neurons labelled by HRP injections of the C laminae of dLGN are a discrete, well characterized population distinct from populations which project to other visual structures. The compactness of the labelled population suggests a tight retinotopic correspondence in this projection. Other subcortical projections to dorsal lateral geniculate nucleus appear to originate from equally distinct subpopulations of cells.

2668 SPATIAL AND TEMPORAL CONTRAST SENSITIVITY IN MONOCULARLY DEPRIVED CATS. Stephen Lehmkuhle, Kenneth E. Kratz, and S. Murray Sherman. Dept. Physiol., Sch. Med., U. Va., Charlottesville, Va. 22908, U.S.A.

We measured spatial and temporal contrast sensitivity functions (CSFs), which plot the reciprocal of the contrast threshold as a function of spatial or temporal frequency, for a normally reared cat and two cats raised with monocular eyelid suture. Using the operant technique of conditioned suppression, we trained cats to suppress a licking response whenever a CRT-generated, counterphased, sine-wave grating replaced a homogeneous field of equal space average luminance. Contrast thresholds were estimated during a testing session using a staircase procedure.

The spatial and temporal CSFs of the nondeprived eyes of the monocularly deprived cats were similar to those of the normal cat. At lower temporal frequencies (e.g., 1 Hz), the spatial CSF showed an attenuation in sensitivity for spatial frequencies lower and higher than the peak frequency (0.5 c/deg). At higher temporal frequencies (e.g., 25 Hz), the spatial CSF showed reduced sensitivity for all spatial frequencies; however, there was no relative attenuation for low spatial frequencies. The temporal CSFs, which were measured at the most sensitive spatial frequency, showed a peak at 3 to 5 Hz, and attenuation for lower and higher temporal frequencies.

We found that contrast sensitivity of the deprived eye was nearly 1.5 log units lower than that for the nondeprived eye for all spatial and temporal frequencies investigated. The magnitude of this sensitivity loss was similar for both monocularly deprived cats, and has remained unchanged over a 9-month period of testing. Also, the shape of the spatial CSF did not change with temporal frequency.

These behavioral results indicate that the visual impairment of the deprived eye is more than a loss in acuity, but also represents a severe amblyopia that covers the entire spatial frequency spectrum. Moreover, these data complement the physiological result that there is a functional reduction of Y-cells in the deprived geniculate laminae.

Supported by USPHS grant EY01565 and NSF grant BNS77-06785.

2669 RECEPTIVE FIELD PROPERTIES OF CELLS RECEIVING CALLOSAL INPUT. Franco Leporé, Jean-Paul Guillemot*. Dept. Psycho., U. of Montreal, Montreal, Canada.

The aim of the present experiment was to study the receptive field (R.F.) properties of cortical cells which receive part of their input from the contralateral hemisphere via the corpus callosum. Two groups of cats were used for recording unit activity: a normal group which served to gather normative data and an experimental group consisting of cats which had their optic chiasma split across the midline three weeks to three months prior to the recording session. Because of the surgery, the normal binocular input was abolished and any cortical cell manifesting this property must be receiving its input directly from the eye ipsilateral to the recording site via the geniculostriate pathway and indirectly from the contralateral eye via a callosal pathway. Acute recordings were carried out in the conventional way using tungsten microelectrodes and N_2O:O_2 anasthesia. The recording site was the 17-18 border. The stimulus consisted of thin bar generated on an oscilloscope screen by a computer. The bar, whose orientation was varied automatically from 0^o to 345^o in 15^o steps, was swept across the screen at constant speed orthogonal to the orientation. Three R.F. properties were studied using quantitative criteria: (a) R.F. position in relation to the vertical meridian, (b) ocular dominance, and (c) orientation tuning. Data from normal cats confirm the published results obtained under similar conditions: i.e. R.F. lie near the vertical meridian which they sometimes straddle, ocular dominance distributions were biased towards binocularity and orientation tuning varied from extremely fine tuned unidirectional cells, to bidirectional cells to untuned cells. The picture was somewhat different for chiasma sectioned cats: few cells were visually unresponsive, especially in recently sectioned cats; their R.F. were situated near or overlapping the vertical meridian; cells were all monocular during the first 200μ of the penetration and beyond about 600μ, between these two limits many of the cells were binocular although the ocular dominance distribution mainly favored the ipsilateral geniculostriate pathway; orientation tuning was similar for both the ipsilateral and contralateral (callosal) eye, the latter tuning curves being as fine or finer than the former.

2670 EFFECTS OF REVERSE SUTURE ON OCULAR DOMINANCE COLUMNS IN RHESUS MONKEY. Simon LeVay, Torsten N. Wiesel and David H. Hubel. Dept. Neurobiol., Harvard Medical School, Boston, MA 02115.

Monocular lid-suture in newborn rhesus monkeys redirects the development of ocular dominance columns in the striate cortex, so that the open- and closed-eye afferents to layer 4C segregate out into columns of unequal width. The effect is clear by 3 weeks of age, and by 6 weeks both the anatomy and physiology are very similar to what is seen in long-term deprived animals.

Can the deprived eye's afferents, once they have segregated out into their shrunken, fragmented columns, be induced to grow back into the territory they have vacated? To answer this question we studied animals in which the closed eye was re-opened and the seeing eye sutured shut. Ages at reverse suture were 3 weeks, 6 weeks and 1 year, and the animals survived for at least 5 months. Techniques included recording during tangential electrode penetrations and autoradiography of transneuronally transported 3H-proline.

In a monkey reverse-sutured at 3 weeks injection of the initially deprived eye gave rise to a surprising labelling pattern in layer 4C. The labelled columns were greatly expanded in the lower part of the layer (4Cβ) but shrunken in the upper part (4Cα). We interpret this pattern to mean that the afferents from the deprived parvocellular laminae of the LGN were induced to re-expand their territory even beyond their normal width, while the deprived magnocellular afferents were not induced to recover at all. Outside of layer 4C, neurons were overwhelmingly dominated by the initially deprived eye. With reverse suture at 6 weeks the autoradiography showed a recovery - in 4Cβ only - to a normal columnar width, but not an expansion beyond that; physiological responses in layer 4C matched the autoradiography. Again, the other cortical layers were dominated by the initially deprived eye. With reverse suture at 1 year there was no anatomical or physiological recovery.

The physiological results are similar to those of Blakemore et al. (J.Physiol.283,1978) in indicating a reversibility of eye preference after the effects of the initial deprivation have taken place. The autoradiography suggests that this process involves a contraction and later re-expansion of the afferents for the deprived eye in layer 4C. The alternative model, by which deprived-eye synapses are suppressed and later derepressed (Blakemore et al.,'78), seems less likely, but more precise anatomical methods will be required to resolve the issue. The period of anatomical plasticity seems to end earlier for the magnocellular than for the parvocellular afferents.

2671 EVIDENCE FOR AN EXTRA-GENICULATE THALAMIC RELAY FROM THE RETINA TO CORTICAL AREAS 19 AND CLARE-BISHOP IN THE CAT. Audie G. Leventhal, Jeremy Keens* and Istvan Törk*. School of Anatomy, Univ. of N.S.W., Kensington, N.S.W., Australia.

A direct retino-pulvinar projection has been reported in several species, including the cat (cf. Berman and Jones, Brain Res. 134:237-248, 1977). We have investigated the afferent and efferent connections of the retinal recipient zone (RRZ) of the cats' pulvinar by 1) injecting tritiated proline into one eye and, in the same animal, injecting horseradish peroxidase (HRP) into the visual cortex, 2) comparing the distributions of labelled cells in the pulvinar following HRP injections into cortical areas 17, 18, 19 and Clare-Bishop, 3) removing one eye of adult cats, injecting HRP into their visual cortex and investigating terminal degeneration electron microscopically and 4) injecting HRP into the RRZ electrophoretically.

The results confirm a direct retino-pulvinar projection since 1) autoradiographic label was present in the RRZ after 72 hours survival, 2) degenerating terminals were found in the RRZ after monocular enucleation and 3) HRP injections into the RRZ labelled ganglion cells. We observed that cells of the RRZ project to cortical areas 19 and Clare-Bishop but not to areas 17 and 18. Labelled cells were observed in the C laminae of the lateral geniculate nucleus (LGNd) and in the medial interlaminar nucleus (MIN) following injections into each of the four areas. RRZ "relay cells" were small. They were similar in size to those of the parvocellular C laminae of the LGNd.

The retinal ganglion cells projecting to the RRZ all had medium sized somas and most were from 18 to 22 microns in diameter. The dendritic fields of over 200 ganglion cells with labelled dendrites were measured and found to be large: most were over 300 and many were over 500 microns in diameter even though complete "golgi-like" filling was not obtained in the HRP processed retinas. Thus, ganglion cells projecting to the RRZ had somas similar in size to those of beta cells but dendritic fields much more like those of gamma cells: no beta cell in Boycott and Wässle's (J. Physiol. 240: 397-419, 1974) sample had a dendritic field larger than 300 microns in diameter.

It has been suggested that gamma cells correspond to the physiological class of W cells (Boycott and Wässle, '74) and that the small relay cells of the parvocellular C laminae receive exclusively W cell afferents (Wilson et al., J. Neurophysiol. 39:1193-1209, 1976). Therefore, we suggest that 1) the RRZ is a region outside of the "conventional" limits of the LGNd via which the activity of W type ganglion cells is relayed to the visual cortex and 2) that the ganglion cells projecting to the RRZ represent a morphological class that has not yet been described.

2672 EFFECTS OF LESIONS OF PARIETO-OCCIPITAL ASSOCIATION CORTEX UPON PERFORMANCE OF OCULOMOTOR AND ATTENTION TASKS IN MONKEYS. James C. Lynch and Jay W. McLaren. Department of Physiology, Mayo Clinic and Foundation, Rochester, Minnesota 55901.

Parieto-occipital association cortex has been implicated in the functions of visual attention and oculomotor control by both clinical and electrophysiological studies. In the present series of experiments, four monkeys were trained to visually fixate a 0.1° target and to follow it as it moved smoothly across a 52° square screen at velocities of 6-30°/sec and also as it suddenly jumped 8-24°. Eye position was measured with chronic electrooculographic (EOG) electrodes. EOG signals were digitized and stored for later computer analysis. After several weeks of baseline data collection, each animal received either a unilateral lesion or a one- or two-stage bilateral lesion. The size of the lesions ranged from about 2/3 of Brodmann's area 7 to all of area 7 plus adjacent prestriate cortex and the anterior bank of the intraparietal sulcus (posterior area 5).

The three monkeys which received bilateral lesions were impaired in their ability to accurately track a target moving 20°/sec or faster. Deficits consisted of either reduced ability to match eye velocity to target velocity or increased latency of initiation of slow pursuit movements. Horizontal and vertical tracking were affected, though not always both in the same monkey. Three monkeys were tested after unilateral lesion and showed no tracking deficit. The ability to accurately maintain fixation of a stationary target did not appear to be affected by any of our lesions. Inspection of raw data plots and preliminary statistical analysis of about 4500 saccade trials showed increased saccade latency following both unilateral and bilateral lesions. Latency was most frequently increased for saccades from the center of the screen toward the side ipsilateral to a unilateral lesion. Detailed statistical analysis of horizontal and vertical saccades is still in progress.

No evidence has been found of contralateral neglect of unilateral visual stimuli following lesion. One monkey was trained on a visual extinction task and showed no tendency to *ignore contralateral stimuli in paired stimulus* presentations following lesion.

These results support the proposal that parieto-occipital cortex plays an important role in the initiation and control of visually-evoked eye movements, and suggest that damage to this cortical region alone is not sufficient to produce the contralateral neglect which has been reported to follow larger parieto-occipito-temporal lesions in monkeys.

2673 RETINAL DIMENSIONS OF RECEPTIVE FIELDS INCREASE DURING GROWTH IN THE GOLDFISH. Alan Macy and Stephen S. Easter, Jr. (SPON: L.T. Rutledge). University of Michigan, Ann Arbor, Michigan 48109

The goldfish retina grows both by expansion and by the addition of new cells at its margins. As the fish lengthens from 70 mm to 200 mm, the diameter of its eye increases by 2.5X. This means that if a ganglion cell's receptive field diameter measured in μm on the retinal surface remains constant during growth, the angular subtense of its receptive field will decrease. The angular subtense will remain constant only if the receptive field diameter measured in μm on the retina, increases by 2.5X. To determine the manner in which the distribution of receptive field diameters changes with growth, we recorded intraocularly from retinal ganglion cells of small (<70 mm) and large (>200 mm) intact, paralyzed, submerged goldfish while spot stimuli were presented on a tangent screen. Area sensitivity functions were used to calculate receptive field diameters.

The mean angular subtense (± SEM) of receptive fields was $15.1^{o} \pm 1.3^{o}$ in small fish and $11.7^{o} \pm 0.8^{o}$ in large fish. This corresponds to an increase in receptive field diameters from 520 μm in the small fish to 1,040 μm in the large. Thus, neither angular subtense nor retinal dimensions of receptive fields remain constant during growth.

Receptive field diameters may change so as to maintain a constant amount of overlap with neighboring fields. To test this hypothesis, ganglion cell densities were determined from retinal area measurements[1] and optic nerve fiber counts in small and large fish. Calculated from these densities, the constant overlap hypothesis predicts a change in receptive field subtense from 15.1^{o} to 11.9^{o}, and is therefore supported by the data. Preliminary data indicate that the small observed decrease in angular subtense is not due simply to poorer image quality in the small fish. If dendritic tree size and receptive field diameter are related, as is widely believed, our results show that dendritic tree size increases during growth. 2674 SOME OBSERVATIONS ON THE ORGANIZATION OF THE RETINAL PROJECTIONS TO THE PRETECTUM AND SUPERIOR COLLICULUS IN THE MACAQUE MONKEY AS DEMONSTRATED BY THE COMBINED USE OF LASER BEAM LESIONS OF THE RETINA AND AUTORADIOGRAPHY. Debra J. Magnuson, Michael Rezak, Louis A. Benevento, Dept. Anat., Univ. Ill. Med. Ctr., Chicago, Ill. 60680.

Seven macaque monkeys received argon laser beam lesions of specified regions of the retina in one eye. Several weeks later an intravitreal injection of ^{3}H-proline was made in the same eye with the idea that the proline would be taken up by the surviving ganglion cells. Monkeys without lesions but with proline injections served as controls. Examination of Nissl stained whole mounts of the lesioned retinae provided confirmation of the distribution of surviving ganglion cells. In addition, the distribution of grains within the dorsal lateral geniculate nucleus, whose retinotopic organization is well known, served to further verify the extent of the lesion. The distribution of grains in the superior colliculus (SC) was in accord with previous workers and followed the precise retinotopic map previously shown to exist. Except in those cases which had lesions restricted to the papulomacular bundle, grains were seen in the appropriate portions of the SC including the anterior or foveal portion. These results may provide evidence for a direct projection from the fovea which was previously in doubt. However, that these results are due to transsynaptic transport of tritium cannot be dismissed. Within the pretectum the sublentiform nucleus (SL) and the olivary nucleus (ON) had a more dense concentration of grains on the contralateral side. In the SL no clear retinotopic organization was found and this region still contained a dense amount of grains in cases with foveal lesions. Within ON, however, the distribution of grains from individual cases suggested that the foveal representation occupies a major part of the nucleus. Although there was an excellent correlation between the boundaries of retinal damage and the distribution of grains in the geniculate and SC, such a correlation was not clear in the ON. The fovea appears to be centered about the ventral portion of the nucleus. A poor retinotopy along with a strong foveal representation, coming directly from retina, in the ON should not be surprising since this nucleus has been shown to project directly to the Edinger-Westphal part of the oculomotor complex which controls, in turn, the intrinsic musculature of the eye. In the case of the pupillary light reflex, for example, it would be necessary for the photopic receptors in the fovea to have rather direct access to the Edinger-Westphal nucleus and this is apparently possible via the olivary nucleus. In contrast a poor retinotopy with a strong representation from the periphery may not be surprising for SL since this region projects to regions of the pulvinar which project to parietal cortex. 2675 GOAL DIRECTED EYE MOVEMENTS BY INTRALAMINAR THALAMIC STIMULATION IN ALERT CATS. H. Maldonado*, J.-P. Joseph* and J. Schlag (SPON: M.L. Schlag-Rey). Dept. Anat. and BRI, Sch. Med. UCLA, Los Angeles, CA 90024.

Presaccadic neuronal activity recorded in the thalamic internal medullary lamina (IML) of cats suggests a participation of this cell population in the command of eye movements (EM). The elicitation of eye movements by electrical stimulation was studied in alert, intact animals (previous results were obtained in encéphale isolé). The head was fixed; vertical and horizontal electrooculographic recordings were made with implanted Ag-AgCl electrodes. Electrical pulses were applied through stereotaxically driven tungsten microelectrodes in and around the IML including nuclei ventralis lateralis (VL), lateralis posterior (LP), lateralis dorsalis (LD) and medial pulvinar (Pul). Pulses of 0.1 msec duration at a 250/sec rate were systematically used. Train duration was varied from 50 to 500 msec and intensity from 10 to 500 μA. Current threshold was defined as that sufficient to evoke EMs in 50% of the trials. All elicited eye deviations were conjugate, contraversive, and dependent on the alertness state of the animal. Three kinds of EMs were distinguished: (1) Goal directed i.e., the direction and amplitude depended on the initial eye position. The goal was an area about 5 deg^{2} located at least 10 deg away from the center. The greater the distance between initial position and goal, the more likely was a threshold stimulus to be effective, the amplitude was larger, and the latency of saccades was shorter. Minimum latency was 35 msec. Stimulus durations longer than 250 msec could produce double saccades of different directions, bringing the gaze to the goal. Head turning was obtained in experiments in which the animal's head was not fixed. Goal-directed saccades were observed exclusively with IML stimulations but only in 20% of the cases. (2) Direction and Amplitude Specific i.e., the direction was specific of the site stimulated and the amplitude was a function of stimulus current and train duration. Minimum latency was 55 msec. Stimulus durations longer than 250 msec could also produce double saccades but in the same direction. This type of saccade was the most commonly observed by stimulation of all sites explored except VL. (3) Centering i.e., whatever the initial eye position, the stimulation brought back the gaze to the center. These saccades were always accompanied by other movements (e.g. of face, ears, whiskers, neck, body). They were evoked only from VL. Minimum latency was 90 msec. The findings that goal-directed saccades were specific of the IML, that minimum thresholds (16μA) and minimum latencies were obtained with IML stimulation, may be related to the role of this structure in visual targeting. Supported by USPHS grant NS-04955 and CONACYT fellowship 16002, Mexico.

2676 INTRINSIC PROCESSING IN THE VISUAL CORTEX OF PRIMATES.
R. J. W. Mansfield and L. K. Simmons.
Psychology Department, Harvard University, Cambridge, MA. 02138.

The multiplicity of retinotopically organized, often reciprocally interconnected cortical areas in the primate brain raises the problem of analysing intrinsic properties apart from those resulting from extrinsic connections. One approach is the use of isolated preparations of cerebral cortex to facilitate the electrophysiological and pharmacological study of neuronal properties under more controlled conditions than are found in vivo.

To determine at a cellular level the nature of the intrinsic processing, we examined in vitro perfused thin slices (600 μm) of monkey visual cortex that were sectioned normal to the pial surface to retain functionally intact their columnar organization. The slices were mounted in a chamber on the stage of a microscope permitting direct visual placement of electrodes. In addition, cell soma and their processes could be visualized with Nomarski optics or viewed for epi-fluorescence after labelling with horseradish peroxidase conjugated with the fluorogen tetramethyl rhodamine isothiocyanate. A multiport perfusion system and small chamber volume allowed the rapid exchange of normal perfusate with perfusates containing various ions or pharmacological agents.

Of particular interest was the initial segment of the cortico-cortical pathway formed by the pyramidal cells in Layers II and III of Area 17, but similar results were obtained from slices from both the prelunate gyrus and the inferior parietal lobule. Previous work indicated that the pyramidal neurons in Layers II and III could be well activated by brief bipolar electrical stimulation in Layer I or IV. Their responses are reversibly abolished by low calcium perfusate or by atropine, but not by nicotinic antagonists, suggesting that the activation is mediated by cholinergic synapses of the muscarinic type. Low frequency stimulation reversibly depressed the response with exponential decay and recovery phases. The depression was not blocked by the gabinergic antagonist bicuculline, but rather this drug released a long latency component.

These results suggest a cellular basis for intracolumnar adaptation and pericolumnar inhibition. (Supported in part by NSF grant BNS75-08437.)

2677 MODULATION OF LGN CELL RESPONSIVITY BY VISUAL ACTIVATION OF THE CORTICOGENICULATE PATHWAY. R.T. Marrocco, J.W. McClurkin*, and Z.H.H. Farooqui*. Dept. Psychol. Univ. of Oregon, Eugene, OR 97403.

Corticogeniculate (CG) cells in layer VI of striate cortex have receptive fields similar to non-CG cells of the same layer. They are usually complex fields and require moving stimuli. Their receptive field areas in monkey average about 4 sq.deg. (Hubel and Wiesel, 1968). Receptive fields of monkey LGN cells average about 0.04 sq. deg., some two orders of magnitude smaller than the CG cells that may contact them. Moreover, there is a strict retinotopic correspondence between the field location of a geniculate cell and its CG feedback. By using a windmill-type (radial grating) stimulus that lacked a circular central disc, we were able to indirectly modulate an LGN cell's response to a flashing spot without directly stimulating its receptive field.

The activity of LGN cells in paralyzed, N_2O anesthetized macaque monkeys was recorded with microelectrodes and their receptive field properties measured with chromatic or achromatic spots on neutral or chromatic backgrounds, and with counterphasing sine wave gratings. Spike latencies to optic chiasm shock were also measured. Averaged responses to small and large spots (1) with and (2) without the stationary windmill were compiled. We also averaged responses to the spot in the presence of the same windmill (3) in radial motion, which by itself had no apparent effect on the cell's spontaneous activity.

Comparisons of conditions (1) and (3) showed that windmill movement produced net excitatory or inhibitory effects in different cells. Effects were seen as a change in the initial transient component of the LGN cell's response, or both the transient and sustained components, but not in the sustained component alone. Of a sample of 86 LGN cells, 18% showed net excitation, 47% net inhibition, and 35% were unaffected. Since the changes could be seen in the initial transient component, the modulation must be capable of acting at relatively short latencies. Effects were seen in opponent and non-opponent cells and in both X and Y types as well but not seen in LGN cells tested in one animal whose striate cortex had been removed. Although we have not conclusively ruled out contributions from the feedforward tectogeniculate pathway, we think it unlikely since most of our recordings were from parvo-, rather than magnocellular or interlaminar layers. These results suggest that the CG input serves to regulate the overall excitability of LGN cells across rather than between information channels. Supported by EY 01286-04.

2678 RETINOTOPIC ORGANIZATION OF AXONS IN THE OPTIC NERVE AND TRACT OF NORMAL AND SIAMESE CATS. C.A. Mason, E.H. Polley+ and R.W. Guillery. Dept. Pharm. & Physiol. Sci., Univ. Chicago, Chicago, IL 60637 and +Dept. Anat., Univ. Illinois Coll. Med., Chicago, IL 60680.

The retinotopic organization of axons in the optic nerve, chiasm, and tract was studied in normal and Siamese cats. We wished to observe the degree to which retinotopy is maintained throughout the system and to determine where along the pathway the abnormally crossed temporal fibers of Siamese cats become misrouted. Fibers arising from specific parts of the retina were followed by making small photocoagulations and tracing degenerating profiles in sections of the pathways. Lesions were made within 5-10 mm of the area centralis in anesthetized cats. Ten days later, animals were anesthetized and perfused with 4% paraformaldehyde in 0.1M Sorenson's phosphate buffer. The optic nerve was transversely sectioned and the chiasm, including the adjacent optic tract, was horizontally sectioned at 35μ with a vibratome. Sections were treated with 1% buffered OsO_4, dehydrated and mounted on slides. The degenerating profiles are strongly osmiophilic, and degenerating fibers could be plotted under a 100x objective with an X-Y plotter.

