Repeated administration of 5DMT or M (5 mg/kg,ip, every 3 hrs for a total of 4 injections) had no effect on resting serum PRL levels in male rats 3 hrs after the last pretreatment dose, but it greatly potentiated PRL stimulation by 5DMT, a potent 5HT agonist. Stimulation of presynaptic 5HT receptors by 5DMT inhibits the activity of 5HT neurons in the brain.We have recently hypothesized (Eur.J.Pharmacol.58:399,1979) that repeated 5DMT administration, according to the schedule outlined above, may, by virtue of its greater and longer-lasting presynaptic effects, produce prolonged disruption of 5HT transmission and lead to increased sensitivity of postsynaptic 5HT receptors. The effect of M on the activity of central 5HT neurons is not known. M-induced increase in midbrain 5HT levels may reflect its ability to decrease the activity of 5HT neurons. If the above hypothesis is correct, the fact that much lower dose of M is needed to alter PRL response to 5HT agonists than to stimulate PRL release suggests that M may have greater affinity for pre- than for postsynaptic 5HT receptors. These findings also suggest that endogenous M rhythm may participate in the regulation of postsynaptic 5HT receptors by altering the activity of central 5HT neurons.

86.9 THE EFFECTS OF INTRAVENTRICULAR AND INTRAVENOUS P-CHLOROAMPHETAMINE ON URINE VOLUMES AND ELECTROLYTE BALANCE. J. M. Stein, R. W. Lind, & A. K. Johnson. Department of Psychology and the Cardiovascular Center, University of Iowa, Iowa City, IA 52242

Systemic administration of any of several aralkylamines (phenylisopropylamines) initiates changes in fluid and electrolyte balance. Diuresis and natriuresis has been shown to occur in rats following amphetamine, methamphetamine, fenfluramine and phentermine and following amphetamine in humans. Whether these effects are exclusively the result of peripheral effects or due to CNS actions is unclear. P-chloroamphetamine (PCA) is an amphetamine derivative, the acute and chronic actions of which on brain monoamines, and food and water intake have been well documented. However, the effects of PCA on fluid and electrolyte balance has received little attention.

The following experiments were performed in order (a) to determine if PCA shares these same diuretic and natriuretic properties, and (b) to determine the relative importance of the CNS vs. the periphery in initiating these effects.

In Experiment 1, nonhydrated unanesthetized rats were systemically administered (i.p.) either PCA (5 mg/kg), fenfluramine (20 mg/kg), pargyline and tryptophan (75 and 180 mg/kg), pargyline (75 mg/kg), tryptophan (180 mg/kg) or saline. Urine volumes, urine Na and K concentrations, fecal weights, and body weights were recorded during the 4 hr post-injection period. A diuresis and a natriuresis was seen following both PCA and fenfluramine.

In Experiment 2, rats were implanted with intraventricular cannulae, jugular catheters, and urinary bladder catheters. A hydrating solution (10 mM NaCl; 4 mM $NaHCO_3$; 130 mM Glucose) was continuously infused into the jugular catheter during the experiment. Following a baseline equilibration period, the unanesthetized rats were administered PCA either intraventricularly (600 µg) or intravenous (i.v.; 5 mg/kg). Intraventricular administration produced an antidiuresis and concomitant natriuresis. In contrast, i.v. administration of PCA produced a diuresis and natriuresis similar to that seen following i.p. administration. The results of Experiment 1 and 2 will be discussed with respect to the biogenic amine and hormonal basis of these effects. (USPHS NIH HLP-14388 & 1 RO1-H124102; NIMH 1-KO2-MH00064)

86.10 BEHAVIORAL EFFECTS OF TRICYCLIC ANTIDEPRESSANTS IN THE RAT AND THEIR MODULATION BY GONADAL HORMONES. A. Biegon* and D. Samuel. (SPON: B.S. McEwen). Weizmann Institute of Science, Rehovot, Israel.

The direct effects of tricyclic antidepressants (TAD) on several behavioral and physiological parameters were studied in male and female rats, in an attempt to correlate these with brain uptake of TAD, which is higher in females than in males, and maximal on the day of estrus (Biegon, A. and Samuel, D., Psychopharmacol. 65:259, 1979). Desipramine and amitriptyline were injected i.p. (10 or 15mg/kg/day) for 14 days. 30min. after the first injection, the animals were observed for 5min. in an 80x80x40cm open field, or subjected to electric footshock of increasing intensity to determine their pain threshold. Total food and water intake was measured the following morning. Both drugs caused decreased locomotion and grooming in an open field: to 60% of control values in males, to 40% in proestrous and diestrous females and to 25% of control in estrous females. This correlates well with brain uptake of TAD. The pain thresholds (in mamp) of the control groups were 1.4 in males, 1.7 in diestrous and 2.0-2.2 in proestrous-estrous. TAD caused a 25-35% increase in pain threshold (comparable to the effect of 10mg/kg morphine in the same paradigm) in all groups. This may mean that the females' pain thresholds, already elevated by circulating hormones, could not be much further elevated by TAD. However, the duration of analgesia was longer in females. Food intake was decreased by TAD; in males by 50%, in diestrous females by 20-30% and in estrous females the decrease was less than 10% and not significant. Thus, the effects of TAD on food intake do not correlate with their brain uptake, but, rather with pretreatment levels of this behavior. On estrous, food intake is already reduced by 50% as compared to males, and it seems that the effects of TAD and circulating gonadal hormones are not additive. The course of the estrous cycle was not affected by a single injection of TAD. However, after 5-7 days of chronic treatment, prolonged diestrous appeared in 10/21 treated females and persistent estrous in 5/21. We conclude that the magnitude and duration of TAD effects are modulated by gonadal hormones, which influence the drugs' metabolism in the liver, but also affect the neurotransmitter systems in the brain at which TAD exert their central action (e.g. Crowley,W.E., O'Donohue,T.L. and Jacobovitz,D.M. Act. Endocrin.89:20,1978). Modulation of drug response by gonadal steroids seems to be a general phenomenon (e.g. Chiodo,L.A., Caggiula,A.R. and Saller,C.F. BRES 172:360,1979) and has to be considered when testing new drugs.

86.11 PHARMACOLOGICAL ISOLATION OF HYPOTHALAMIC DOPAMINE NEURONS. Susan R. George* and Glen R. Van Loon, Departments of Medicine and Physiology, University of Toronto, Toronto, Canada.

Study of hypothalamic(HYP) dopamine(DA) neurons involved in neuroendocrine regulation is complicated by the fact that they constitute only a small percentage of the HYP aminergic neurons. Also, it is not possible to clearly differentiate in hypothalamus precursor DA in NE neurons from neurotransmitter DA in DA neurons. Furthermore, uptake of DA occurs not only into DA neurons, but also into the more predominant population of NE neurons in hypothalamus. Study of median eminence alone compared to whole hypothalamus improves localization with regard to study of HYP DA neurons, but does not obviate the above problems and introduces the additional technical problem of requiring dissection of many animals for each study. To circumvent these difficulties, we have attempted to isolate HYP DA neurons pharmacologically in order to provide a means by which the effects of physiological alterations of neuroendocrine parameters on HYP DA neurons may be studied. We have characterized the uptake of ^{3}H-DA into a HYP synaptosomal preparation. Desmethylimipramine(DMI) $5x10^{-7}$M, was added to block DA uptake into NE nerve terminals. This concentration of DMI had no effect on ^{3}H-DA uptake into synaptosomes(SYN) from striatum which contains very few NE neurons and a large number of DA neurons. In contrast, DMI produced a profound inhibitory effect on ^{3}H-DA uptake into cerebellum which contains a significant number of NE neurons and almost no DA neurons. SYN from hypothalamus were intermediate in showing inhibition of ^{3}H-DA uptake by DMI. The DMI-insensitive ^{3}H-DA uptake into HYP SYN showed a further dose-related reduction with addition of benztropine, a drug known to block catecholamine uptake into DA neurons. Thus, DMI-insensitive ^{3}H-DA uptake into HYP SYN probably represents DA uptake into HYP DA neurons. Although HYP DA neurons include a variety of DA neuronal systems (A12,A13,A14),a large percentage of these neurons appears to be comprised of the tuberoinfundibular (A12) DA neurons. DMI-insensitive ^{3}H-DA uptake into HYP SYN may then provide an index of DA uptake into tuberoinfundibular DA neurons. Lineweaver-Burke analysis yielded an affinity constant (Km) of $0.79\pm.07x10^{-6}$M for DMI-insensitive ^{3}H-DA uptake into HYP SYN compared with $0.26\pm.02x10^{-6}$M for striatal SYN. These data showing a 3-fold lower affinity constant for ^{3}H-DA uptake into HYP DA neurons are similar to findings of Demarest and Moore (Brain Res.171:545,1979). However, they do not support the conclusion that these neurons lack a high affinity amine transport mechanism but rather suggest that the efficiency of their DA transport mechanism is lower than that of other brain DA neuronal systems. CONCLUSION: DMI-insensitive HYP DA uptake appears to provide an index of DA uptake into tuberoinfundibular DA neurons.

87.1 THE EFFECT OF CHRONIC UNDERNUTRITION FOR 10 GENERATIONS ON BRAIN DEVELOPMENT IN YOUNG AND AGING RATS. Stephen Zamenhof and Edith van Marthens*. Mental Retardation Research Cntr., and Brain Research Inst., UCLA School of Medicine, Los Angeles, CA., 90024.

In the previous communication (Zamenhof and van Marthens, J. Nutr., 108, 1719, 1978) we have reported the effects of chronic undernutrition over five generations on newborn rats. In the present work we have studied the effect of chronic undernutrition over ten generations on rat brain development in neonatal, adolescent (30 days) and aging (150 days) rats. The animals and their nutrition regimes were described previously: undernutrition (2/3 of normal (control) ad libitum diet) started at the time of mating of Fo (maternal) generation, and continued throughout pregnancy and post-weaning.

In the newborns, chronic undernutrition resulted in highly significant reduction of brain parameters in almost all generations. The reduction in the weight of cerebral hemispheres was up to 21% (F_4 generation) and decreased to 13% in F10. In contrast, the reduction in cerebral DNA (cell number) was severe (16 to 19%) only in the first two generations and disappeared in F8 and F10. The reduction in cerebral protein was severe in almost all generations, and most severe in F10 (26%).

In adolescent animals (30 days old males) individual brain parts could be analyzed separately. The reductions in cortical weight were moderate (up to 10%) as compared with the reduction in cortical DNA (up to 29%) and cortical protein (up to 32%); all reductions persisted through F10. Cerebellar and brain stem reductions were, in general, less pronounced, but the reductions in diencephalon were up to 18% in weight, up to 27% (F_4) in DNA and up to 39% (F_{10}) in protein.

In aging animals (150 day old females) increases rather than decreases were found in cortical weight and DNA (in most generations); they may represent multiplication of glial cells in an attempt to compensate for permanent neuron deficit caused by prenatal undernutrition. On the other hand, diencephalon still shows full reductions in weight (up to 33%), DNA (up to 33%) and protein (up to 30%)

If one adds, for comparison, the deficits in individual brain parts, one finds that the deficits in brain weight and protein essentially do not change between 30 and 150 days, but DNA deficit decreases by 68%. There was no consistent pattern of changes of deficits through generations; in general the deficits were lower in the last five generations than in the first five for brain weight and DNA ("adaptations"), but the reverse was true for protein. There was no cumulative effect of this undernutrition on offspring parameters over generations.

87.2 Behavioral and neurochemical effects of prenatal imipramine exposure. K.M. Jason and E. Friedman*, Dept. of Psychiatry, New York Univ. Med. Ctr., New York, N.Y. 10016.

Tricyclic antidepressants (TCA's) are lipid-soluble substances which readily cross the placenta. In adult rats, chronic exposure to TCA's alters neurotransmission, and when exposure takes place throughout pregnancy, the number of live offspring is decreased. These experiments investigated effects of TCA exposure during late gestation on behavioral and neurochemical development in neonatal rats.

Control and experimental animals (8/gp) received 1 ml/100g oral doses of water or 15mg/kg imipramine-HCl (IMI) daily on days 8 through 20 of gestation. On the day following birth, pups were randomly distributed within treatment group, 9 per dam. Control females had a 52% weight gain from day 8 to day 20 of gestation compared to a 40% weight gain for IMI-treated dams ($p<.01$). Neither the number of pups born per litter nor the number of stillborn pups was affected by the IMI treatment. IMI-treated pups weighed significantly less than controls day 1 and 7 postpartum, but not on days 14, 21 or 30. Brain weights of treated offspring were also significantly lower than controls on days 7 and 14, but were equivalent at day 30.

The development of 3 reflexes was assessed in pups 3-10 days old. The appearance of surface righting was significantly delayed in IMI-treated offspring. This reflex was observed daily in 2 trials per day in which each rat was placed on its back on a smooth surface and timed until it righted itself and all 4 feet were in contact with the surface in $\leq$ 2" on both trials on a given day. Negative geotaxis, completing a 180° turn on a 25° inclined plane in $\leq$ 60", was also altered. Treated offspring took significantly longer to complete the task even after all animals reached criterion. There were no group differences in the cliff avoidance reflex, which consisted of sideward or backward movement away from a table edge in $\leq$ 30".

Offspring were examined for eye-opening as a developmental landmark. The percentage of pups with eyes open was significantly higher in the IMI-treated group at 13 and 14 days; by day 15, eye-opening was nearly complete in both groups.

Steady-state levels of dopamine (DA), noradrenaline (NA) and adrenaline (A) were measured in hypothalamus of offspring 7, 14 and 30 days old. As is the case for NA and DA in adults after chronic TCA exposure, the prenatal exposure to IMI did not alter levels of either DA or NA, nor were A levels affected at these ages. Experiments are now in progress to determine the effects of prenatal IMI exposure on specific binding to α and β-adrenergic receptors.

87.3 DEVELOPMENT OF CATECHOLAMINERGIC SYSTEMS IN THE HUMAN FETUS. J. Pearson, L. Brandeis*, M. Goldstein and K. Markey*. New York University Medical Center, New York, NY 10016.

A highly specific antibody for human tyrosine hydroxylase(TH) is used immunocytochemically to detect the enzyme. In the developing human sympathetic chain TH is present at 5½-6 weeks of gestational age. By 9-10 weeks sympathetic ganglia are well developed and contain increased amounts of the enzyme. At this age sympathetic plexi and axon terminals can be demonstrated. The cells migrating from paraganglia into the adrenal medulla are also positive (only on reaching the adrenal do these cells acquire immunoreactivity for phenylethanolamine N-methyl transferase). The carotid body glomus cells also become positive for TH at this stage. Within the central nervous system medullary, locus coeruleus and substantia nigra neurons as well as the rich axon terminal complex in the striatum contain the enzyme. Thus the major catecholaminergic systems are developed before the end of the first trimester.

By 12-13 weeks the sympathetic axons acquire more reactivity than the perikarya; these are the staining characteristics of adult catecholaminergic neurons. The ductus venosus attains rich sympathetic innervation. Older fetuses are being studied with reference to innervation of the ductus arteriosus.

The peroxidase anti-peroxidase technique of Sternberger works well in stored, paraffin embedded, formalin fixed tissue. It is thus applicable to archival specimens. It will provide valuable information regarding biochemical ontogenesis.

87.4 DEVELOPMENT OF A DESCENDING ADRENERGIC PATHWAY IN THE CHICK SPINAL CORD. M. T. Caserta and L. L. Ross. Dept. Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Previous work from this laboratory has described the developmental sequence of the descending serotonergic and noradrenergic pathways in the chick spinal cord that originate in the medulla and terminate in the region of the preganglionic sympathetic nucleus (nucleus of Terni) and on ventral motor neurons. The serotonergic terminals first appear between 8-10 days in ovo and the noradrenergic terminals at 12-14 days in ovo.

As part of a continuing investigation of the role of the descending aminergic pathways in the development of the chick spinal cord, the possible existence of an adrenergic pathway was investigated since several studies have shown the presence of epinephrine and PNMT (phenylethanolamine-N-methyl transferase) containing neurons in the mammalian and avian central nervous systems. The methods used were: 1) in vitro uptake of ^{3}H-epinephrine in the presence or absence of various drugs; 2) a modification of the PNMT assay as described by Saavedra et al. 1974; 3) spinal cord transection at 12 days in ovo at T_1-T_2 levels followed by the above procedures after 4-6 day survival.

There is a specific, saturable uptake mechanism for epinephrine in the adult spinal cord with a Km of 6×10^{-7}M and a Vmax of .02nM/gm/min. This uptake mechanism can be abolished by ouabain (10^{-4}M) and reduced to 50% of control by desmethylimipramine (10^{-7}M). Norepinephrine at 10^{-5}M reduces uptake by 50% but at 10^{-7}M (10x the concentration of ^{3}H-epinephrine) has no effect. Serotonin (10^{-7} to 10^{-5}M) also has no effect. This uptake mechanism can first be detected at 14 days in ovo. There is a 2-3 fold increase at 18-20 days followed by a decline until 4 days posthatching at which time there is another peak which lasts until 7 days and then gradually declines to adult levels. When the spinal cord is transected at 12 days in ovo, there is a reduction of uptake to between 14-32% of control by 16-18 days in ovo below the lesion.

PNMT activity can first be measured at 14 days in ovo (1.7 pm/hr/mg protein) and gradually increases until approximately 3-4 days posthatching when maximal values are attained (26 pm/hr/mg protein) followed by a gradual decline to adult levels.

Thus, there appears to be a separate adrenergic uptake mechanism which is markedly reduced by transection and which has a difference developmental pattern from the noradrenergic and serotonergic mechanisms. The presence of PNMT in the spinal cord at the time that an adrenergic uptake mechanism is also present supports the hypothesis there is a distinct descending adrenergic pathway in the chick spinal cord.

87.5 EFFECT OF FETAL LESION WITH METHYLAZOXYMETHANOL ACETATE ON THE DEVELOPMENTAL NEUROCHEMISTRY OF THE RAT STRIATUM AND FRONTAL CORTEX. M. Beaulieu* and J.T. Coyle. Dept. of Pharmacol. and Expt. Therapeut., Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

Methylazoxymethanol acetate (MAM), a potent alkylating agent, when administered to the rat fetuses at the beginning of the last third of gestation, causes a selective reduction of neurons intrinsic to forebrain . We have examined the effects of this lesion on the development of neuronal markers for GABAergic, cholinergic and dopaminergic neurons in striatum and frontal cortex following a single intraperitoneal injection of 20 mg/kg MAM to pregnant dams at 15 days of gestation. At birth and throughout maturation, the body weights of treated offspring did not differ from controls.