Immediately behind the eye, degenerating axons produced by localized lesions form a well-localized group in both normal and Siamese cats. However, many individual axons are scattered away from the main grouping, and a considerable number of normal axons are mixed amongst degenerating fibers. These normal axon segments could be followed through the whole thickness of the section. In normal cats, this localized grouping is maintained in the optic nerve and can still be seen close to the chiasm, following either a nasal or temporal lesion. In contrast, after lesions of the Siamese cat's temporal retina, which gives rise to abnormally decussating fibers, sections from 1-2mm anterior to the chiasm show degenerating profiles which lie much more evenly scattered throughout the entire section of the nerve.

In normal cats, fibers crossing in the chiasm from the nasal retina occupy the entire cross sectional area of the chiasm. The small component that crosses from the temporal retina in normal cats tends to concentrate in the posterior part of the chiasm. In Siamese cats, the abnormally crossed axons that arise in the temporal retina also scatter throughout the cross-sectional area of the chiasm. Further, as described by others, there is little retinotopic order in the optic tract of normal cats, and the same is true for Siamese cats. In both, there is a segregation of fiber sizes in the tract, coarser fibers lying laterally. It is significant that at geniculate and tectal terminations, retinotopic order is re-established in normal as well as Siamese cats. (Supported by PHS NS 14283 and EY 02374).

2679 Development of Somal Synapses in Visual Cortex (Area 17) of the Macaque Monkey S. Mates* & J.S. Lund, Dept. of Ophthalmology, University of Washington, Seattle, WA 98195

As a continuation of previous studies on the developmental sequence of neurons in visual cortex (Area 17) of Macaque monkeys (Lund et al 1977) we have been studying the formation of somal synaptic contacts of identified cortical cell populations receiving thalamo-cortical axons. Cell bodies containing no synapses or only type 2 synapses were classified as spiny stellate or pyramidal neurons based on the shape of the cell and the laminae in which they were found. Intrinsic cortical neurons, the spine-free and sparsely spined neurons were found less frequently and were identified by their amount of cytoplasm and their mixed synaptic profiles, containing both type 1 and type 2 somal contacts. They are known to form type 2 contacts onto cells in the local milieu.

Type 2 somal contacts in 4cα increase until 5 weeks of age and then remain constant until some time between 6 and 9 months of age. During this time, a reduction in cell size causes the percentage synaptic covering of the neuronal surface length (mean covering) to increase until 12 weeks of age. Between 6 and 9 months a decline of synapses accompanies loss in cell size and by adulthood synapse number and somal size resemble that seen at birth. In 4cβ synaptic number and somal size increase during the first 12 weeks postnatal. From 12 weeks to adult there is a steady decline in both synaptic contacts and cell size. Pyramidal neurons of both upper and lower 6 show a rapid increase in synapses to 5 weeks of age. Between 8 and 12 weeks there is an increase in synapse number which remains constant until at least 9 months of age. Between 9 months and adult there is a further reduction in both somal size and number of contacts to reach the adult level. The mean covering is greatest in upper 6 at 8 weeks postnatal and lower 6 at 3 weeks postnatal.

In a monkey deprived of vision during the first 8 weeks of life, somal contacts and cell size resemble that seen at birth for 4cα, while in 4cβ the number of contacts is only slightly diminished from that of the normal 8 week animal. The differential effects seen in synapse formation in 4cα and 4cβ follows the same trend as the developmental sequence of dendritic spines onto cells of these laminae (Lund & Boothe, in press). Cells receiving primarily magnocellular influence reach a plateau in both spine number and somal synapses, and remain constant for a period of time, whereas cells receiving parvocellular information reach a spine and synaptic contact peak, followed by a rapid decline. Change in cell size alone does not account for synaptic and spine changes during this period. The differential effects seen in synapse formation may reflect functional differences in the establishment of intrinsic domains in area 17 during this time. Using Golgi EM techniques, we are examining the relationship between the formation of somal contacts and contacts seen on dendritic spines.

Supported by NIH grants EY-01086 and EY-07013, Lund, J.S., R.G. Boothe, and R.D. Lund, 1977. J. Comp. Neur. 159:305-344.

2680 SYNAPTIC ORGANIZATION OF THE FROG'S OPTIC TECTUM. Dan E. Matsumoto* and Frank Scalia. Dept. Anat. & Cell Biol., Downstate Medical Center, Brooklyn, N.Y. 11203.

The terminals of retinal ganglion cell axons (OT) were examined in the optic tectum of R. pipiens by EM. OT were identified by four experimental markers. (1) Frogs were unilaterally enucleated to induce a terminal degeneration; (2) ^{3}H-proline was injected intraocularly to label OT for EM autoradiography; (3) OT were labeled by anterograde transport of HRP injected intraocular; (4) HRP was applied to the transected optic nerve to fill OT diffusely. The last method labeled OT in large numbers, and their morphology was relatively unaffected for usefully long survival periods. For details of methodology and background see Scalia and Colman, Br. Rs.'74, Colman et al., Br. Rs. '76, Matsumoto and Scalia, An. Rec.'79. Labeled axons and OT were observed in layers A-F and layer G (Potter, J.C.N.'69). The presence of OT in layer A confirms LM findings (Scalia, Br. Rs.'73; Scalia and Colman,'74). Labeled OT in layers B and D in frogs killed within 2 days of optic nerve transection and application of HRP were absent after survivals of 2 weeks. Labeled OT in layers C and E (and layer A) continuous with unmyelinated axons in the same layers were abundant after short survivals and were present in frogs surviving retinal ablation for up to 69 days before nerve transection and application of HRP. (This extends the potential for long-term survival of transected unmyelinated optic nerve axons beyond the time reported in Matsumoto and Scalia '79). Labeled OT in layers F and G were observed in continuity with large diameter axons in the same layers. Therefore, layer G axons terminate in their own layer. OT contained medium-sized, clear, spherical vesicles and relatively pale mitochondria. They made asymmetric contacts on dendrites, and on other unlabeled neurites, containing pleomorphic vesicles and dark mitochondria. No definite instances of axosomatic synapse were observed.

Szekeley et al. (J. Hirn.'73) distinguished four types of synaptic profile in material fixed by immersion in osmium tetroxide. OT identified in the present study resemble their optic, or type 1, terminals. However, type 1 was reported to be absent from layer A, whereas type 2 was prevalent there and was the most numerous throughout the superficial tectum 30 days after eye removal. Since OT labeled by HRP were present in layer A and remained intact in layers A,C and E in significant numbers for 30 days, it may be that some type 2 were OT. Few terminals having the given characteristics of types 2 and 3 were observed in the present study, while the impression was gained that the population of terminals is more highly differentiated than a four category schema would suggest. (Supported by NSF grant BNS 75-21308).

2681 THE WEBER-FECHNER RELATION IN RETINAL RODS. Gary G. Matthews, King-Wai Yau* and Denis A. Baylor. Dept. of Neurobiology, Stanford University Medical School, Stanford, CA 94305

The membrane current of a rod outer segment in a piece of isolated toad retina was recorded by drawing it into a glass suction electrode connected to a current-to-voltage transducer. The sensitivity to brief light flashes was determined in darkness and in the presence of various levels of background illumination. The relation between flash sensitivity, S_F, and background light intensity, I_B, was fitted by the Weber-Fechner relation,

$$S_F = \frac{S_F^D}{1 + I_B/I_o}$$

where S_F^D is the flash sensitivity in darkness and I_o is a constant with dimensions of light intensity. The constant I_o has been interpreted as representing the level of a "dark light" or intrinsic excitation present in photoreceptors in darkness: only when background illumination is appreciable relative to this dark light does it cause a significant reduction in sensitivity. For thoroughly dark-adapted toad rods, the value of I_o at 500 nm was 0.19 ± 0.05 photon μm^{-2} sec^{-1} (mean ± S.D., N=7). In comparison, Fain's (1976) intracellular recordings give a value for I_o of 0.43 photons μm^{-2} sec^{-1}. Our value for I_o is equivalent to about 3 photoisomerizations sec^{-1}. This rate is two orders of magnitude greater than the rate of thermal isomerization of rhodopsin, which was determined by suction electrode recording to be about 0.02 sec^{-1} under the same conditions. This indicates that the dark light does not represent spontaneous isomerization of rhodopsin, as has sometimes been assumed. Assuming that the dark light represents a finite resting level of the internal transmitter which regulates outer segment conductance, the dark light may be converted to a steady "response" in darkness from the values of I_o and dark step sensitivity. This steady dark "response" and the measured dark current then give the fractional closure, B_D, of the light-sensitive channels in darkness. In seven experiments B_D was 0.35 ± 0.11 (mean ± S.D.). This value is similar to the mean value found in cones by Lamb and Simon (1977), using a different technique.

2682 THE MIDDLE TEMPORAL AREA (MT) IN THE MACAQUE: ARCHITECTURE, FUNCTIONAL PROPERTIES AND TOPOGRAPHIC ORGANIZATION. J. H. R. Maunsell*, J. L. Bixby* and D. C. Van Essen (SPON: M. Konishi). Division of Biology, California Institute of Technology, Pasadena, CA 91125.

We have used anatomical and physiological techniques to study the organization of MT, an area in the superior temporal sulcus (STS) of the macaque receiving direct inputs from the striate cortex. MT is situated in a region characterized by heavy myelination relative to that of adjacent cortical regions. The projections to the STS revealed by lesions and ^{3}H-proline injections are restricted to the heavily myelinated zone, and all parts of this zone receive striate projections. Thus, cortical myeloarchitecture provides an adequate basis for identifying the borders of MT. MT occupies an elongated region of cortex about 35 mm^2 in surface area, which is less than 3% of the size of striate cortex.

Physiological recordings within the STS confirm Zeki's (J. Physiol. 236, 1974) finding that MT contains a high percentage of directionally selective (DS) cells. The region immediately adjacent to MT along its dorsolateral border contains very few DS cells, and the transition in functional properties occurs over a distance of 0.25 mm or less. In contrast, the region medial to MT contains numerous DS cells which differ from those within MT mainly in terms of their larger receptive field sizes. Thus, there are at least two visual areas in the STS concerned with the analysis of movement in the visual field.

The topographic organization of MT in the macaque is similar to, but more complex than that found in the owl monkey and the bushbaby. The complexities are indicated by several observations. a) Receptive fields of cells encountered along the perimeter of MT are not always close to the perimeter of the visual hemifield (vertical meridian and far periphery), and fields recorded midway between the borders of MT are not always on the horizontal meridian. Also, relatively large shifts in receptive field locations sometimes occur over short distances within the cortex. b) Anatomical experiments demonstrate instances of single loci within striate cortex projecting to multiple sites within MT. c) Interhemispheric connections, which in the bushbaby and owl monkey terminate preferentially along the perimeter of MT (Newsome, ARVO Abstr., 1979), are distributed irregularly within MT in the macaque, without any noticeable increase in density along the border. Analysis of receptive field locations and anatomical inputs also suggests that the relative emphasis of central vs. peripheral visual fields in MT is comparable to that found in striate cortex.

2683 TEMPORAL SUMMATION IN GANGLION CELLS OF THE TURTLE. J. H. Maxwell, J. E. Fulbrook and A. M. Granda. Inst. for Neuroscience, U. of Delaware, Newark, De 19711.

Temporal summation characteristics were determined for single long-wavelength-sensitive ganglion cells in the turtle, Pseudemys scripta elegans. Extracellular recordings were made with tungsten microelectrodes in the optic nerves of curarized and locally anesthetized animals.

Initially, the receptive field of each cell was mapped with both moving spots and stationary flashes of monochromatic light projected on a hemispherical screen 1 m in radius centered on the turtle's left eye. Subsequent test stimulation was restricted to the receptive field centers which ranged in diameter from 2 to 6 degrees. Spike responses to three to five stimulus presentations were summed by computer. Intensity-response curves for individual wavelengths and flash durations were plotted using both latency and spike count response measures.

Close agreement was observed between spectral sensitivity curves derived from latency and spike count measures. In all cells, high criterion responses were associated with peak sensitivities in the area of 620 to 650 nm indicating red cone dominance. In some cells, thresholds determined with low criterion responses revealed significant gains in sensitivity to short wavelength light indicating multiple receptor mechanism input.

Temporal summation curves at each cell's peak sensitivity were determined using flashes 10 msec to 2 sec in duration. Summation curves derived from spike count and latency response measures were not always in close agreement. For some cells, latency-derived curves reflected no change in threshold as a function of stimulus duration while, for the same cells, spike-count-derived curves accurately defined the reciprocal relationship between threshold intensity and flash duration. Critical duration values fell between 130 and 200 msec but, for low criterion responses, cells with multiple receptor mechanism input summed beyond 500 msec. These findings are consistent with previously obtained behavioral data for this same species.

2684 CONNECTIONS OF THE CLARE-BISHOP AREA WITH AREA 17 AND THE DORSAL LATERAL GENICULATE NUCLEUS IN THE CAT. A. J. McGrath,* G. R. Leichnetz, and J. Astruc, Department of Anatomy, Medical College of Virginia, Richmond, Virginia 23298.

The Clare-Bishop (CB) area of the cat cortex bears the names of the investigators who first (1954) recognized a region, located primarily on the lateral aspect of the middle suprasylvian gyrus, which electrophysiologically responded to both striate cortex and optic nerve stimulation. More recent studies (Palmer et al, 1978; Kennedy and Magnin, 1977) have supported its role in visual and/or oculomotor functions. Anatomical studies were performed in order to provide a morphological basis for its proposed function. In the process of this investigation it was found that a substantial reciprocity of connections exists between the CB area and Area 17, using both orthograde (silver impregnation) and retrograde (HRP) methods. Silver techniques (Nauta, Fink-Heimer) revealed that CB projects primarily to laminae III-IV of Area 17. However, some degenerating fibers were also observed to traverse lamina II and enter lamina I, giving rise to preterminal and terminal degeneration running parallel to the surface of the lateral gyrus. HRP studies, on the other hand, revealed that medium-sized pyramids located primarily in lamina III of Area 17 projected to the CB cortex. Anterogradely transported HRP also confirmed the presence of a terminal field in both laminae III and I of Area 17. In addition to finding these intimate connections of CB with Area 17, it was also observed that the Clare-Bishop area apparently receives substantial input directly from the dorsal lateral geniculate nucleus (dLGN). Whereas earlier investigations (Heath and Jones, 1971; Rosenquist et al, 1974) have held that CB only receives innervation from the medial interlaminar nucleus and lamina C of dLGN, this study demonstrated that all of the main laminae (A, A1 and C) have direct projections to the CB cortex. Thus it appears, based on the data presented in this study, that the Clare-Bishop area is indeed an intergral portion of the primary visual cortex in the cat, due to its receiving input directly from the dorsal lateral geniculate nucleus, and its heavy reciprocal connections with Area 17. The data from this study provide an important anatomical substratum for CB's proposed role in visual activities.

2685 QUANTITATIVE STUDIES OF OPTOKINETIC NYSTAGMUS IN MONKEYS BEFORE AND AFTER LESIONS OF PARIETO-OCCIPITAL ASSOCIATION CORTEX. Jay W. McLaren and James C. Lynch, Department of Physiology, Mayo Clinic and Foundation, Rochester, MN 55901.

Damage to parieto-occipital cortex in humans results in asymmetric optokinetic nystagmus (OKN) with the slow phase diminished toward the side of the lesion. In the present study eye position (electrooculogram) was recorded during OKN in rhesus monkeys before and after unilateral and bilateral lesions of parieto-occipital cortex. OKN was induced with either a large vertically striped drum which could be rotated around the monkey, or projected black and white stripes that could be moved across a 52° square screen in front of the monkey. Stimuli were presented at angular speeds which ranged from 20-160°/sec. In all cases the rotating drum was found to be a considerably stronger stimulus than the projected stripes. When sufficient data had been recorded to establish a baseline level of response, lesions were made under sterile conditions. Four monkeys received unilateral or bilateral lesions in one or two stages. The smallest lesion was limited to about two-thirds of Brodmann's area 7, while the largest included all of area 7, part of the immediately adjacent prestriate cortex (areas 18 and 19), and the anterior bank of the intraparietal sulcus (area 5).

Immediately after the unilateral lesion, monkeys showed a marked depression of OKN slow phase in the direction toward the side of the lesion. Following the second lesion (and in the single stage bilaterally lesioned monkey) slow phase velocity was depressed in both directions. In addition, two monkeys showed temporary spontaneous nystagmus following unilateral lesion.

OKN has been studied as a function of stimulus velocity in one monkey. Before lesion OKN slow phase velocity accurately matched angular velocity of the rotating drum at 40°/sec or less. When stimulus velocities were increased above 40°/sec, mean slow phase eye velocity increased at a lower rate than stimulus velocity. After unilateral lesion, the monkey's ability to maintain slow phase eye velocity close to the stimulus velocity was significantly reduced in the direction toward the side of the lesion at velocities of 40°/sec or higher. At 20°/sec, however, slow phase was not changed from the prelesion response. Slow phase in the direction away from the side of the lesion was also reduced slightly at velocities above 80°/sec. These results indicate that the parieto-occipital region in rhesus monkeys plays an important role in the generation and maintenance of the slow phase of OKN, particularly at high stimulus speeds.

2686 SPATIAL AND TEMPORAL VISION OF MACAQUES AFTER CENTRAL RETINAL LESIONS. William H. Merigan, Tatiana Pasternak and Donald Zehl.* Univ. Roch. Med. Ctr., Rochester, NY 14642.

The spatial and temporal modulation transfer functions (MTFs) of two pigtailed macaques (Macaca nemestrina) were measured behaviorally before and after small laser burns were placed in their foveas. The spatial MTF was determined with stationary sinusoidal grating patterns. The temporal MTF (deLange function) was measured with both large (5°) and small (0.5°) unpatterned flickering targets. Preoperative sensitivity functions of both monkeys were similar to those of human subjects tested in the same apparatus. An argon laser was used to place small (2° radius) circular lesions in the center of the fovea of both eyes of each monkey. Fundus photographs confirmed the location, size and completeness of the lesions.

The post-operative spatial MTF revealed no loss of sensitivity at the lowest spatial frequencies, a loss of less than 0.5 log unit at middle frequencies and a loss approaching 1 log unit at the highest spatial frequencies. The temporal MTFs measured with the 5° stimulus showed no loss of modulation sensitivity. However, the temporal MTF for the 0.5° stimulus indicated a 0.3 log unit loss of modulation sensitivity at the low frequencies and no loss at the high temporal frequencies. These results will be discussed in relation to the spatio-temporal properties of human foveal vision.

2687 A NEUROBEHAVIORAL INVESTIGATION OF ORIENTING BEHAVIOR IN THE SUPERIOR COLLICULUS AND VISUAL CORTEX LESIONED RAT. Glenda C. Midgley* and Richard C. Tees*. (SPON: J.P.J. Pinel). Psychology Department, University of British Columbia, Vancouver, Canada.

The orienting behavior of rats with variously sized lesions of the superior colliculus (SC) and visual cortex was assessed. Orienting behavior to auditory stimuli and 5 patterns of apparently moving light displays was measured by examining the disruption of ongoing behavior and the animals head and postural adjustments to repeated presentations of the stimuli.

Lesions of the SC did not result in visual agnosia or an inability to perform the motor responses involved in orienting. These rats were capable of orienting even in the complete absence of the SC. Rather, the orienting response was available in the behavioral repertoire of the lesioned animal, but, it was not always emitted in response to the visual displays that the intact animal treated as less salient. Rats with SC lesions oriented to and localized an apparently approaching and receding light display and lights which appeared to circle the entire visual field of the animal, but, did not orient to and localize lights which appeared to circle in smaller segments of the visual field. Deficits in orienting to the less salient light displays were reduced or eliminated by manipulating the amount of deprivation prior to testing and SC lesioned animals were capable of using the less salient displays as a signal of shock. The SC lesioned animals and animals with lesions of the cortical projections of the SC habituated more quickly than intact animals and did not dishabituate to changes in the visual displays. The results suggest a modulating role of the SC and cortex in orienting behavior and the stimulus parameters which must be considered in models of the neural basis of orienting behavior.

2688 EVOKED POTENTIALS TO DYNAMIC RANDOM-DOT CORRELOGRAMS IN MONKEY AND MAN: A TEST FOR CYCLOPEAN PERCEPTION. Francis M. Miezin*, Joel Myerson, Bela Julesz*, and John M. Allman. Biology, Caltech, Pasadena, CA 91125 and Bell Labs, Murray Hill, N.J. 07974.

Large evoked potentials are elicited in humans by dynamic random-dot correlograms of binocularly identical noise alternating with binocularly negatively-correlated noise (Julesz, Kropfl and Petrig, 1978). These correlograms contain no monocular cues; thus the evoked potentials are an objective indicator of a cyclopean perception (Julesz, 1971). We tried to elicit evoked potentials to these stimuli in alert macaque monkey so as to compare them with human evoked potentials and to develop a fast, objective test for cyclopean perception in animals. The monkey was trained to sit quietly in a chair placed facing a rear-projection screen. Dynamic random-dot correlograms, alternating at 0.5 Hz, were generated at 60 frames/sec. Stimuli for the left and right eyes were fed into the red and green channels, respectively, of an Advent projection TV set. Stereo separation was achieved by placing red and green Wratten filters over the red and green projection optics. In the cyclopean condition, goggles with red and green filters over the left and right eyes,respectively,were worn by monkey and human observers. After every even reversal,left and right dynamic noise was identical giving the percept of a flat depth plane; after every odd reversal, dynamic noise for one eye was the negative image of the noise for the other eye giving rise to binocular rivalry and an uncertain depth percept. To test for monocular cues, we used three control conditions: A) placing identically colored filters over both eyes; B) vertically shifting the green image relative to the red image; C) placing a 0.5 log neutral density filter in front of the green filter (this delays conduction from that eye (Julesz and White, 1969) thereby reducing the amount of time the two images are correlated). In a fourth control condition (D), 0.5 log neutral density filters were placed over both filters; this delays conduction from both eyes equally so that the images appear as in the cyclopean condition but dimmer. While the cyclopean condition and control D gave large evoked potentials, controls A and B gave none and control C gave a greatly diminished evoked potential. This proves that the evoked potential was a response to only the cyclopean aspects of the stimulus. Human subjects were told to look at the screen's center whereas the monkey's gaze wandered freely over the entire screen. Nonetheless, the monkey's evoked potentials were as large as those of the human, demonstrating that the method does not depend upon steady fixation of the stimulus. This result testifies to the robustness of evoked potentials to dynamic random-dot correlograms and extends their usefulness as a test for cyclopean perception. 2689 SENSORY REARRANGEMENT AND EYE POSITION. H.H.Mikaelian, M.Linton*, and M.Phillips*. Dept. of Psych., Univ. of New Brunswick, Fredericton, New Brunswick, Canada E3B-5A3

The generalizability of response alterations produced by sensory rearrangement was explored. Experiment 1 dealt with auditory rearrangement induced by pseudophones that rotated the interaural axis by 40° (right ear lead). The subject listened, for 20 min., to a hand held sound target emitting clicks while moving it from side to side in a semi-circle. Tests consisted of a)pointing to sound targets with the hand b)orienting the eyes towards the sound targets, and c)orienting the eyes to the straight ahead. All testing was done in the dark. Ear-hand coordinations were measured on a semi-circular target board in front of the subject, and eye position was monitored by infrared oculography. The results, measured as differences between pre and post-exposure responses, showed adaptive changes in ear-hand coordination of 30%. No systematic changes in orienting the eyes to the sound targets or to the straight ahead were found.