Striatum was dissected according to white matter landmarks. The weight of the MAM lesioned striatum was reduced by 18% in the neonate but by 37% ($p<0.001$) in the adult. Nissl-stained sections of the adult MAM striatum revealed a reduction in mass with no apparent disruption of neuronal organization. The markers for dopaminergic terminals - dopamine and tyrosine hydroxylase (TH) - were increased in concentration by 31 and 38% ($p<0.01$) respectively in the adult striatum; this increment was constant throughout postnatal development. In contrast, the presynaptic markers for GABAergic neurons - glutamate decarboxylase (GAD) and GABA - were unchanged in concentration from birth to adulthood. Whereas the specific activity (sp. ac.) of choline acetyltransferase (CAT) was consistently increased by 40%, the concentration of acetylcholine was not elevated.

The lesion resulted in a 53% ($p<0.001$) reduction in frontal cortical weight in the adult but only 37% ($p<0.01$) decrease in the neonate. Nissl-stained sections revealed loss of neurons in the intermediate layers of the frontal cortex. In the adult, the sp. ac. of TH was increased by 52% ($p<0.01$) in the neonate and by 82% ($p<0.001$) in the adult. Although CAT sp. ac. was increased by 44% ($p<0.001$) in the adult, it was slightly depressed(-13%) in the neonate; the increase in the sp. ac. of CAT became apparent by10 days after birth in the lesioned cortex. The sp. ac. of GAD was not altered by the lesion in the neonate or the adult.

These studies indicate that the development of dopaminergic projections to striatum and frontal cortex are insensitive to a fetally induced loss of neurons within these regions; regional hypoplasia results in a relative hyperinnervation by dopaminergic terminals, a phenomenon present at birth. In contrast, the intrinsic GABAergic neurons are reduced commensurate with the loss of cortical or striatal volume. Cholinergic neurons intrinsic to the striatum differ from basalis projection to frontal cortex in their response to the lesion.

87.6 SURFACE GLYCOCONJUGATES CHANGE IN DIFFERENTIATING NEUROECTODERM. J.R. Currie, M.-F. Maylié-Pfenninger* and K.H. Pfenninger. Department of Anatomy, Columbia University, College of Physicians and Surgeons, New York, New York 10032.

Different cell surface saccharide compositions have been described for neural crest and neural tube derivatives at the stage of neurite formation. We have examined the neuroectoderm of rat embryos at 9 1/2 days of gestation to determine whether these differences are present at earlier stages. Our probes are several well-characterized lectin-ferritin and lectin-HRP conjugates (Con A, WGA, RCA I and II, SBA, LTA and PA). The neuroectoderm is pretreated with collagenase and hyaluronidase or high ionic strength solutions to remove glycoconjugates not integral to the plasmalemma, incubated at 0°C with saturating concentrations of the lectins, rinsed, and processed for EM. Control tissues (incubated with the lectins and 0.2M hapten sugar) are free of the label. In some experiments, the neural tube region which has already fused is cut open before the application of the markers. The apical plasmalemma of both neural crest and neural tube cells is very rich in binding sites for 4 of the lectins: Con A, WGA, RCA I and II (monosaccharide spec.: glc/man, glcNAc, gal, galNAc, respectively). The neural crest cells bind the lectins more heavily than the neural tube cells (approx. 12,000 WGA binding sites/μm^2 of plasmalemma for crest cells versus 7000 for tube cells). These values can be compared to more mature derivatives of the crest and tube: an average of 2500 for sprouting dorsal root and superior cervical ganglion cells and 900 for sprouting spinal cord neurons, respectively. No binding sites are present on crest or tube cells for SBA, LTA or PA (monosaccharide spec.: galNAc, fuc, gal, respectively). Pre-exposure of the ectoderm to high ionic strength solutions does not change the pattern or density of the markers, indicating the integral nature of the plasmalemmal lectin receptors. A marked decrease in the number of binding sites for WGA, RCA I and II is observed to occur as fusion takes place. Few or no binding sites are observed even after artificially reopening the fused tube. Con A, however, continues to bind to the apical plasmalemma of the fused tube. Therefore, the apical surfaces of neuroectodermal cells at the onset of neurulation contain glycoconjugates rich in receptors for a variety of lectins, but not for LTA, SBA or PA. Crest and tube derivatives can already be distinguished at this stage by their surface sugar composition. As neurulation takes place, changes in membrane saccharides occur. Thus, the dissociation of the peripheral from the central nervous system may involve the development of a dichotomy in the surface properties of crest and tube cells, and subsequent developmental stages of the derivatives of the crest and tube are reflected in changes in the composition of their cell-surface saccharides. (Supported by NSF BNS78-15910.)

87.7 SYNCHRONOUS MATURATION OF SOMATOSENSORY ISOCORTEX AND SOMMER'S SECTOR OF AMMON'S HORN: QUANTITATIVE HISTOCHEMICAL STUDY OF CELL REPLICATION, DIFFERENTIATION, AND MYELINATION IN THE RAT. S.T. DeKosky and N.H. Bass, Department of Neurology, University of Kentucky, College of Medicine and Lexington VA Medical Center, Lexington, Kentucky 40536.

Frontal association isocortex and Sommer's sector of Ammon's horn have been associated with a wide variety of disorders of intellectual function in man, some of which have been attributed to selective vulnerability during critical periods of perinatal life. In an effort to explore the developmental synchrony of these regions in the albino rat brain, we have compared postnatal neural cell migration and differentiation in the six-layered somatosensory area of cerebral cortex with the three-layered CA1 region of hippocampus. Expression of biochemical components per unit volume of fresh-frozen tissue reveals that in both instances DNA initially declines (83% during the first 10 days of cortical maturation; 50% between 5 and 20 days of hippocampal maturation) due to decrement of cell packing density and cell death. Protein synthesizing capacity per cell, reflected as RNA/cell, increases 3-fold at 10 days of cortical maturation and 2-fold at 20 days of hippocampal development. This is a reflection of marked metabolic activity of neuronal perikarya associated with massive axodendritic arborization. Ganglioside sialic acid, a index of axodendritic proliferation peaks at 20 postnatal days in cortex (4-fold increase) and hippocampus (2-fold increase) paralleling maturation of Golgi-staining neurons,cortical electrical activity and behavior. Although the cerebral cortex reaches adult laminar size by 10 postnatal days, in the CA1 region maximum depth of apical and basal dendritic lamina of the pyamidal cells is attained by 20 postnatal days. Beginning on day 10 in cortex and day 20 in hippocampus, there is a continuous acquisition of small cells, probably representing replication and differentiation of oligodendrocytes. Accordingly, galactocerebroside, an index of myelination, increases 6-fold between 20 and 50 postnatal days in both brain regions. These studies show a marked synchrony in regional maturation of cerebral cortex and hippocampus with respect to neuronal differentiation and myelinogenesis associated with glial cell replication and differentiation. Intellectual deficits induced by perinatal environmental insults previously ascribed solely to cortical vulnerability, may in fact be due to abnormalities of both cortex and hippocampus and their integrated activity. (Supported in part by NIH Grant NS16009.)

87.8 Developmental changes in cerebral energy metabolism in the chick embryo. T. Gonya-Magee and R. C. Vannucci.* Dept. of Pediatrics; M. S. Hershey Medical Center, Pennsylvania State Univ.; Hershey, PA 17033

In mammals, cerebral metabolic rates are low at birth and increase with postnatal age. The low energy demands of the immature brain are thought to favorably influence its resistance to hypoxia. Rates of cerebral metabolism have not been thoroughly studied in the fetus or embryo, even though it is often quoted that the developing brain possesses a high glycolytic capacity to sustain energy requirement. We have investigated oxidative metabolism in brains of chick embryos at 9, 14, 16 and 19 days of incubation and in 1 day post-hatch peeps. Chicks were decapitated at 37°C and frozen in freon (-197°C) at 0, ½, 1, 2 and 5 minutes post-sacrifice. Brains were dissected, powdered and extracted into 3M perchloric acid, and were assayed for ATP, P-Creatine, lactate and glucose by fluorometry. Changes in these metabolites post-decapitation were used to calculate cerebral metabolic rates [$\Delta\sim P = 2\Delta ATP + \Delta PCr + 2\Delta glucose + 1.45\ (\Delta lactate - 2\Delta glucose)$] as well as rates of maximal glycolytic flux (Δlactate):

Embryonic Age (days)	Δlactate (mmole/kg/min)	$\Delta\sim P$ (mmole/kg/min)	$\frac{\Delta lactate}{\Delta\sim P}$
9	1.00	2.90	0.34
14	1.55	3.10	0.50
16	2.15	2.90	0.74
19	2.70	5.50	0.55
22 (1 day post-hatch)	4.75	8.65	0.55

The steady increases in Δlactate were different ($p < 0.05$) from each preceding age group. In contrast, $\Delta\sim P$ did not change from embryonic day 9 through 16 but thereafter increased 3-fold through the first post-hatch day ($p < 0.01$). The percent of total energy utilization ($\Delta\sim P$) that could be derived from glycolysis (Δlactate) increased from day 9 through 16 and subsequently declined. The relative peak in the potential glycolytic contribution to energy utilization at day 16 correlates temporally with the maximum resistance of the embryonic CNS to hypoxic-induced inhibition of neural activity (Gonya-Magee and Stokes, 1980). The findings also suggest that anaerobic glycolysis is never capable of totally supporting the metabolic requirements of the embryonic brain, and that a capacity for oxidative phosphorylation is required by primordial tissue.

87.9 GABA AND GLUTAMATE FLUXES IN DEVELOPING NERVE ENDING PARTICLES. R. Hitzemann, C. Mark* and A. Panini*. Lab. of Psychobiology, Dept. of Psychiatry, Univ. of Cincinnati Coll. of Med., Cincinnati, OH 45267.

It is still unresolved as to whether or not the development of the high affinity GABA transport (uptake) system can be used as a marker of neuronal and synaptic maturation. Some workers have suggested that a significant portion of the transport occurs into gliosomes which contaminate immature nerve ending preparations (Levi et al, J. Neurochem. 33, 1043, 1979). Redburn et al (Brain Res. 152, 511, 1978) have found that GABA taken up into immature nerve endings is not taken up into a functionally releasable pool. We have suggested (Hitzemann and Loh, Brain Res. 159, 29, 1978) that it is difficult to assess the competency of developing transport systems unless special precautions are taken in the preparation of the developing nerve ending particles. In the present study we have examined various aspects of GABA and glutamate transport and release in both the granular (type I) and mature (type II) appearing nerve endings found in the developing rat cortex. For type II nerve endings the IC_{50} values to inhibit GABA transport were 1.15, 3.6 and $2.3X10^{-3}M$ for B-alanine (a glial GABA transport inhibitor) and 7.1, 9.2 and $6.6X10^{-5}M$ for diaminobutyric acid (a neuronal GABA transport inhibitor) in 7 and 14 day and adult animals, respectively. Type I nerve endings had similar IC_{50} values. Compared to the adult preparation, 7 day type II nerve endings showed a greater Na^+ dependent change in the Km values for both GABA and glutamate transport. In contrast, the Vmax values for transport were less Na^+ dependent in the 7 day animals. The Km but not Vmax values for GABA and glutamate transport showed greater temperature dependent changes in 7 day animals. These effects on Km were most obvious at low (19mM) Na^+ concentrations. Many of the differences in transport between 7 day and adult nerve endings are probably related to the differences in membrane fluidity (see Hitzemann and Johnson, Fed. Proc. Abst. #2390, 1980) since it was possible to duplicate the transport properties of 7 day type II nerve endings by fluidizing adult nerve endings with cis-vaccenic acid. Type II but not type I nerve endings show a Ca^{++} dependent K^+-induced release of pre-accumulated labeled GABA. Overall it is concluded that (a) GABA transport in our preparation of type I and II nerve endings is not occurring into gliosomes, (b) many of the developmental differences on transport are related to the differences in synaptic membrane viscosity, and (c) some but not all developing nerve endings can sustain a Ca^{++} dependent release of pre-accumulated GABA. This study was supported in part by grant NS-16061.

87.10 ONTOGENETIC DEVELOPMENT OF GLUTAMATE RECEPTORS IN RAT HIPPOCAMPUS. M. Baudry*, D.S. Arst*, M. Oliver*, and G. Lynch. Dept. of Psychobiology, Univ. of California, Irvine, CA 92717

Various groups have reported the existence in the adult rat brain of a class of Na-independent glutamate binding sites which exhibit characteristics of postsynaptic glutamate receptors. We previously showed that these sites are markedly labile and that Ca^{++} ions are able to increase the number of glutamate receptors possibly by stimulating a Ca^{++}-sensitive protease (Baudry and Lynch, Proc. Nat. Acad. Sci., 1980, in press). We now report the developmental pattern of both ^3H-glutamate binding and the Ca^{++}-induced stimulation of the binding in rat hippocampal membranes.

The amount of Na-independent glutamate binding sites (pmol/hippocampus) represents 4% of the adult level at postnatal day (PND) 4, increases very rapidly until PND 9 and then increases at a slower rate reaching 80% of the adult value at PND 23. In contrast, the density of binding sites (pmol/mg protein) exhibits a maximum at PND 9 and slowly decreases to reach the adult value at PND 23. The changes are only quantitative since the affinity and Hill coefficient of these binding sites remain constant throughout development. Ca^{++} is unable to stimulate glutamate binding until PND 8. The stimulatory effect appears and develops rapidly between PND 9 and PND 16 when it is similar to that seen in the adult rat. These changes in the Ca^{++} effect are also only quantitative since no changes in the EC_{50} for Ca^{++} (about 30 μM) nor in the Hill coefficient (n_H=2) occurred between PND 9 and adult. In addition, we determined the minimum age at which long-term potentiation (LTP) of synaptic transmission could be detected in the hippocampal slice preparation following repetitive electrical stimulation of the Schaeffer collateral-commissural system. LTP was only rarely detected at PND 8 whereas it could be reliably obtained after PND 10.

These results indicate that the development of Na-independent glutamate binding sites closely parallels synapse formation in the hippocampus, further supporting the idea that these binding sites are associated with a physiological receptor. In addition they show that the appearance of the Ca^{++} stimulation of the binding occurs at a time when several functional events take place in the hippocampus. The correlation of the development of LTP with the Ca^{++} stimulation of glutamate binding thus strengthens the previously proposed link between these two phenomena (Baudry and Lynch, Exp. Neurol., 1980, 68, 202-205).

88.1 IN VIVO SINGLE CELL RECORDING FROM HYPOTHALAMIC NEURONS EXHIBITING MONOAMINERGIC PROPERTIES. S. A. Rasmussen* and B. S. Bunney (SPON: J. Ebersole). Departments of Psychiatry and Pharmacology, Yale University Sch. Med., New Haven, CT 06510

Anatomical studies have demonstrated that monoaminergic neurons are present in a number of hypothalamic nuclei. In an effort to identify and electrophysiologically characterize these neurons, we have begun in vivo studies of these nuclei in the rat, using extracellular single unit recording and microiontophoretic techniques. A homogeneous group of neurons has been identified in the periventricular zone of the posterior hypothalamus. These cells are remarkably similar to norepinephrine containing neurons of the locus coeruleus. They exhibit firing rates of 0.5 to 5 spikes per second and their duration is 3.5-4.5 msec. The shape of their action potentials is biphasic with an initial positive component. The α-agonist, clonidine, induces a 50% decrease in firing rate at a dose of approximately 4 ug/kg (i.v.). This inhibition is rapidly and completely reversed by the α-antagonist, piperoxane (0.5 mg/kg i.v.). The burst-pause firing pattern following foot pinch, characteristic of noradrenergic neurons in the locus coeruleus (Korf, J. et al., Eur. J. Pharm. 25: 165, 1974) is also present in these cells, and has aided in their identification. Histologically, these cells appear to coincide with the group of norepinephrine containing neurons in the hypothalamus described by Björklund et al. (Brain Res. 51: 171, 1973).

A group of neurons has also been found that exhibit a wide, biphasic action potential, a firing rate of 0.5 to 5 spikes/second, and a 50% decrease in firing rate after i.v. administration of apomorphine (8 ug/kg). The inhibition induced by apomorphine is completely reversed by haloperidol (50 ug/kg, i.v.). These cells appear similar to the dopamine containing neurons of A9 and A10 and have all been located in the periventricular zone of the mesencephalo-diencephalic junction. Although cells with firing rates and action potentials characteristic of dopaminergic neurons have also been found in the region of the arcuate nucleus, these cells have shown no response to haloperidol or apomorphine. Further characterization, including the effects of several hypothalmic and pituitary peptides on these various cell types, will be presented. (Supported by NIMH grants MH-28849, MH-25642 and the State of Connecticut.)

88.2 INTRACELLULAR RECORDINGS FROM NIGRAL DOPAMINE NEURONS IDENTIFIED BY L-DOPA INJECTION COMBINED WITH FLUORESCENCE HISTOCHEMISTRY. A. A. Grace and B. S. Bunney. Departments of Psychiatry and Pharmacology, Yale University Sch. Med., New Haven, CT 06510

Intracellular recordings were obtained from positively identified dopamine (DA)-containing neurons in the rat substantia nigra zona compacta. DA cells were identified by intracellular injection of the DA precursor L-dihydroxyphenylacetic acid (L-DOPA) and subsequent processing of the brain for fluorescence histochemistry. DA cells injected with L-DOPA could be identified by their markedly increased fluorescence in contrast to surrounding, non-injected DA cells. Zona reticulata (non-DA) cells injected with L-DOPA did not fluoresce. As only DA cells in the area possess the enzyme necessary to convert L-DOPA to DA (aromatic amino acid decarboxylase), this was a specific direct histochemical verification of recordings from DA-containing cells in this region.

Intracellular recordings from DA neurons were judged sufficiently stable for electrophysiological measurements if the resting potential was greater than -55 mV, spike amplitude was above 50 mV and the cells fired at a rate below 8 hz. Generally, stable resting potentials centered around 60-65 mV, with further hyperpolarization occuring with recording times greater than 20 min. DA cells recorded intracellularly were antidromically activated from the ipsilateral caudate nucleus. The antidromic activation met the criteria of: (1) constant latency, (2) follow of 100 hz stimulation without spike failure, (3) one spike per stimulus, and (4) collision with directly elicited spike. Antidromic spikes exhibited a latency of 11.9 $\pm$ 1.1 msec (mean $\pm$ S.E.M.), corresponding to a conduction velocity of approximately 0.54 meters/second, which is similar to that reported previously for indirectly identified dopaminergic neurons (Guyenet, P. G. and Aghajanian, G. K., Brain Res. 150: 69, 1978). Commonly, an attenuated antidromic spike (15-30 mV) was seen to ride on an i.p.s.p.--presumably resulting from orthodromic activation of a striatonigral GABAergic inhibitory pathway. In addition, fast prepotentials, spontaneous depolarizations leading to burst firing, and 5-10 mV fast potentials were also observed. Action potentials were often seen to arise from these fast potentials.

These intracellularly recorded cells, positively identified as DA neurons, were found to possess all of the extracellular electrophysiological characteristics and pharmacological responses previously attributed to indirectly identified DA neurons (Bunney, B. S. et al., J. Pharmacol. Exptl. Therapeut. 185: 560, 1973; Guyenet, P. G. and Aghajanian, G. K., Brain Res. 150: 69, 1978). (Supported by NIMH grants MH-28849, MH-25642, MH-14276 and the State of Connecticut.)

88.3 DOPAMINERGIC NEURONS IN THE RAT VENTRAL TEGMENTAL AREA: ELECTROPHYSIOLOGICAL EVIDENCE FOR AUTOREGULATION. Rex Y. Wang, Dept. Pharmacol., St. Louis Univ., Sch. Med., St. Louis, MO 63104.

Recently Beart et al (Neurosci lett. 15:165, 1979) reported that the rat ventral tegmental area (VTA or A-10 area) contained high levels of dopamine (DA) and tyrosine hydroxylase, possessed the ability to synthetize and metabolize the transmitter and could accumulate and release ^{3}H-DA. Somadendritic DA stores of A-10 DA neurons therefore have the capacity to play a functional role in regulation of neuronal activity. German et al (Brain Res. 181:191, 1980), on the other hand, made the observation that there is a post-stimulus period of inhibition in the activity of presumed A-10 DA neurons following antidromic activation. The aim of this study was to investigate the possibility that the inhibition of A-10 DA neurons induced by antidromic activation may be mediated by DA somadendritic varicosities (or axon collaterals).

Chloral hydrate anesthetized rats were used. In addition to routine histology, histofluorescence was performed in some cases to verify locations of cells recorded at the end of experiments. Presumed A-10 DA neurons had a slow-bursting or regular firing rate (0.5-8 spikes/sec). Their action potentials were unusually wide (>2.5 msec). The majority of VTA neurons with these characteristic firing patterns and spike shapes could be antidromically activated by electrical stimulation of the nucleus accumbens (NAc). The mean latency of activation was 16.4 msec. The estimated conduction velocity was 0.47 m/sec. The firing rate of these presumed DA cells was markedly reduced following i.v. injection of apomorphine (ID 50 = 7.8 µg/kg) or by iontophoretic application of DA or γ-aminobutyric acid (GABA).

Following electrical stimulation of the NAc, DA neurons usually showed a period of suppression of firing. Some cells responded with excitation preceding the suppression. The NAc-induced suppression was either blocked or markedly reduced by iontophoresis of trifluoperazine or i.v. injection of haloperidol. The effect of these DA antagonists on DA cells is rather selective in that they antagonize the inhibition produced by iontophoresis of DA but not GABA. Little or no increment of firing rate was observed following the administration of either trifluoperazine or haloperidol. Picrotoxin (a GABA antagonist) applied either systemically or directly by microiontophoresis also produced a reversal of the post-stimulus suppression; however, there was also a marked increase in DA neuron's baseline firing rate.

These results are consistent with evidence for the existence of DA autoreceptors on A-10 DA neurons. They further suggest that release of DA from the somadendritic varicosities or axon collaterals may act upon these DA autoreceptors and serve a regulatory function. (Supported by a PMA Starter Grant and the St. Louis University Biomedical Research Support Grant.)

88.4 AMPHETAMINE ISOMERS HAVE DIFFERENT POTENCY RATIOS FOR REDUCING DORSAL VS. VENTRAL SUBSTANTIA NIGRA DA IMPULSE FLOW. S. Browder and D.C. German. Depts. of Psychiatry and Physiology, U. of Texas, Health Sci. Ctr., Dallas, Tx, 75235.

The nigro-striatal dopamine (DA) neuron has been used extensively to study the mechanisms of amphetamine (AMP) action. The d-isomer of AMP is more potent than the l-isomer in releasing and blocking DA uptake in striatal synaptosomes. The d-isomer binds to striatal synaptosomes at the DA-uptake carrier, much more than does the l-isomer. Electrophysiologically, d-AMP is more potent than l-AMP in reducing nigro-striatal-DA impulse flow. Because anatomical evidence indicates that dorsal cells in the substantia nigra zona compacta (SNC) project to nonstriatal forebrain regions and the ventral SNC cells project to the striatum, we sought to determine whether both groups of DA cells responded the same to the AMP isomers. Single unit activity was recorded from SNC-DA neurons in the chloral hydrate anesthetized rat. All drugs were administered via a jugular catheter. d-AMP produced 50% inhibition of ventral SNC-DA impulse flow at 1.0-1.5 mg/kg, while, l-AMP had little effect on impulse flow, doses as high as 21 mg/kg of l-AMP producing <50% inhibition of cell firing. However, both d- and l-AMP reduced dorsal SNC-DA impulse flow by 50% at doses of 1.0-1.5 mg/kg. These results suggest that DA neurons which project to different anatomical regions respond differently to l-AMP, but about the same to the d-isomer. The present data, along with our previous finding that d- and l-AMP are about equipotent in reducing ventral tegmental area DA impulse flow (Browder, et al, Catecholamine: Basic and Clinical Frontiers, 1979, pp. 734-736), suggest that the AMP isomers have equipotent effects on nonstriatal DA neurons. (Research supported by NIMH grants MH-30546 and MH-33513).

88.5 NOREPINEPHRINE - DOPAMINE INTERACTION: AN ELECTROPHYSIOLOGICAL DEMONSTRATION. M.K. Sanghera, S. Browder, P.A. Shore, R.S. Kiser and D.C. German. Depts. of Physiology, Psychiatry and Pharmacology, U. of Texas Health Sci. Ctr., Dallas, TX 75235.

Both anatomical and pharmacological data suggest that noradrenergic (NA) neurons communicate with dopaminergic (DA) neurons. Dopamine-β-hydroxylase-containing neuronal processes are found in the region of the substantia nigra zona compacta and ventral tegmental area (VTA), both areas which contain DA neurons. Furthermore, there is evidence of a locus coeruleus NA input to the VTA. Lesioning ascending NA axons decreases the DA turnover of VTA-DA neurons. We have previously found that systemic d- and l-amphetamine (AMP) both have very potent effects in decreasing the firing rate of VTA-DA neurons (Browder, et al, Catecholamines: Basic & Clinical Frontiers, 1979, pp. 734-736). Because both the AMP isomers also potently influence NA neuronal impulse flow, we sought to determine whether the effects of the AMP isomers on VTA-DA impulse flow were mediated via AMP's effects on NA neurons. Single unit activity was recorded from VTA-DA neurons in the chloral hydrate anesthetized rat. The firing rates of these cells were decreased by 50% or more after intravenous doses of from 0.5-1.0 mg/kg of d- or l-AMP. This decrease in impulse flow was reversed by an intravenous injection of the NA uptake inhibitor, desipramine (DMI) (0.5-1.0 mg/kg). The firing rate could then be decreased again by an intravenous injection of the DA agonist, apomorphine. These data suggest that AMP decreases DA impulse flow in part, at least, by releasing NA onto VTA-DA neurons. DMI blocks AMP's ability to release NA (shown in in vitro studies), and thereby reverses the AMP-induced decrease in DA impulse flow. These data provide electrophysiological evidence suggestive of a noradrenergic dopaminergic interaction. (Research supported by NIMH grants MH-30546 and MH-33513).

88.6 NEOSTRIATAL AND DORSAL RAPHE NEURONS: RECIPROCAL CHANGES IN FIRING RATE FOLLOWING LOCAL INFUSIONS OF D-AMPHETAMINE. George V. Rebec, Stephen D. Curtis and Kenneth S. Zimmerman. Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

Apart from acting on central catecholaminergic systems, amphetamine appears to produce its behavioral effects, at least in part, by altering the activity of serotonin (5-HT)-containing neurons. In fact, the anterior neostriatum (ANS), which has been implicated in the amphetamine behavioral response, receives 5-HT input from the dorsal raphe nucleus (DRN). To further elucidate the neural mechanisms of action of amphetamine, we infused the drug directly into the DRN, while simultaneously recording single unit activity in this site and in the ANS of immobilized, locally anesthetized rats. The spontaneous firing rate of neurons in both sites ranged from approximately 25-75 spikes/min. d-Amphetamine ($1x10^{-6}$-$2.75x10^{-4}$M) was infused at a rate of 1.5 µl/hr for a period of 5-9 min; single unit activity was monitored until firing rate returned to the pre-infusion baseline rate.

A local infusion of d-amphetamine into the DRN inhibited unit activity in this site but produced a mirror-image excitation in the ipsilateral ANS. It is unlikely that a catecholaminergic mechanism is involved in these effects since similar results were obtained in animals pretreated 4 hrs previously with 250 mg/kg α-methyl-para-tyrosine. Moreover, local infusions of d-amphetamine outside the DRN into the surrounding brainstem reticular formation failed to produce consistent changes in neostriatal activity. Thus, by acting locally in the DRN, amphetamine appears to release neurons in the ANS from an inhibitory serotonergic influence.

This research was supported, in part, by USPHS Grant DA-02451-02 from the National Institute on Drug Abuse.

88.7 EFFECTS OF α -ADRENERGIC DRUGS ON NIGRAL DOPAMINE CELL ACTIVITY: MEDIATION BY THE SEROTONERGIC RAPHÉ SYSTEM. S. A. DeRiemer* and B. S. Bunney (SPON: W. Huttner). Departments of Psychiatry and Pharmacology, Yale University Sch. Med., New Haven, CT 06510

Neuroanatomical studies in the rat suggest that noradrenergic projections to the substantia nigra are meager or non-existent. Consistent with these anatomical findings, we have reported previously that the α -agonist clonidine (20-800 ug/kg, i.v.) has no effect on identified dopaminergic (DA) cell activity (Svensson, T. H. et al., Brain Res. 92: 291, 1975). However, we have now found that when an imbalance is induced in basal ganglia function by pretreatment with direct or indirect acting DA agonists (i.e. apomorphine or d-amphetamine) an effect of α noradrenergic drugs on the DA system emerges. Thus, under these conditions, low doses of i.v. clonidine (< 10 ug/kg, i.v.) reverse DA agonist induced inhibition. In addition, using the same extracellular single unit recording techniques, Kim et al. (Kim, H., et al., Fed Proc. 39(3): 258, 1980), as well as ourselves, have found that α-antagonists (e.g. piperoxane), reverse DA agonist-induced inhibition of DA neuron activity. When given alone, these drugs have little effect on the spontaneous activity of identified zona compacta DA neurons.

Clonidine has been demonstrated to inhibit serotonergic raphé neurons, most likely through an action on α_2 receptors (Svensson et al., Brain Res. 92: 291, 1975). Alpha antagonists have also been shown to decrease the activity of serotonergic neurons through an action on α_1-receptors (Gallager, D. W. and G. K. Aghajanian, Eur. J. Pharm. 39: 341, 1976; Baraban, J. and G. K. Aghajanian, Neuropharm. 19: 355, 1980). As multiple lines of evidence have demonstrated a noradrenergic input to the raphé and a serotonergic input to the substantia nigra it is possible that the α-adrenergic drugs are affecting DA cell activity indirectly through an action mediated via raphe neurons. In confirmation of this hypothesis we have found that destruction of the serotonergic neurons within the dorsal raphé nucleus totally prevents α-antagonist reversal of DA cell inhibition.

Our studies provide evidence for an indirect influence of noradrenergic systems on DA cell function. In addition, they suggest that some drugs may have actions on a particular neurotransmitter system in the brain only after that system's normal functioning has been altered. (Supported by NIMH grants MH-28849, MH-25642, a NSF graduate fellowship to S.D., and the State of Connecticut.)

88.8 NORADRENERGIC NEURONS OF THE A-5 GROUP: ELECTROPHYSIOLOGICAL CHARACTERIZATION BY SINGLE CELL RECORDING TECHNIQUES. Rodrigo Andrade and George K. Aghajanian. Depts.of Pharmacology and Psychiatry. Yale Univ. School of Medicine, New Haven, CT 06510

Anatomical studies indicate that the noradrenergic innervation of the hypothalamus, brainstem, and spinal cord is derived to a considerable extent from the lower brainstem catecholamine cell groups. While substantial information has been accumulated on the more rostrally located locus coeruleus (A-6 of Dahlstrom and Fuxe), very little is known about the lower brainstem catecholamine cell groups. Among the latter, the A-5 group (Dahlstrom and Fuxe) has been recently shown to project to motor areas of the brainstem[1] and the intermediolateral cell column of the spinal cord[2] and has been implicated in the control of blood pressure[2]. Cells in this group are concentrated in the ventrolateral tegmentum between the superior olive and the exiting VIIth nerve; two thirds of all cells in this region have been reported to be catecholamine containing[2]. We have attempted to characterize electrophysiologically the cells of the A-5 group located in this area using single cell recording techniques.

In these experiments chloral hydrate anaesthetized rats were used. Recording sites were marked by iontophoresis of pontamine sky blue and localized in brain sections processed for either glyoxylic acid histofluorescence or cresyl violet staining. In the A-5 region a subpopulation of cells was found which exhibited regular spontaneous activity, wide action potentials, low to moderate rates of firing (<8/sec), and a characteristic response to noxious stimulation consisting of a brief excitation followed by a transient period of inhibition. These cells were invariably associated with the A-5 catecholamine cell cluster visualized by the histofluorescence method. The firing of these cells was suppressed by intravenous administration of low doses of the α_2-agonist clonidine; this effect was readily reversed by the α-antagonist piperoxane (0.1 mg/kg). As ℓ-amphetamine also suppressed their spontaneous activity, these cells share many of the characteristics previously reported for cells in the locus coeruleus and it is suggested they correspond to the A-5 noradrenergic cell group. These neurons could be readily distinguished from cells in immediately adjacent areas based upon their physiological and pharmacological properties. Further characterization of these presumed noradrenergic neurons in the A-5 area using antidromic stimulation and microiontophoresis is currently in progress.

88.9 DIAZEPAM ATTENUATES SINGLE UNIT ACTIVITY IN THE RAT LOCUS COERULEUS, AND LOCUS COERULEUS-ASSOCIATED BEHAVIORS IN THE MONKEY. S.J. Grant, Y.H. Huang and D.E. Redmond, Jr. Department of Psychiatry, Yale Univ. Sch. of Med, New Haven, CT 06510.

Electrical or pharmacological stimulation of the locus coeruleus (LC) elicits a consistent set of behaviors in chair restrained monkeys. The same set of behaviors have also been observed during periods of impending danger or uncertainty. This has led to the suggestion that the LC may act as an "alarm" center and might be involved in the generation of anxiety in hymans (1). This hypothesis predicts that anxiolytic agents would 1) attenuate increases in LC single unit activity or reduce net LC function and 2) attenuate LC-stimulation associated behaviors. These predictions have been tested in single unit recordings in anesthetized and awake, paralyzed rats, and in behavioral observations of chair restrained monkeys during LC stimulation.

Following administration of yohimbine (0.5-1.0 mg/kg I.V.), the firing of LC neurons (N=12) increased from 1.6±0.23 spikes/sec (Mean±S.E.M.) to 2.75±0.35 spikes/sec through blockade of inhibitory alpha-2 adrenergic norepinephrine "autoreceptors" found on LC neurons. Subsequent administration of diazepam (0.1-0.2 mg/kg I.V.) decreased firing rates to 1.86±0.3 spikes/sec. Diazepam (0.1-0.2 mg/kg I.V.) also decreased the accelerated firing rate of LC units in rats subjected to immobilization stress (unanesthetized, paralyzed preparations) from 5.1±0.27 to 1.8±0.24 spikes/sec.

A behavioral correlate of this action was observed in chair-restrained monkeys (Macaca arctoides) (N=5). Electrical stimulation of the LC (trains of biphasic 0.5 msec pulses of 0.15-1.25 mAMP amplitude through bipolar electrodes) was given intermittently over a one hour testing period. During a non-stimulation, pre-drug baseline period, LC-stimulation associated behaviors were emitted spontaneously at a rate of 13.6±5.0 (Mean units behavior/minute (1) ± S.E.M.). Stimulation of the LC increased the rate of LC-associated behaviors to 20.5±6.2. Subsequent administration of diazepam (0.1-0.2 mg/kg I.V.) during LC stimulation reduced the behaviors to 8.2±4.7.

The results demonstrate that diazepam, a major anxiolytic, can effectively attenuate both neural and behavioral aspects of LC activation. These results are compatible with the suggestion that anxiolytic agents can act by attenuated LC activity or net function.

88.10 PARALLEL REGULATION OF BRAIN NOREPINEPHRINE (NE) NEURONS AND PERIPHERAL, SPLANCHNIC NE NERVES BY CHEMORECEPTORS BARORECEPTORS AND BLOOD VOLUME RECEPTORS. T.H. Svensson, M. Elam*, T.Yao* and P. Thorén*. Depts of Pharmacology and Physiology, University of Göteborg, S-400 33 Göteborg, Sweden.

Brain NE neurons in locus coeruleus (LC) which innervate almost the entire central nervous system, seem to participate both in behavioural reactions (alerting and alarm responses) and in modulation of cardiovascular function. Utilizing single cell recording techniques to analyze the LC function and parallel recording of splanchnic nerve activity (SNA), we have studied the effects of activation of chemoreceptors, baroreceptors and blood volume receptors.

Chemoreceptor activation by hypercapnia (3-20% CO_2 in the inspired gas mixture) with associated elevation of blood pCO_2-level (36-103 mm Hg) caused an immediate, dose-dependent and marked increase in the firing rate of central NE neurons as well as in the SNA. During hypercapnia blood pressure, heart rate and pO_2-level did not change significantly. Deafferentiation by a low cervical sympathectomy, cutting the superior laryngeal nerves and by local destruction of the carotid sinus did not change the responses of LC neurons or SNA, indicating a central chemoreceptor regulation.

Baroreceptor activation, induced by intravenous injection of NE in incremental doses (0-8 µg/kg), caused a dose-dependent, significant, immediate and parallel reduction in both the firing rate of all LC units tested and in the sympathetic discharge. Both these effects were abolished by deafferentiation (cf. above).

Blood volume load (0.5-5 ml of heparinized blood, intravenously administered) induced a volume-dependent decrease in LC neuronal firing rates and sympathetic activity, effects which both were readily reversed by withdrawal of the corresponding amount of blood: The effects seemed unaffected by deafferentiation of the baroreceptors but abolished by bilateral vagotomy in the neck.

Consequently, brain NE neurons in the LC are subject to regulation by chemoreceptors, baroreceptors and blood volume receptors entirely analogous to the peripheral, splanchnic NE nerves.