In a second experiment rearrangement was produced by prisms. The subject, moving the arm on a table, viewed it through 20 diopter wedge prisms. Testing consisted of a)pointing to visual targets with the hand, b)orienting the eyes towards the visual targets, and c)orienting the eyes to straight ahead. The results parallelled those of experiment 1. Up to 40% adaptive shifts in pointing with the hand were found; no systematic changes in orienting the eyes to the visual targets or to the straight ahead were observed.

These results indicate that sensory-motor changes produced by arm reafference during rearrangement are confined to responses in that arm. Following rearrangement, in both experiments, the subject locates the target in one position with the arm, and in a different position(same as pre-exposure) with the eyes. Recalibration of target directed responses, therefore, are limited to the system regulating arm movements, and adaptation does not represent a generalized change. It is possible to account for these results in terms of the proprioceptive change hypothesis(Harris, 1964), although previous studies have shown that response alterations tend to also be specific to the sensory modality that is rearranged, contrary to predictions of that theory.

2690 NEURONAL SPIKE TRAINS FROM SPONTANEOUSLY ACTIVE CELLS IN THE LATERAL GENICULATE NUCLEUS AND THE SUPERIOR COLLICULUS. Stéphane Molotchnikoff et Pierre Lachapelle. Dept. Sci. Biol. Université de Montréal, Montréal, Qué. Canada.

In anesthetized and immobilized rabbits, spike trains from spontaneously active neurons were recorded simultaneously with two tungsten microelectrodes aimed at the Lateral Geniculate Nucleus (L.G.N.) and the Superior Colliculus (S.C.). Autocorrelation and cross-correlation histograms were triggered by spontaneously occurring action potentials recorded from each location.

In the L.G.N. two patterns can be dissociated. Cells of the first group showed a tendancy not to fire after production of an action potential, and presented a slow recovery of their firing probability up to 250 msec. They were units with an initial decrease of excitation (I.D.E.). By contrast in cells of the second group the generation of an action potential led to an initial increase of excitation (I.I.E.) within 20 msec. Amongst this second group interneurons and relay cells must be distinguished according to standard criteria: response pattern to single optic nerve shock.

In the S.C. same patterns of histograms are found, that is: I.D.E. and I.I.E. However, the collicular depth profile is different for each class. Thus I.I.E. are almost exclusively encountered in the upper part of the Stratum Griseum Superficial. (Stratum zonal and upper third of the S.G.S.). While I.D.E. are more numerous deeper. Cross correlations between units of L.G.N. and S.C. suggest the possibility of mutual excitatory and inhibitory interactions. Such relationships may shed some light on the basis of visuomotor integration.

Sup. by D.G.E.S. (Québec), N.S.E.R.C. (Canada) and Université de Montréal to S.M.

2691 THE ANURAN ACCESSORY OPTIC SYSTEM: NEUROANATOMICAL ANALYSIS Neil Montgomery*, Katherine Fite & Lynn Bengston*. University of Massachusetts, Amherst, Massachusetts, 01003

The accessory optic system of Rana pipiens and Bufo Americanus was investigated using autoradiographic (^{3}H proline), horseradish peroxidase and Golgi techniques. Retinal afferents project via the basal optic root (BOR) to a "nucleus" (neuropil) of the basal optic root (nBOR) in the ventral mesencephalon, and are primarily large-diameter axons with well-defined terminal boutons, although some smaller caliber axons are also present. The major retinal projection is contralateral, with a small ipsilateral component. At least some nBOR optic axons appear to originate from giant and displaced ganglion cells.

The cellular constituents of nBOR resemble those previously described for the superficial layers of the optic tectum (Szekely & Lazar, 1976), and four morphologically distinct cell types were identified within the terminal field: 63% stellate, 19% amacrine, 14% elongate and 4% ganglionic cells. Both stellates and amacrines appear to be intrinsic neurons. In addition, pyriform neurons located in the region medial to nBOR send their dendrites into the terminal field and their axons to the anterior-ventral cell groups located paraventricularly. Optic afferents, as well as the dendritic and axonal processes of stellates, converge upon the dendrites of both ganglionic and pyriform cells in a glomerular configuration. Preliminary data suggest that the ganglionic cells project to the caudal thalamic-pretectal region, and elongate neurons project to the hypothalamus. Other neurons in the anterior-ventral cell group which send dendrites into nBOR include commissural neurons which project to the opposite nBOR, and pyriform neurons which interconnect nBOR and the oculomotor nucleus (n. III).

No evidence of direct efferent projections to the cerebellum was obtained despite numerous HRP injections of cerebellum. However, cells from the anterior-ventral cell group (whose dendrites penetrate nBOR) appear to project to the ventral medulla where several cell groups (n. raphe and n. reticularis) have been previously reported to give rise to cerebellar climbing fibers (Cochran & Hackett, 1977) in frog.

These observations strongly imply that the accessory optic system may play an important role in anuran oculomotor behaviors, a possibility first suggested by Herrick (1948) three decades ago.

2692 SINGLE UNIT AND BEHAVIORAL ASSESSMENT OF ECTOMAMILLARY NUCLEUS FUNCTION. B. Morgan* and B. J. Frost (Spon: M. Donald). Dept. of Psych., Queen's Univ., Kingston, Ont., Canada, K7L 3N6

The avian accessory optic nuclei receive direct projections from displaced retinal ganglion cells, and project directly to the oculomotor complex and the vestibulo-cerebellum (Brecha and Karten, 1979). It has been suggested that this system may play a specific role in visual control of head and eye stabilization. Fite, Reiner and Hunt (1977) found that lesions of the basal optic root or nucleus ectomamillaris (EM) virtually eliminated optomotor response (head nystagmus) to optokinetic stimulation.

The present study compared pre and post EM lesion behavior of pigeons to optokinetic stimulation presented both binocularly and monocularly. Single EM cell response characteristics were also investigated.

Before EMlesions, binocular head nystagmus was normal and characterized by a pursuit phase where head velocity matched stimulus velocity, both for clockwise and counterclockwise motion. In contrast, monocular head nystagmus approximated binocular conditions only with forward motion (posterior to anterior in the visual field). Backward monocular motion was far less effective in producing nystagmus and when it occurred head velocity was inappropriate. After unilateral EM lesions, head nystagmus was not elicited even by forward optokinetic stimulation of the contralateral eye. Post-lesion binocular nystagmus resembled pre-lesion monocular response.

Electrophysiological recordings of EM cells showed they were directionally selective, and preferred slow velocities of stimulus movement. Large single spots of light were generally ineffective, whereas very large textured patterns were optimal. These cells also exhibited a high spontaneous firing rate which was modulated up and down for preferred and null directions of motion respectively.

These observations lend support to the notion that the accessory optic system is involved in the processing of whole-field motion required for stabilization of the visual world.

2693 TWO-DIMENSIONAL SPATIAL FREQUENCY TUNING OF CAT STRIATE CORTICAL NEURONS. J. Anthony Movshon, Department of Psychology, New York University, New York, NY 10003.

Neurons in the striate cortex of cats and monkeys are selectively sensitive to the orientation and spatial frequency of sinusoidal grating patterns; this has been adduced as evidence in support of the idea that the visual system performs a kind of spatial Fourier analysis. But in order for the visual cortex to function as a global Fourier analyzer, the properties of striate neurons should permit them to signal the detailed harmonic structure of spatial patterns; this requires that the spatial frequency and orientation bandwidths of cortical neurons be inversely proportional to their optimal spatial frequencies.

Orientational half-width (in degrees) and spatial frequency bandwidth (in octaves) were determined for a large population of striate cortical neurons recorded from acutely prepared anesthetized cats. Optimal spatial frequencies ranged from 0.25 to 2.7 c/deg, and all receptive fields lay within 5 deg of the visual axis. Measurements on some cells taken over a matrix of orientations and spatial frequencies showed that within a cell the selectivity for one of these variables did not depend strongly upon the value of the other at which measurements were made.

Orientation selectivity and spatial frequency selectivity are well correlated with one another: orientation half-widths increase by about 10 deg for each octaves increase in spatial frequency bandwidth. Thus in a conventional two-dimensional frequency-space plot, the "receptive fields" of striate cells tend to be roughly round. Neither orientation half-width nor spatial frequency bandwidth, however, decreases strongly with spatial frequency: spatial frequency bandwidth decreases by about 0.5 octaves for each 1 c/deg increase in optimal spatial frequency, with considerable variability across the population. From these data it appears that if each striate neuron is to signal the presence of a particular spatial Fourier component, then only the first three or four spatial harmonics may be unambiguously extracted.

Thus the relations among the orientation tuning, spatial frequency tuning and optimal spatial frequency of striate neurons show these neurons to be ill-suited to performing a global Fourier analysis of the visual world. Their spatial properties are more consistent with a less extreme frequency analysis model which involves only the extraction of the first three or four spatial harmonics of images falling on a particular region of the retina.

2694 DARK REARING DELAYS ONSET OF THE CRITICAL PERIOD IN KITTEN VISUAL CORTEX. George D. Mower*, Frank H. Duffy, James L. Burchfiel. Seizure Unit & Dept. of Neurology, Children's Hospital & Harvard Med. School, Boston, MA 02115.

The critical period in kitten visual cortex begins around the time of eye opening and ends at three months of age. We were interested in determining whether visual experience plays a role in the timing of the critical period or if it reflects a fixed maturational process. Kittens were visually deprived from birth to an age of 14-16 weeks by binocular lid suture or rearing in complete darkness. They were then given monocular experience for a period of up to 1 year.

Prolonged monocular experience following binocular lid suture resulted in little improvement of visual acuity for simple behavioral tasks (placing, tracking, obstacle avoidance, avoidance of a visual cliff). Recordings in area 17 revealed no dominance of the open eye. Twenty eight percent of the cells were driven only by the open eye, 27% only by the closed eye, and 21% were binocular. Twenty four percent of the cells were visually unresponsive. Many visually responsive cells, particularly binocular ones, had abnormal receptive fields. There were no significant differences in cell sizes between LGN laminae devoted to the opened or closed eye.

Dark reared kittens showed dramatic behavioral recovery during the course of monocular experience. Recordings in are 17 revealed clear dominance of the experienced eye. Eighty percent of the cells were driven exclusively by the open eye and these cells typically had normal receptive fields. Fourteen percent of the cells were binocular, and 6% were driven only by the closed eye. These cells typically had abnormal receptive fields. Anatomical studies of these kittens are in progress, but preliminary results suggest that only slight shrinkage (10%) occurs in geniculate laminae associate with the closed eye.

We conclude that in the total absence of visual stimulation considerable plasticity is maintained in visual cortex. Apparently there is sufficient visual stimulation through closed lids to produce permanent abnormal development.

2695 TECTAL AND CORTICAL AFFERENTS TO NUCLEUS LATERALIS POSTERIOR IN THE RAT. Sandra M. Nagel* and Charles M. Butter. Dept. of Psych., Univ. of Michigan, Ann Arbor, MI 48109.

Recent neuroanatomical investigations in various mammalian species have described a pathway from the superficial layers of the superior colliculus (SC), which receive retinal input, to particular thalamic nuclei, including nucleus lateralis posterior (NLP) in the rat. These nuclei project to visual cortical areas including prestriate cortex. However, the tecto-thalamic pathway in the rat has not been analyzed in detail; specifically, the characteristics of tectal cells which project to NLP have not been described. Likewise, other afferent projections to NLP have not been investigated. In the present study, horseradish peroxidase (HRP) was injected into NLP and adjacent diencephalic structures in the rat in order to describe these projections.

Following microiontophoretic injection of HRP confined to NLP, neurons containing HRP granules were found in the ipsilateral, and to a lesser extent contralateral SC. These neurons were confined to ventral stratum griseum superficiale and dorsal stratum opticum; they were identified as wide-field or narrow-field vertical cells, or stellate cells, as described by Langer and Lund. Following HRP injections into the dorsal lateral geniculate nucleus, labelled cells were also found in superficial layers of ipsilatersl SC. Pretectal injections resulted in labelling of superficial and intermediate tectal cells. Labelled pyramidal neurons were also found in layers IV - VI of ipsilateral prestriate (18a and 18b) and striate cortex, and in layer IV of temporal cortex (Krieg's area 20). These findings suggest that specific cell groups in particular sublayers of the dorsal SC project to NLP, which projects to visual cortical areas. These present findings also suggest that particular cell groups within these cortical areas project back to NLP.

2696 CHRONIC BLINDNESS FOLLOWING NONVISUAL CORTICAL LESIONS IN MONKEYS. Richard K. Nakamura and Mortimer Mishkin, Lab. of Neuropsychology, NIMH, Bethesda, MD 20205.

We previously reported that blindness can be produced in monkeys by a large cortical removal that preserves all areas known to be necessary for visual discrimination learning (Neurosci. Abs. 3:571, 1977). The large lesion spared the visual cortex (striate, prestriate, and inferior temporal) and limbic cortex (medial temporal, ventral frontal, and cingulate) but included all other cortical areas. Bilateral paralysis was prevented by placing the lesion in only one hemisphere, the other hemisphere having been left intact but visually deafferented by optic tract section and forebrain commissurotomy. Monkeys prepared in this way were behaviorally blind for periods ranging from 25 to more than 400 days, despite anatomical and physiological evidence that the retino-geniculo-striate pathway in the hemisphere with the ablation was preserved as intended.

The extreme variability in the duration of the blindness has not only been puzzling but has impeded analysis of the phenomenon. New studies indicate that this variability can be eliminated and a predictably long-term effect produced in two different preparations.

First, the original findings suggested a species difference that has now been confirmed with additional animals given the standard lesion. Thus, whereas a total of four rhesus monkeys (Macaca mulatta) have recovered from blindness after a median of only 28 days, none of four cynomolgus monkeys (Macaca fascicularis) has yet shown recovery despite a median postoperative survival period of 180 days.

Second, the rhesus monkey also will show prolonged blindness if the standard lesion is expanded to include most of the limbic cortex. Three animals prepared in this way have thus far remained blind for a median period of 100 days with no signs of recovery. It is important to note that the limbic lesion alone will not cause this effect as evidenced by two monkeys with such a limbic ablation that demonstrated accurate visual guidance immediately after surgery.

We have proposed on the basis of other evidence that the blindness results from a failure of visual processing within the intact visual system due to the loss of an essential activation normally provided, directly or indirectly, by the territory included in the ablation (Neurosci. Abs. 4:639, 1978). The present findings strengthen this hypothesis by rendering highly unlikely the alternative possibility that the blindness reflects some transient state such as surgical shock or diaschisis. We can now test our hypothesis directly by examining stimulus-evoked neuronal activity within the intact visual system of chronically blind animals.

(Aided by NEI fellowship 9F32EY-05292.)

2697 REMOTE INHIBITORY AND FACILITATORY INPUT TO SIMPLE AND COMPLEX CELLS IN CAT STRIATE CORTEX. J. I. Nelson and D. M. Mitchell* Dept. Ophthalmology, NYU Med. Cntr., New York, NY 10016.

Large annular striped patterns (adapting fields) presented beyond the limits of conventionally-defined cortical receptive fields affect unit responsiveness. All but one of 49 simple cells showed greater than 10% inhibition of response to an optimal central stimulus upon presentation of the annular adapting field. 22 of 25 complex cells showed some effect, either facilitation, inhibition, or both. We have studied the spatial distribution, transfer across the visual midline, and interocular transfer of this effect in conventional acute cat preparations.

Interocular transfer was tested in 5 cells by presenting the adapting field to one eye and measuring a change in responsiveness to conventional (central) stimulation of the other. Transfer was always obtained; the observed inhibition was always stronger with adapting field stimulation of the dominant eye.

In 6 cells, the adapting field stimulus was presented on one side or the other of the vertical midline, making allowance for the inward cyclorotation of the eyes under paralysis and for the midline region of partial X-cell decussation. Thus we stimulated predominantly one cortical hemisphere or the other. Peripheral inhibition was equally strong, driven predominantly from contra- or ipsilateral cortical hemispheres for the one complex cell fully tested, whereas in the remaining simple cells, contralateral cortical stimulation was only 21 to 67% as effective as ipsilateral.

The spatial distribution of regions giving rise to remote interactions was studied with various adapting field sizes and shapes. The area of spatial integration for the remote inhibition of simple cells within 10° of the area centralis projection is about 8°. Many simple cells exhibit disinhibition for one sweep direction of an adapting field over a range of orientations closely matched to the optimal stimulus orientation of the cell under test. In one cell, response to a central stimulus was facilitated, not merely disinhibited, although the adapting field was unable to drive the unit directly. Disinhibitory regions are confined to areas along extensions of the receptive field's long axis. There are no preferentially inhibitory regions, though inhibition varies regularly across a broad range of orientations. Thus, simple cells may be said to display orientation domain inhibition which is general across space, and spatial domain facilitation which is specific to units sharing co-oriented and co-axially aligned receptive fields. Reports of remote influence upon complex cells have been variable, and indeed complex cells appear to display both inhibitory and disinhibitory regions. However, these interactions may be linked to a two-stimulus antagonism in complex cell responses which varies with response strength and not the peripheral region stimulated.

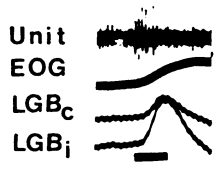
2698 PGO BURST NEURONS TRANSMIT EYE MOVEMENT INFORMATION TO THE VISUAL SYSTEM IN DESYNCHRONIZED SLEEP. John P. Nelson, Robert W. McCarley and J. Allan Hobson. Laboratory of Neurophysiology, Department of Psychiatry, Harvard Medical School, Boston, MA 02115

PGO waves are EEG macroelectrode spikes which are prominent in the pons, lateral geniculate bodies (LGB) and occipital cortex during the transition (T) from slow wave sleep to desynchronized (D) sleep, and during D when they are associated with rapid eye movements (REMs). Carefully placed bilateral LGB electrodes reveal variations in PGO wave amplitude during T and D--the larger wave occurs sometimes on one side, then on the other. During D, we have found, isolated saccades in one horizontal direction are virtually always associated with a larger PGO wave in the ipsilateral LGB (in one series, 88/90 in the predicted direction, chi square = 143, 1 df, $p < 10^{-4}$).

We have also described a class of neurons called PGO burst cells which are located in the midbrain in close apposition to the brachium conjunctivum and which discharge in stereotyped bursts of 5-6 spikes 12 msec before onset of PGO waves. A PGO burst cell (26 studied to date in 5 cats) fires in virtual 1:1 correspondence to larger PGO waves in the ipsilateral LGB and virtually never fires when the smaller wave is in that LGB. Their high correlation with PGO waves strongly suggests that PGO burst neurons are output elements in the system which generates PGO waves.

We conclude that PGO waves and the PGO burst neurons code eye movement direction, at least for horizontal saccades in D; they may represent the neuronal substrate for corollary discharge or efference copy of occulomotor signals which has long been speculated to be important for maintenance of perceptual stability of the visual world during saccades. The PGO burst neurons also fire single spikes before the eye movement potentials (EMP) seen in the visual system during waking (W). The possibility is thus raised that these cells may perform a similar function during W. Since the D state combines a highly activated brain with profound inhibition of sensory input, the functional characteristics of these cells may be more evident in D than in W.

The figure shows a characteristic discharge of a PGO burst cell, a large ipsilateral PGO wave, and a saccade to the ipsilateral side.
time bar = 50 msec



2699 EVIDENCE THAT CYCLIC GMP REGULATES MEMBRANE POTENTIAL IN VERTEBRATE ROD PHOTORECEPTORS. G.D. NICOL* and W.H. MILLER. Departments of Physiology, and Ophthalmology and Visual Science, Yale University School of Medicine, New Haven, CT 06510.

Injection of cyclic GMP (cGMP) intracellularly in dark-adapted rod outer segments (ROS) of the toad, *Bufo marinus*, causes a maximum depolarization of 40 mV within milliseconds. Based on two independent methods of estimation, this depolarization of the membrane pontential is *approximately* the Na^+ equilibrium potential; the data is consistent with the interpretation that the excess cGMP renders the ROS plasma membrane permeable to Na^+.

Injection of cGMP in the absence of illumination initiates a repolarization after a time lag that is proportional to the amount injected. A light flash delivered during the depolarization caused by excess cGMP initiates a repolarization of amplitude equal to the depolarization plus the control amplitude and of latency inversely proportional to the flash intensity but from 5 to 50 times control latencies. Previous light adaptation antagonizes the depolarization caused by injection of excess cGMP.

Our data is interpreted in terms of a model in which membrane potential is controlled by the intracellular concentration of cGMP which is in turn regulated by the resultant of cyclase and phosphodiesterase (PDE) velocities. The PDE velocity of hydrolysis in the dark is increased by additional substrate (injection of cGMP) up to a V_{max} orders of magnitude lower than that of the light activated enzyme. The high V_{max} caused by light activation of PDE is assumed in the model to decay with the time constant of dark adaptation so that subsequent injections of additional substrate shortly after prior light adaptation are capable of eliciting high enough velocities to antagonize the depolarization by causing a rapid repolarization. The data suggests that cGMP is an important factor in the regulation of the membrane potential of the ROS for both transduction and adaptation.

2700 A QUANTITATIVE MORPHOMETRIC ANALYSIS OF TRANSNEURONAL CHANGES FOLLOWING LONG-TERM DENERVATION OF THE OPTIC TECTUM IN XENOPUS. Jeanette J. Norden and John A. Freeman. Department of Anatomy, Vanderbilt University School of Medicine, Nashville, TN 37232.

The effects of denervation on post-synaptic tectal cells of metamorphic Stage 66 Xenopus laevis were investigated using standard anatomical quantitative methods and morphometric methods derived from stereology. Differences in the number of cells present and in the nuclear volume of cells in Layers 8 and 9 between denervated and control tecta were used to indicate transneuronal effects following short-term unilateral enucleation (30 days), long-term unilateral enucleation (120 days), and following a single optic nerve crush (150 days). Changes in the number of cells present were determined by computing an areal density (number cell nuclei/ μm^2) or by computing the volume fraction (V_V) of nuclei in Layers 8 and 9. Nuclear volumes were determined from measurements of the mean diameter of cell nuclei (under oil immersion optics).

Following long-term (120 days) enucleation, there is a decrease of 18% in the number of cells present in the tectum contralateral to the eye removal compared to the control (ipsilateral) tectum. Furthermore, there is a drop of 45% in the nuclear volume of the cells which remain in the denervated tectum, in addition to a substantial loss in total tectal volume. By contrast, no significant changes, except in tectal volume, could be shown at 30 days post-enucleation or following unilateral optic nerve crush and subsequent regeneration and reinnervation of the tectum. These results indicate that post-synaptic cells are capable of maintaining apparently normal cell functions, including the ability to synthesize proteins involved in the formation of new synaptic sites, for an appreciable time following denervation. The dramatic changes seen following long-term enucleation, however, suggest that a significant proportion of the products of nuclear gene expression (reflected in the volume of the nucleus) are involved in the maintenance of synaptic connections and that retinal input is necessary for the integrity of the majority of post-synaptic tectal neurons. (Supported by NIH Grant #EY 01117-07).