88.11 RAPHE UNIT ACTIVITY IN FREELY MOVING CATS. I. EFFECT OF SENSORY STIMULATION. Barry L. Jacobs, Michael E. Trulson and James Heym.* Prog. in Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

Single unit recordings of serotonergic (raphe) neurons in mammals have provided a good deal of evidence regarding their spontaneous activity, and the influence of both drugs and various neurotransmitters upon this activity. By contrast, little information is available concerning the afferent control of these cells. The present study examined the effect of brief visual (flash) and auditory (click) stimuli upon the activity of serotonergic neurons in the dorsal raphe nucleus of the freely moving cat. Unit activity was recorded by means of movable 32 or 62 µ dia insulated nichrome wires (see complete methodology in Brain Res. 163: 135-150, 1979). Raphe neurons were initially identified on-line on the basis of their characteristic slow and rhythmic firing pattern. This identity was later confirmed by means of histological analysis (all cells were in the densely serotonergic dorsal raphe nucleus) and in some cells by examining their response to drugs known to depress the activity of serotonergic neurons. Click or flash stimuli were presented once every two sec. during periods of quiet or active waking. These stimuli elicited almost exclusively excitatory effects in serotonergic neurons, with a latency from approximately 30-60 msec to approximately 150 msec. This envelope of excitation was found in virtually every cell studied, and showed little variation across cells. The unit response to both stimuli typically showed some degree of habituation across trials. Clearcut inhibition was rarely seen, although some cells appeared to manifest an inhibitory phase following the initial excitation. However, upon closer examination, this was found to be the normal pause that is characteristic of the slow regular discharge of all serotonergic neurons (i.e. the spontaneous ISI). Click stimuli were generally more effective than flashes in driving raphe unit activity, however when both stimuli affected the unit, their temporal effects were largely coincident. This latter fact, plus the relatively long response latency, leads us to hypothesize that serotonergic neurons are not directly responsive to sensory stimuli, rather they appear to be under the influence of some common intermediary arousal system. Finally, these data should be contrasted with previous data on raphe unit activity in chloral hydrate anesthetized rats showing no effect of light flashes (Physiol. Behav. 13: 589-593, 1974), and showing a suppression by low frequency sciatic nerve stimulation (Brain Res. 153: 169-175, 1978). (Supported by NIMH grant MH 23433).

88.12 RAPHE UNIT ACTIVITY IN FREELY MOVING CATS. II. EFFECTS OF ADRENERGIC DRUGS. James Heym*, Michael E. Trulson, and Barry L. Jacobs (Spon: W. E. Gladfelter). Prog. in Neurosci., Dept. of Psychol., Princeton Univ., Princeton, NJ 08544.

Spontaneous activity of serotonin (5HT)-containing neurons of the dorsal raphe nucleus (DRN) is characterized by a slow and regular discharge rate. In freely moving cats, unit activity of 5HT cells within the DRN is positively correlated with the level of behavioral arousal, and in addition, the firing of these neurons appears to be driven by simple sensory stimuli (see preceding abstract). In anesthetized rats, recent neuropharmacological data have indicated the necessity of an excitatory adrenergic input to 5HT neurons for maintaining their spontaneous activity. This is of interest since the discharge of norepinephrine (NE)-containing neurons of the locus coeruleus has been reported to exhibit a relationship to behavioral arousal and sensory stimulation which parallels that demonstrated for 5HT neurons. When these findings are considered with anatomical evidence which indicates the existence of NE afferents to DRN neurons, it is reasonable to hypothesize that the responses of 5HT cells to arousal and sensory stimuli follow alterations in NE neuron activity, and are in fact mediated by changes in the adrenergic input to the DRN. We have explored this hypothesis by examining the effects of adrenergic manipulations upon the activity of 5HT neurons within the DRN of freely moving cats. Single unit activity of 5HT cells was recorded utilizing a methodology previously described (Brain Res.: 163, 135-150, 1979). A 30 min. period of baseline activity was recorded and included episodes of active waking, quiet waking, and sleep as judged by EEG and behavioral criteria. Following this pre-drug period, animals were administered, i.p., either WB4101 (0.5 or 1.0 mg/kg), clonidine (50-300 µg/kg), d-amphetamine (0.5-5.0 mg/kg), or saline. Although producing strong sedation, WB4101, an α adrenoceptor antagonist, did not significantly alter the activity of 5HT cells when similar pre- and post-drug behavioral states were compared. Clonidine, in doses that suppress NE cell activity through a presynaptic action, also produced strong sedation and was without effect on the activity of 5HT neurons when similar behavioral states were compared. Similarly amphetamine, a catecholamine releaser, at a dose which produced clear behavioral effects (0.5 mg/kg), failed to alter 5HT neuron activity. These data suggest that the discharge rate of 5HT neurons is not affected by alterations in adrenergic neurotransmission. Thus, arousal effects on 5HT cells may not be mediated by NE afferents. These results may be contrasted with data from chloral hydrate anesthetized rats in which WB4101 and other alpha antagonists produce complete suppression of 5HT cell firing. It seems likely that overriding influences, perhaps blocked by anesthesia, are operative in the freely moving animal.

88.13 RAPHE UNIT ACTIVITY IN FREELY MOVING CATS. III. REM SLEEP WITHOUT ATONIA. Michael E. Trulson, Barry L. Jacobs and Adrian R. Morrison. Prog. In Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544 and Dept. Animal Biol., Univ. Pennsylvania Sch. Vet. Med., Philadelphia, PA 19104.

The discharge of brain serotonin-containing neurons is almost completely suppressed during REM sleep in normal cats. Since the activity of these neurons is grossly correlated with the level of behavioral arousal, or tonic motor activity (see Brain Res. 163: 135-150, 1979), one might expect a decrease in activity during REM simply because tonic EMG activity or motoric output is at a minimum. On the other hand, raphe unit activity may be related to the state (i.e. REM sleep) of the organism. To test these competing, but not mutually exclusive, hypotheses (oneiric vs motoric), we examined raphe unit activity in cats with bilateral lesions of the pontine tegmentum (partially damaging the locus coeruleus and n. reticularis pontis oralis) which display REM sleep without atonia (C.R. Soc. Biol. 159; 895-899, 1965; Acta Neurobiol. Exp.: 34, 215-232, 1974). That is, these cats display episodes which, by all criteria, appear to be REM sleep, except that they display overt behavior, presumably because the mechanism normally responsible for producing atonia has been disrupted. The activity of raphe neurons during the waking state in lesioned cats was virtually identical to what we have previously reported for normal cats. Overall, raphe unit activity still showed a large decrease and long silent periods during REM sleep in lesioned cats. However, every cell tested frequently fired in short bursts in relation to intense gross body movements. It is interesting to note that while many raphe units are virtually silent during an entire REM epoch in normal cats, approximately one-third of the units would also occasionally discharge in short bursts in relation to eye movements and head and limb twitches. The overall level of raphe unit activity during REM sleep in lesioned cats was approximately four-fold greater than in normal cats. A few cells, however, manifested much greater increases in activity during REM sleep (10-20 times that seen in unlesioned cats). Our preliminary analysis indicates that these large increases may be related to a higher level of tonic EMG activity seen during REM sleep on these occasions. Thus it appears that the overall decrease in raphe unit activity during REM sleep is a function of the state, while motoric activity during REM is correlated with an increase in unit activity. These data indicate that increased motor output appears to "drive" raphe neurons. Whether the increased activity is directly related to the motor output, the associated proprioceptive feedback, or some other aspect of the behavior in these animals remainsto be determined. (Supported by USPHS grants MH 23433 and NS 13110).

89.1 FURTHER STUDIES ON THE ENDOGENOUS BENZODIAZEPINE RECEPTOR LIGANDS PEAK I AND PEAK II ISOLATED FROM RAT CORTEX.
P.J. Marangos*, S.M. Paul*, E. Trams*, and P. Skolnick*. (SPON: J. Axelrod). CPB/NIMH, 9000 Rockville Pike, Bldg. 10, Room 4S239, Bethesda, Maryland 20205 U.S.A.

Recent studies attempting to isolate endogenous ligands for the benzodiazepine receptor have produced a growing list of ligand candidates which include the purines inosine, 2-deoxy-inosine and hypoxanthine, nicotinamide, GABA modulin, β-carboline ethyl ester and various other unidentified factors. The purines and nicotinamide have also been shown to possess "benzodiazepine-like" pharmacologic and neurophysiologic properties. Recent reports from our laboratory have described two non-purine ligand candidates extracted from bovine brain using dilute Tris-chloride buffer (Marangos, et al., Psychiat. Res., 1:121, 1979). Both factors, designated peak I and II competitively inhibit ^{3}H diazepam binding, are heat stable and not inactivated by proteolytic enzymes. Peak I is only found in brain tissue and pituitary extracts.

We now report the existence of peak I and II in rat cerebral cortical extracts and their further characterization. Several methods of tissue processing including microwave or decapitation sacrifice and buffer or dilute acetic acid extraction were tried. All procedures yielded qualitatively similar diazepam binding inhibitory profiles when chromatographed on sephadex G-10, suggesting that the factors are not artifacts of tissue preparation. The purines inosine and hypoxanthine are also obtained in all procedures with hypoxanthine being greatly reduced in the extracts prepared from microwaved animals. Rat brain peak I and II are both resistant to proteolytic enzyme degradation and incubation with ribonuclease and deoxyribonuclease suggesting that they are not simple polypeptides or polynucleotides. Molecular weight estimates for peak I range from 1,000-5,000 daltons and 500-600 daltons for peak II. Further purification of peak I using ion exchange chromatography and high pressure liquid chromatography indicate that several active factors may be present.

Kinetic characterization of peak I reveals it to be unique when compared to peak II, the purines and nicotinamide in that it specifically inhibits the GABA induced enhancement of ^{3}H diazepam binding at concentrations 10-fold below those that inhibit basal diazepam binding. This observation, coupled with the known high concentration of GABA in vivo, suggest that peak I may function by inhibiting the GABA mediated increase in diazepam binding. The physiologic relevance of peak I and II should become clearer when these factors are identified and the appropriate pharmacologic experiments are performed.

89.2 PROPERTIES OF SOLUBLE AND PARTIALLY PURIFIED BENZODIAZEPINE AND γ-AMINO BUTYRIC ACID (GABA) RECEPTORS. Moshe Gavish and Solomon H. Snyder. Dept. of Pharmacol. Johns Hopkins School of Medicine, 725 North Wolfe Street, Baltimore, Maryland 21205.

Benzodiazepine and GABA receptors have been solubilized from calf brain using Triton X-100 as a detergent. Both receptors retained their drug specificity in the soluble state. GABA increases ^{3}H-flunitrazepam binding in the membrane and in the soluble states, indicating that the benzodiazepine receptor possesses GABA recognition sites. In membranes we have shown that both benzodiazepines and GABA selectively protect ^{3}H-muscimol binding from heat inactivation demonstrating that GABA receptors possess specific benzodiazepine recognition sites. The drug specificity for protection by benzodiazepines is the same as at benzodiazepine receptors. Both GABA and benzodiazepine receptors can be purified using concanavalin A-Sepharose 4B column, Sepharose 6B, DEAE-cellulose and hydroxylapatite columns, each affording 10-20 fold purification. GABA enhancement of benzodiazepine receptor binding is retained throughout these four steps of purification, the GABA recognition site appears to be intimately linked to the benzodiazepine recognition macromolecule.

89.3 COUPLING OF BARBITURATE-PICROTOXININ RECEPTORS TO BENZODIAZEPINE RECEPTORS IN RAT BRAIN. Fredrik Leeb-Lundberg*, Adele Snowman*, and Richard W. Olsen. Division of Biomedical Sciences, University of California, Riverside 92521.

CNS depressant drugs such as barbiturates and SQ 20009 (a non-benzodiazepine (BZ) anxiolytic), enhanced the binding of [^{3}H] BZ to high-affinity sites in rat cortex membranes. This effect was seen with all potent depressant drugs which bind to sites labeled by [^{3}H]α-dihydropicrotoxinin (DHP), a convulsant which blocks inhibitory GABAergic synapses at sites linked to Cl^- channels but distinct from GABA receptors. SQ 20009 (EC_{50} 8 μM) or pentobarbital (EC_{50} 100 μM) enhanced BZ binding maximally by about 100% in fresh, well-disrupted and washed membranes, assayed by filtration with 0.5 nM [^{3}H]diazepam in 10 mM $NaPO_4$, 200 mM NaCl, pH 7.0 at 0°. Background was estimated with 10 μM nonradioactive diazepam. Micromolar picrotoxinin competitively inhibited the barbiturate or SQ 20009 enhancement of BZ binding, which showed a chemical specificity (secobarbital> pentobarbital>>phenobarbital≥ barbital) correlating well with pharmacological actions of barbiturates as hypnotics or in enhancement of GABAergic postsynaptic responses. Other convulsants binding to the DHP sites (e.g. bicyclophosphates) at 10 μM also inhibited barbiturate or SQ 20009 enhancement of BZ binding. Barbiturate activation of BZ binding was stereospecific, with the active hypnotic, (+) hexobarbital much more effective than the pharmacologically less active (-) isomer. Enhancement of BZ binding by maximal concentrations of SQ 20009 (10 μM) was not further enhanced by maximal pentobarbital (0.5 mM), consistent with action at the same site (the DHP site), but GABA (10 μM) could further enhance BZ binding in an additive fashion, consistent with action at a different site. GABA enhancement of BZ binding was not Cl^--dependent but that of barbiturates and SQ 20009 required anions permeable to the GABA regulated Cl^- channels. Barbiturates increased the affinity of BZ binding with no change in the number of binding sites, and the enhancement was fully reversible. These in vitro effects of barbiturates represent a reasonable receptor site for at least part of the action of these drugs. These barbiturate receptors seem to be coupled to BZ receptors; since some BZ receptors seem to be coupled to GABA receptors, an in vitro link between DHP-barbiturate receptors and GABA receptors is now evident. The three drug receptors appear to form a complex which regulates Cl^- channels and which is the site of action for many convulsant, anticonvulsant, and sedative-hypnotic drugs.

89.4 ^{3}H-GABA BINDING TO SYNAPTIC PLASMA MEMBRANES AND ENDOGENOUS PHOSPHOLIPIDS. G. Toffano, C. Aldinio*, M. Balzano*, A. Leon*, and G. Kirschner*. Fidia Research Laboratories, Abano Terme, Italy.

The affinity binding of ^{3}H-GABA to synaptic plasma membranes increases after freezing, thawing and Triton X-100 treatment because of the removal of soluble endogenous inhibitors (Toffano, G., et al., in "Receptors for neurotransmitters and peptide hormones" Pepeu, G., Kuhar, M.J. and Enna, S.J., eds., Raven Press, New York, 1980). Since Triton X-100 treatment removes also lipid membrane components, we investigated whether endogenous phospholipids play a role on the regulation of ^{3}H-GABA binding to its recognition sites. When single phospholipids are added to Triton X-100 treated membrane preparations, we can detect a 30% decrease of ^{3}H-GABA binding induced by phosphatidylethanolamine, with phosphatidylserine and phosphatidylcholine practically inactive. Treatment of synaptic plasma membranes with a Ca^{++}-stimulated phospholipase A_2 results in a 40% decreased binding due to the formation of lysophospholipid derivatives which solubilize ^{3}H-GABA receptors. Incubation with phospholipase C increases ^{3}H-GABA binding by about 20-30%, while phospholipase D has no effect. The increased ^{3}H-GABA binding induced by Triton X-100 treatment is 5-8 times higher than that obtained by using phospholipase C at doses that duplicate the effect of the detergent on membrane phospholipid depletion. Moreover in aged rat brains, the regional decrease of ^{3}H-GABA binding does not correlate with endogenous membrane phospholipid changes. In conclusion, the removal of endogenous membrane phospholipid, particularly phosphatidylethanolamine, only partially accounts for the increase of ^{3}H-GABA binding determined by Triton X-100 treatment.

89.5 HIGH AFFINITY GTP BINDING IN BRAIN. J.E.Rosenblatt*, R.del Carmen, R.J.Wyatt*, M.Franczak, and B. Layton. Lab. of Clin. Psychopharmacol., NIMH, St. Elizabeths Hosp., Wash., D.C. 20032

Guanine nucleotides play a role in the activation of adenylate cyclase. Although the mechanism by which GTP apparently mediates adenylate cyclase activation is not known, it is thought to involve a guanine nucleotide binding protein associated with both the cell surface hormone receptor and adenylate cyclase. We therefore studied the binding of 3H-GTP to rat brain homogenates. 3H-GTP binding was saturable; Scatchard analysis revealed a higher affinity lower capacity binding site (Kd=2.0 nM, Bmax=164 pmoles/gm tissue) and a lower affinity higher capacity site (Kd=13 nM, Bmax=690 pmoles/gm tissue). Association was rapid, reaching equilibrium within five minutes; by fifteen minutes of incubation 30-40% of 3H-GTP binding dissociated spontaneously. Scatchard analysis at this incubation time revealed only the higher affinity component of binding. By 45 minutes following addition of 100 micromolar unlabelled GTP at equilibrium 80-90% of 3H-GTP binding had dissociated. GTP was ten and one hundred times more potent in displacing 3H-GTP binding than GDP and CTP, respectively; guanosine and guanine failed to inhibit 3H-GTP binding at concentrations less than 1 mM. ATP was completely inactive in displacing 3H-GTP. 3H-GTP binding was reduced by over 90% following exposure of brain homogenate to 53 degrees Cent. for 15 minutes. Binding of 3H-GTP was relatively similar in all brain areas studied (caudate, cerebral cortex, hippocampus, cerebellum, hypothalamus, and medulla-pons). It is hoped that direct binding techniques will prove useful in studying interactions among agonists, cell surface receptors and adenylate cyclase.

89.6 PSYCHOACTIVE DRUGS MODIFY NEUROTRANSMITTER RECEPTOR CIRCADIAN RHYTHMS IN THE RAT BRAIN. M.S. Kafka, A. Wirz-Justice,* D. Naber,* P. Marangos,* I. Tobler,* A. Borbely* and T.A. Wehr*. NIMH, Bethesda, MD 20205 and University of Zürich, Zürich, Switzerland

Endogenous circadian rhythms in the number of α-adrenergic ([^{3}H]WB4101), β-adrenergic ([^{3}H]dihydroalprenolol), dopamine ([^{3}H]spiroperidol), muscarinic cholinergic ([^{3}H]QNB), opiate ([^{3}H]naloxone), and benzodiazepine ([^{3}H]diazepam) receptors have been characterized in the rat brain. Chronic treatment with the antidepressant drugs imipramine, clorgyline, and lithium, and with the neuroleptic drug, fluphenazine, alter some or all of the characterisitcs of these receptor rhythms. In contrast, 24 hours of sleep deprivation (a transient antidepressant in man) had little effect.