2701 MICROELECTRODE STUDY OF RETINAL AND CORTICAL AFFERENTS TO TREE SHREW SUPERIOR COLLICULUS. Thomas T. Norton. Dept. Physiological Optics, School of Optometry/the Medical Center, University of Alabama in Birmingham, Birmingham, AL 35294

The superior colliculus in tree shrew (Tupaia glis) appears to play an important role in the mediation of form vision following striate cortex ablation, perhaps by relaying visual information rostrally to the thalamus and, potentially, to the neocortex. In a recent study, Albano, et al. (1978) found an electrophysiological subdivision of the superficial gray layer (SGS) of the tree shrew superior colliculus. The upper SGS contains mostly SR (Stationary-Responsive) cells while the lower SGS contains fewer SR cells and an increased proportion of other cell classes. Anatomically, Graham and Casagrande (1979) reported that the upper SGS contains many afferent terminals from retina and few from striate cortex, while the lower SGS contains many terminals from both sources. These studies suggested that cells in the upper SGS, particularly SR cells, might receive their excitatory extracolliculus inputs primarily from retina, and might be only slightly, if at all, influenced by striate cortex. To functionally examine the excitatory inputs to the upper and lower SGS from these sources, I recorded extracellularly in acutely prepared, N_2O/O_2 anesthetized tree shrews. After identifying the receptive-field class, electrical stimulation was applied, in turn, through implanted optic chiasm (OX) and striate (VC) electrodes. Eighty-three percent of the cells sampled in the upper SGS were activated by OX stimulation (mean latency 3.5±1.4 msec). As expected, a similarly high proportion (89%) of the cells in the lower SGS were also activated by OX stimulation (mean latency 5.4±2.9 msec). Surprisingly, nearly half (47%) of the cells in the upper SGS were activated by VC stimulation (mean latency 4.0±2.1 msec). In the lower SGS, a significantly higher proportion (80%) of the cells were activated by VC stimulation (mean latency 6.2±2.4 msec). In both upper and lower SGS, SR cells were driven from retina and cortex in about the same proportion and at about the same latency as were the other cell classes. However, the mean latency of all cells, both to OX and VC stimulation, was slightly longer in the lower SGS. These results are consistent with the anatomical data in that there does appear to be less influence from striate cortex in the upper SGS. However, cortical activity clearly can affect cells in the upper SGS, including many SR cells. These results thus suggest that striate cortex activity in normal tree shrews, and striate cortex ablation, may affect the relay of visual information through the superior colliculus, both in the upper and lower SGS.

2702 DIENCEPHALIC ORIGIN OF PULVINAR NEURONS IN NONHUMAN PRIMATES Marilee Ogren and Pasko Rakic. Yale Univ. School of Medicine Section of Neuroanatomy, New Haven, Ct. 06510.

In comparison with structures that comprise the primary visual pathways in primates (Rakic, 1976, Nature, 261), little is known about the ontogenetic development of the structures that comprise the secondary pathways including the pulvinar. Previous developmental analysis of human fetuses indicates that some pulvinar neurons may be of telencephalic origin, in part because this major thalamic nucleus attains its large size only after the proliferative zones of the diencephalon have been exhausted (Rakic & Sidman 1969, Z. Anat.Ent.-Gesch., 129). Also, dense bands of undifferentiated cells can be observed streaming to the dorsal thalamus from the cerebral ganglionic eminence during midgestation in human fetuses. Definitive evidence for a telencephalic origin of pulvinar neurons cannot be obtained from human histological material. We therefore determined the time of origin of pulvinar neurons in rhesus monkeys that had been exposed to ^{3}H-thymidine from embryonic day (E) 25 through birth (E165) and sacrificed 2-3 months postnatally. Heavily labeled pulvinar neurons were observed only in animals that had been exposed to ^{3}H-thymidine between E36 and E45, when diencephalic proliferative zones are still mitotically active; all of the dorsal lateral geniculate nucleus neurons are generated over roughly the same period (Rakic, 1977; J. Comp. Neurol., 176). Neurons that comprise the inferior and lateral subdivisions of the pulvinar are generated during the beginning and middle of this period while those destined for the medial pulvinar are generated at the end of this period. The site of origin and migratory pathways of these neurons were determined in a series of animals that had been exposed to ^{3}H-thymidine between E36 and E45 and sacrificed at various short intervals after injection. Neurons destined for the pulvinar arise only from the diencephalic ventricular and subventricular zones that border the 3rd ventricle. They migrate to positions medial and dorsal to the lateral geniculate where they remain during the first third of gestation. Subsequent expansion of the pulvinar occurs after all of its neurons have been generated and is probably attributable to ingrowth of afferents during the middle of gestation (Shatz and Rakic, 1978, Neurosci. Abs. 4), differentiation of neurons and elaboration of their processes, as well as the addition of glial cells. Although in rhesus monkeys, pulvinar neurons appear to have an exclusively diencephalic origin, the possibility remains that in man this same structure acquires an additional population of neurons of telencephalic origin which does not exist in nonhuman species. (Supported by NIH Grant EY02503).

2703 COMPARISON OF NEURONAL PROPERTIES IN AREAS 17 AND 18 OF THE CAT. Guy A. Orban, Henry Kennedy* and Hugo Maes*. Laboratorium voor Neuro- en Psychofysiologie, K.U.L., Campus Gasthuisberg, B-3000 Leuven, Belgium.

Single unit recordings were made in areas 17 and 18 in anaesthetized (N_2O/O_2) and paralyzed cats. Properties of neurons in areas 17 and 18 were compared over a wide range of eccentricities (0-45° in 17 and 2-28° in 18). Histological reconstruction, Receptive Field (RF) position and velocity sensitivity enabled us to determine whether the neuron belonged to area 17 or 18. Hand plotting allowed classification of units, and measurement of RF dimensions and orientation selectivity. Direction selectivity and velocity sensitivity were assessed quantitatively with a multihistogram technique. In both areas similar proportions of the four cortical families (A, B, C, S) were found. More area 17 neurons were end-stopped (H cells). In both areas the proportion of S and H family cells decreased with eccentricity. In area 17 orientation specificity decreased with eccentricity, this is not so in area 18. In central area 17 S cells were more narrowly tuned than the other cell types and more so than S cells of central 18. Only Area 17 S cells showed meridional differences with preferred orientation (oblique effect). In area 18 and not in area 17 direction selectivity decreased with eccentricity. The proportion of direction selective cells is significantly greater in area 18 than in area 17. Velocity sensitivity allowed classification of area 17 and 18 neurons into 4 types: velocity tuned, broad band, high pass and low pass cells. Area 18 has a substantial proportion of cells measuring velocity either in a discrete way (50% of central 18 neurons are velocity tuned) or in a continuous way (66% of peripheral 18 neurons are high pass cells). These velocity signalling units are scarce (10%) in area 17. Most (83%) cells of central 17 are low pass cells. The apparent RF width of these cells is almost invariant with velocity. These neurons thus carry more precise information on position. In both areas the latencies decrease with eccentricity and central 17 is on average slightly slower than central 18. Our results indicate that in both areas the peripheral neurons are less selective and that the two areas are involved in a parallel analysis of different aspects of the visual scene.

2704 DISTRIBUTION, SIZE, AND MORPHOLOGY OF RABBIT RETINAL GANGLION CELLS. Clyde W. Oyster and Ellen S. Takahashi. School of Optom. University of Alabama in Birmingham, Birmingham, AL 35294.

As determined from extensive cell counts in flat-mounted retinas, ganglion cell density can be shown to vary about ten-fold from peripheral retina to the region of highest density. Even so, the maximum density is only about 5000 cells/mm^2. The peak is more of a ridge, extending some 90^o along the center of the visual streak, the region within which the cell density is greater than 2000 cells/mm^2. Although there is some elevation in cell density in the center and temporal end of the streak, there do not seem to be any clearly defined local regions of especially high cell density. Measurement of the total retinal area and areas enclosed by isodensity contours allowed estimates of total cell population to be made; the mean estimate for three retinas was 406,000 ganglion cells, a figure which agrees well with recent counts of the number of axons in rabbit optic nerve. Like previous studies, we found that large ganglion cells form a large portion of the cell population in peripheral retina than in the streak, while the reverse was true for small ganglion cells. These differences were not large, however; for cells in a given size range, the proportions changed only 10% or so between streak and peripheral retina. The superior retina appears to be different; there are considerably more large cells here than in other retinal regions having comparably low cell density ($<$ 500 cells/mm^2). Golgi stains show the rabbit ganglion cells to have a number of characteristic dendritic ramification patterns. Some are predominantly unistratified, with dendrites confined to either the scleral or vitreal sublamina of the IPL. Others ramify throughout the thickness of the IPL and, like the unistratified groups, show several variations in the complexity of the branching patterns. An obvious group of ganglion cells are bistratified, a configuration which is consistent with the notion that they are on-off cells. Some one-fifth to one-fourth of the stained cells have the bistratified morphology, a proportion which is similar to the frequency with which on-off direction-selective cells have been recorded in rabbit retina. (Supported by USPHS Grant EY02207).

2705 RECEPTIVE FIELD STRUCTURE IN STRIATE CORTEX OF CAT. Larry A Palmer and Thomas L Davis* Department of Anatomy, University of Pennsylvania, Phila., Pa.

We have used 3 methods to define the receptive field structure of striate cortical neurons in the cat: PST response planes, moving narrow bars, and moving edges. Best insight into field structure were obtained with a combination of response planes and edge analysis.

The spatial and temporal distribution of excitatory and inhibitory domains in response planes of striate neurons allows for easy recognition and subdivision of simple and complex cells. Simple cells always have spatially non-overlapping regions of excitation and inhibition (spatially heterogeneous response planes). Complex cells, on the other hand, always exhibit the same sequence of excitation and inhibition at all points in the receptive field (homogeneous planes). Based on their planes, 2 distinct types of complex and 5 distinct simple cell types have been discerned.

Field structure as defined in the response plane can be used with most cells to quantitatively predict the results of moving slit or edge analysis. This was accomplished by staggered addition of the PSTs comprising the plane. On-times were chosen to correspond to particular velocities of moving slits or edges. Most complex cells show overlapping light and dark edge discharge centers which correspond to the 2 primary excitatory domains in their planes. Many simple cells show a single light edge discharge center corresponding to a single excitatory domain surrounded by inhibition. The most common simple cell has spatially offset light and dark edge discharge centers which correspond to two similarly offset excitatory domains, one at light off and one at light on. In all these cells, the strengths and positions of inhibitory domains modify responses to moving edges and slits. While staggered addition of PSTs of a response plane will usually quantitatively predict symmetrical or mildly asymmetrical responses to moving stimuli, it usually fails to predict direction selectivity of 5:1 or more.

We regularly find 8 distinct types of striate neurons based on receptive field structure alone. We anticipate that this physiological diversity will help to account for the variety of neuron morphologies recently described with serial electron microscopy (Davis and Sterling). NSF Grant BNS-78-25147.

2706 LIGHT GENERATED HEAT IN THE EYE: THE ROLE OF THE CHOROIDAL CIRCULATION AS A HEAT SINK. Leonard M. Parver*, C.R. Auker, and D.O. Carpenter. Georgetown University, Washington, DC, and AFRRI, Bethesda, MD 20014.

The choroidal circulation accounts for 85% of the total ocular blood flow. In comparison with the circulation in the renal cortex the choroid has four times the volume of blood flow per 100 grams of tissue. The question arises as to whether the high flow choroidal circulation is functioning solely to supply nutrients to the outer avascular retinal layers. The exceptionally high oxygen content of venous choroidal blood, about 95% of that found in arterial blood, suggests some other role. One such role might be the dissipation of heat generated by the absorbtion of focused light in the outer retinal layers and the retinal pigment epithelium.

To study this hypothesis temperature measurements were taken from the macula of the cynomologous monkey eye. A thermistor probe was inserted through the pars plana and positioned in the macula under direct ophthalmoscopic control. The animals were exposed to two light environments (1) a dimly lit room, or (2) a lamp delivering 1.09 mW/cm^2 at the corneal surface. Temperature measurements were taken under these two light conditions while choroidal blood flow was decreased by raising intraocular pressure.

Raising the intraocular pressure with the animals exposed to the illumination in a dimly lit room produced a decrease in temperature recorded in the macula. In comparison, those animals exposed to the 1.09 mW/cm^2 light source showed an increase in macular temperature when the intraocular pressure was elevated. Temperature measurements were also taken from a peripheral retinal site. Increasing the intraocular pressure here produced a decrease in temperature irrespective of the light source. The decrease in temperature was slightly less marked with the 1.09 mW/cm^2 light source, but ran a parallel course with the changes observed with only background illumination.

We conclude that in low light environments the choroidal cirdulation acts as a heat source, maintaining a constant temperature environment for the retina and the retinal pigment epithelium. In high light environments the choroidal vasculature switches to a "heat sink", dissipating the heat generated by the absorption of focused light at the macula.

2707 CORPUS CALLOSUM SECTION DECREASES BINOCULARITY IN CAT VISUAL CORTEX. B.R. Payne*, Andrea J. Elberger, Nancy Berman and E. Hazel Murphy. (SPON: T.J. Cunningham). Depts. Anat. and Physiol/Biochem., Medical College of Pennsylvania, Philadelphia, Pa. 19129 and (A.J.E.) Dept. Anat., Sch.Med., University of Pennsylvania, Philadelphia, Pa. 19174.

The property of binocularity in visual cortex neurons has been assumed to depend upon convergence of fibers originating in adjacent lateral geniculate laminae. This study indicates that the corpus callosum is essential for normal binocularity.

Following section of the posterior corpus callosum, single units were recorded from area 17 in cats two or more days after surgery. The response properties and ocular dominance of each cell were determined as were the size and location of the receptive fields. The extent of the lesion was verified histologically after the final recording session. One sham operated and five normal cats were studied for comparison.

In normal and sham-operated cats over 80% of the neurons are binocularly driven. In posterior corpus callosum sectioned cats the proportion of such cells decreases to 37%. Surprisingly this effect is not limited to cells which have receptive fields in a narrow band adjacent to the vertical meridian but can be found up to 30^o lateral.

Other properties such as the proportions of simple and complex cells sampled in area 17 were unaffected by the lesion.

A reduction in binocularly driven cortical cells has been shown in cats given surgically induced strabismus or monocular suture prior to the time of natural eye opening. Such cats also have abnormal callosal connections (Lund; Innocenti and Frost). These data and our evidence on the role of the corpus callosum in binocular integration suggest that disruption of the normal development of callosal connections may underlie the loss of binocularity following early visual deprivation and strabismus.

2708 VISUAL RESPONSE PROPERTIES OF SINGLE NEURONS IN THE DORSOLATERAL CRESCENT (DL) IN THE OWL MONKEY: SELECTIVITY FOR STIMULUS SIZE, DIRECTION, AND ORIENTATION. S. E. Petersen*, J. F. Baker*, K. S. Rockland, and J. M. Allman. Div. of Biology, California Institute of Technology, Pasadena, CA 91125.

The Dorsolateral area (DL) is one of the five visual field representations that adjoin the anterior border of V-II and collectively constitute the third tier of visual areas in the owl monkey. DL wraps around the Middle Temporal area (MT) and relates to it topographically much as V-II does to V-I. We have quantitatively studied the response properties of 54 neurons in DL to stimuli of different size, direction of movement, and orientation. 23 of the 54 neurons showed a striking size selectivity. Many of these cells responded only to a narrow range of preferred sizes, and the preferred sizes were often smaller than the receptive field. Other units exhibited spatial summation up to a certain stimulus size, but were decreasingly responsive to larger stimuli. Neurons with similar size preferences were encountered sequentially in penetrations made normal to the brain surface. We also have observed qualitatively that many of these neurons were very responsive to expanding and/or contracting stimuli around the preferred size. The response properties of size-selective cells were largely independent of stimulus intensity and contrast.

DL neurons differ from cells in other extrastriate areas in their directionality and tuning to moving bars and spots. Directionality was quantified by comparing the response in the best direction to response in the opposite direction. Tuning was measured by comparing the response in the best direction to the responses in the surrounding directions within $\pm$ 90 degrees.

DL neurons were compared to neurons in MT and in a medial group of third tier areas: Dorsomedial (DM), Dorsointermediate (DI), and the Medial (M) areas. Cells in the medial group of areas are strongly orientation selective because they exhibit sharp tuning to bars and weak directionality. Medial group neurons are much more narrowly tuned to bars than to spots. MT neurons are strongly directional and only marginally more narrowly tuned to bars than to spots. DL neurons are significantly less directional than MT neurons but much more directional than neurons in the medial group. DL neurons are more broadly tuned to bars than MT neurons and much more broadly tuned than medial group neurons. DL neurons are only slightly more tuned to bars than to spots. In many cases, however, the most remarkable property of DL neurons is their selectivity for stimulus size.

2709 THE ROLE OF VISUAL RECEPTORS IN MAGNETIC FIELD DETECTION: RETINULA 7 AND 8 CELLS, MAGNETORECEPTORS IN THE HOUSEFLY? John B. Phillips*. (SPON: P.G.Aitken) Neurobiology and Behavior, Cornell U., Ithaca, N.Y. 14850.

Behavioral tests of the compass orientation of houseflies (Musca domestica) under different lighting and magnetic field conditions have been carried out in order to test the theory of the mechanism of magnetic field reception proposed by Leask (Nature 267: 144, 1977). This theory implicates visual receptors capable of detecting the phosphoretic emission of the lowest triplet excited state of a functional molecule following light absorption. As a consequence, magnetic sensitivity is predicted to be dependent on the spectral and polarization characteristics of light absorption by the functional molecule. The 'optical/radio frequency double resonance process' proposed by Leask to mediate magnetic sensitivity is consistent with a dependence on (1) the axis, but not polarity and (2) a total intensity which must closely approximate that of the earth's magnetic field which has been demonstrated by Wiltschko (In: Animal Orientation and Navigation, NASA SP-262, 569, 1972) for the magnetic response of birds. In advanced flies, a subpopulation of the retinula 7 and 8 cells appears to be ideally suited to discriminate the phosphoretic emission of a single triplet substate of a pteridine pigment(s) present in the visual cells. Results of the present study on the orientation of houseflies indicate (1) the presence of a magnetic compass response, (2) a dependence on the axis, but not the polarity, of the magnetic field and (3) an influence of the wavelength of incident light.

2710 ROD VISION: SENSITIVITY OF INFANTS APPROACHES THAT OF ADULTS. Maureen K. Powers. Dept. Psychol., Univ. Wash., Seattle, WA 98195

Single rod photoreceptors can signal the absorption of a single quantum of light. That this must be so was demonstrated long ago in psychophysical experiments on adult humans. Are the rods born with such exquisite sensitivity, or does it develop after birth? The results of the present experiment suggest that the former is more likely to be the case, because the sensitivity of the infant eye approaches that of the adult by 3 months of age.

Dark-adapted infants, 11-13 weeks old, were held in front of a rear-projection screen in a totally dark room. The infant's face was illuminated with infrared light, to which a TV camera trained on the face was sensitive. Stimuli (17^{o} diameter, monochromatic spots) appeared on the screen, 20^{o} to the infant's left or right.

The forced-choice preferential looking (FPL) technique was used for data collection. An adult observer (O), who could not see the stimulus, viewed the infant's face on a TV monitor. Following each presentation O made a forced-choice judgment of whether the stimulus was on the left or right based on the infant's preferred direction of gaze. Several intensities were presented per session. At the highest, O was nearly always able to judge the position of the stimulus correctly. At the lowest, O was only able to guess correctly 50% of the time; i.e., performance dropped to chance. Sessions were 1 hour daily for 10 days, about 60 trials per session.

The intensity of 502 nm light that allowed the observer to guess the position of the stimulus correctly on 75% of the trials delivered about 100,000 quanta/sec to the retina; a conservative calculation shows that 1 isomerization occurred per 100 rods covered by the stimulus. Two adult subjects tested under similar conditions, but using the method of adjustment, required 1 isomerization per 1400 rods to barely detect the stimulus. A 610 nm stimulus yielded higher thresholds for both infants and adults, by nearly equivalent amounts, and the difference was close to that expected from the CIE scotopic sensitivity curve.

This is the first measurement of the absolute visual sensitivity of human infants. It shows that the sensitivity of the rod system at 3 months of age is no more than an order of magnitude lower than in adulthood when the infant's natural behavior is observed. We conclude that a single rod in the infant's eye can be stimulated by a single quantum, just as a rod in the adult eye can be. The infant eye is therefore similar to other vertebrate eyes in the sensitivity of individual rod receptors.

2711 CONNECTIONS OF THE LATERAL POSTERIOR-PULVINAR COMPLEX WITH THE EXTRASTRIATE VISUAL CORTEX IN THE CAT. Denis Raczkowski*(Spon: Alan Rosenquist). Dept. Anat., Sch. Med., Univ. of Pennsylvania, Phila., Pa. 19104.

We have examined the projections from the lateral posterior (LP)-pulvinar (P) complex to several extrastriate visual cortical areas that were defined by electrophysiological mapping studies in this laboratory (Palmer, et al.,J.Comp.Neur.177:237-256,1978). Our method was first to record multiple unit activity through a micropipette during visual stimulation to confirm that the electrode tip was in the proper area and retinotopic locus. We then injected small quantities (0.1 ul) of a mixture of horseradish peroxidase (HRP) and tritiated amino acids into that cortical site. An analysis of our HRP results show first that there are at least three representations of the visual field in the LP-P complex that roughly correspond to parcellation schemes based upon cortical and subcortical afferent zones (Updyke, J.Comp.Neur.,173:81-122, 1977; Graybiel, Invest.Ophthal.,11:322-332, 1972). Using the terminology of Updyke, we find that small injections into the area centralis (AC) representation of both areas 21a and PLLS produced bands of labeled cells in the rostral portion of the LP-P complex. The label resulting from the area 21a injection was equally dense along the lateral border of P and the common border between LPl and LPi; after the area PLLS injection, the label was situated in the lateral half of LPi. Injections in the peripheral field representation of the horizontal meridian (HM) in area 20a led to labeling along the P-LPl border and the medial half of LPi throughout the rostro-caudal extent of the LP-P complex. Second, concerning the representation of the upper and lower fields in the LP-P complex, an injection in the lower field representation of areas AMLS labeled neurons in the ventral portion of LPi, whereas an injection in the representation of the upper fields (15^{o} above HM) in areas VLS produced equal amounts of labeled cells across the dorsal portion of LPl and LPi. Third, HRP results suggest that a great proportion of the LP-P complex is devoted to the AC and HM portions of the visual field. These experiments also refine our understanding of cortical subdivisions. Some cortical areas, such as PLLS, receive input from only one of the three thalamic zones (LPi), whereas other areas such as 20b receive from all three zones (LPl, LPi and P). Preliminary comparisons of thalamocortical and corticothalamic connection patterns indicate the presence of reciprocal connections in every case. Finally, every extrastriate visual cortical area thus far examined receives a bilateral input from the claustrum and an ipsilateral input from the central lateral nucleus. Supported by 1 R01 EY02654 and EY T32 07035.

2712 DORSAL LATERAL GENICULATE ORGANIZATION IN TURTLES, PSEUDEMYS SCRIPTA AND CHRYSEMYS PICTA. Wm. Todd Rainey. Dept. Anat., Univ. of Chicago, Chicago, IL 60637.