The daily changes in receptor number are of the same order of magnitude as those measured when rats, chronically treated with drugs, are compared at a single time point with controls. A change in the receptor number, which in most studies has been measured at only one time point, could reflect a change in the 24-hour mean receptor number, a shift in the timing of the circadian rhythm (a phase shift), or both. As changes in the timing of a number of circadian rhythms have been implicated in the pathophysiology of affective illness, the drug-mediated changes in the timing of receptor rhythms may be related to their therapeutic actions in man.

Repeated measurements throughout the year have shown that the circadian rhythms in receptor number appear to undergo seasonal changes. The rhythms, seasonal as well as circadian, may function to synchronize brain neuronal transmission to the environmental light:dark cycle.

89.7 ATP- OR GTP-INDUCED INCREASE IN ^{3}H-ADTN BINDING TO RAT STRIATAL DOPAMINE RECEPTORS IS ABOLISHED BY UV IRRADIATION. Nancy R. Zahniser, Kim A. Heidenreich* and Perry B. Molinoff. Dept. of Pharmacology, Univ. of Co. Health Sci. Ctr., Denver, CO 80262.

Dopamine receptor agonists appear to be less potent in the presence of GTP. This effect, which is not seen with antagonists, has been explored using a rigid analogue of dopamine, ^{3}H-2-amino-6,7-dihydroxy-1,2,3,4-tetrahydronapthalene (^{3}H-ADTN). In initial experiments performed at 37° C, samples were equilibrated without nucleotide and the dissociation rate of ^{3}H-ADTN was determined. There was an increase in the rate of dissociation of ^{3}H-ADTN when GTP was added along with the competing ligand. Thus, the agonist-specific decrease in affinity appeared to be due, at least partially, to an accelerated rate of dissociation of agonist from the receptor. At 37° C in the presence of either ATP or GTP, however, ^{3}H-ADTN binding to striatal membranes did not appear to reach steady-state; binding increased for approximately 10 min and then progressively declined. When ^{3}H-ADTN binding was examined at 20° C, the system reached equilibrium within 45 minutes either in the presence or absence of nucleotides. Scatchard analysis of binding isotherms performed in the absence or presence of nucleotide showed that the affinity of ^{3}H-ADTN decreased in the presence of GTP (K_D values: control = 6.8 ± 1.1 nM; experimental = 19 ± 1.7 nM). The most striking finding was that the number of binding sites increased by five-fold (Bmax: control = 3.4 ± 0.93 pmol/mg protein, experimental = 18 ± 2.9 pmol/mg). This latter effect was not specific for guanine nucleotides since ATP was equipotent with GTP (EC_{50} = 30 μM). Both compounds were maximally effective at a concentration of 300 μM. The nonhydrolyzable purine nucleotide analogs GMP-PNP and AMP-PNP did not substitute for GTP or ATP. The pharmacological specificity of ^{3}H-ADTN binding in the absence or in the presence of nucleotide was characteristic of binding to dopamine receptors. The addition of GTP or ATP did not alter the affinity, number of binding sites or dissociation rate of the antagonist ^{3}H-spiroperidol. In other experiments the tissue was exposed to UV irradiation (λmax=310 nm) prior to the initiation of the binding reaction. After 30 minutes of UV exposure, ATP no longer had any effect on ^{3}H-ADTN binding. In contrast, ^{3}H-ADTN binding in the absence of ATP and ^{3}H-spiroperidol binding in the absence or presence of ATP were stable in tissue exposed to UV irradiation. Dopamine-sensitive adenylate cyclase activity also persisted following UV irradiation. These results suggest that in the presence of purine nucleotides ^{3}H-ADTN binds to a site in the rat striatum which is labile to UV irradiation and which is not associated with ^{3}H-ADTN binding sites detected in the absence of nucleotides, with ^{3}H-spiroperidol binding sites, or with dopamine-sensitive adenylate cyclase. As expected, ^{3}H-ADTN has a lower affinity in the presence of nucleotides than in their absence; however, the amount of ^{3}H-ADTN binding increases, rather than decreases, in the presence of either GTP or ATP.

This work was supported by USPHS (NS 15756 and 09199) and by an NIH fellowship (NS 05970).

89.8 HIGH AFFINITY BINDING OF [^{3}H]DOXEPIN TO RAT BRAIN TISSUE. J. E. Taylor and E. Richelson. Depts. of Psychiatry and of Pharmacology, Mayo Foundation, Rochester, MN 55901.

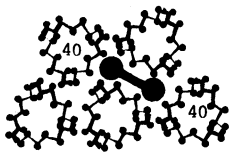
Some tricyclic antidepressants have been shown in pharmacological assays to be potent inhibitors of histamine H_1 receptors (E. Richelson, Mayo Clin. Proc., 54:669, 1979). However, the direct binding of tricyclic antidepressants to H_1 receptors in neural tissue has not been reported. In the present study we have characterized the binding of the radioactively labeled tricyclic antidepressant, [^{3}H]doxepin, to H_1 receptors in rat brain. The binding of [^{3}H]doxepin was time-dependent, and at 37°C reached equilibrium by 30 min. At 0.05 nM [^{3}H]doxepin, the association rate constant (k_1) at 37°C was $1.38 \times 10^9 M^{-1}$ min^{-1} and the dissociation rate constant (k_{-1}) was 0.038 min^{-1}. The equilibrium dissociation constant (K_B) determined from the ratio k_{-1}/k_1 was 0.027 nM. The Scatchard plot of specific [^{3}H]-doxepin binding was nonlinear indicating a multiplicity of binding sites. The K_B for the site of highest affinity was 0.043 nM ± 0.005 (mean ± S.E.M., n=6) with a maximal binding (B_{max}) of 34 ± 6 fmol/mg protein. This high affinity binding of [^{3}H]doxepin was sensitive to inhibition by pharmacologically relevant concentrations of histamine H_1 receptor antagonists such as pyrilamine (K_i=1.2 nM), d-chlorpheniramine (K_i=10 nM), and 1-chlorpheniramine (K_i=355 nM). The histamine H_2 antagonist, metiamide and the anticholinergic, atropine, were weak inhibitors with K_i's of 10,000 nM and 500 nM, respectively. The K_B for [^{3}H]doxepin binding agrees very well with its K_B value obtained from biological assays (E. Richelson, Mayo Clin. Proc., 54:669, 1979) and from the inhibition of [^{3}H]pyrilamine binding (J. E. Taylor and E. Richelson, unpublished observations). The B_{max} for [^{3}H]-doxepin binding to H_1 receptors, however, is much less than the B_{max} using [^{3}H]pyrilamine to label the H_1 receptor. These results suggest that [^{3}H]doxepin may be binding to a subclass of histamine H_1 receptors. (Supported by the Mayo Foundation and USPHS grants MH 27692 and MH 07925.)

89.9 Modification of Cholinergic Receptor Channel Properties by Sulfhydryl Reagents. A. Steinacker, Biophysics, Rockefeller University, New York, N.Y. 10021.

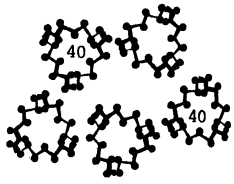
Disulfide bonds are a critical structural component of the nicotinic cholinergic receptor. It has been shown using biochemical analysis with the isolated receptor that sulfhydryl reagents show specificity for locus of action on the receptor sub-units. In addition, the locus of action of several sulfhydryl reagents has been shown by electrophysiological methods. This report concerns the modification of channel open time at the lizard neuromuscular junction (nmj) by the sulfhydryl reagents, sulfite and diamide. Sulfite has been shown to attack a disulfide bond on the α chain (Steinacker, A. Nature 278, 358-360, 1978). Using the lizard intercostal muscle and mepc decay time as an index of mean channel open time, I have shown that sulfite produces an increase in response of the receptor to ACh which is due to an increase in mean channel open time. Diamide, a sulfhydryl oxidizing agent, has been shown to act preferentially at the β chain in the isolated native receptor (Hamilton et al., Biochem. 18, 155-163, 1979). Diamide, when applied to the lizard nmj produces an increase in receptor response to ACh which is shown to be due to an increase in mean channel open time. The effects of both these reagents are extremely variable in occurrence and amplitude of response, indicating that the oxidative reductive state of these disulfide bonds vary in the in vitro nmj being predominately in the reduced state.

89.10 MODEL OF THE ACETYLCHOLINE RECEPTOR-CHANNEL COMPLEX. H. R. Guy* (SPON: D. Livengood). Armed Forces Radiobiology Research Institute, Physiology Department, Bethesda, MD 20014.

Although the acetylcholine receptor-channel complex (AChRC) has been studied extensively, its molecular structure is not known. The AChRC structure proposed here attempts to account for various data with a single model. Data suggest that the AChRC from the electric organ of Torpedo californica is a dimer in which each monomer has two 40-K, one 50-K, one 60-K, and one 65-K MW subunits (Raftery, M. et al., Adv. Cytopharmacol., 3:159-182, 1979; Lindstrom et al., Biochemistry, 18: 4465-4470, 1979). I have assumed that all of the subunits have similar backbone structures and that a channel is formed between the subunits of each monomer. The extracellular receptor portions of each model subunit have three β sheets that form triangular structures. Arrangement of the β triangles shown below is consistent with dimensions observed with electron microscopy (Klymkowsky, M. W. and Stroud, R. M., J. Mol. Biol., 128:319-334, 1979). The β backbones of the snake neurotoxins bind to the tops of the 40-K β triangles, and their invariant tails bind in the region between the two β triangles [probably corresponding to the 50-K and 65-K subunits (Raftery ref.)] that separate the 40-K subunits. When two snake neurotoxins bind to the receptor, their invariant tails meet in a manner that mimics the structure of the very potent competitive inhibitor alloferin. The binding site of the competitive inhibitors is represented below by the dumbbell. The receptor has two nonidentical agonist-binding sites: one between the 40-K and 65-K subunits and the other between the other 40-K and the 50-K subunits. The portions of the subunits that extend across the membranes are predominantly helical. Residues 5 to 20 of the 40-K subunit (Hunkapiller, M. W. et al., Biochem. Biophys. Res. Commun., 91:164-169, 1979) can form an amphiphilic α helix in which all of the side chains on one side of the helix are apolar, those in a narrow region opposite the apolar side are charged, and indifferent residues separate the apolar and charged regions. These types of amphiphilic helices probably extend through the membrane with their charged side chains extending into the channel and their hydrophobic side chains extending into the lipid phase. The model channel forms between the subunits and opens when the subunits move farther apart.



Competitive inhibitor bound to closed AChR



Open AChR

89.11 ^{3}H-2-CHLOROADENOSINE LABELS ADENOSINE RECEPTORS IN BRAIN MEMBRANES. P.H. Wu* and J.W. Phillis. Department of Physiology, College of Medicine, University of Saskatchewan, Saskatoon, Sask. Canada. S7N 0W0

Studies on the depressant actions of adenosine and its analogs on central neurons and biochemical investigations on the stimulation of cyclic AMP formation by adenosine and its analogs in brain slice preparations indicate the existence of adenosine receptors in CNS. We have sought evidence of binding of adenosine or its analogs to brain membranes to validate this concept of central adenosine receptors.

^{3}H-2-chloroadenosine (a ligand, 33nM) was incubated with rat cerebral cortical membranes (0.5mg protein) for a period of 60 minutes at 4°C. At the end of incubation, 5ml of the 75mM Tris-HCl buffer (pH 7.5; containing 25mM $MgCl_2$ and 25mM $CaCl_2$) was added to stop the reaction. The labelled membranes were collected on a Whatman GF/C glass fibre filter with suction. For the determination of non-specific binding of ^{3}H-2-chloroadenosine, a 2.5×10^{-4}M solution of 2-chloroadenosine was present in the incubation mixture. IC_{50} values for the inhibition of ^{3}H-2-chloroadenosine binding were obtained by adding test agents to the incubation medium at a final concentration of $10^{-8} \sim 10^{-4}$M.

The specific binding of ^{3}H-2-chloroadenosine to rat brain cortical membranes appeared to be saturable. It was linear from 0.3mg to 1.2mg of membrane protein and the amount of binding appeared to vary amongst different brain regions. A high binding capacity was found in the caudate nucleus, low binding capacity was found in hippocampus. Analysis of the binding data by the method of Scatchard gave a linear plot, suggesting the presence of a single binding site which had an apparent dissociation constant (K_D) of 23.5nM and a maximal binding capacity (B_{max}) of 476 femto mole/mg protein. Binding of ^{3}H-2-chloroadenosine to subcellular fractions indicated that the binding was mainly to the membranes prepared from the synaptosomal fraction of rat cortex. Adenosine competitively displaced ^{3}H-2-chloroadenosine binding from cortical membranes with a K_i value of 0.12μM at 10^{-5}M adenosine concentration. Other purines displaced the binding of ^{3}H-2-chloroadenosine to cortical membranes with IC_{50} values of; adenine, 0.45μM; inosine, 0.4μM; theophylline, 0.35μM; and isobutylmethylxanthine, 0.13μM. Binding was weakly inhibited by uracil, 18μM and hypoxanthine, 27μM. Guanosine and cytidine were inactive at 100μM. These findings strongly support the suggestion that there are adenosine receptors on brain cell membranes and extend previous observations that methylxanthines (caffeine and theophylline) act as adenosine receptor antagonists.

89.12 Are there separate Binding Sites for a Neurotransmitter and its Agonists or Antagonists. Marvin H. Winkler, (Spon: Sol Berl) Dept of Neurology, Mt. Sinai School of Medicine, New York, N.Y.

It is often difficult to find topographical similarities between the structure of a specific neurotransmitter and its physiologically active competitive binders. Frequently the chemical characteristics of the postulated topographical similarities, even when they are found, preclude the existence of a single rigid binding site. The alternatives are either configurational adaptability in a single primary site which binds both the neurotransmitter and its competitors or a primary site which binds the neurotransmitter and a secondary site which binds the competitor but can transmit information to the primary site. The large number of configurationally distinct agonists or antagonists which displace dopamine from striatal homogenates makes it difficult to conceive of even a configurationally adaptable site which could bind all of them. It is simpler to assume in analogy to serum albumen, that a component with a wide range of binding activities is to be found in neural membranes and that a configurational change induced by binding to one of a number of secondary sites is transmitted to a primary site. This configurational change must be assumed to distort the primary site in such a fashion as to render it less complementary to a bound neurotransmitter. Evidence will be discussed for the existence of communicating primary and secondary sites existing on the same molecule. However, they may exist on separate molecules which communicate through the membrane structure. According to the postulate which is to be discussed, the difference, between an agonist and antagonist is simply that while both distort the primary site upon binding, the distortion caused by an agonist alters ionic channels in the same manner as does the neurotransmitter. Antagonist binding does not cause similar alteration in ionic channels.

90.1 PHARMACOLOGICAL ANALYSIS OF MULTIPLE ^{3}H-5HT BINDING SITES IN RAT BRAIN, N.W. Pedigo, H.I. Yamamura and D.L. Nelson*, Department of Pharmacology, University of Arizona Health Sciences Center and College of Pharmacy, Tucson, Arizona 85724.

A number of antipsychotic drugs can discriminate between two populations of ^{3}H-5HT binding sites in rat brain. These two distinct sites show a differential distribution in various rat brain regions. Cortical areas (frontal, parietal and occipital) and the hippocampus contain a high proportion of sites having a high affinity for neuroleptics (about 60%) while the corpus striatum contains mostly sites with a low affinity for antipsychotic drugs (about 80%). The butyrophenone neuroleptic spiperone shows the greatest selectivity for these two ^{3}H-5HT binding sites having at least a 3000-fold difference in Ki values (2-12 nM vs. 35,000 nM) for the high and low affinity sites, respectively. Drug inhibition of ^{3}H-5HT binding by spiperone in the frontal cortex, hippocampus and corpus striatum yields distinctly biphasic inhibition curves with Hill slopes significantly less than 1. Furthermore, results from saturation studies of ^{3}H-5HT binding assayed in the absence or presence of 1 μM spiperone (a concentration which completely blocks the high affinity site while exerting minimal effects at the low affinity site) reveals a parallel shift in the Scatchard plot with no change in the K_D of ^{3}H-5HT, but a significant 60% (frontal cortex) or 20% (corpus striatum) decrease in the number of specific ^{3}H-5HT binding sites.

The ^{3}H-5HT binding site with a high affinity for neuroleptics exhibits a marked degree of pharmacological specificity. Drugs which have a structure similar to spiperone, such as haloperidol, pipamperone and metoclopramide, are from 40 to 200-fold less active at this high affinity site than spiperone. The antispychotic drug (+)butaclamol is only about 3 times less active than spiperone while chlorpromazine is 50 times less potent at the high affinity site. All of these drugs show varying degrees of selectivity between the two ^{3}H-5HT binding sites, whereas the atypical neuroleptic sulpiride appears to act only at the low affinity site. While it is unlikely that the differential activities of antipsychotic drugs at these multiple ^{3}H-5HT binding sites account for differences in their theraputic efficacy, there may be a correlation to certain side effects of neuroleptics such as sedation, sleep disturbances, etc. Further characterization of these multiple ^{3}H-5HT binding sites is therefore warrented.

Supported by USPHS grants RR-09094, NS-06217 and a RSDA (MH-00095) to H.I.Y.

90.2 ^{3}H-MIANSERIN BINDING IN CALF CAUDATE. Patricia M. Whitaker and Alan J. Cross*. Division of Psychiatry, Clinical Research Centre, Harrow, England.

Mianserin has been shown to be a serotonin receptor antagonist both in peripheral and central receptor systems. It has also been well established as a clinically effective non-tricyclic antidepressant. Recently a tritiated form of mianserin has become available with a specific activity high enough for use in direct binding assays of central neurotransmitter receptors. These assays would be of interest for two reasons: (i) they could introduce a new ligand for central serotonin receptors and (ii) the results would be interesting to compare with recent findings in ^{3}H-tricyclic antidepressant direct binding assays in order to establish a possible common site of action shared by the tricyclics and a novel antidepressant.

The direct binding assays were done in calf caudate using 5 nM. ^{3}H-mianserin and 1000 nM. cold mianserin to define the specifically bound radioligand. The unbound ligand was removed by filtration. The K_i values of a variety of drugs were determined and are given in the following table:

Drug	K_i (nM)
Tryptamines:	
Serotonin	390
Tryptamine	780
N,N Dimethyltryptamine	780
5-Methoxy-N,N-DMT	620
Ergots:	1030
LSD	
Metergoline	1.7
Dihydroergocryptine	1.7
Dihydroergotamine	30
Antidepressants:	52
Mianserin	
Imipramine	1.2
Chlorimipramine	5
Trazodone	7.2
Amitriptyline	16.7
Nortriptyline	26
Maprotiline	28
Nomifensine	38.6
	200

The sites labelled were of one type with a K_D of 0.7 nM and a B_{max} of 139 fmoles/mg. protein.

The results will be discussed in terms of antidepressant site of action.

(Supported by the MRC of Canada).

90.3 PROTEIN NEUROTOXIN FROM RUSSELL'S VIPER SELECTIVELY INHIBITS ^{3}H-SPIROPERIDOL BINDING TO DOPAMINE AND SEROTONIN RECEPTORS. Jonathan E. Freedman and Solomon H. Snyder. Dept. Pharmacol. and Exptl. Ther., Johns Hopkins University School of Medicine, 725 N. Wolfe Street, Baltimore, Maryland 21205

A neurotoxin has been purified to apparent homogeneity from the venom of Vipera russelli russelli, a snake whose bite does not cause neuromuscular paralysis, and whose venom is thought to block dopamine synapses. The toxin is a protein of molecular weight 10,000 and isoelectric point 8.9. Its activity is stable to 5 min. of boiling.

The toxin inhibits in a dose-dependent manner the specific binding of ^{3}H-spiroperidol to dopamine receptors in rat caudate nucleus and serotonin receptors in rat frontal cortex, with Ki values around 20-100 nM. Scatchard analysis reveals that the toxin lowers Bmax without raising K_D values, indicating either that the inhibition is noncompetitive or, if competitive, is of slow dissociation. The inhibition is fairly selective, in that toxin concentrations up to 1 μM have no effect on ligand binding to alpha-adrenergic, beta-adrenergic, muscarinic cholinergic, GABA-ergic, or benzodiazepine receptors, and only partially inhibit ^{3}H-doxepin binding to histamine receptors.

The molecule also possesses phospholipase A_2 activity, which appears not to account for the inhibition of binding. Binding data are obtained in the presence of 1 mM $CoSO_4$, which selectively and completely abolishes the phospholipase activity. Other phospholipase A_2 enzymes present in the same venom are substantially less potent than the toxin at inhibiting spiroperidol binding in the absence of cobalt.

The ^{125}I-toxin may be of use for receptor labeling, while toxin affinity columns may facilitate receptor purification.

90.4 CHARACTERIZATION OF ^{3}H-APOMORPHINE BINDING IN MAMMALIAN BRAIN. G. Arana,* R. J. Baldessarini. (SPON.: A. Pope) Mailman Research Center, Harvard Medical School, McLean/Massachusetts General Hospital, Belmont, MA 02178.

^{3}H-Apomorphine (APO) was employed as a radioligand to study binding to putative dopaminergic receptors in subsynaptosomal preparations of mammalian brain. With unlabeled APO, dopamine (DA), ADTN, or (+)butaclamol to displace non-specific binding, specific binding ranged from 80 to over 90% with calf caudate preparations. Optimal conditions for incubation occurred at pH 7.0-7.5 at 25°C. Binding was nearly complete within 60 min; $t_{1/2}$ for association = 14 min and $t_{1/2}$ for dissociation = 18.5 min. Analysis of kinetic data yielded K_d = 2.1 to 3.4 nM and B_{max} = 681 fmol/mg protein for a high affinity component and K_d = 212 nM and B_{max} = 1293 fmol/mg for a low affinity, high-capacity component of binding of ^{3}H-APO. Caudate nucleus or corpus striatum had the greatest density of binding sites among brain regions of several species, including man. Most monovalent or divalent cations had no significant effects on binding, but Ca^{++} and Mn^{++} decreased binding (EC_{50} = 10 to 20 mM). Several nucleotides showed no significant effect, but both GTP and ATP reduced binding of ^{3}H-APO.

Of the many aporphines tested in this system, those with a free catechol moiety yielded EC_{50} values in the low nM range; non-catechol analogs showed 10 to 1000-fold less affinity. Of a large series of phenethylamines tested, non-catechols showed 10 to 1000-fold less affinity than DA; N-alkylated analogs of DA inhibited binding of ^{3}H-APO at nM concentrations, while norepinephrine and other catechols had little effect. Other DA agonists such as ADTN and lergotrile were potent inhibitors, while a series of dopaminergic antagonists or various putative neurotransmitters, enzyme inhibitors, and other neuropharmacologically active agents were weak or inactive as displacers of ^{3}H-APO.

90.5 INTERACTIONS OF MOLINDONE WITH SEROTONIN AND DOPAMINE RECEPTORS AND WITH ADENYLATE CYCLASE IN RABBIT BRAIN. M.R.Rosenfeld* and M. H.Makman*. (SPON:R.Ginzberg). Depts. Molecular Pharmacology and Biochemistry, Albert Einstein Coll. Med., Bronx, New York 10461.

Molindone (MOBAN), a tetrahydroindole derivative is a clinically used antipsychotic agent that has been shown to be a specific antagonist of serotonin (5-HT) stimulated adenylate cyclase (AC). (Ahn and Makman, Life Sci. 23:507, 1978). We have studied the ability of molindone to bind to aminergic receptors and its effect on hormone-stimulated AC in homogenates of rabbit frontal cortex (FC) and caudate nucleus (CN).

In both regions, molindone is a weak displacer of all [3H] ligands tested. In FC IC_{50}'s for molindone are 7μM for [3H] LSD, 8.4μM for [3H] 5-HT and 6.9μM for [3H] spiroperidol. In CN IC_{50}'s are 6.5μM for [3H] LSD, 5.1μM for [3H] 5-HT and 3.6μM for [3H] ADTN (2-amino-6,7-dihydroxy-1,2,3,4-tetrahydronaphthalene). In FC the guanine nucleotide analog Gpp(NH)p failed to alter the IC_{50} for displacement of [3H] spiroperidol by molindone indicating that the interaction of molindone at these sites is as an antagonist. In FC molindone is able to antagonize 5-HT and lisuride stimulation of AC but is inactive in antagonizing dopamine (DA) stimulated activity, except at high concentrations (0.1mM).

In CN we find that 66% of the [3H] LSD binding sites are serotonergic and 34% are dopaminergic. At 1μM molindone interacts with approximately 21% of the total sites of each class. At 10μM molindone interacts with 46% of the 5-HT sites and 90% of the DA sites. We also studied the interaction of molindone with the guanine nucleotide sensitive (SEN) and insensitive (INS) components of [3H] ADTN and [3H] 5-HT binding in CN. Molindone displaces both SEN and INS classes of [3H] ADTN binding sites and displays a small preference for the SEN component of [3H] 5-HT binding sites. At 1μM and 10μM molindone binds to 25% and 42% of the total INS sites respectively, and 44% and 67% of the total SEN sites, respectively.

The data show molindone to have relatively weak interactions with 5-HT and DA receptor sites in FC and CN of rabbit brain. If the guanine nucleotide sensitive component of 5-HT binding represents receptors that are coupled to AC, this, together with the ability of molindone to antagonize 5-HT-stimulated AC, raises the possibility that an important site of action of molindone is at 5-HT receptors coupled to AC. Molindone appears not to be selective for AC-coupled DA receptors but rather binds weakly to both AC-coupled and non-coupled DA receptors. The relative binding potency of molindone in these studies at either 5-HT or DA receptors is less than predicted based upon its antipsychotic potency. Molindone presents itself as an atypical neuroleptic with stronger interactions at 5-HT receptors coupled to AC than at coupled or non-coupled DA receptors. Supported by NIH Grant MH 31773.

90.7 SOLUBILIZATION OF THE NEUROLEPTIC (DOPAMINE, D-2) RECEPTOR FROM DOG STRIATUM. B.K. Madras, A. Davis and P. Seeman. Psychopharmacology Section, Clarke Institute of Psychiatry, Toronto, Ontario, M5T 1R8 and Department of Pharmacology, University of Toronto, Toronto, Ontario, M5S 1A8.

Neuroleptic drugs bind to the post-synaptic dopamine receptor (D-2) in an order of potency that parallels clinical dosage (Seeman et al., Nature 261, 717, 1976). Purification of the receptor would help clarify the molecular mechanisms involved in neuroleptic action.

We have solubilized the neuroleptic receptor from dog striatum (Gorissen and Laduron, Nature 279, 72, 1979) membrane preparations as a preliminary to purification. The receptor is solubilized with digitonin and assayed on Sephadex G-50 columns, using 3H-spiperone to label it. The soluble receptor retains the binding characteristics of the membrane-bound receptor.

	IC_{50} (nM)	
	Membrane	Soluble
Antagonists		
Spiperone	1.8	3.8
Fluphenazine	14	4
Haloperidol	19	42
(+)-Butaclamol	23	4
(-)-Butaclamol	5,000	3,900
Chlorpromazine	37	150
Agonists		
ADTN	630	950
Apomorphine	1,100	1,700
Dopamine	4,000	5,100
Serotonin	95,000	200,000
Norepinephrine	100,000	100,000
Characteristics		
K_D	0.4±0.04 nM (3)	0.8±0.1 nM (3)
Specific binding	410 fmoles/mg	193 fmoles/mg
Recovery	20.6 pmoles/g	4.2 pmoles/g

Evidence that soluble striatum receptor is dopaminergic stems from: 1) The failure of solubilized binding sites from a non-dopaminergic region, cerebellum, to bind either stereoselectively or in a saturable manner. 2) Soluble receptors from the frontal cortex have different binding profiles than the soluble receptor of the striatum. 3H-Spiperone binding in the frontal cortex is primarily serotonergic. 3) The higher affinity of dopamine for the receptor compared with other neurotransmitters is retained after solubilization.

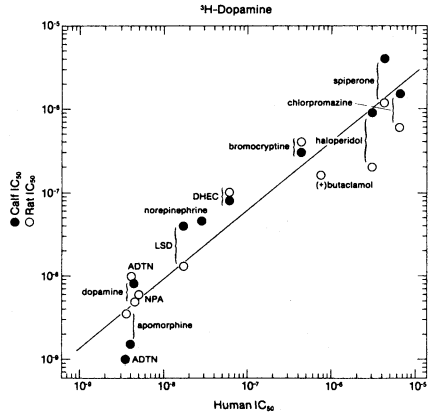
Dr. A. Davis is financed by a NATO/Science Research Council (U.K.) Fellowship.

90.6 HIGH-AFFINITY 3H-DOPAMINE RECEPTORS IN THE HUMAN BRAIN. S.J. List* and P. Seeman. Department of Pharmacology, University of Toronto, Toronto, Ontario, Canada.

Although a high-affinity binding site for 3H-dopamine has been extensively studied in the calf brain, some workers have been unable to detect this site in the rat brain (Creese et al., Eur. J. Pharmacol. 60, 55, 1979). Under our binding assay conditions, we have recently found a high-affinity 3H-dopamine binding site in the rat, similar to that found in the calf (List et al., Neurosci. Abst. 5, 654, 1979). We now report the existence of this same high-affinity binding site in post-mortem human brain tissue.

Scatchard analyses of specific 3H-dopamine binding (as defined by 10^{-6}M apomorphine) in tissue homogenates of five separate human brains revealed a high-affinity 3H-dopamine binding site in the caudate (B_{max} = 63 ± 10 fmoles/mg protein; K_D = 2.2 ± 0.4 nM) and the putamen (B_{max} = 57 ± 11 fmoles/mg protein; K_D = 2.8 ± 0.3 nM). No such sites were detectable in dopamine-poor regions in the human brain.

The high-affinity 3H-dopamine binding site in the human brain appeared to be similar to the sites previously characterized in the rat and calf, having high affinity for dopaminergic catecholamines, intermediate affinity for dopaminergic ergot agonists, and low affinity for a number of neuroleptics (as shown in the figure below). (Supported by the Medical Research Council of Canada and the Ontario Mental Health Foundation.)



90.8 IRREVERSIBLE BLOCKADE OF DOPAMINE RECEPTORS. M. Titeler. Department of Pharmacology, University of Toronto, Toronto, Ontario M5S 1A8.

In order to investigate the binding sites of dopamine receptors, a specific irreversible ligand is desirable. In order to determine whether there is a functional moiety at the dopamine receptor binding site capable of irreversible interactions, the effect of phenoxybenzamine on the specific binding of 3H-spiperone and 3H-dopamine to calf caudates was investigated. Phenoxybenzamine has been shown to block α-adrenergic receptors specifically and irreversibly (1), using direct binding assays to monitor the blockade of the receptors. 3H-Spiperone has been shown to label primarily a dopamine receptor in the caudate with properties associated with classical dopamine receptors (2). 3H-Dopamine labels a dopamine receptor with extremely high affinity for dopamine and low affinity for neuroleptics (2). Calf crude homogenates were prepared as previously described with minor modifications (2). The specific binding of 3H-spiperone and 3H-dopamine were determined as previoulsy described with minor modifications (2). The results in fig. 1A demonstrate that phenoxybenzamine irreversibly inhibited 3H-spiperone specific binding, while spiperone itself did not. Figure 1B demonstrates that phenoxybenzamine had no effect on 3H-dopamine specific binding. These results indicate that there is a functional moiety at the dopamine receptor capable of irreversible interaction with phenoxybenzamine, and that the receptor labelled by 3H-spiperone is molecularly distinct from that labelled by 3H-dopamine.

90.9 EQUILIBRIUM DIALYSIS -- A NEW AND MORE SENSITIVE METHOD FOR MEASURING 3H-DOPAMINE.

A.Hitri*, H.L.Klawans*, W.J.Weiner, P.A.Nausieda, and C.G.Goetz* Department of Neurological Sciences, Rush-Presbyterian, St.Luke's Medical Center, Chicago, IL 60612

The ultrafiltration technique using naturally occurring dopamine in its radioactive form have yielded controversial results in the study of CNS dopamine receptors. In our recent studies, we compared equilibriaum dialysis with the ultrafiltration method using a multiple semimicro equilibrium dialyser. We performed simultaneous kinetic and saturation studies of 3H-dopamine binding to striatal membranes of guinea pigs. The studies were carried out at various temperatures. The results indicate that the amount of stereospecifically bound dopamine is greatly enhanced by the equilibrium dialysis method. Moreover, the simultaneous kinetic and saturation studies allow estimation of the intrinsic affinity constants and a direct comparison with the equilibrium constant. The equilibrium dialysis method provides a more specific means for studying dopamine receptors using the naturally occurring agonist 3H-dopamine. The equilibrium dialysis apparatus and methods will be discussed as well as the comparative results between equilibrium dialysis and ultrafiltration.

90.10 The Effects of Chronic Lithium Administration on Serotonin Receptors in Rat Brain.

Susan L. Treiser*, Nguyen B. Thoa,* Tom L. O'Donahue, David M. Jacobowitz, Caren S. Cascio* and Kenneth J. Kellar. Department of Pharmacology, Schools of Medicine & Dentistry, Georgetown University, Washington, D.C. 20007, Lab. Clin. Sci., NIMH, Bethesda, Md. 20205.

The mechanisms of action by which lithium ion exerts its therapeutic and prophylactic effects in manic-depressive illnesses remain unknown. Several recent studies have shown that chronic administration of Li alters neurotransmitter receptor processes in rat brain. Since alterations in serotonin neurotransmission are thought to be involved in affective disorders, we have examined the effects of chronic Li administration on serotonin receptors in rat brain. Two types of serotonin receptors have been described. One type binds ^{3}H-5-HT and the other binds ^{3}H-spiperone. These binding sites have been referred to as serotonin$_1$ and serotonin$_2$ receptors, respectively (Peroutka and Snyder Mol. Pharm. 16, 1979). Chronic Li administration affects both types of receptors in the rat hippocampus, but neither type appears altered in the rat cerebral cortex.

Male Sprague-Dawley rats (200-250 g) were fed a diet containing 0.25% lithium carbonate mixed in powdered rat chow. Control rats received the identical powdered rat chow without the added Li. After 4-6 weeks on the diet, rats were sacrificed by decapitation and blood was collected for measurement of Li and sodium levels by flame photometry. Blood levels of Li were approximately 1-1.2 meq/liter.

The serotonin receptor binding sites were measured using both ^{3}H-5-HT and ^{3}H-spiperone in the cortex and hippocampus.

We found no difference in either ^{3}H-5-HT or ^{3}H-spiperone binding in rat brain cortex following Li treatment. However, in the hippocampus there was a significant decrease, approximately 20%-30% in the number of binding sites measured by both ligands.

To determine whether Li exerts differential actions on presynaptic serotonin processes in cortical and hippocampal neurons which could account for the differential effects on receptor numbers in these two areas, we examined the effects of chronic Li administration on the uptake and release of 5-HT. Chronic Li administration did not alter 5-HT uptake in the hippocampus or cortex. However, our preliminary results indicate that chronic Li decreases serotonin release in the cortex, but increases serotonin release in the hippocampus. Thus, chronic Li administration appears to exert brain area specific effects on both pre- and post-synaptic neurotransmitter processes.

91.1 EFFECTS OF M-ENKEPHALIN (ME) AND SUBSTANCE P (SP) ON THE SENSORY DISCHARGE AND RESPONSE OF CAROTID BODY CHEMORECEPTORS TO ACH AND DOPAMINE. L. Monti-Bloch* and C. Eyzaguirre. Dept. Physiol., Univ. of Utah Col. Med., Salt Lake City, UT 84108.

The carotid body and its nerve, removed from anesthetized cats, were placed in a superfusion chamber through which flowed modified Tyrode's solution equilibrated with 50% O_2 in N_2 at 36° and pH 7.43. Drugs were applied in volumes of 1-10 µl and sensory discharges were recorded from the nerve. Low concentrations (3.3 µM) of SP did not change the basal discharge or the stimulatory effect of ACh 100 µg. They did, however, reverse the normal inhibitory effect of dopamine (DA) 100 µg which induced excitation after SP. Larger concentrations of SP (33 µM) depressed the sensory discharge and potentiated the normal excitatory effect of ACh 100 µg. Low concentrations of ME (10 µM) increased the basal discharge, depressed the excitatory effect of ACh 100 µg and blocked the inhibitory effect of DA 100 µg. Larger concentrations of ME (100 µM) increased the basal discharge, reversed the excitatory effect of ACh, which after ME induced discharge depression, and also blocked the inhibitory effect of DA. Naloxone 10^{-6} g/ml (an enkephalin blocker) blocked the discharge increase induced by ME 10 µM and restored the inhibitory effect of DA on the sensory discharge. Preliminary experiments have shown that both SP and ME tend to depress the excitatory effects of anoxia (100% N_2), hypercapnia (6% CO_2 in 50% O_2 and 44% N_2) and NaCN 5 µg on the sensory discharge.

These experiments show potent effects of neuropeptides on the basal and evoked chemosensory discharge. The physiological meaning of these observations is still uncertain although peptides may have an important role in chemoreception. SP occurs in the carotid body (presumably afferent) nerves while ME has been found in the carotid body (presumably the glomus or type I) cells. If peptides are released at rest and/or during stimulation, they may interact with the better known putative neurotransmitters (ACh and DA) which are released under those circumstances. Supported by grants NS 05666 and NS 07938 from the U.S. Public Health Service.