Dorsal lateral geniculate complex is the dorsal thalamic region that receives primary retinal input in pond turtles. This complex has two structural components: a cell lamina (CL) and a neuropil region (N). N is a cell-poor region medial to the optic tract (OT). Frequency histograms of soma areas from CL and N reveal significant differences in areas between regions, such that N neurons tend to be smaller. Autoradiographic materials reveal that optic optic nerve axons are distributed throughout N. When these axons are anterogradely filled with HRP, it appears that axon collaterals, as well as some axon shafts, can be traced within N. Most of the collaterals are so thin that their diameters cannot be resolved. CL is medial to N. Cortical and, possibly, tectal inputs terminate in this component. CL can be cytoarchitecturally divided into rostral and caudal regions. Rostral CL neurons have densely packed somata. Many of these contribute to tightly packed clusters. Caudal CL neurons have less densely packed somata. Analyses of Golgi material, and of neurons solidly filled with retrogradely transported HRP, reveal two cell types shared by both regions: CL neurons and N neurons. CL neurons display at least one of two types of dendritic arborizations. The characteristic arbor type consists of sparsely branching dendritic trunks that form large fields. The distal third to half of these fields is oriented parallel to the medial surface of OT. This region of the fields is found in the transitional region that consists of the medial edge of OT and the lateral half of N. Most dendritic segments in these fields are oriented perpendicular to OT axons. However, some distal segments turn and are oriented parallel to OT fibers. Both types of distal segments may bear one or more lobulated appendages that form tufted or ball-shaped arbors. Appendages with less complex arborizations are scattered sparsely along more proximal segments of dendrites within N. A second type of dendritic arborization is found, in addition, on many CL neurons. This type consists of one or more relatively thin dendritic segments that originate from the soma or proximal dendritic trunks and sparsely branch within CL. N neurons form the second type of geniculate neuron. Their dendriarborizations are sparsely branched and oriented parallel to optic tract fibers. These arborizations usually do not spread into CL. (Supported by PHS Grant GM-00094 and PHS Grant NS-12518.)

2713 DISTRIBUTION AND CENTRAL PROJECTIONS OF GANGLION CELLS IN THE RETINA OF THE GRAY FOX (UROCYON CINEREOARGENTEUS). David H. Rapaport, Michael A. Sesma*and Michael H. Rowe. Department of Psychology, University of California, Riverside 92521.

The overall pattern of retinal ganglion cell distribution in the gray fox, as seen in nissl-stained whole mounts, is quite similar to that of the domestic cat. The two most prominent features of ganglion cell isodensity maps are an area centralis, located above and temporal to the optic disc, and a visual streak which extends well into nasal retina approximately along the horizontal meridian. However, the area centralis of the fox seems somewhat less developed than in the cat. Ganglion cells in the fox retina range in soma diameter from 8-45 μm and appear to form 4 distinct size groups: 8-15, 16-23, 24-32 and 33-45 μm. Each of these 4 groups has a distinctive pattern of retinal distribution, so that cell size histograms from various retinal locations reveal striking differences between them in ganglion cell composition. Cells in the largest group form 2-5% of the total population in most areas, their absolute frequency being highest in the visual streak and superior temporal retina and falling off sharply in inferior regions. Cells in the 24-32 μm range form a high proportion of cells in temporal retina, but are much less frequent in nasal retina. Although the range of cell sizes in the area centralis is contracted due to the high density, it is clear that the cells in this group (24-32) are by far the most frequent type in the area centralis. Cells in the 16-32 μm range are relatively much more frequent in nasal than in temporal retina, and along with cells of the 8-15 μm group, concentrate to form the visual streak. Injections of HRP into one optic tract demonstrate that all groups in nasal retina project to the contralateral hemisphere. From temporal retina most cells in the 8-15 and 33-45 μm groups project to the contralateral hemisphere, but most cells in the 24-32 and 16-23 μm groups project to the ipsilateral hemisphere. An analysis of field potentials recorded around the perimeter of the optic disc in response to stimulation of the optic chiasm and the ipsilateral or contralateral tracts reveals at least 3 conduction velocity groups among retinal ganglion cell axons whose retinal origins and central projections suggest that they are the axons of the 3 larger cell size groups seen in retinal whole mounts. Thus, although the basic organization of the retinal ganglion cell population is similar in the cat and fox, the functional differentiation of this population into distinct groups seems more complete in the fox.

2714 AN ASCENDING VESTIBULO-RETICULO-MLF PATHWAY IN CAT. R.S. Remmel & R. D. Skinner, Depts. of Physiology and Anatomy, Univ. of Ark. for Med. Sci., Little Rock, Ark. 72201.

This electrophysiological study indicates that functional excitatory pathways exist from both vestibular nerves (V-nerves) through the vestibular nuclei (synapse), then to the pontine reticular formation (PRF) rostroventral to the abducens nucleus (one or more synapses) and to axons ascending in the region of the medial longitudinal fasciculus (MLF) ipsilateral to the PRF neurons. Cats were either anesthetized with pentobarbital, or decerebrated under ether and anesthesia discontinued. The cerebellum was removed. Body functions were maintained. The right MLF was electrically stimulated 1 mm caudal to the trochlear nucleus to antidromically excite right PRF neurons, which were recorded extracellularly with glass micropipettes, as previously reported (Exp. Brain Res. 32 (1978) 31). The left medial vestibular nucleus (MVN) was stimulated near its ventral border in 15 experiments. Electrode locations were confirmed histologically. Stimuli were 0.1 msec cathodal shocks of < 50 μA (MLF) and < 300 μA (MVN). Of the neurons antidromically excited from the MLF, 77 could be orthodromically excited from the contralateral MVN (latencies: range, 1.15 to 7.4 msec; av. and std. dev., 3.2 ± 1.2).

In 5 of these experiments both V-nerves were also electrically stimulated by pins stuck into the round windows at < 1000 μA (< 4X threshold), 28 neurons could be excited from the ipsilateral V-nerve (latencies: 1.8 to 7.3; av., 3.8 ± 1.4) and 31 neurons from the contralateral V-nerve (latencies: 1.65 to 6.9; av., 3.6 ± 1.3). A large fraction could be excited from both nerves and the MVN. The extracellular technique made testing for inhibition difficult. If one takes into account the 0.3 msec nerve conduction time, the 0.5 msec vestibular synaptic delay, the > 0.4 msec conduction time for vestibuloreticular neurons (> 5 mm distance divided by < 14 m/sec conduction velocity (Peterson and Abzug, J. Neurophysiol. 38 (1975) 1421), and 0.5 msec for the PRF synaptic delay, then > 1.7 msec should be required for excitation. The shortest latencies were only slightly longer than this, suggesting no additional intervening synapses. Other units were excited at longer latencies with more intertrial variability, suggesting either a slowly-rising, varying EPSP or else an additional synapse(s). The data suggests that some vestibularly-related MLF fibers originate in the PRF. This vestibulo-reticulo-MLF pathway might participate in the vestibulo-ocular reflex, in accord with Lorente de No's finding (Arch. Neurol. Psychiat. 30 (1933) 245) that the vestibulo-ocular reflex could still be elicited after the direct vestibulo-ocular fibers were cut.

2715 LATERAL INHIBITION, EXCITATION, AND THE CIRCADIAN RHYTHM OF THE LIMULUS COMPOUND EYE. G. H. Renninger and R. B. Barlow, Jr., Inst. for Sensory Research, Syracuse University, Syracuse, NY 13210.

Excitatory responses of the eye of Limulus exhibit a circadian rhythm. At night, nerve impulses in efferent fibers of the lateral optic nerve increase the sensitivity of each ommatidium of the eye. At dawn, the efferent activity stops and the sensitivity returns to the low daytime level. The nighttime sensitivity of a dark-adapted ommatidium can exceed daytime levels by as much as 10^5 (Barlow et al., Science 197, 86-89, 1977).

Lateral inhibitory interactions, on the other hand, are not significantly influenced by the circadian clock. When the eye is in the nighttime state, the strength of inhibition exerted by a small cluster of ommatidia on a neighboring ommatidium is equal approximately to that exerted in the daytime state.

Strong inhibitory interactions give rise to a striking "bursting" behavior of the response of the eye to diffuse illumination. Bursting is a sustained, periodic discharge of the optic nerve, in which impulses occur nearly synchronously in the individual nerve fibers. Depending upon the level of illumination, an ommatidium may respond with one or more impulses in each burst period. The bursting response was first observed only at high levels of light in the daytime state (Barlow and Fraioli, J. Gen. Physiol. 71, 699-720, 1978); we now find that bursting occurs over a wide range of light intensities in the nighttime state.

The burst period does not depend strongly upon the intensity of illumination. In the nighttime state, for example, the burst period is constant over a range of 3 log units above the threshold intensity for the bursting behavior. Interspike times in the response of an ommatidium during bursting do not depend strongly upon the level of sensitivity. In one preparation exposed to steady diffuse light, for example, the response of an ommatidium experiencing a fixed mean level of excitation consisted of a repetition every 0.14 s of two impulses, separated by approximately 0.03 s, in both the nighttime and daytime state.

The constancy of the burst period with increasing illumination and the negligible influence of the level of sensitivity upon the interspike intervals in the burst suggest that the temporal properties of lateral inhibition are not strongly affected by the circadian clock.

2716 DIFFERENCES IN THE IPSILATERAL RETINOCOLLICULAR PROJECTION IN ALBINO VERSUS FULLY PIGMENTED RABBITS. Michael Rezak, Dept. of Anatomy, University of Illinois at the Medical Center, Chicago, Illinois 60680.

It has been well established in a wide variety of mammalian species that the lack of retinal pigment is closely related to aberrant retinofugal projections. In general, it has been shown that the number of optic fibers decussating in the chiasm is abnormally increased in animals lacking retinal pigment. Although much detailed work has been done on the retinogeniculate organization relatively few studies have focused upon the retinocollicular pathway. The present study examines the differences in the ipsilateral optic projection to the superficial layers of the superior colliculus in albino and fully pigmented rabbits. Three albino and three wild type (fully pigmented) rabbits received intravitreal injections of 3H-proline and allowed to survive for three days. Upon sacrifice, the brains were removed and processed for autoradiography. Although the fully pigmented rabbits received a heavier ipsilateral retinal projection than the albino rabbits, in both types of animals the the grains formed distinct clumps or patches and were restricted to the ventral portion of the stratum griseum superficiale. In the fully pigmented rabbit the patches appeared either in isolation or in aggregates of two to three. In the albino rabbit, on the other hand, only two distinct and widley spaced patches appeared. In contrast to an earlier report using the degeneration method, the present results indicate that the ipsilateral projection in the fully pigmented rabbit occurs throughout the medial-lateral extent in the anterior portions of the colliculus. The patches in the ipsilateral colliculus of the albino rabbit occur in a ventrolateral position and in a mid-dorsal position within its anterior portion. It appears then that a large portion of the ipsilateral projection to the colliculus present in the fully pigmented rabbit decussates in the albino rabbit and terminates in the contralteral colliculus. It is worthy to note a recent report demonstrating a similar pattern in retinotectal projection in another albino animal, the Siamese cat (Weber et al., '78). Furthermore, it is of interest to know whether aberrant input in the albino rabbit colliculus is handled in a fashion similar to that in the Siamese cat, e.g., via a suppressive mechanism or by some other means.

2717 RECEPTIVE FIELD PROPERTIES OF LUXOTONIC UNITS IN MACAQUE STRIATE CORTEX. Ronald R. Riso*, Héctor Brust-Carmona, John R. Bartlett† and Robert W. Doty. Center for Brain Research, University of Rochester School of Medicine and Dentistry, Rochester, N.Y. 14642.

Taking strict precautions to assure the animal's comfort (as described in J. Neurophysiol. 37: 621, 1974), initial methohexital anesthesia was allowed to subside while chronically prepared monkeys were immobilized with pancuronium, thus allowing study of receptive fields (RFs) and of luxotonic properties of single units in striate cortex. General anesthesia, or even N_2O, produces severe disruption of luxotonic activity. In its absence about 30% of 244 units encountered were luxotonic, i.e., their average maintained discharge for 2 min of diffuse, patternless illumination vs. darkness showed at least a two-fold difference. Photergic units (those discharging fastest in light) were 2.5 times more common than the scotergic type (firing fastest in dark). Detailed study of 46 luxotonic and 85 nonluxotonic units, for which demarcated fields could be demonstrated, revealed that 72% of the luxotonic units were indifferent to the orientation of either a rectangular or edge stimulus, whereas 28% were selective for stimulus orientation. The latter type included both "simple" and "complex" units. In contrast, nonluxotonic units were about equally likely to be orientation selective or not. Some luxotonic units had small, punctate RFs with no antagonistic surround, while others had intermediate sized fields which were either entirely homogeneous in responsivity or had a centrally more responsive area surrounded by a synergistic, less sensitive region. Many luxotonic units were driven according to the total luminous energy present in their RFs irrespective of the geometrical distribution of the luminous energy. This was determined by comparing the response to a pattern, having discrete light and dark elements, to the response for a uniform grey stimulus having the same total luminous flux as the pattern. Several pairs of patterns and their respective flux-matched, neutral density equivalents were tested, covering a 2 $\log_{10}$ unit range. Other luxotonic units were driven primarily by the intensity of the illumination and were relatively insensitive to changes in stimulus area. The large majority of luxotonic units showed luminance properties. Some units showed monotonic luminance functions over the full 4 $\log_{10}$ unit range tested, and others showed much more restricted operating ranges. A class of luxotonic units had exceptionally large RFs (>60°) which extended well into the ipsilateral visual hemifield, thus raising the question as to how this information achieves the striate cortex. About 66% of luxotonic units were binocular, and these revealed a variety of binocular interactions. For half of them a diffuse light stimulus to one eye was excitatory, while for the other eye it was inhibitory. (†Deceased)

2718 CONNECTIONS FROM PRESTRIATE CORTEX TO THE SUPERIOR TEMPORAL SULCUS IN THE RHESUS MONKEY. Kathleen S. Pockland and Deepak N. Pandya. Boston University School of Medicine; Neurological Unit, Beth Israel Hospital, Boston, MA; V.A. Medical Center, Bedford, MA.

Various subdivisions of the occipital lobe project to the superior temporal sulcus (STS) in rhesus monkey. Recently the projections from striate cortex (area 17) to STS have been shown to be topographically organized (Ungerleider and Mishkin, Anat. Rec., 1978). In regards to the connections from peristriate cortex (area 18 and 19) to STS considerably less information is available. In present study using the autoradiographic technique with horseraddish peroxidase (HRP), the connections of peristriate cortex to STS are investigated in the rhesus monkey. A series of tritiated amino acid injections in different parts of area 18 (striate-recipient cortex) and area 19 indicated that the connections from these two regions also have distinct organization. The connections from area 18, like those from area 17, are directed to the caudal third of the STS and are topographically organized. Projections from the dorsomedial part of area 18 terminate in the caudal most part of the sulcus, predominantly in its lower bank, while projections from the lateral and ventral surfaces are directed to progressively more rostral portions of the STS. Connections from the ventral part of area 18, like those from the ventromedial portions of area 17, terminate dorsal to those from more lateral and medial parts of area 18. The apparent overlap of connections from area 17 and 18 was confirmed by an injection of horseradish peroxidase (HRP) in the STS. This injection resulted in HRP-filled neurons in visuotopically corresponding parts of area 17 and 18. A somewhat different organization was observed for the connections of area 19 to the STS. These terminate mainly rostral to the 17- and 18-recipient zone in the STS. Furthermore, connections from lateral as well as ventral portions of area 19 are directed to similar regions of the STS, where they both terminate in the lower bank and depth of the sulcus. Differences were also observed in the laminar arrangement of these connections. The connections from areas 17 and 18 terminate mainly in layer IV of the STS, whereas those from area 19 terminate in vertical bands in layers I through IV. HRP injections in areas 17, 18, or 19 consistently resulted in HRP-filled neurons in the STS. After injections of areas 17 or 18, these are predominantly in the infragranular layers (VI and Vb), with some located superficially in layer III. Neurons projecting to area 19 are more evenly distributed between the supra- and infragranular layers in the STS.

2719 **FIRING CHARACTERISTICS OF NEURONS IN THE VENTROLATERAL AND ORBITAL PREFRONTAL CORTEX IN MONKEYS DURING COGNITIVE BEHAVIOR.** **Carl E. Rosenkilde, Richard H. Bauer and Joaquin M. Fuster. Brain Res. Inst. and Dept. Psychiat., UCLA, Los Angeles, CA 90024.**

Extracellular activity of 258 single units from 3 rhesus monkeys performing two short-term memory tasks was analyzed with computer. The tasks, spatial delayed response and visual delayed matching to sample, have been described in a progress report of the present research (Neuroscience Abstracts, 1978, p80). The cells were located in the ventrolateral prefrontal cortex, including the lower bank of the principal sulcus (n=118), and in the orbital cortex medial to the lateral orbital sulcus (n=140).

One of two discharge patterns was observed during presentation of the cue in 86% of the cells. About half of these cells responded in a uniform manner to all four types of stimuli (red, green, left and right white lights) independent of the animal's subsequent behavior. The remainder of the cells displayed differential activity related to the color or position of the cue. However, this activity was either abolished or replaced by new firing components in those trials where the animal with a later and incorrect choice indicated that the cue was deficiently processed.

Increased or decreased activity was observed, equally often, in 48% of the neurons during the delay period interposed between cue and choice; two thirds of these cells differentiated between the qualities of the no longer present stimuli. So far, we have found no indication of regional differences within the prefrontal cortex in activity during cue or delay.

Forty-seven percent of the cells altered firing after the animal, with its choice, indicated which stimulus had been presented prior to the delay. This activity was related to the delivery of the liquid reinforcement. Thus, type I cells changed activity after reinforced trials, and showed no change, or a change in opposite direction, after unreinforced trials. In type II cells, post-trial alterations were observed only after unreinforced choices, but opposite frequency changes in some units followed unconditional delivery of the reward. Type III cells displayed comparable post-choice firing changes after all trials. A chi-square test showed that these cell types did not have a uniform topographic distribution. Type I cells were most common in lateral cortex, whereas type II cells predominated in orbital areas. No clear differences were revealed in distribution of type III neurons.

These results indicate participation of the prefrontal cortex in visual processing and in short-term memory. The post-trial activity of some neurons may represent reaction to interoceptive and motivational information; in other cells, this form of discharge may reflect their role in suppression of prior mnemonic traces (Supported by the Danish Medical Research Council and NSF grant BNS 76-16984)

2720 LECTIN-BINDING TO ISOLATED CELLS FROM TURTLE RETINA. P. Vijay Sarthy*, C. David Bridges*, Francis L. Kretzer* and Dominic M.K. Lam. Cullen Eye Institute, Baylor College of Medicine, Houston, TX 77030.

The presence of specific saccharides on the surface of retinal cells was examined by reacting FITC-labeled lectins with cells dissociated from papain-treated retinas. The pattern and intensity of binding was found to vary among the cells examined. With Con A (α-mannopyranosides, α-glucopyranosides and oligomers of mannose) there was strong surface binding to both rods and cones, with an intense ring of fluorescence just above the nucleus. Bipolars also showed strong surface labeling with intensification on the soma and at the synaptic ending. The pattern seen with Muller cells was quite striking in that intense fluorescence was observed in the apical, microvillous region. In contrast, the horizontal cells were devoid of any surface label. These observations are in agreement with the binding of ferritin-Con A seen in sections of turtle retina. When Ricin-60 (N-acetyl galactosaminyl and β-galactosyl residues) or Ricin-120 (β-galactopyranosides) or wheat germ agglutinin (oligomers of β(1 → 4) linked N-acetyl glucosamine) were incubated with photoreceptors (devoid of outer segments), bipolars or horizontal cells, little or no fluorescence was visible. However, all the three lectins bound strongly to the apical portion of the Muller cells. Asparagus pea lectin (α-L-fucopyranosides) did not bind to any of the cells examined, although patches of amorphous fluorescent material were often seen. In all cases examined, lectin-binding was inhibited by the appropriate haptene sugar: Me-α-Man for Con A, GalNAc for RCA 60, Gal for RCA 120 and GlcNAc for WGA. Furthermore, prior treatment of cells with neuraminidase did not significantly alter lectin-binding to any cell type. While the specificity of lectin labeling must be viewed with caution, the abundance of lectin receptors on the apical surface of Muller cells suggests the presence of membrane glycoproteins or glycolipids containing mannose, galactose, N-acetylgalactosamine and N-acetylglucosamine residues. Some of these sugars are probably present in the terminal, non-reducing position. In contrast, the horizontal cells have few accessible receptors for the lectins tested, while Con A binding to the bipolars and photoreceptors suggests the presence of surface saccharides containing mannose residues.

2721 PHYSIOLOGICAL PROPERTIES OF PHOTORECEPTORS IN THE COMPOUND EYE OF DAPHNIA MAGNA. Robert Schehr* and E. Macagno (SPON: E. Holtzman). Dept. Biol. Sciences, Columbia University, New York, N.Y. 10027.

Intracellular recordings have been made for the first time from the photoreceptors of the compound eye of the branchiopod crustacean Daphnia magna. These cells, 176 of which form 22 fused rhabdoms, are about 10μm in diameter and 30μm in length. Their axons project some 100μm to the optic ganglion, where they synapse onto 110 laminar neurons. These synaptic projections have been mapped in detail (PNAS 70: 57, 1973).

The photoreceptors have resting potentials in the range of -30 to -50 mV and slowly depolarize when illuminated. These depolarizations are composed of a transient phase and a maintained phase and are generally similar to other invertebrate photoreceptor potentials. Both the size and shape of the potential and its latency are strongly affected by the state of adaptation of the receptor and by the intensity of illumination. The transient phase is especially reduced in duration in the light-adapted state, revealing a spike-like response. There is, however, no evidence of impulse activity nor can the spike-like response be evoked by current injection in the cell body. Although Daphnia have been reported to show wavelength discrimination, our initial measurements of spectral sensitivity have detected only photoreceptors with a peak response in the blue.

2722 THE NATURE OF THE GENICULO-STRIATE INPUT TO THE SUPERIOR COLLICULUS. Peter H. Schiller*, Joseph G. Malpeli, and Stanley J. Schein (SPON: B.M. Dawson). Dept. Psyc., MIT, Cambridge, MA 02139 and Dept. Psyc., U. Ill., Champaign, Ill. 61820.

In the rhesus monkey the superior colliculus (SC) receives a visual input both directly from the retina and indirectly via the visual cortex. We have shown previously that inactivation of the indirect pathway by cooling visual cortex disrupts all visually driven activity in the SC except for the cells in the superficial laminae which receive the direct retinal input (Schiller, Stryker, Cynader, and Berman. J. Neurophysiol. 37: 181-194, 1974.)

The aim of this study was to determine to what extent the color-opponent (X) and the broad-band (Y) channels contribute to the indirect visual pathway to the SC. We reversibly inactivated these channels at the level of the lateral geniculate nucleus (LGN) by small (15-30 nanoliter) injections of 2% Lidocaine into either magnocellular or parvocellular LGN laminae while recording from single cells in topographically corresponding areas of the SC. The effects of these injections were directly compared with the effects of cooling visual cortex.

Our results were straightforward. Inactivation of magnocellular LGN laminae disrupted the activity of collicular cells the same way as did cortical cooling: superficial SC cells were unaffected while cells in the deeper laminae became unresponsive to visual stimulation. By contrast, inactivation of the parvocellular LGN laminae had no discernible effect on collicular cells.

These results suggest that in the monkey the indirect geniculostriate pathway to the superior colliculus is activated only by the broad-band (Y) system. (Supported by NSF grant #BNS 76-82543, NIH grants 5 R01 EY00676 and 5 F32 NS05799, and the Sloan Foundation grant #BR-1895).

2723 MOTOR SIGNIFICANCE OF VISUAL RESPONSES IN INTRALAMINAR THALAMUS OF CATS. J. Schlag and M. Schlag-Rey. Dept. Anat. and BRI, Sch. Med. UCLA, Los Angeles, CA 90024.

The saccade-related activity of most eye-movement (EM) neurons in the thalamic internal medullary lamina (IML) of alert cats is direction-specific. More than 90% of these cells also respond to visual stimuli. Thus, upon presentation of a target that produces a saccade in the preferred direction, they fire twice: first, when the target appears and, second, starting slightly before the targeting movement. The initial visual response and the EM discharge have the same direction specificity. This led to the hypothesis that the stimulus time-locked pattern of discharge already contains information about the anticipated motor response. The notion of "adequate motor response" in proposed as a counterpart to the classical notion of adequate stimulus, to characterize the conditions in which a given visual-oculomotor neuron would fire. To test this hypothesis, we sought to create experimental situations in which the predictions of responding would be different on the basis of stimulus spatial (receptive field) and on the basis of movement spatial parameters (direction of targeting). Fast, linearly moving targets were used for this purpose. Unable to seize the target at the site of its appearance on the screen, the animals eventually would try to capture it further along its trajectory. IML units were activated even in the absence of saccades; they respond to fast moving stimuli well before the latter penetrated into the receptive field as determined with stationary stimuli. The visual responsiveness was better accounted for in terms of direction of eventual saccades appropriate for catching up with the targets than in terms of receptive field. Distinguishing between sensory and motor neuronal events appears meaningless when, time-wise, such events are related to the sensory input while, information-wise, they are related to the motor output.

2724 DISTRIBUTION OF NEURONS CONTAINING CYTOPLASMIC LAMINATED BODIES (CLB) IN THE dLGN OF MONOCULARLY DEPRIVED (MD) AND DARK REARED (DR) CATS. Marie Luise Schmidt. Union College, Schenectady, N.Y. 12308.

Large samples of cells of the cat's dLGN including the projection of the area centralis in lam.A, A1 and the monocular segment (MS) were examined for the presence of CLBs in paraffin sections. CLBs were stained with Luxol fast blue and nerve cells with Carbol fuchsin or Cresyl violet.

Considerable variation in the proportion of CLB-containing cells among nearby regions of the same dLGN as well as among corresponding regions from different normal cats had been described (Schmidt, Neurosc.Abstr. 1977, 576). The mean percentage ofCLB-containing neurons in four cats vary between 40-61% in lam.A(medial), 40-53% in lam. A1 and 36-47% in the MS.

Similar distributions were observed in four dLGNs of MD cats: lam.A(medial) 46-66%; lam.A1 42-53%; MS 33-53%. The proportion of CLB-containing neurons in lam. A1 of the individual dLGNs was either equal or lower than in lam. A(medial) regardless which lamina had input from the deprived eye. A high or low proportion of neurons containing CLBs in the MS corresponded to a high or low percentage of these cells in the medial portions of lam.A and A1 in the particular dLGN. The percentage of nerve cells containing CLBs in two dark reared animals are in the range found in normal animals: lam.A(medial) 62 and 58%; lam. A1 55 and 50%; MS 42 and 48%.

A very small percentage of neurons in the dLGN of normal cats contained two CLBs. As a group deprived animals had a higher percentage of these cells. There may be a true increase in the number of neurons containing two CLBs in visually deprived animals. However it is possible that cells containing two CLBs are observed more frequently in these cats since their nerve cells may be smaller due to deprivation.

These data do not indicate a significant change in the proportion of CLB-containing nerve cells in the dLGN after visual deprivation as would be expected when CLBs serve as markers for X-cells (LeVay & Ferster, J.Comp.Neur.,172(1977),563-584). However fewer Y-cells have been recorded in the dLGN of visually deprived cats. Three interpretations are possible: (1) CLBs are not found in either X- or Y-cells exclusively or(2) only a very small fraction of Y-cells are lost or (3) Y-cells are not lost due to visual deprivation but the probability of recording from these cells is decreased.

2725 COLUMNAR PATTERN AND SPATIAL FILTERING IN VISUAL CORTEX: SEGMENTATION OF THE VISUAL SCENE BY COLOR,DEPTH AND TEXTURE Eric L. Schwartz, Brain Res. Dept. Psychiat. N.Y.U. Med. Ctr.

In recent work, it has been shown that several visual illusions (Mackay after-image,fortification illusion) may be explained in terms of the cortical representation of the visual field (Schwartz,1979). In previous work, it had been shown that the global retinotopic map, and the size of cortical ocular dominance columns, were sufficient to provide a prediction of rhesus monkey binocular disparity tuning (Schwartz,1977) which was subsequently verified (Schwartz,1979). The implication of this work is that neuronal trigger features such as binocular disparity tuning may be viewed as epi-phenomena of underlying anatomical structure. In the present paper, this work is extended to show that regular interlacing of discrete receptor input is sufficient to encode the difference map of the receptor mosaics as a spatial frequency modulated signal. Binocular disparity and color opponency are examples of visual sub-modalities which are represented by columnar structure at the cortex, which by definition are difference maps of discrete receptor systems, and which are known from psychophysical work to have differential spatial frequency sensitivity. It is shown by analytic calculation, and by digital and optical simulation, that columnar structure and spatial filtering are sufficient to provide segmentation (feature extraction) of the visual scene based on spatial texture of the cortical map, for color and depth channels.Visual texture may be extracted by means of lateral inhibition between spatial frequency channels, which is shown to provide spectral estimates of the higher order moments of the visual scene.Thus, the spatial pattern of cortical activity is capable of encoding color,depth,projected form, and texture without reference to "labeled lines", contingent only on the existence of columnar pattern and spatial frequency filtering. The existence of well defined neuronal trigger features is consistent with this analysis, and in fact, may be quantitatively derived. However, segmentation (feature extraction) may be conceptualized entirely in terms of spatio-temporal pattern, with no reference to the discrete cellular properties of the nervous system, beyond the receptor level. This provides a field theory of vision which is anatomically,physiologically, and psychophysically consistent.

2726 INTERHEMISPHERIC CONNECTIONS OF RETINOTOPICALLY DEFINED VISUAL CORTICAL AREAS IN THE CAT. Mark A. Segraves. Dept. Anat., Univ. of Pa., Phila., PA 19104.

The distribution of visual cortical cells whose axons pass through the corpus callosum was examined using HRP/o-dianisidine. In 2 cats, the posterior 2/3 of the callosum was cut and a cotton pledget soaked in 50% HRP placed between the cut ends of the callosum for a survival period of 48 hours. HRP labelled cells were found along the entire 17/18 border and the lateral half of area 19. A comparison with the visuotopic maps of Palmer, Rosenquist, and Tusa indicated that labelled cells in 17 were confined to within an estimated 5° from the vertical meridian (VM), cells in 18 to about 10° from VM, and about 20° from VM in 19. In contrast, extensive label was present in nearly all portions of lateral suprasylvian (LS) cortex, areas 20, and 21. Furthermore, callosal cells in these areas appeared to convey information from a more widespread portion of the visual field, out to as much as 40° from VM. Callosal cells at the 17/18 border and in 19 were primarily restricted to lower layer III (60%) and upper layer IV. Medium to large pyramids were found in both laminae and a few stellate cells were labelled in IV of 17 and 18. A small percentage of label in 19 consisted of pyramidal and fusiform cells in layers V and VI. In LS areas, medium to large pyramids in III still accounted for about 60% of labelled cells, but there was a decrease in the number of cells in IV and a substantial increase in the number of labelled cells in V and VI.

A number of small, combined HRP/tritiated leucine injections were made from a recording micropipette at electrophysiologically defined cortical injection sites. Injection sites included a range of receptive fields from loci on VM to about 40° from VM. We found that injections restricted to specific LS areas, area 20, and 21 always received the heaviest callosal input from the homotypic cortex of the contralateral side; thereby connecting visual field representations that were mirror symmetrical in the case of injection sites located away from VM. In addition, there was a convergence of projections to the injection site from other visual areas known to contain callosal cells in visual field representations that were mirror symmetrical to the receptive field of the injection site. 2727 VISUAL-VESTIBULAR INTERACTION IN HEMIDECORTICATE HUMANS. James A. Sharpe and Alex W. Lo*. Div. Neurology, University of Toronto, Toronto M5T 2S8, Canada.

Visual modulation of the vestibulo-ocular reflex (VOR) was quantitated in 5 subjects 8 to 12 years after cerebral hemidecortication for the control of epilepsy. The results were compared with data from 14 control subjects. Horizontal vestibular smooth eye movement velocity/head velocity gains were measured during passive sinusoidal whole body rotation at frequencies from 0.3 to 1.0 hertz.

While attempting fixation of a target moving with the head, hemidecorticate subjects had abnormally high gains of vestibular smooth eye movement contralateral to the side of cortical removal at each frequency. During attempted fixation of a stationary target, the VOR gain toward the side of cerebral damage was abnormally low at low rotational frequencies so that eye velocity failed to match head velocity. The impaired visual suppression of the contralateral VOR while fixating targets moving with the head and the defective augmentation of the ipsilateral VOR while fixating stationary targets were compensated by foveating saccades toward the side of cortical ablation. In darkness, VOR gains were horizontally symmetrical and normal.

With the subjects' heads immobilized to eliminate vestibular eye movements, smooth pursuit of 20° amplitude target motion was examined at 8 frequencies, from 0.125 to 2.0 hertz. During tracking toward the decorticate hemisphere smooth pursuit velocity/target velocity gains were subnormal at target frequencies over 0.125 hertz. During tracking away from the side of cerebral cortical ablation, gains exceeded unity at target frequencies up to 0.75 hertz. With the head immobile each subject had primary position jerk nystagmus toward the decorticate hemisphere. The nystagmus stopped in darkness.

Symmetry of the horizontal VOR in darkness and failure of the nystagmus slow phase velocity to increase in darkness implicated the horizontal pursuit system imbalance in the genesis of the fixation nystagmus. The unidirectional impairment of smooth pursuit correlated with the impaired visual augmentation of the ipsilateral VOR and with the impaired visual suppression of the contralateral VOR. These enduring manifestations of hemidecortication demonstrate roles of the cerebral hemisphere in visual-vestibular interaction.

2728 AXONAL TRANSPORT OF LECTINS FROM CAT VISUAL CORTEX DEMONSTRATED WITH AN IMMUNO-PEROXIDASE METHOD. H. Sherk* and S. LeVay. Dept. of Neurobiology, Harvard Medical School, Boston, Mass. 02115.

Certain plant lectins, proteins with high affinities for specific carbohydrate groups, have recently been shown to be transported retrogradely with great efficiency by CNS neurons (Schwab et al, Brain Res. 152: 145-150, 1978.) An injection of one such lectin, wheatgerm agglutinin (WGA), labeled as many cells as a control injection of horseradish peroxidase (HRP) that was several 100 to 1000 fold more concentrated. These studies used autoradiography of ^{125}I-lectins. We have investigated whether axonally transported lectins can instead be visualized with an indirect immuno-peroxidase method.

Antibodies to WGA and concanavalin A (Con A) were raised in rabbits. 0.1 ul of a 2% solution of WGA was injected into the left visual cortex of a cat, and a similar amount of Con A into the right cortex. After 24 hours, the cat was perfused with 4% paraformaldehyde. Alternate frozen sections were incubated with rabbit anti-WGA and rabbit anti-Con A, followed by HRP-coupled goat anti-rabbit IgG. Sections were then reacted in a diaminobenzidine-H_2O_2 solution at pH 5.1.

The injection sites in the cortex and cells in the lateral geniculate nucleus (LGN) were clearly labeled using this method. Each injection site was labeled only by the appropriate antiserum. Compared to the results of equivalent injections of HRP, these injection sites were remarkably small, dense, and well-defined. Presumably the diffusion of these lectins is limited by their high affinity binding to cell surface sugars.

Sections of the thalamus incubated with anti-WGA showed labeled cells in the left LGN, while those incubated with anti-Con A showed labeled cells in the right LGN. Cells were limited to a small part of the nucleus, indicating that the effective injection site was indeed restricted to the dense region of reaction product visible with this method. Reaction product in these neurons took the form of dense cytoplasmic granules similar to those resulting from HRP transport. In addition, many neurons containing granular reaction product were visible in the vicinity of the cortical injection sites.

This method has two potential advantages over conventional HRP tracing techniques. First, the restricted nature of the injection site should facilitate the study of local connections. Second, it offers the possibility of demonstrating multiple projections from a single region by the injection of several different lectins in one animal. Compared with the autoradiography of ^{125}I-lectins, the immuno-peroxidase method is faster and, since the reaction product is contained within cells, allows them to be unequivocally identified throughout the section thickness. (Supported by 1 F32 EY 05296-01 and EYRO-1960.)

2729 THE ORGANIZATION OF VISUAL INPUTS TO THE INFERIOR OLIVARY COMPLEX. Barbara A. Smythe*, Joseph T. Weber, Michael F. Huerta and John K. Harting. (SPON: P.B. Schechter) Dept. of Anatomy, University of Wisconsin, Madison, WI 53706

We have used the horseradish peroxidase (HRP) tracing method to identify visually related cell groups which project upon the inferior olivary complex. Subsequent to the identification of these cell groups, autoradiographic tracing procedures were used to define the specific termination sites of these inputs.

In our studies we have used three mammals, ie; the rat, the tree shrew and the cat. Thus far, the results of our experiments reveal that four visually related nuclei project upon the inferior olive. These are: (1) the superior colliculus, (2) the pretectal complex, (3) the nucleus of Darkschewitsch, and (4) the interstitial nucleus of Cajal.

The tecto-olivary pathway arises primarily from cells within layer IV of the superior colliculus. This pathway is predominantly crossed, and terminates within the caudal medial accessory olive of all three mammals. In the cat, an identifiable ipsilateral projection is apparent which also terminates in the medial accessory olive.

The pretecto-olivary pathway has also been studied. This pathway is entirely uncrossed. In the tree shrew, HRP experiments reveal that only the nucleus of the optic tract (NTO) projects upon the inferior olive. In contrast, HRP experiments in the rat and the cat show that in addition to the NTO, the anterior and the posterior pretectal nuclei also project upon this region. As determined from the autoradiographic data, the pretecto-olivary pathway in all three mammals terminates within the dorsal cap of Kooy. This projection is especially dense in the tree shrew and the rat. Two additional pretectal olivary projections were observed in the rat and the cat, ie, one to the rostral portion of the dorsal accessory olive and one to the beta nucleus.

Our findings regarding the olivary projection zone(s) of the nuclei of Darkschswitsch and Cajal are as yet not complete. We can, however, report observations made following large injections of HRP placed within the inferior olivary complex of all three animals. The results of these experiments show that the inferior olive receives an ipsilateral input from the nucleus of Darkschewitsch. On the other hand, the pathway to the inferior olive from the interstitial nucleus of Cajal is predominately ipsilateral, however, a small contralateral component is present.

2730 EFFECTS OF STRIATE CORTEX AND/OR SUPERIOR COLLICULI ABLATIONS ON ACCURATE REACHING BY MONKEYS. Stephen J. Solomon*, Tauba Pasik and Pedro Pasik. Dept. Neurol., Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029.

Ten monkeys (M. mulatta) were trained on a spatial localization task before and after sequential total ablation of the striate cortices with partial damage to circumstriate cortices, and bilateral aspiration of the superior colliculi in balanced order. Lesions were histologically verified. The task, given under normal room illumination, required the animals to reach for a target randomly placed in one of 8 equal segments of a 46 cm diameter white disc located frontally at 20 cm from the monkey's eyes. An apple cube, affixed to the center of the target served as the reward for accurate reaching. A correct response consisted of an initial contact with either the target or the apple cube directly. The animal was trained sequentially to a criterion level of performance using black discs of decreasing diameter (90, 55, 35 and 15 mm). Finally only the apple cube of about 10 mm was presented.

Six of the monkeys with only bilateral striatectomies could be retrained to reach accurately for all targets but with marked deficits on the first test. In general, error scores were higher in the upper quadrants. No defect was noted on subsequent targets. An additional decrease in performance of similar magnitude occurred when the apple cube alone was presented. This time errors were greater in the lower quadrants. Four animals with bilateral colliculectomies performed just as accurately as before the lesion. Three of these subjects were operated in two unilateral stages. In one of them, there was a transient increase in errors to targets on the right side after initial removal of the left colliculus. This monkey, however, had also some accidental damage to the left occipital lobe.

The ablations were combined in six of the subjects. Four of these monkeys, with almost total collicular destruction and/or degeneration, failed to reach criterion in 6,000 trials. The presence of a minimal remnant on one side correlated with higher number of correct responses to contralateral target locations. The other two monkeys with as much as 60% of the collicular tissue destroyed showed a minimal deficit only in the first test.

Conclusions: Results confirmed previous studies which showed that monkeys with total bilateral striatectomy can reacquire the ability for visually guided accurate reaching. Moreover, the present findings indicate that the superior colliculi are dispensable structures for this capacity. They become critical, however, in the absence of striate cortex. These results together with previous findings do not support a sharp dichotomy between two visual systems in monkeys, one subserving discrimination capacities (cortex) and the other localization functions (colliculi). Aided by NIMH Grant #MH-02261.

2731 SUBCORTICAL PROJECTIONS TO THE PULVINAR-LATERALIS POSTERIOR COMPLEX IN THE CAT. R. Spreafico*, C. Kirk*, S. Franceschetti* and G. Avanzini*, Depts. of Anat. and Physiol., UNC, Chapel Hill, NC 27514 and Dept. of Physiol., Neurological Inst. "C. Besta", 20133 Milan, Italy. (SPON: R.L. Montgomery)

The Pul-LP complex is considered part of the extrageniculate visual system and receives its major ascending afferents from tectal and pretectal regions. Since discrepancies exist in the literature about which subdivisions of the pretectal area project to the Pulvinar Lateralis (Pul (lat)), the present study was undertaken to elucidate this issue and at the same time to verify other structures which also project to the Pul-LP complex in the cat. In adult cats under barbiturate anesthesia, 0.2 to 1.0 ul of 30% HRP were injected stereotaxically in the Pul-LP complex. After 24-48 hours all animals were perfused with mixed aldehydes. After overnight wash in 30% sucrose buffer, brains were cut frozen in 40 um thick sections and reacted with either 3,3' diaminobenzidine (DAB), 3,3', 5,5' tetramethylbenzidine (TMB; Mesulam 1978) or Hanker-Yates substrate (H-Y; Hanker et al., 1977). Labelled cells were charted with an X-Y plotter, and in some cases their distribution was reconstructed tridimensionally with the aid of a PDP11/40 computer. With DAB or TMB, neuronal perikarya were intensely labelled, and proximal dendrites were visualized as well; with H-Y, cells were generally less intensely labelled and sometimes difficult to detect. Labelled cells were found in all subdivisions of the pretectal area after injection in Pul(lat) although their largest number was in NTO and NPP (Kanaseki and Sprague, 1974). Throughout the pretectal area, fusiform and triangular neurons were identified in the HRP material. When impregnated by the Golgi technique, both types of neurons showed long dendritic branches with only sparse ramifications. The majority of labelled neurons after LP injection were found in the second layer throughout the entire antero-posterior extent of the superior colliculus (SC). After more restricted injections, computer reconstruction of serial sections demonstrated that the medial part of the SC projects to the posterior LP, while more lateral parts of the SC project to the antero-ventral LP. Neurons from intermediate collicular layers also project to this portion. The parabigeminal nucleus also projects to LP, and other projections to Pul(lat) arise from locus coeruleus, subcoeruleus, reticular formation, periaqueductal gray, and hypothalamus.

2732 THE SPATIOTEMPORAL ORGANIZATION OF X-, Y-, AND W- CELLS. Alan Stein*, Walter H. Mullikin*, John K. Stevens. Depts. of Anatomy and Physiology, Univ. of Pennsylvania, Phila., Pa. 19104

Stevens and Gerstein have described two types of receptive fields (RFs) in cat retina: one group has a spatially homogeneous distribution of excitation and inhibition, and the second group has a spatially heterogeneous distribution. In contrast, many other investigators have described three basic groups: X-, Y-, and W-RFs. We have repeated the conventional tests for X-, Y-, and W-RFs and compared them directly to the heterogeneous/homogeneous characterization.

All units classified as X-cells by conventional methods had heterogeneous-RFs. Mean latency from the optic chiasm (OX) was 2.20 msec. (s.d.0.35,n=37). The velocity preference, using small bright bars, ranged from 0.5 to 64 deg/sec with the mode at 16 deg/sec. The spatial frequency at which these heterogeneous cells stopped their modulated response to drifted gratings was 1.94 c/deg or higher. Mean center size was 0.94 deg. (s.d.0.35, n=44). Cells with strong surrounds showed a clear null position to gratings.

All units classified as Y-cells had homogeneous-RFs. Mean latency from the OX was 1.16 msec. (s.d.0.23,n=54). Twenty-two of these cells could be activated from the superior colliculus (SC) and their OX latency was 1.12 msec. (s.d.0.18). When a bar 1 by 0.25 deg. was used as a stimulus, these cells had velocity preferences ranging from 32 to 256 deg/sec, with the mode at 128 deg/sec. The spatial frequency cutoff for modulated responses was 1.33 c/deg or below. Mean center size was 1.92 deg. (s.d.0.57,n=57). A null position could never be demonstrated in homogeneous-cells.

Units which were classified as W-cells had a mean latency of 3.47 msec. (s.d.0.80,n=33). Ten of these cells could be activated from the SC. The OX latency for this subgroup was 3.51 msec. (s.d.0.98). Mean center size was 1.24 deg. (s.d.0.65,n=33). These cells gave very poor responses to all but the slowest moving stimuli (0.5-1 deg/sec). Eleven of these cells had the same spatiotemporal organization as heterogeneous cells. The remaining 23 units had RFs which could be synthesized from standard heterogeneous and/or homogeneous components, and we call these hybrid RFs.

These data demonstrate that all X-cells have heterogeneous RFs; all Y-cells have homogeneous RFs; and all W-cells have heterogeneous or hybrid RFs. Most importantly, these data suggest that all retinal RFs can be constructed from a basic set of homogeneous and heterogeneous "building blocks". (Supported by NIH EY01832).

2733 SUPERIOR COLLICULUS INFLUENCES ON EYE MOVEMENT IN THE NEONATAL CAT. Barry E. Stein, H. Peter Clamann and Stephen J. Goldberg. Departments of Physiology and Anatomy, Medical College of Virginia, Richmond, Virginia 23298

The present experiments were initiated to (a) determine whether eye movements can be generated via the superior colliculus even before colliculus neurons are activated by visual stimuli (7 days of age) and (b) compare the movements to those evoked in adult cats. Twenty-six kittens, 2-77 days of age, and six adult cats were studied. A steel chamber was implanted over a cranial opening in each animal and a small mirror was glued to each anesthetized eye (the eyelids were surgically opened when necessary). Electrical stimulation of the superior colliculus consisted of 70 msec. trains of .1 msec. pulses at 200 pps. delivered through glass insulated tungsten microelectrodes. The electrodes were lowered to the colliculus through the visual cortex and eye movements were measured using the displacement of light beams which were reflected off each mirror onto a translucent hemisphere positioned in front of the animal. Adult cats exhibited many spontaneous conjugate saccadic movements, as well as some conjugate drifts of the eyes. Evoked eye movements, however, were always contraversive and conjugate. Neonates (2-12 days of age), on the other hand, showed many spontaneous slow drifts of the eyes and few ballistic-like movements. Surprisingly, the eyes often moved independently of one another spontaneously. With electrical stimulation, eye movements, as well as ear, neck and vibrissae movements, could be evoked in even the youngest animals studied. However, the eye movements elicited in kittens were of smaller amplitude, sometimes nonconjugate and required higher stimulus currents than those evoked in adult cats. Thus, in some cases only one eye moved or the eyes moved in different directions and/or had different amplitudes of displacement. Consequently, while eye movements can be generated by the superior colliculus in neonatal (and perhaps prenatal) kittens, this control system is not fully organized until after visual cells normally develop in the colliculus.