91.2 TASTE RESPONSES TO ELECTROLYTES IN ORDINARY WATER AND DEUTERIUM OXIDE. Inglis J. Miller, Jr., Dept of Anatomy Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103

Solutions of deuterium oxide (D_2O) elicit larger taste responses from rat chorda tympani nerves than corresponding solutions of ordinary water (H_2O). The study of this effect has been extended to the hamster and to a wider variety of cations and anions than in a prior report. Stimuli consisted of cations Na, Li, K, Mg and Ca with anions Cl, acetate (Ac) and benzoate (Bz) in concentrations from .03 m to 1.0 m. Summated responses from the entire chorda tympani nerves were compared during the tonic phase of a 20 sec stimulation period followed for 40 sec by an inter-stimulus rinse period. Animals were male Sprague-Dawley rats weighing 250 gm and golden hamsters weighing 125 gm. Responses to pure D_2O applied to an H_2O-adapted tongue ranged from .15 to .3 (re: 0.1 m NaCl in H_2O) in both rats and hamsters. Responses to all salts were greater for solutions in D_2O at concentrations below 0.1 m than corresponding solutions in H_2O, while at higher concentrations the responses to H_2O were greater than D_2O. The disparity between D_2O and H_2O responses was greater for potassium salts and divalent cations, Mg and Ca, than for Na and Li salts in the hamster. Suppression of the background activity produced by lower concentrations of KCl and KBz was diminished or absent in the hamster. In the rat, low concentrations of K, Ca and Mg salts in D_2O elicited larger responses than in H_2O. Rinsing KBz from the tongue with H_2O elicited responses with H_2O and D_2O as the stimulus solvent. No adequate explanation for the disparate effects of H_2O and D_2O can be demonstrated currently. It is speculated that D_2O may be sequestered differently than H_2O in the receptor phase of the taste cell membrane. An altered interaction between electrolyte stimuli and the receptor membrane may be sufficiently different in D_2O than in H_2O to enhance the response to low concentrations of stimuli and diminish the response to higher concentrations. (Supported in part by NIH Grant NS 10389).

91.3 MODIFICATION OF STIMULUS-RECEPTOR INTERACTIONS IN OLFACTORY RECEPTOR NEURONS BY ASCORBATE AND GLUTAMATE. N.S. Nadi* and T.V. Getchell, Morin Memorial Lab., Dept. Anatomy, Wayne State Univ. School of Medicine, Detroit, MI 48201.

The bipolar olfactory receptor neuron is readily accessible to electrophysiological and biochemical probes. The properties of molecular receptor and axonal membranes were investigated in the olfactory epithelium of the tiger salamander. The characteristics of the receptor membrane were studied by recording unitary spike potentials in response to orthodromic stimulation with odors in the vapour phase. The mechanisms of impulse initiation and transmission were studied by recording unitary spike and compound olfactory nerve (CONP) potentials in response to electrical stimulation. Several compounds were chosen to characterize the functional properties of each type of membrane. Their effects were studied by applying µl quantities in solution to the epithelial surface. The peak to peak amplitude of the CONP was reduced 40% by ethanol (ET, 0.5M), n-butanol (B, 0.5M), ethyl-n-butyrate (ENB, 0.5M), N-ethylmaleimide (NEM, 0.05M). Ascorbate (ASC, 0.5M), glutamate (GLU, 5mM) and carnosine (CAR, 5mM) had no effect on the CONP or the antidromically driven single units (su). At concentrations higher than 10mM ASC blocked su responses evoked by phenyl ethyl alcohol (PEA), benzaldehyde (BAL) and benzyl acetate (BAC). This was presumably due to an interaction of ASC with molecular receptor sites. At concentrations greater than 0.1mM GLU caused facilitation of the response to odor stimulation. Facilitation consisted of a decreased response latency, increased firing frequency and a prolonged response duration. In contrast, treatment with ET (0.5M) and NEM (0.05M) resulted in a decrease in the excitatory response parameters and an increased response latency. The observations with NEM suggest that both the molecular receptor and the axonal membranes may rely on sulfhydryl groups for proper function. B and ENB in solution as well as CAR had no effect on su responses elicited by PEA, BAL and BAC. The results indicate that B, ENB, NEM, and ET effect both the receptor and axonal membranes. CAR, a dipeptide found in the olfactory receptor neurons had no effect on the CONP or the odor-evoked responses. GLU caused facilitation of response to odors which may be due to a nonspecific depolarization of the neuronal membrane resulting in a decrease of its threshold to odor stimulation. Alternatively, the GLU effect could be due to its interaction with a receptor site. These two hypotheses are currently being investigated. Previously reported experiments have shown that ASC reduces the binding of neurotransmitters to membrane preparations from the brain. In agreement with these results we have shown that ASC modifies the molecular interaction of odors with receptor sites on olfactory receptor neurons. Supported by NSF-BNS-7912601.

91.4 OLFACTORY RECEPTORS RESPOND TO ODORANTS INJECTED INTO THE BLOODSTREAM. J.A. Maruniak*, W.L. Silver, and D.G. Moulton. V.A. Medical Center and Department of Physiology, School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania 19104.

When human subjects receive odorant injections intravascularly they report an odorous sensation. How these odorants reach the receptors (either exhaled from the lungs or more directly) has long been a matter of controversy. To clarify this question and investigate the phenomenon further, we recorded pigeon olfactory nerve twig responses to both intravascularly (IV) and intranasally (IN) delivered odorants. IN odorants were generated in an air dilution olfactometer and delivered by a teflon tube inserted into the bird's external nares. Odorous solutions were injected into the arterial blood supply through cannulas in either the internal or external carotids. To stimulate IV, we injected 0.3ml of odorant in saline solution or a saline control over a 3 sec period.

IV injection of an odorant, but not the saline control elicited olfactory nerve twig responses. These responses were similar to those obtained from vapor phase stimulation, exhibiting an initial phasic component followed by a decline to a steady state tonic level. The response to IV stimulation did not arise from odor diffusing from the lungs into exhaled air since tracheotomized birds also exhibited the response. The IV response magnitude was concentration dependent, increasing with increasing odorant concentration. The highest concentrations of odorants used were determined by the solubilities of the compounds in saline. Odorants delivered IV for prolonged periods in high concentrations did not completely adapt the receptors since concurrently delivered IN odorants always produced strong responses. When the olfactory receptors were adapted to an IN delivered saturated odorant, no response to the same odor could be obtained by concurrent IV stimulation. However, IV stimulation with a dissimilar odorant did produce a response. This suggests that odors delivered IV can be discriminated and that the response is odorant specific. It is also established that the odorants do not reach receptors in exhaled air. Otherwise, it is not clear how IV delivered odorants reach the receptor sites or by what mechanisms they stimulate. What does emerge, however, is that the magnitude of the IV response approaches that of IN responses to odorants. This indicates the need for further research to determine whether such effects can lead to alterations in olfactory sensitivity following food intake or in certain disease conditions. (Supported by NIH grants HD 05547 and NS 10617.)

91.5 TRANSDUCTION PROCESSES IN REGENERATING OLFACTORY EPITHELIUM. Gloria D. Adamek*, Robert G. Mair* and Robert C. Gesteland, Northwestern University. Evanston, IL 60201.

Frog olfactory receptors bear different types of cilia which appear to be related to the age of the cell. Wigglers are 10 to 20 µm long, move rapidly and can bend in more than one plane. Strokers are 15 to 50 µm long, move more slowly than wigglers and move only in one plane. Streamers are 30 to 180 µm long and are immotile. Treatment with 0.5% Triton X-100 removes all cilia. At 8 hours after treatment, the olfactory epithelium is covered with short, immotile cilia, 3 to 16 µm long. All three cilia types can be distinguished at 16 hours. Strokers (10 to 30 µm) and wigglers (8 to 12 µm) approximate their normal lengths. Streamers continue growing from 14 to 34 µm at 16 hours post-treatment to 50 to 180 µm by 9 days post-treatment. Perfusion of frog olfactory sac with 3% $ZnSO_4 \cdot 7H_2O$ causes degeneration of the entire olfactory epithelium. Sparsely occurring motile cilia are first apparent 12 days post-treatment. By 16 days post-treatment, the epithelium is more densely covered with wigglers (8 to 16 µm) and strokers (16 to 18 µm). Sparse streamers (30 to 40 µm) are visible 27 days post-treatment. Streamers become more numerous and their length increases to 60 to 140 µm by day 45. The orderly regrowth of cilia following these treatments provides a means to isolate cilia types for electrphysiological study. EOG studies show that electrical excitability returns to near normal levels by 16 hours after detergent treatment. Activity of single units immediately after deciliation is abnormal, a brief burst of regular, 0.2 second interval action potentials interspersed between long (ca 1 minute) silent periods, or single, constant-interval continuous firing. Normal unit activity is also restored withing 16 hours. We have previously shown that receptor selectivity is different at different stages of development. We conclude that the proximal portions of the cilia are the site of olfactory reception and transduction and that the receptor neurons elaborate ciliary membranes with different properties at various stages of development.

This work was supported in part by NSF Grant No. BNS 78-17479 and NIH Grant Nos. NS 14663 and 1-F32-NS06070.

91.6 ODORANT SPECIFIC MAPS OF RELATIVE SENSITIVITY INHERENT IN THE SALAMANDER OLFACTORY EPITHELIUM. Alan Mackay-Sim* and David G. Moulton. Dept. of Physiology, Univ. of Penn. and V.A. Med. Ctr. Philadelphia, PA, 19104.

When patterning due to sorptive effects is eliminated the anterior and posterior regions of the salamander olfactory epithelium still show differential sensitivity to some odorants (Kubie and Moulton, Soc. Neurosci. Abstr., Vol. 5, p. 129, 1979). We have undertaken a more detailed mapping to elucidate the resolving power of inherent spatial patterning. Electro-olfactograms (EOGs) were recorded at different points on the epithelium after punctate odorant stimulation at the electrode tip. We directly compared relative sensitivity to different odorants, by measuring EOGs at 30 points across the ventral olfactory mucosa. At each of these points amplitudes of at least 3 EOGs were measured in response to 1s pulses of each of two odorants. Maps for each odorant pair were made of epithelia from at least 8 animals. These maps reveal differential sensitivity across the epithelium that is more complicated than simple anterior/posterior differences. For example, the maps for pinene and limonene, both generally posterior stimulators, also reveal smaller areas ($\frac{1}{2}$-$1mm^2$) with extremely high sensitivity. At present though, no differences in the distribution of sensitivity to pinene and limonene can be detected. In contrast, the distributions of sensitivity to eugenol and isoeugenol can be clearly distinguished. In addition to a distinct separation of the points of maximal sensitivity to each of these odorants (often 2mm apart), the epithelium can be divided into a postero-lateral segment (1/4-1/3 of the ventral olfactory epithelium) which is absolutely more sensitive to eugenol, and the rest, which is absolutely more sensitive to isoeugenol. Sensitivity maps for other odorants (propanol, butanol, decanol, heptaldehyde) reveal areas on each epithelium that are highly sensitive to these compounds. The locations of these areas are more variable, but distinct from the area most responsive to pinene and limonene. The map of sensitivity to amyl acetate reveals a distinct ridge of high sensitivity commonly stretching anteriorly for about 2mm from the posteriorly located pinene or limonene sensitive area. We conclude that there exist regions of enhanced sensitivity specific for different odorants. The variations in the shapes and positions of these regions indicate that the olfactory epithelium may have a well developed capacity to discriminate among odorants on a topographic basis.

91.7 POSTNATAL DEVELOPMENT OF RAT OLFACTORY BULB NEURONS. Robert G. Mair* and Randy L. Gellman* (Spon: C. Enroth-Cugell). Dept. Biol. Sci. Northwestern University, Evanston, IL 60201.

Mammalian olfactory bulbs contain several distinct classes of interneurons, at least two of which (periglomerular and granule cells) make direct synapic contacts onto mitral and tufted cells. The complexity of synaptic connections within mature olfactory bulbs makes if difficult to determine the effects of interneurons on the response properties of mitral and tufted cells. Autoradiographic studies of histrogenesis in the bulb reveal that whereas the full complement of mitral and tufted cells are present at birth, most interneurons develop postnatally. Likewise, electronmicroscopic studies have suggested that synapses between receptor axons and second order neurons are more precocious than those formed by interneurons. This study describes the development of different types of interneurons and compares some response properties of olfactory bulb neurons in adult & neonatal rats. Material for anatomical study was obtained from two day postnatal (P2), P2, P15, P29 and adult rats and processed for cresyl and golgi staining. Examinationof cresyl stained material shows that the mitral cell body layer occupies a relatively large proportion of the olfactory bulb in P2 rats. The relative volumes of the external plexiform layer, the internal plexiform layer, and the granule cell layer increase dramatically by P15. With golgi impregnation we see all cell types apparent in the adult bulb by P15. In accordance with the previously cited evidence, at P2 few cell types are present, the population consisting mainly of mature and immature mitral cells and a few immature interneurons. Single unit electrophysiological studies demonstrate that the P2 rat is a useful preparation for describing response properties of mitral and tufted cells in isolation of many interneural influences.

91.8 DISTRIBUTION OF LABEL IN THE HAMSTER MAIN AND ACCESSORY OLFACTORY BULB AFTER INTRANASAL ADMINISTRATION OF [3H]ß-ALANINE. Gail D. Burd, Barry J. Davis, Foteos Macrides, and Frank L. Margolis. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545 and Roche Institute of Molecular Biology, Nutley, NJ 07110.

Biochemical studies have shown that labeled ß-alanine, when administered to the nasal cavity, is specifically incorporated into carnosine, and this labeled dipeptide is transported to the olfactory bulb. The purpose of the present investigation was to visualize the distribution of radioactive label in the olfactory (OE) and vomeronasal (VE) epithelia and main (MOB) and accessory (AOB) olfactory bulbs after intranasal administration of [3H]ß-alanine.

Hamsters were anesthetized with Nembutal and also given 0.2 cc epinephrine I.P. to facilitate movement of fluids into the vomeronasal organ. Anesthetized hamsters received unilateral intranasal administration of purified [3H]ß-alanine (83 µCi in 50 µl). After survivals of 6 hrs, 24 hrs, or 4 days, the animals were perfused with 1% paraformaldehyde and 1% glutaraldehyde. The olfactory bulbs and decalcified nasal cavities were embedded in paraffin and processed for autoradiography.

On the side of intranasal administration, both the OE and VE were intensely labeled at 6 hrs. Label was associated with sensory and nonsensory epithelia, bundles of axons, and the lamina propria. The overall labeling of these tissues was reduced at 24 hrs and 4 days with most of the remaining labeling confined to bundles of axons. The primary nerve layer and glomeruli of the MOB and AOB were labeled at the three survival times examined. However, unlike the periphery, the most intense labeling in the MOB and AOB was observed at 24 hrs after intranasal [3H] ß-alanine administration. Less intense labeling of these areas was present after 6 hrs and 4 days. Medial portions of the contralateral nasal cavity and olfactory bulb were also labeled, but with less intensity than the ipsilateral side. The contralateral labeling was due to movement of fluids from the side of administration through the septal window of the nasal cavity.

The present results are consistent with the interpretation that carnosine is transported to the olfactory bulb in the primary afferent fibers. The similar pattern and time course of labeling in the main and accessory olfactory systems suggest that these two systems have similar transport mechanisms for carnosine.

91.9 DISTRIBUTION OF MET-ENKEPHALIN, SUBSTANCE P AND SOMATOSTATIN IMMUNOREACTIVE NEURONS IN THE MAIN OLFACTORY BULB IN THE HAMSTER. Barry J. Davis, Gail D. Burd and Foteos Macrides. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545

The unlabelled antibody peroxidase method (PAP) was used to study the locations of met-enkephalin (MET), substance P (SP) and somatostatin (SS) immunoreactive neurons in the laminae of the main olfactory bulb (MOB) in the hamster. The animals were anesthetized with Nembutal and perfused with a 2% paraformaldehyde - saturated picric acid fixative. The brains were cut on a Vibratome and sections were incubated freely floating in the primary antiserum (1:200) for 24 - 48 hrs. The size and distributions of immunoreactive neurons were compared to those of neurons in Golgi-impregnated material.

MET immunoreactive somata and dendrites were observed in all layers of the MOB. These MET somata were mostly ovoid in shape and had minor and major diameters which averaged 7 and 10 microns, respectively. Intense staining of MET somata and dendrites was observed in the periglomerular region (PGR) of the MOB. These somata outlined the glomeruli, and dendritic arborizations extended into the individual glomeruli. The location and size of these MET somata correspond with those of periglomerular cells in the Golgi material. Less numerous and more lightly stained MET somata and dendrites of the same size as the cells in the PGR were observed in the granule cell (GCL), internal plexiform, and mitral body layers. These MET somata are comparable in distribution and size to granule cells. Isolated MET somata were also observed in the external plexiform layer (EPL).

SP immunoreactive somata and dendrites were also present in the PGR. SP somata were both fusiform and ovoid in shape and had minor and major diameters which averaged 11 and 13 microns, respectively. SP somata were restricted to the PGR and these somata appeared more numerous in the deep aspect of the PGR near the EPL. The location and size of these SP somata are similar to those of superficial short axon and external tufted cells in the Golgi material.

Isolated SS immunoreactive somata were observed in the deep aspect of the GCL near the ventricle. These SS somata were well-defined, primarily ovoid in shape and had minor and major diameters which averaged 11 and 13 microns, respectively. The SS somata are larger than the somata of granule cells and correspond in size with the somata of deep short axon cells in the Golgi material.

These results suggest that the three neuropeptides are associated with different classes of neurons in the MOB.

91.10 CHEMICAL SENSES INVOLVED IN GARTER SNAKE AGGREGATION AND SHELTER SELECTION. Steven B. Heller* and Mimi Halpern, Prog. Biol. Psychol. and Dept. Anat. Cell Biol. Downstate Medical Center, S.U.N.Y., Brooklyn, N.Y. 11203.

Recent studies have demonstrated the importance of the garter snake's vomeronasal (VN) system in prey extract trailing, prey attack and male courtship behavior. The present study investigates the relative contribution of the VN and main olfactory systems in aggregation and shelter selection by garter snakes.

Initial studies demonstrated that when groups of garter snakes are tested repeatedly in aquaria that are left uncleaned between trials, the snakes predictably return to certain (preferred) shelters and not to others. Following group testing, snakes tested individually in the same aquaria return to previously preferred shelters. Cues used by snakes in returning to preferred shelters appear to be chemicals deposited by the snakes on the substrate underlying the preferred shelter.