2734 DISSECTION OF A NEURONAL CIRCADIAN OSCILLATOR SYSTEM IN THE EYE OF APLYSIA: INTRACELLULAR RECORDING FROM SINGLE DISCONNECTED PHOTORECEPTORS IN CELL CULTURE. Felix Strumwasser, D. P. Viele* and J. M. Scotese*. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

The isolated eye of Aplysia californica produces a circadian rhythm (CR) in the frequency of optic nerve compound action potentials (CAPs), under conditions of total darkness, whose period is temperature compensated. The CR of CAPs is entrainable, in vitro, by light as well as chemical agents. Thus this eye contains all the cellular machinery for a temperature-compensated, entrainable circadian oscillator (CO).

In an attempt to dissect the CO further we have produced primary cultures of disconnected eye cells. We incubate eyes in a neutral protease (2.5% w/v) for 12 hr (15°C), followed by 7 hr (23°C) and gently triturate to dissociate cells. (After this enzyme treatment of intact eyes, the CR is not abolished.) Photoreceptors (PRs) and monopolar (MP) neurons are easily recognized. Our best cultures have yielded approximately 800 single PRs and 1000 MPs from a single eye. These cells as well as others attach to plastic culture dishes, produce webs and, in the case of MPs, grow long neurites in either modified MEM or L15 medium.

PRs can be recognized by a microvillous bush (rhabdomere) which marks the portion of the cell oriented toward the lens. Dimensions of selected PRs, from scanning electron microscopy (EM) of fixed, dehydrated specimens (n=4), reveal a cell body $\sim$ 30x14 µm with microvillous extensions ranging between 4-30 µm. Sections of PRs from cell culture viewed with transmission EM exhibit a normal morphology with three distinct parts, including a rhabdomere forming the apical portion, a cluster of pigment granules in the mid-portion, and a nucleus and a dense population of photic vesicles in the basal portion.

Stable intracellular recordings from isolated PRs have lasted 36-48 hr in exceptional cases but can normally be maintained for over 12 hr. PRs respond to light with graded depolarizations and do not produce action potentials. During the light response, there is a conductance increase, as measured by the steady state membrane voltage obtained in response to constant current pulses. Some preparations exhibit "spontaneous" quantum bumps whose frequency increase (up to $\sim$ 20/min) during dark adaptation and are suppressed after a light pulse. Light sensitivity in dark adapted cell cultures extends over at least 5 decades of intensity with $\sim$ 25 mV responses to 10^{-3} lux (5 second pulse). We find, using a programmer to scan the dynamic range of a PR, that light responses, after dark adaptation, are stable and have no circadian components thus eliminating the PR as a source of the CO in the eye of Aplysia. [Supported by NIH (NS 13896) and NASA (NSG-7387) grants.]

2735 VISUAL CORTICAL INPUT TO AREA 20 OF THE CAT: ANATOMICAL EVIDENCE FOR SUBDIVISION OF THIS REGION INTO TWO AREAS. Laura L. Symonds and Alan C. Rosenquist, Dept. of Anatomy, School of Medicine, University of Pennsylvania, Phila., PA. 19104.

Area 20 of the cat visual cortex was first defined by Heath and Jones on the basis of the patterns of connections with cortical and thalamic regions. Recently, our laboratory has electrophysiologically mapped this region of the visual cortex and subdivided it into two areas called 20a and 20b. We have shown that areas 20a and 20b are somewhat unique among other cortical areas because they receive projections from three separate subdivisions of the lateral posterior complex. We have studied the cortical connections of areas 20a and 20b to determine the degree of retinotopy, the pattern of cortical connectivity, and whether anatomical evidence could be found to support the division of this region into two functional areas. Our method was to make small combined horseradish peroxidase (HRP)/^{3}H-leucine injections from a recording micropipette at electrophysiologically defined regions of either 20a or 20b. The results reported here are based on the HRP data providing information about the cortical afferents to 20a and 20b. First, our results show that after injections into physiologically defined regions of 20a or 20b the labelled cells in other cortical areas are located only at similar retinotopic loci. Second, both areas 20a and 20b receive projections from many of the same cortical areas, including areas 17, 18, 19, 21b and 7. Third, areas 20a and 20b receive projections from different lateral suprasylvian visual areas. 20a receives input from PLLS and DLS on the lateral bank; 20b receives input from PMLS and VLS on the medial bank.

Our data thus provide additional evidence for the existence of two separate cortical visual areas within area 20 of the cat brain, confirming the electrophysiological findings. In addition, although areas 20a and 20b are regions which receive converging input from the posterior thalamus, they also receive input from separate cortical areas. (Supported by NIH Grant 1R01EY02654 and NIH Training Grant 5T32EY0703503).

2736 SIZE AND DISTRIBUTION OF RETINAL GANGLION CELLS PROJECTING TO THE RABBIT MEDIAL TERMINAL NUCLEUS. Ellen S. Takahashi, Clyde W. Oyster, John I. Simpson and Robert E. Soodak. School of Optometry/the Medical Center, University of Alabama in Birmingham, Birmingham, AL 35294 and Department of Physiology & Biophysics, New York University Medical Center, 550 First Avenue, New York, NY 10016.

Recent evidence from extracellular recording studies indicates that the medial terminal nucleus (MTN) of the rabbit diencephalon receives major, if not exclusive, inputs from a specific class of retinal ganglion cells, the on-type direction-selective cells. These ganglion cells have been selectively labeled by the retrograde transport of horseradish peroxidase (HRP) injected into the MTN. The number of labeled cells, their distribution over the retina, and their soma areas were determined. In one animal, in which the HRP injection completely filled the nucleus, some two thousand ganglion cells were labeled in the contralateral eye. This number agrees with previous estimates of the number of retinal axons terminating in the MTN. Unlike results in other species, none of the ganglion cells were displaced (Dogiel's cells). The density of labeled cells was highest in the visual streak and, overall, the distribution of labeled cells corresponded with the regional distribution of on-type direction-selective cells as previously determined in electrophysiological studies. Cells labeled by the HRP injection were among the 20% largest cells in the retina. This result, in conjunction with conclusions from other studies, leads to the prediction that on-type direction-selective cells can be characterized morphologically as having large cell bodies, very extensive dendritic spreads, and dendrites which ramify in the vitreal sublamina of the inner plexiform layer.

Although the ipsilateral retinal projection to the MTN in pigmented rabbit, as demonstrated by autoradiography, is considerably less dense than the contralateral projection, the number of labeled cells (seven) in the ipsilateral retina was lower than expected. This difference may reflect the relative sensitivities of the retrograde HRP method and the orthograde autoradiographic technique. (Supported by NIH Grants EY 00771 and EY 02207).

2737 MONOAMINE OXIDASE ACTIVITY IN RETINA—DISTRIBUTION AND DRUG INHIBITION. Thomas N. Thomas, David L. Sparks*, Neil S. Buckholtz, and John W. Zemp. Departments of Biochemistry and Psychiatry, Medical University of S.C., Charleston, S.C. 29403

Dopamine (DA) and serotonin (5-HT) are putative neurotransmitters of the retina.[1,2] Monoamine oxidase (MAO) catalyzes the enzymatic degradative deamination of these monoamines. Evidence points to the existence of at least two different forms of MAO (type A and B) having different substrate specificities and inhibitor sensitivities in the brain and other tissues. In brain, norepinephrine and 5-HT seem to be MAO-A specific whereas DA can be deaminated by both MAO-A and B. There is very little information available regarding the types of MAO and drug sensitivities of MAO in retina. This report deals with the distribution of MAO A and B in bovine retina and their inhibition by a number of drugs known to affect brain MAO activity. Fresh bovine retinas were homogenized in ice-cold 0.32 M sucrose and fractionated to give two synaptosomal fractions. One fraction (P_1) was enriched in photoreceptor terminals and the second fraction (P_2) contained synaptosomes derived from the inner plexiform layer. Type A MAO activity in these fractions was assayed using 1.5 μM [^{3}H]-serotonin as substrate and type B with 4 μM [^{14}C]-β-phenylethylamine. The distribution of MAO activity (nmoles/hr/μg protein) in retinal fractions is shown in the table below (mean ± SEM).

Fraction	Type A	Type B
Homogenate	0.67 ± 0.23	7.22 ± 0.21
P_1	0.79 ± 0.26	9.53 ± 1.11
P_2	2.29 ± 0.26	27.41 ± 0.84

The ratio of MAO-A to B activity is approximately equal in all fractions. Monoamines in retina have been shown to be localized in the inner plexiform layer and the P_2 fraction derived from this region contains most of the MAO activity. Therefore, the P_2 fraction was used to determine the IC_{50} values of a number of known MAO inhibitors. Pargyline and nialamide were of about equal potency in inhibiting both MAO A and B. 6-Methoxy-1,2,3,4-tetrahydro-β-carboline and clorgyline were more potent inhibitors of type A, whereas deprenyl was more effective in inhibiting type B. Similar actions of these drugs have been demonstrated on brain MAO except that, in brain, pargyline is a more potent MAO-B inhibitor. Drugs that inhibit MAO have proven useful in the treatment of depression and mild to moderate hypertension. Our observations raise the possibility that these drugs, by inhibiting retinal MAO activity, may alter retinal neurotransmission and possibly vision.

2738 PHYSIOLOGICAL EFFECT OF UNEQUAL ALTERNATING MONOCULAR DEPRIVATION. David G. Tieman*, Maureen A. McCall*, and Helmut V.B. Hirsch (SPON: H. Ghiradella). Neurobiology Research Center, State University of New York at Albany, Albany, NY 12222.

Kittens reared with equal periods of normal monocular vision in each eye but no binocular vision (alternating monocular deprivation or AMD) show a reduction in the number of binocular units in the visual cortex and a loss of stereopsis. In this study we report that unequal stimulation of the two eyes of an AMD kitten produces a shift in the distribution of ocular dominance for cells recorded in the visual cortex (Area 17).

Four experimental kittens (AMD-8/1) were reared in the dark from birth to 4 weeks of age, after which they were brought out for daily periods of exposure with one eye occluded. One eye was exposed for 8 hr and the other for 1 hr on alternate days. In control kittens each eye was exposed for either 8 hr (AMD-8/8) or 1 hr (AMD-1/1) on alternate days. In control cats, most cells were monocular and the numbers of cells dominated by either eye were approximately equal. In contrast, in experimental kittens the cells were more likely to be dominated by the 8-hr eye (79%) than by the 1-hr eye (16%). The distribution of ocular dominance of the cortical cells, thus, resembles that for monocularly deprived cats. However, unlike cells driven by the deprived eye of a monocularly deprived cat, many cells driven by the 1-hr eye exhibited well-defined receptive fields and normal tuning for orientation. Some of the cells were excited through one eye and inhibited through the other.

Therefore, even though both eyes received repeated patterned input which is sufficient to maintain or induce normal properties for receptive fields of cells in Area 17, more cells are dominated by the eye which was exposed for a longer period of time. Behavioral tests of these AMD-8/1 cats showed the 1-hr eye to have a restricted visual field (Tumosa, S. Tieman and Hirsch, 1979). The behavioral and physiological results suggest that a difference in the duration of stimulation may place one eye at a competitive advantage (supported by Alfred P. Sloan Foundation Fellowship BR1677 and USPHS Grant RO1EY01268).

2739 LOSS OF GENICULOCORTICAL TERMINALS FROM DEPRIVED LAMINAE IN MONOCULARLY DEPRIVED CATS. Suzannah Bliss Tieman, Neurobiology Research Center, State University of New York at Albany, Albany NY 12222.

In monocularly deprived (MD) cats, few cells in the visual cortex respond to input from the deprived eye, while most cells in the lateral geniculate nucleus (lgn) respond relatively normally. This suggests that the connections to visual cortex from the deprived geniculate laminae may have been disrupted. I have examined these connections in MD cats using both light (LM) and electron (EM) microscopic autoradiography of visual cortex after injections of tritiated lysine into single laminae of lgn. The placement of isotope was guided by recording cellular activity with the same micropipette used for injection. At the LM level, I found a shrinkage of ocular dominance patches from the deprived laminae (Tieman, 1977; cf Stryker and Shatz, 1976; Shatz and Stryker, 1978). At the EM level, after injections into either deprived or experienced laminae, I have found label over terminals which contain mitochondria and round synaptic vesicles and which make asymmetric contacts with dendritic profiles. However, the percentage of grains lying over these terminals was much higher when the experienced lamina was injected than when the deprived lamina was injected. To correct for variations in injection size and for a probable reduction in protein synthesis by cells in the deprived laminae, I have computed the ratio of labeled terminals to labeled myelinated axons. When the experienced lamina was injected, slightly more than three terminals were labeled for every labeled myelinated axon, whereas when the deprived lamina was injected, fewer than two terminals were labeled for every myelinated axon. These results suggest that geniculocortical axons from deprived laminae have fewer terminals than geniculocortical axons from experienced laminae. This reduced number of terminals could help to explain the reduced effectiveness of the deprived eye in driving cortical cells (supported by 1 F22EY01277, NS11614 and RO1EY01268).

2740 VISUAL ACUITY IN CATS FOLLOWING SURGICAL ROTATION OF ONE OR BOTH EYES. Brian Timney* and Carol K. Peck. Psych. Dept. Univ. Western Ontario, London, Canada, N6A 5C2 and Pomona Coll., Claremont, CA 91711.

It has been observed that, following surgical rotation of an eye, cats show substantial evidence of visual functioning in the rotated eye (cf Mitchell et al. Exp. Brain Res. 1976, 25, 109-113; Peck et al. Exp. Brain Res. 1979, 34, 401-418). Visuomotor behaviour is adequate, the animals can learn simple pattern discriminations and they appear to be able to compensate for their rotated visual world. The present experiments measured the visual acuity of cats which had undergone surgical eye rotation. Rotations were accomplished by sectioning the extraocular muscles and repositioning the globe within the orbit. Acuity was assessed using the jumping stand technique Mitchell et al., 1976, 6, 181-193), in which the cats were trained to discriminate a high contrast grating pattern from a gray field matched for luminance.

One group of kittens underwent unilateral rotations of about 90° at approximately the time of natural eye opening. In all cases, when each eye was tested separately, the acuity of the rotated eye was significantly worse than that of the normal eye by a factor of 2 or more, even though visuomotor coordination through the rotated eye seemed quite adequate. Kittens which were given smaller degrees of rotation suffered correspondingly less severe deficits. A second group of kittens received unilateral rotations at 2 months of age or older. Those cats with very large rotations (around 90°) also showed severe deficits in the rotated eye and those with smaller rotations were less impaired. A final group underwent bilateral rotations of approximately equal magnitude. Although there was some indication that acuity was reduced in both eyes of these cats, there was little difference between the two eyes.

Control experiments, and, in some cases, anatomical and physiological observations, suggest that the deficits are not due primarily to physical disturbance of the visual pathways. It seems more likely that the reduction of vision is a form of ambylopia produced by discordant binocular stimulation.

2741 THE EFFECT OF STIMULUS RATE AND STIMULUS PATTERN ON 14C-DEOXYGLUCOSE UTILIZATION IN THE VISUAL SYSTEM OF THE RAT. Arthur W. Toga, Simon Horenstein and Robert C. Collins, Dept. of Neurology, St. Louis Univ., and Dept. of Neurology, Wash. Univ. Med. Sch., St. Louis, MO 63110

The metabolic response to visual stimuli has been previously studied with the 14C-deoxyglucose autoradiographic technique (DG) in several species. There is still little known about the relationship between the site and intensity of metabolic response to changes in stimulus rate or stimulus pattern. We have studied these issues in albino rat.

The day prior to experiment, we enucleated the right eye and inserted an intravenous line. Animals were fasted overnight. To study the effect of stimulus rate, 4 to 6 animals each were assigned to one of six groups: total darkness, ambient light and full screen photo flash at 1, 4, 16.5 or 33/sec. White noise was used to mask auditory signals. During stimulation 14C-DG, 50 μCi/kg, was injected i.v. and animals were killed 45 minutes later, perfused-fixed, frozen, and brains cut at 20 μm thickness for autoradiography on Kodak SB-5 film. Since 90% of retinal fibers cross at the chiasm the visual system contralateral to the enucleated eye was used as a blind control. With visual stimuli the greatest changes in metabolism occurred in superior colliculus, with a 40% increase with either darkness or ambient light, and a linear 60 to 190% increase with full screen flash from 1 to 33/sec. By comparison the linear increase in geniculate was 50% as great and did not occur in visual cortex. Changes in metabolism were also studied during on/off pattern flash and pattern reversal (4 mm black/white squares) at 16.5/sec. There was only a small increase (10-20%) in metabolism during pattern reversal compared to total darkness control. During pattern flash there was 57% increase in superior colliculus, 27% in lateral geniculate and none in cortex. These changes did not differ compared to full screen flash at 16.5/sec when controlled for luminance flux. The results of this study provide evidence that different anatomical structures of the visual system have different metabolic requirements in processing visual information. The role of the superior colliculus in visual attention may be responsible for the greater increase in glucose utilization observed in this structure.

2742 EFFECTS OF BINOCULAR DEPRIVATION ON RESPONSES OF CELLS IN THE CAT'S LATERAL SUPRASYLVIAN VISUAL CORTEX. Lillian Tong*, Peter D. Spear, and Carol Sawyer*. Dept. of Psychology, U. Wisconsin, Madison, WI 53706.

Eight cats were raised with binocular lid suture (BD), and single cells were recorded in the binocular and monocular segments of the lateral suprasylvian visual area (LS area). Only about 25% of the cells could be driven by visual stimuli in BD cats, compared to 87% of the cells in normal cats. In addition, among 165 responsive cells that were studied in BD cats, 50% had diffuse, ill-defined receptive fields and responded best to whole-eye illumination. Cells with well-defined receptive fields generally responded better to stationary flashing stimuli (39%) than to stimulus movement (11%), and none of the cells were direction selective. Less than 5% of the cells had inhibitory receptive field surrounds. In contrast, 93.5% of the responsive cells in normal cats have well-defined receptive fields and over 80% are direction selective. In addition, nearly 40% of the cells in normal cats have inhibitory receptive field surrounds. Thus, binocular deprivation produces severe abnormalities in the response properties of LS area neurons. In addition, cells in the binocular segment showed somewhat abnormal ocular dominance. Only 48% of the cells could be driven by the ipsilateral eye in BD cats, compared to 70% of the cells in normal cats. There was no difference in the effects of BD on receptive field properties of cells in the monocular and binocular segments of LS cortex.

Many of the abnormalities observed in the LS area of BD cats resemble those that are present in normally reared cats after visual cortex (areas 17, 18, and 19) has been removed (e.g., loss of direction selectivity, increased response to stationary flashing stimuli, and reduced input from the ipsilateral eye), while others differ (e.g., loss of responsive cells, increase in cells lacking well-defined receptive fields, and loss of inhibitory surrounds). To investigate the extent to which the changes following BD are due to abnormal cortico-cortical inputs, five additional BD cats were studied after visual cortex had been removed. There was no difference between the results in these animals (69 responsive cells were studied) and those in BD cats with visual cortex intact. Thus, efferents from visual cortical areas 17, 18, and 19 have lost (or failed to develop) their influence on LS area neurons following rearing with binocular lid suture. In addition, the differences between LS area response properties in BD cats with visual cortex removed and those in normally reared cats with visual cortex removed indicate that binocular deprivation produces abnormalities in the thalamic-LS cortex pathway independent of the geniculo-striate system.

2743 PROJECTION OF THE SUPERIOR COLLICULUS UPON THE DORSAL LATERAL GENICULATE NUCLEUS IN THE CAT. F. Torrealba*, G.D. Partlow[1] and R.W. Guillery. Dept. Pharmacolog. & Physiolog. Sci., Univ. of Chicago, Chicago, IL 60637; [1]Dept. Biomed. Sci., Univ. Guelph, Guelph, Ont. N1G2W1, Canada.

The cat's dorsal lateral geniculate nucleus (LGN) is known to receive afferents from the superior colliculus (SC) as well as from the retina. It was our interest to study the precise relationship between these two pathways. Fink-Heimer (FH) and autoradiographic methods confirm that SC projects to the most ventral laminae in the LGN (Niimi, et al., 1970; Graybiel, 1972; Graham, 1977). The terminals extend broadly in the nucleus, from the most caudal regions to the anterior fourth of the nucleus, where the layers bend ventrally. This connection is in register with the known retinotopic organization of the LGN and of the SC. In addition, there is a thin band of terminals just medial to the medial interlaminar nucleus and also the more extensive thalamic projections described previously.

By combining an intraocular injection of radioactive proline on one side with a tectal lesion on the other side it has been possible to show that tectal connections go mainly to C_3 (a layer of small cells to which a retinal input has not been demonstrated) and that both retinal and tectal afferents may overlap in layer C_2. This overlap was not complete, but rather patchy, especially in the medial regions of LGN. In some cases at the level of the optic disc representation in LGN, there is a gap in the band of tectal terminals, but no evident rarefaction of cell bodies. This gap is wider than the one in the A and C layers.

In separate experiments, HRP was injected into the brachium of the SC, and this gave Golgi-like staining of tecto-LGN axons and terminals. This method and the FH show that these axons are of fine caliber, and travel dorsally in the optic tract (OT). They give off terminals near to the main branches, so that terminals from one axon occupy a thin leaflet about 100μ in the medio-lateral plane and less than 40μ in the dorso-ventral dimension. The endings can be linked in a short chain (boutons en passant); they may form small clusters of 3-5 swellings, or they may be individual swellings joined by a thin stem to a branch. Some of these axons end among small islands of 2-6 neurons in the OT, where the ventral part of C_3 is invaded by OT fibers.

EM studies of these HRP filled axons reveal that tectal terminals in the LGN are small in diameter, have round vesicles and form asymmetrical contacts on smooth dendrites.

2744 QUANTITATIVE STUDIES OF VISUAL RECEPTIVE FIELDS IN FROG TECTUM. Evangelia Tzanakou*, Richard J. Michalak* and Erich Harth.
Physics Department, Syracuse University, Syracuse, NY 13210.

The receptive fields of retinal fibers and tectal cells in the frog have been re-examined in a quantitative way. The method used is computer controlled, and the stimuli are square spots of preselected size and luminance generated on a CRT screen. The positions of the spots were varied in a random manner in order to minimize systematic errors. The responses of the unit monitored are recorded extracellularly as a function of the spot location. Spot sizes could be selected conveniently subtending angles from about 1° to 15° at the frog's retina. In this way the available field represented by the CRT screen could be scanned at different resolutions, with the finest scan consisting of 1024 field elements. The response matrices are translated into intensity patterns, and the global responses to these patterns are recorded. In some cases the patterns were modified by use of clustering techniques while observing the resulting responses. Data will be presented of over 900 independent runs of about 70 cells. Most of the fields found were approximately circular with angular widths between 1° and 20°. Others were either elongated or showed irregular shapes. The majority of the cells showed a preference for dark stimuli on bright background rather than the opposite. When different resolutions were used, the results showed consistently that the responses of the different parts of the receptive field did not add linearly. Non-linear behavior and interactions between different areas of the receptive field were examined for some cells, by scans in which two spots were presented simultaneously with randomly changing locations. The temporal characteristics of the responses were also examined; successive runs show that good stability and reproducibility can be achieved over long periods of time.

2745 THREE CORTICAL PROJECTION FIELDS OF AREA 17 IN THE RHESUS MONKEY. Leslie G. Ungerleider and Mortimer Mishkin. Lab. Sensorimotor Research, NEI and Lab. Neuropsychology, NIMH, Bethesda, MD 20205.

Although the projections of lateral striate cortex, the part representing central vision, have been extensively studied in the rhesus monkey, little information exists regarding the projections of posterior and medial striate cortex, parts representing peripheral and far peripheral vision, respectively. We therefore investigated the cortical efferents from all parts of area 17, with the aim of defining the locus, extent, and topographic organization of the entire striate-prestriate projection system.

One series of monkeys (Macaca mulatta) was prepared with unilateral lesions of lateral, posterior, or medial striate cortex, such that collectively the lesions included all of area 17 with little or no invasion of area 18; their brains were processed for terminal degeneration by the Fink-Heimer procedure. In a second series, selected striate sites were injected with tritiated amino acids, and the brains processed for autoradiography; representations of the injection sites ranged from 4° to 25° from fixation in either the upper or lower visual field. The results indicate that striate cortex projects to at least three separate and topographically organized visual areas within prestriate cortex.

The largest projection field is a circumstriate cortical belt which corresponds remarkably closely to area OB of von Bonin and Bailey. It completely surrounds area 17 along the 17-18 border except at the representation of fixation. Within this visual area, the representations of the upper and lower visual fields are entirely separate. Progression from central to far peripheral vision is represented: a) in the lower field, by a progression into the posterior bank and depth of the lunate sulcus, medially along the surface of the buried annectent gyrus into the parieto-occipital sulcus, and then rostrally along the upper lip of the calcarine fissure; b) in the upper field, by a progression into the inferior occipital sulcus, ventromedially into the occipitotemporal and collateral sulci, and then rostrally along the lower lip of the calcarine fissure.

A second, smaller projection field is located in area OA along the caudal portion of the superior temporal sulcus; here, progression from central to far peripheral vision is represented by a progression down the posterior bank of the sulcus and continuing along its floor (Ungerleider & Mishkin, Anat.Rec. 190:568,1978).

Finally, a third, even smaller projection field, also located in area OA, begins in the anterolateral part of the annectent gyrus and extends forward to occupy the depth of the lateral bank of the intraparietal sulcus. Despite its small size, evidence of a complicated topographic organization within this field raises the possibility that it may contain more than one visuotopic map.

We thank Dr. E.G. Jones for assistance with the autoradiography.

2746 EVIDENCE FOR ADDITIONAL EXTRASTRIATE CORTICAL PROJECTIONS TO THE DORSAL LATERAL GENICULATE NUCLEUS IN THE CAT. B. V. Updyke. Department of Anatomy, Louisiana State University Medical Center, New Orleans, Louisiana 70112

Substantial cortical projections onto the dorsal lateral geniculate nucleus arise from visual areas 17, 18, and 19 in the cat. Areas 17 and 18 project onto all of the laminae and the intralaminar zones of the nucleus, and area 19 projects to the parvocellular C laminae (Updyke, J. Comp. Neur., 163: 377, 1975). These connections appear to reciprocate the known projections originating from the geniculate laminae (Gilbert and Kelly, J. Comp. Neur., 163: 81, 1975).

In the course of investigating the projections arising from lateral suprasylvian areas, it was noted that certain of these areas also project onto the dorsal lateral geniculate nucleus. In these experiments, individual cortical areas - as defined by Tusa et al. (Soc. for Neurosci. Absts., 1: 52, 1975) - were identified by electrophysiological mapping, and then injected with tritiated proline. Projections onto the thalamus were identified autoradiographically.

No projections to the dorsal lateral geniculate nucleus were evident from areas ALLS, PLLS, and DLS occupying the lateral bank of the suprasylvian sulcus, or from area AMLS on the medial bank of the sulcus.

Areas PMLS on the medial wall of the suprasylvian sulcus, and area 21a on the crown of the posterior suprasylvian gyrus do project sparsely onto the parvocellular C laminae of the dorsal lateral geniculate nucleus. In addition, sparse terminal labeling of these laminae occurs after injections made more posteriorly on the suprasylvian gyrus. Because of the complex juxtaposition of areas 20a, 20b, VLS, and 21b in this region, it has not yet been possible to unequivocally identify the exact source of these corticogeniculate fibers.

The results indicate that a strip of the lateral suprasylvian cortex extending from the medial wall of the middle suprasylvian sulcus over the surface of the posterior suprasylvian gyrus contributes a sparse projection to the parvocellular C laminae of the dorsal lateral geniculate nucleus. These observations suggest that a strict reciprocity of connections may not be an essential feature of corticogeniculate projections in the cat.

2747 AREAL BOUNDARIES AND TOPOGRAPHIC ORGANIZATION OF VISUAL AREAS V2 AND V3 IN THE MACAQUE MONKEY. D. C. Van Essen, J.H.R. Maunsell* and J. L. Bixby*. Division of Biology, California Institute of Technology, Pasadena, CA 91125

The organization of areas V2 and V3 in the macaque was studied by analyzing cortical myeloarchitecture, projections from striate cortex (V1), and interhemispheric connections. Results were displayed on two-dimensional cortical maps that permit accurate measurements of spatial relationships within the cortex. 1) All of V1 projects to V2, but only dorsal V1, representing inferior visual fields, projects to V3. Thus, V3 may contain an incomplete representation of the visual field and be restricted to dorsal extrastriate cortex; alternatively, it may extend further but have a highly asymmetric pattern of inputs. 2) We found no evidence for projections from foveal V1 to V4, as claimed by Zeki (J. Physiol. 277, 1978). 3) V2 is 10-15 mm wide along much of its extent, except near the representations of the far periphery (medially) and the fovea (laterally). In the region of far peripheral representation, near the anterior tip of the calcarine sulcus, there is a complete gap of about 1 cm between dorsal and ventral subdivisions of V2; the intervening strip of cortex (the prostriate area of Sanides) is characterized by its distinctive architecture and by an absence of interhemispheric connections along the border with V2. Laterally, near the foveal representation, there is a distinct transition in myeloarchitecture at the border between V2 and V4. The minimum width of V2 in this region varies from 2 mm in one case to less than 1 mm (with a possibility of a complete gap) in two other cases we have examined. 4) The detailed organization of inputs to V2 was examined by making lesions and ^{3}H-proline injections focally (up to several mm in extent) within V1. As reported by others, dorsal V1 projects to dorsal V2, ventral V1 to ventral V2, and the horizontal meridian representation of V1 to both subdivisions of V2. Within each V2 subdivision, however, the pattern of inputs from V1 is variable. In some cases the projection terminates as a single patch 2-4 mm across, but in other cases there are two distinct patches, each 2-3 mm across and separated by a gap of 0.5-1 mm (cf. Weller et al., Arvo Abstr., 1979). Moreover, the inputs to individual patches are arranged as irregular clusters that may reflect a specific pattern of organization at a sub-millimeter level. Altogether, these experiments indicate several significant differences in the organization and connections of V2, V3 and V4 compared to previous descriptions.

2748 SELECTIVE ATTENTION IN MIRROR IMAGE DISCRIMINATION BY MONKEYS. Betty A. Vermeire* and Charles R. Hamilton, Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Normal animals often find left-right mirror images (LR) harder to discriminate than up-down mirror images (UD). One popular interpretation ascribes the difficulty to confusion between the normal topographic representation in the cortex and a duplicate but reversed projection through the interhemispheric commissures. In support of this, optic chiasm sectioned monkeys taught to discriminate LR monocularly, reversed their performance when tested through the other eye. This paradoxical transfer, however, may be interpreted as a selective attention to cues on the side of the stimulus contralateral to the eye being tested, which occurs because of the temporal hemianopia present when using each eye. Selective attention caused by stimulus masking successfully predicts the otherwise uninterpretable result that split-chiasm monkeys find LR easier to learn than UD.

A more generalized concept of selective attention to stimulus cues could interpret confusion of left and right in normal animals. For example, animals could code stimulus orientation relative to asymmetries in the world or they could attend to cues near the place of response, often at the top or bottom of the stimuli. To see if an obvious asymmetry or place of response is a significant factor, split-chiasm monkeys were trained monocularly on UD or LR in a WGTA equipped with a vertical panel containing planimetric patterns and a peg for responding located near one edge of the patterns. With the peg aligned with the axis of symmetry of the stimuli, discriminations were easier than with an orthogonal placement, as predicted by selective attention. In addition, because of the split chiasm, LR were learned more easily than UD, as previously found. In the aligned peg condition interocular transfer tested with the peg position changed 180° led to reversed transfer of both UD and LR. Testing LR showed, in addition, increased magnitude of reversed transfer associated with masking by the retinal scotoma. Reversal associated with manipulating the place of response was half the magnitude of that associated with masking. A similar experiment with normal monkeys showed that they, too, reversed their performance on LR and UD discriminations when the place of response was reversed. Thus it appears that attention to cues near the place of response, or coding orientation relative to asymmetries in the world, can occur during discrimination of mirror images. Therefore in conjunction with the prominent up-down asymmetries in the world and the tendency for animals to respond to the upper or lower edges of test stimuli, mechanisms of selective attention can explain confusion of left and right by normal animals.

2749 POTASSIUM RELEASE AND CURRENT FLOW IN THE FROG RETINA: A TEST OF THE MÜLLER CELL HYPOTHESIS OF ELECTRORETINOGRAM (ERG) B-WAVE GENERATION. David A. Vogel and Daniel G. Green. University of Michigan.

The electroretinogram is an electrical potential that develops across the retina in response to a flash of light. One of the components of the ERG, the b-wave, has been used by many investigators as a measure of responsiveness of the retina. Despite its common use, the exact origin of the b-wave remains unknown.

It has been postulated that extracellular accumulations of potassium ions may act to locally depolarize the membrane of the Müller cell. This depolarization should then be the site of the sink for the extracellular current flow which causes the b-wave. A strong test of the Müller model is to compare the distributions and the time courses of development of the known K+ increase and the b-wave current sources and sinks.

The light adapted eyecup preparation from Rana pipiens was used for this experiment. Local ERG's and K+ concentration were measured simultaneously using a double barrel microelectrode. The extracellular sources and sinks were calculated by computer.

The prediction from the Müller cell model is that the ERG current sinks should occur at the same locations as the K+ increases. Further, the time courses of the development of the K+ increase and the ERG current sinks should be identical. It is quite apparent from the results that the profiles of the K+ increase and the b-wave sinks are not identical. The potassium profile has only one peak which occurs at a depth of 60μ and 1.5 seconds after the light was presented. The source/sink surface has two peaks, the proximal one being somewhat larger than the distal one. The time courses of development of the two profiles are also dissimilar.

The above findings are a direct contradiction to the results predicted by the Müller cell hypothesis. Therefore, if the Müller cell plays any role in b-wave generation, it must be in conjunction with other retinal cells.

2750 THE EFFERENT CONNECTIONS OF THE PRETECTAL COMPLEX OF THE TREE SHREW (TUPAIA GLIS). Joseph T. Weber, Michael F. Huerta and John K. Harting. Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53076.

The efferent connections of the pretectal complex of the tree shrew (Tupaia glis) have been analyzed using anterograde (autoradiography) and retrograde (horseradish peroxidase) tracing techniques.

The autoradiographic data reveal that the targets of the pretectal complex can be grouped into several categories. First, there are ipsilateral, descending pathways which terminate within the dorsal cap of Kooy of the inferior olivary complex, the dorsolateral and dorsomedial griseum pontis, the mesencephalic reticular formation dorsal and lateral to the red nucleus, the medial terminal nucleus, and the superficial layers of the superior colliculus. Rostrally located targets include the ipsilateral lateral and reticular nuclei of the thalamus, the zona incerta, and the central lateral and paracentral intralaminar nuclei. A bilateral projection to the ventral lateral geniculate nucleus is also present. A third category of targets includes nuclei which are closely associated with cranial nerve nuclei related to eye movements. Thus, fibers arising from the pretectum terminate ipsilaterally within the nucleus of Darkschewitsch, bilaterally within the nucleus of the posterior commissure and the interstitial nucleus of Cajal, and contralaterally with the somatic cell column of the oculomotor and trochlear nuclei. There are also commissural projections to contralateral pretectal cell groups.

Injections of horseradish peroxidase (HRP) were placed within eleven pretectal targets. These data confirm and extend our autoradiographic findings. For example, they show that (1) most pretectal targets receive input from several pretectal nuclei, and (2) the size of pretectal neurons, rather than their location with the pretectum, indicates the target of their axons, i.e., the cells of origin of descending pretectofugal pathways are larger than the cells of origin of ascending pretectofugal pathways.

Our findings reveal several important points regarding overall pretectal connectivity. First, the pretectum does not project directly upon the cells of origin of the preganglionic parasympathetic outflow involved in the pupillary light reflex. The pretectum does, however, project upon the nucleus of the posterior commissure, which in turn sends a projection to the visceral cell column of the oculomotor complex. Second, the pretectum has direct connections with several precerebellar relay nuclei. Finally, the pretectum projects upon a region of the dorsal thalamus, called the lateral nucleus, which others have shown projects upon visually associated cortical regions.

2751 C57BL/6J-c^{2J} MOUSE OPTIC NERVE: ELECTRON MICROGRAPHIC AXON COUNT. I. S. Westenberg. Neurobio., Barrow Neur. Inst., Phoenix, AZ 85013.

Baseline data on optic nerve axonal composition are fundamental for studies on visual systems, e.g., the effects of neurological mutants. The inbred C57BL/6J mouse strain is valuable in this area, because of the availability of various neurological mutants with normal littermate controls that are otherwise genetically identical, e.g., albino and black C57BL/6j-c^{2J} mice. To resolve small axons in mouse optic nerve, electron microscopy is required.

In early estimates, C57BL/6J mouse optic nerve axon counts ranged to over 60,000; axon densities ranged to 1/μm^2. However, the axon count and density were estimated recently to be lower by as much as a factor of 4. The goal of the present study was to resolve the discrepancy between the earlier, higher estimates and the later, lower estimates.

The left optic nerve of a black, 111-day-old, male C57BL/6J-c^{2J} mouse was fixed (aldehyde), stained (osmium tetroxide), dehydrated (ethanol) and embedded (Epon 812). A thin whole-nerve cross section was stained (uranyl acetate, lead citrate) on a Formvar-coated slot grid. A photomontage of the section was made from serial electron micrographs. Axons were counted in 25 sample areas (each representing 10μm X 10μm, magnification = 3,750 X) evenly distributed across the entire section.

The section's shape was round-to-oval. Its longest diameter was 400μm; its shortest diameter was 325μm. The section's area was about 100,000μm^2. Thus, the total sample area of 2,500μm^2 (25 samples, 100μm^2 each) represented about 2.5% of the section. The total number of axons counted in this small sample was 2,650. This leads to an estimated axon count on the order of 100,000, with a density of about 1/μm^2.

The present data suggest that the earlier, higher estimates of axon count and density were more accurate than the recent, lower estimates. Further, the present data suggest that even the earlier estimates, though high, were conservative. This conclusion is supported by data from a recent complete axon count, albeit in a different mouse strain. On the other hand, the data from the complete axon count suggest that the present estimated axon count may be too high.

2752 DISSECTION OF A NEURONAL CIRCADIAN OSCILLATOR SYSTEM IN THE EYE OF APLYSIA WITH X-RAYS. John C. Woolum* and Felix Strumwasser. (SPON: B. Peretz). Division of Biology, California Institute of Technology, Pasadena, CA 91125.

The rhythm of compound action potentials (CAPs) from the isolated eye of Aplysia has been shown to exhibit all the properties of a classical circadian oscillator. The number, location and mechanism of the oscillator(s) are not as yet known. We have used X-rays to "dissect" the oscillator function of the eye from its other functions. Irradiation of the eye with 50 kvp X-rays at a dose of 40 krad will stop the expression of the circadian oscillation of CAPs. However, the size and shape of the CAPs, the CAP average rate and bursting rhythm, and the response to light are not changed at this dose rate. These results indicate that the circadian oscillator mechanism is unlikely to be associated with the actual generation of the CAPs, the bursting pattern, or the light response mechanisms. Irradiation at lower doses (e.g., 16 kr) allows a circadian rhythm of smaller amplitude to be expressed than in the unirradiated control eye. This result seems to imply that there are probably a number of oscillators in the eye. At large doses all oscillators are inactive but at lower doses some oscillators are active so a rhythm of smaller amplitude is observed. Results of irradiating parts of the eye by using lead shields reveal that irradiation of the anterior (corneal) part of the eye decreases the amplitude of the rhythm slightly while irradiation of the posterior (optic nerve) part decreases the rhythm greatly (perhaps totally) implying the largest concentration of oscillators is in the posterior part of the eye. Of the 82 eyes irradiated with doses between 2 and 500 kr, none showed any sign of an ultradian rhythm--as previously reported in eyes with the front part cut away (Jacklet and Geronimo, 1971). This X-ray "dissecting" technique appears to be superior to the technique of cutting away parts of the eye as far as separating the oscillator function of the eye from its other functions. These X-ray results are similar to the Actinomycin D effects in blocking the circadian rhythm (Rothman and Strumwasser, 1977) and imply that RNA transcription may be important in generating the CR. [This work was supported by NIH grant NS-07071 to F.S.]

2753 FUNCTIONAL ORGANIZATION AND LAYERING OF VISUAL INPUT TO THE OPTIC TECTUM OF AMBYSTOMA. Daniel F. Wunk* (SPON: L. Aulsebrook). Vanderbilt University, Nashville, TN 37232.

Visual input to the optic tectum of the larval Tiger salamander, Ambystoma tigrinum, is being studied using field potential analysis, extracellular unit recording, and intracellular recording from postsynaptic tectal neurons. In response to optic nerve shock, surface-negative field potential waves are recorded which reverse polarity deeper in the tectum. Laminar current source-density analysis of these waves indicates the existence of three major current sinks located approximately 150, 75, and 50 μm. below the tectal surface, and occurring 4-7, 7-10, and 30-50 msec., respectively, after optic nerve shock. These depths correspond to layers of coarse terminal degeneration following enucleation (Riss & Jakway, Brain Beh. Evol., 5; 401, 1972). Current sources are located adjacent to the sinks. Since very few cell bodies are located in this region of the tectum, these results suggest that the retinal fibers make mostly excitatory synapses onto the distal dendrites of deeper-lying tectal cells.

Visual stimulation using flashed spots of light also reveals a functional layering of retinal afferents in the superficial tectal neuropil. ON-OFF and OFF unit responses are localized to the same depths as the two deeper current sinks evoked by optic nerve shock. On-going experiments are attempting to associate visual afferent units with the most superficial and slowest current sink. These responses are also being correlated with postsynaptic potentials elicited by similar stimuli and recorded intracellularly in deep tectal cells that are being recovered after dye injection. The presence in most cells of inhibitory postsynaptic potentials of a transient ON-OFF nature and large visual receptive field indicate that the ON-OFF retinal afferents participate, either directly or indirectly, in a global tectal inhibitory system.

2754 THE GABA SYSTEM IN GOLDFISH RETINA: A COMPARATIVE ANALYSIS WITH ^{3}H-GABA AND ^{3}H-MUSCIMOL: Stephen Yazulla* and N. Brecha (SPON: P. Witkovsky). Depts. of Biology and Psychiatry, SUNY, Stony Brook, NY 11794.

Muscimol, a GABA analogue with a reported low affinity for GABA uptake sites, was used initially to study synaptic binding to GABA receptors in goldfish retina. In retinal homogenates ^{3}H-muscimol (M*) shows saturable binding with a Kd of 10^{-8}M, a receptor concentration of 160 fM/mg-protein and is blocked by GABA at an IC_{50} of $4x10^{-7}$M. Localization of M* labeling by autoradiography shows heavy label over 4 distinct lamina in the inner plexiform layer (IPL) and over a population of amacrine cell bodies and lightly over cone horizontal cell bodies (HC). GABA (1mM) abolished M* labeling over HCs and the proximal IPL but had little inhibitory effect on amacrine cells and the distal IPL. Since the M* labelling pattern appeared partially due to uptake and was differentially inhibited by GABA, we performed parallel incubations in M* and ^{3}H-GABA (G*) under a variety of conditions designed to block uptake mechanisms. The normal G* pattern differs from that of M* and includes intense label over cone HC bodies and axon terminals (HAT), some amacrine cells and in the proximal IPL rather than throughout. Incubation in the presence of 1mM muscimol does not inhibit G* uptake. The specific GABA-uptake blocker DABA (0.2mM) slightly suppresses M* label in the IPL and strongly inhibits G* label in the proximal IPL while sparing the remaining patterns. Incubation in Na^{+}-free Ringers or in the presence of 0.4mM oubain eliminates somatic label of M* leaving a reduced but obvious pattern in the IPL. Oubain similarly affects the G* pattern, while in Na^{+}-free Ringers, considerable G* uptake is seen in amacrine cells and the distal IPL (i.e., resembles the GABA block on M*). From these results we conclude that the binding of M* at GABA synaptic receptors can be measured biochemically in the retina. Localization of M* binding by ARG is severely limited by uptake contamination, although with proper controls M* binding is seen in the IPL but not in the OPL. There are at least 3 "species" of GABA uptake sites: 1. HC and proximal IPL, 2. amacrine cells and distal IPL, and 3. HAT. Finally there is some, as yet undetermined, relation between M* labeling and Na^{+}-independent GABA uptake. These results are not unique to goldfish but have been duplicated to a large extent in chick retina.

2755 PUPILLARY RESPONSES REVEALING RECEPTOR CHARACTERISTICS IN WILD-TYPE AND MUTANT DROSOPHILA. H. Zuidervaart*, D. G. Stavenga*, W. S. Stark 1 and G. D. Bernard*2. Dept. of Biophysics, Rijksuniversiteit, Groningen, the Netherlands (1 Johns Hopkins University; 2 Yale University).

The pupil mechanism in flies is a migration of intra-retinula-cell pigment granules elicited by a change in illumination. We studied the pupillary response by measuring the reflection in the deep pseudopupil which is maximal around 550 nm in Drosophila (see Franceschini, Thesis, Grenoble, 1972, CNRS (Paris) #A03802).

We determined intensity and spectral responses in wild-type flies. Univariance was shown since pupillary responses as a function of intensity were parallel across wavelengths. The dynamic range from threshold to saturation is 10^{10}-10^{13} quanta/cm^{2}s at 500 nm. The action spectrum for a criterion reflection increase is the same as the electrophysiological sensitivity of the predominant photoreceptor type, R1-6; the curve is like one obtained by measures of antidromic transmission in the deep pseudopupil of the white-apricot (w^a) mutant (Franceschini, ibid.)

Bright short wavelength irradiation induces a post-stimulus Prolonged Pupillary Response (PPR) which is very long-lived (several hours). This is like the Prolonged Depolarizing Afterpotential (PDA) induced after intense blue light substantially converts the 480 nm absorbing rhodopsin to its 580 nm absorbing stable metarhodopsin. The PPR is extreme at $\lambda<530$ nm and is absent at $\lambda\geq550$ nm. The PPR becomes noticeable after delivering $I\cdot t \cong 8x10^{13}$ quanta/cm^2 and saturates around $I\cdot t = 2x10^{15}$ quanta/cm^2 (λ=441 nm). Both PPR induction and suppression are determined by the total number of quanta delivered. Thus, the PPR is an integrating phenomenon as is the PDA. The PPR is eliminated by vitamin A deprivation as is the PDA.

The mutant transient receptor potential (trp, discovered by Cosens and Manning, Nature 224, 285, 1969) exhibits a transient pupillary response upon light adaptation. The full response is reached only after a long dark adaptation time (5-10 min.). This is slightly longer than the several minutes for receptor potential recovery in trp (Minke, Biophys. Struc. Mech. 3, 59, 1977). The PPR induced by blue light in trp is only a partially closed pupil in accordance with trp's receptor potential's PDA. Long wavelength light is necessary to renew the pupil's excitability (after a dark adaptation period). The sensitivity of the trp pupil has the same dynamic range as the wild-type pupil (after long wavelength illumination then dark adaptation).

Pupil and receptor potential mechanisms in Drosophila have very similar characteristics. Thus, with the pupil, one can actually witness manifestations of electrophysiological events using non-invasive optical techniques.