Snakes with VN nerve lesions or VN duct sutures (which prevent chemical access to the VN organ) do not return to previously preferred shelters when tested individually. However, when tested with a group that includes "control" animals, they return to the previously preferred shelters. The behavior of animals with olfactory nerve lesions, sham lesions or sham duct sutures is indistinguishable from preoperative levels when these animals are tested individually or in groups. Animals that fail to go to previously preferred shelters when duct sutures are in place, return to preoperative levels of performance when their sutures are removed.

Normal snakes tested in aquaria in which the substrate and other contents are cleaned between trials make shelter choices that are random with respect to position, but they select shelters occupied by a number of other snakes more often than would be expected by chance. This tendency for group aggregation is unaffected by blindfolding, olfactory nerve cuts or combined visual and olfactory deprivation. When the snakes' VN ducts are sutured closed, however, they fail to aggregate; following removal of the sutures they resume aggregating.

These studies strongly suggest that use of chemical signals by garter snakes in shelter selection and aggregation is mediated by the VN system and that neither the olfactory nor the visual system is critical for these behaviors.

91.11 BLOOD SUGAR LEVELS AFFECT TASTE RESPONSES IN THE RAT NUCLEUS TRACTUS SOLITARIUS. Barbara K. Giza* and Thomas R. Scott. Dep't. Psychol. and Inst. for Neurosci. and Behav., U. Delaware, Newark, DE. 19711.

Subjective experience tells us that taste perceptions change with levels of satiety. Glenn and Erickson reported a neural counterpart to this experience: stomach distension caused a decrease in afferent activity in the rat's NTS. We studied the effect of blood sugar levels on NTS responses to the four basic taste qualities. Subjects were 32 undeprived female albino rats, divided into equal sized experimental and control groups. We intubated each subject in both the jugular and femoral veins for the injection of solutions and retrieval of blood samples, respectively. We inserted etched tungsten semi-micro electrodes (tip length = 20-30 mμ) into the NTS until we encountered robust gustatory activity evoked by chemical stimulation of the tongue. Stimuli were 1.0 M glucose, 0.1 M NaCl, 0.03 M HCl and 0.01 M QHCl. In each case we flowed 18 ml of solution over the tongue in 4 sec and followed that with a 30 sec DH_2O rinse and a rest period of 50 sec. We applied each stimulus four times over a 25-min period which served to monitor the stability of our recording and to establish a pre-injection response level. We regularly took small blood samples throughout this and the succeeding periods. At time T=0 we injected either 500 mg/kg glucose (1.25 ml/kg of a 40% glucose solution) or an equivalent volume of isotonic saline into the jugular vein and continued to monitor blood sugar levels and taste activity for the next 60 min. Blood glucose concentration increased in experimental animals from approximately 90 mg% pre-injection to a peak of 220 mg% at 12 min, after which it declined to almost pre-injection levels over 60 min. Controls showed no major changes in blood sugar. Integrated multiunit activity evoked by glucose declined in experimentals relative to pre-injection and control levels ($t = 2.41$; $p < .05$), reaching a nadir at 12-15 min and recovering gradually over 60 min to form a mirror image of the blood glucose curve. NaCl and HCl responses in experimentals each showed only insigificant decreases relative to their controls ($t = 0.65$; $p > 0.2$) and QHCl showed no change. Additional control animals from whom we recorded touch-evoked responses from adjacent trigeminal nuclei showed no changes with blood glucose levels. The mechanism which causes taste activity to be sensitive to blood sugar levels could be peripheral (an adaptation effect) or central. Hypothesized central mechanisms include direct inhibition of NTS, or descending inhibition imposed by forebrain feeding areas.

91.12 PREFERENCES FOR NONSEXUAL ODORS ARE INFLUENCED BY TESTOSTERONE IN HAMSTERS. Catherine A. Cornwell-Jones and Kathryn Kovanic*, Dept. of Psychology, Princeton University, Princeton, NJ 08544.

Aversion to novel odors declines with age in male hamsters (Cornwell-Jones, J. Comp. Physiol., Psych., 93). The present experiments examined the possibility that increases with age in testosterone might mediate the decrease in olfactory neophobia.

A first experiment compared the effects on olfactory neophobia of castrating juvenile vs. adult male hamsters to test the prediction that castration effects on preferences increase with age as testosterone levels rise in intact males. Male hamsters reared in pine shavings were castrated either as juveniles or adults. Sham operated males served as controls at both developmental stages. After a postsurgical recovery period of 7-10 days, animals were tested in a two-choice situation allowing them to smell but not taste or touch shavings in two compartments below a screen floor.

Adult castrates preferred the odor of familiar pine shavings to unfamiliar cedar odor, while adult sham operates showed no preference. Juveniles in both treatment groups tended to prefer pine to cedar odor. The results were consistent with the hypothesis that age-dependent increases in testosterone reduce olfactory neophobia.

A second experiment examined the effects of testosterone replacement on olfactory neophobia in castrated adult male hamsters. Pine-reared males were either sham operated or castrated. Castrates were then implanted with constant timed-release capsules of silastic tubing containing either no testosterone (T) a dose estimated to produce subnormal plasma T levels, or a dose estimated to produce physiologically normal T levels. These animals were tested on fresh cedar vs. fresh pine, and on the odor of cedar-nest in which a female had been housed vs. pine.

Castration reduced the time spent investigating both fresh cedar and cedar-nest, while the larger but not the smaller dose of testosterone restored investigation of both odors to the level of sham operates. Sham-operated animals and those treated with the higher testosterone dose, showed no preference between the fresh odors, and showed statistically similar preference for female cedar-nest odor vs. pine. In contrast, castrates receiving either no testosterone or the smaller dose, preferred pine to either cedar odor.

These data imply that testosterone dampens neophobic responses to nonsexual odors by male hamsters. Hamsters do not appear to live in social groups in the wild. High endogenous testosterone levels may help insure that novel aversive odors do not interfer with a male hamster as he searches for a female mate in unfamiliar olfactory territory.

92.1 UNMYELINATED AXONS IN THE DORSAL WHITE COLUMN. Lauren A. Langford and Richard E. Coggeshall. Depts. of Anatomy and of Physiology and Biophysics and the Marine Biomedical Institute. The University of Texas Medical Branch, Galveston, Texas 77550.

According to classical studies, the dorsal white column in the spinal cord consists of myelinated primary afferent fibers, many of which pass cranially to end in nuclei in the medulla oblongata. These fibers give rise to collaterals which enter the gray matter. Descending primary afferent fibers have also been described. The classical studies were done with light microscopy, however, and thus these conclusions are restricted to myelinated fibers since unmyelinated axons are beyond the resolution of the light microscope.

In the study we used the electron microscope to count both myelinated and unmyelinated axons in the normal S3-S4 rat dorsal white columns. Fixation was improved by the addition of potassium ferricyanide to the osmic acid postfixation. The axonal counts are listed in the table below. Before proceeding, however, it should be noted that the corticospinal tract can be distinguished from the dorsal column proper because it lies in the ventro-medial area of the dorsal white column and its myelinated axons are much smaller than in other parts of the dorsal white column. These 2 areas are:

		DORSAL COLUMN PROPER		CORTICOSPINAL TRACT		DORSAL COLUMN TOTAL	
RAT	SEG	MY	UN	MY	UN	MY	UN
1	S3	3654	4338	1695	2880	5299	7218
2	S3	3818	5214	1568	2794	5386	8008
3	S4	2162	4702	1035	3451	3197	8153
Avg.		3211	4751	1433	3042	4627	7793

In conclusion we have found that the ratio of unmyelinated to myelinated axons in the dorsal white column is approximately 1.5 to 1. Selective surgical procedures will be done to determine the origins and destinations of these unmyelinated axons in the posterior white columns. Supported by grants NS 10161, NS 11255 and NS 07377.

92.2 PAIN AND DORSAL RAPHE INPUTS TO THE PARAFASCICULARIS NUCLEUS OF THE RAT E. Andersen, B.M. Rigor and N. Dafny Depts. of Neurobiology and Anatomy and Anesthesiology, Univ. of Texas Health Science Center, Houston TX 77025.

The raphe nuclei have been implicated in an endogenous descending mechanism of pain control which suppresses pain perception at the spinal cord level. The dorsal raphe nucleus (DR) also has extensive projections to forebrain structures, including the parafascicularis nucleus of the thalamus (PF), an area which has been shown to be responsive to noxious stimuli. The present study was initiated to test the hypothesis that the DR is involved in an ascending pain modulation system.

Male Sprague Dawley rats were anesthetised with urethane and placed in a stereotaxic instrument. Bipolar concentric stimulation electrodes were lowered into the DR according to the atlas of Konig and Klippel (AP=0 L=0 H=-1). The DR was stimulated with monophasic square wave pulses (.2msec width, .1-1mA) at various frequencies. Glass micropipettes were filled with 4M NaCl saturated with fast green and lowered into the PF (AP=3.3mm L=1.0 H=0) for single unit recordings. A period of baseline firing of spontaneously active cells was recorded for 10 min. Each cell was then given four stimulation treatments: noxious tail pinch, DR electrical stimulation at 1 cycle/sec (c/s), DR stimulation at 20c/s, and both DR at 20c/s and tail pinch together. Each stimulation period lasted 2 minutes and was followed by a 2-4 min recovery period. At the end of the experiment, the animals were sacrificed, perfused with 10% formalin, and electrode sites were histologically verified. Fifty cells were analysed.

Tail pinch was found to cause an increase in the firing rate of 83% of the PF cells, a decrease in 9% and no change in 8%. DR stimulation at 1c/s caused a change in firing patterns in only 26% of the PF cells. Total number of spikes increased in 8%, decreased in another 8% and a period of inhibition lasting 20-30 msec after each stimulus pulse was seen in 10% of the cells. In contrast DR stimulation at 20c/s caused changes in 85% of the PF cells tested: 50% decreased and 35% increased firing rates. The changes usually outlasted the period of stimulation for several seconds. When DR stimulation at 20 c/s was combined with tail pinch, tail pinch did not cause the increase in firing rates as it would without the DR stimulation.

In conclusion, tail pinch causes an increase in the firing rates of PF cells in the rat, DR stimulation at 1 c/s causes only minor changes, and DR stimulation at 20c/s causes significant changes in PF firing rates. DR stimulation at 20c/s also inhibits the response of PF cells to tail pinch. It is suggested that the DR causes pain modulation in the PF.

Supported by NIH grant DA00803-04A1.

92.3 MEDIAL THALAMIC RESPONSE TO NOXIOUS INPUTS: INHIBITORY INTERACTIONS WITH LATERAL THALAMIC STIMULATION. A.L. Benabid*, S.J. Henriksen, J.F. McGinty, F.E. Bloom (SPON: E. Battenberg). A.V. Davis Ctr. for Behav. Neurobiology, The Salk Institute, La Jolla, 92037.

Neuronal interactions in the thalamus between sensory (specific) and noxious (non specific) inputs were investigated by analyzing the response in nucleus parafascicularis (PF) to subcutaneous electrical noxious stimulation (NS) of the limbs, with and without ventro-postero-lateral nucleus (VPL) thalamic stimulation. Extracellular recordings in chloral hydrate anesthetized rats were accomplished with either glass micropipettes (in PF), or 25 μ stainless steel electrodes (in VPL; also used for stimulation). The latter method provided information on VPL multiple unit activity and simultaneously directed the stimulating electrode placement. Computer generated post-stimulus time histograms demonstrated that, in the absence of VPL stimulation, PF cells respond to NS with peaks corresponding to A, Aδ and C fiber inputs or by inhibition of spontaneous activity. The multiunits recorded in VPL following NS consistently exhibited a response to A, Aδ and C inputs; in addition, a "M-like" histogram pattern, (as defined by Emmers (1) in the S-2 area of VPL) was also observed in S-1. Single or triple pulse stimulation of VPL without NS frequently elicited a response in PF cells with a latency from 50 to 250 msec. For the majority of PF cells, train stimulation of VPL induced a strong alteration in the post stimulus time histogram elicited by NS, ranging from the disappearance of one peak (A, A or C fibers response) to, more often, a complete and long-lasting (>500 msec) inhibition of the PF cells activity. This inhibition was positively correlated with the VPL stimulation parameters. Medial thalamic cells responsive to NS but not in PF were differentially influenced by VPL stimulation, depending on their anatomical location. The long lasting inhibition of PF cells by VPL train stimulation suggests the existence of a lateral to medial thalamic mechanism modulating pain. The intrathalamic connection between medial and lateral thalamus is supported by the time-locked response of PF cells to VPL single shocks. The possible chemical and anatomical basis underlying this VPL stimulation-induced PF inhibition are under investigation. 1) EMMERS, R.: J. Comp. Neur., 1965, 124, 215-228. Supported by DA 01785 and a NATO fellowship to A.L.B.

92.4 RESPONSE OF PRIMATE SI CORTICAL NEURONS TO NOXIOUS STIMULI. D. R. Kenshalo, Jr. and O. Isensee*. Division of Neurobiology, Barrow Neurological Inst., Phoenix, AZ 85013.

Previous results indicated that many neurons in VPLc responsive to noxious stimuli project to SI cortex. To study the possibility that SI neurons receive nociceptive information, we recorded from single cortical neurons in the Java Monkey (Macaca fascicularis). The animals were anesthetized with α-chlorolose and maintained with supplements of sodium pentobarbital. Single units were isolated using tungsten microelectrodes and in 5 cases the position of the electrode was marked with an electrolytic lesion. The cutaneous receptive field was tested with innocuous and noxious stimuli. Innocuous stimuli included hair movement, light tough and joint rotation. Noxious stimuli applied to the skin included pinching and noxious heat pulses (from 35° adapting temperature to 43, 45, 47, 50, 53 and 55°C)

To date 20 cortical neurons have been sampled that responded to noxious stimuli. Of these 13 were classified as having a wide dynamic range receptive field (responded to both innocuous and noxious stimuli) and 7 were classified as having a narrow dynamic range high threshold receptive field (responded to noxious stimuli). Cortical cells responsive to noxious stimuli exhibited a progressive increase in the discharge rate as the intensity of a mechanical stimulus increased. The threshold for initiation of activity during an ascending series of noxious heat pulses was near a mean of 50°C. The threshold for cortical neurons is higher than that reported for either spinothalamic tract or thalamic neurons. The increase in the thermal threshold may be due to anesthesia. Reconstruction from electrolytic lesions for 5 cells indicated that the neurons responsive to noxious stimuli were located in area 1.

From these data, we speculate that neurons in SI receive nociceptive information and thereby play a role in the processing of this information.

92.5 CORRELATIONAL ANALYSIS OF HYPERALGESIA IN HUMANS WITH RESPONSES OF NOCICEPTIVE PRIMARY AFFERENTS IN THE MONKEY. J.N. Campbell, R.A. Meyer*, and S.M. Lancellotta*, Dept. Neurosurgery, Appl. Physics Lab., The Johns Hopkins Univ., Baltimore, Md. 21205

Thermal injury to the skin induces hyperalgesia in man and increases the response of certain nociceptive primary afferents in monkey. Previous investigators have described an increased response (i.e., sensitization) in C-fiber polymodal nociceptive afferents (CPNs) that innervate the hairy skin of the monkey following a thermal injury. We demonstrate here that in the glabrous skin of the hand hyperalgesia resulting from a 53°C thermal injury correlates better with activity in A-fiber nociceptive afferents, sensitive to mechanical and heat stimuli (AMHs), than with activity in CPNs. The responses of AMHs and CPNs to noxious radiant heat before and after thermal injury to their receptive fields were compared with estimates of the magnitude of pain by human observers given the same stimuli. An infrared laser under radiometer feedback control provided a step increase in skin temperature over a 7.5 mm diameter spot with rise rates greater than 30°C/s. Using standard methods of single fiber recording in monkeys, we studied the changes in the response properties of 18 CPNs and 41 AMHs after injury to the skin caused by a 53°C stimulus of 3 to 30s duration. The changes in response were similar in all cases though more pronounced after the 30s, 53°C stimulus. In 7 CPNs, 8 AMHs, and 5 experiments with 3 human subjects, we measured the response to thermal stimuli before and at varying times after an injury induced by a 53°C, 30s stimulus using a random sequence of stimuli (3s duration, delivered every 30s) ranging from 41° to 49°C. Stimuli below 45°C failed to elicit pain prior to the thermal injury. However, 10 minutes after the injury, even the initial 38°C base temperature evoked pain. Also, all stimuli from 41 to 49°C were quite painful, and the 42°C stimulus was judged more painful than the 49°C stimulus prior to the injury. The 49°C stimulus after injury induced 5.5 times more pain than it did before injury. Before the injury, 63% of the AMHs failed to respond to 49°C and none responded to stimuli below 44°C. After injury, 63% responded to the initial 38°C base. The mean response to 49°C was 110 impulses compared to 12 impulses prior to injury. The mean threshold of CPNs was 44.1°C prior to the injury and 45.2°C after injury. The response to 49°C decreased from a mean of 15.3 (±2.7 S.E.M.) impulses before injury to 6.6 (±1.8) impulses after injury. These results suggest that activity in the AMHs and not the CPNs is responsible for the hyperalgesia that occurs after a 53°C, 30s thermal injury to the glabrous skin of the hand.

92.6 DETECTION THRESHOLD AS AN OBJECTIVE INDICATOR OF SENSITIVITY TO THERMAL PAIN IN NORMAL AND HYPERALGESIC SKIN IN HUMANS. C.J. Robinson, R.H. LaMotte, J.G. Thalhammer* and H.E. Torebjörk*. Dept. of Anesthesiology, Yale University Sch. of Med., New Haven, CT 06510.

We have found that the capacity of human observers to discriminate differences in painful heat stimuli is preserved at the expense of the capacity to make judgments of the absolute magnitude of a painful stimulus temperature. As a possible consequence of this, human observers appear to have a remarkably precise and accurate capacity to detect very small increments in temperature superimposed upon base temperatures that are continuously rated as painful.

Five human subjects, each of whom gave informed consent to an approved protocol, made continuous ratings of the magnitude of pain sensations evoked by brief temperature increments superimposed on a base temperature maintained either at 38°C or 47°C. Stimulus increments were also delivered on a 38°C base to skin made hypo- or hyperalgesic. Subjects additionally made forced choices as to which of two paired intervals of time contained each increment (regardless of whether or not it was painful). Detection threshold (DT) was the minimum increment in temperature detected on 75% of the trials in the forced choice task. Pain threshold (PT) was the minimum increment rated as painful, or as an increase in pain sensation on 50% of the trials.

For a 38°C base, perceived as warm but never painful in normal skin, DTs averaged 0.4° and PTs 5.0°C. In contrast, on a base of 47°, which was continuously rated as painful, DT and PT were each equal to 0.1°C or lower. Following a conditioning stimulus (CS) of 50°C and 20 sec duration the skin became hypoalgesic and thresholds elevated to 0.8° (DT) and 6-8° (PT). Following a longer 50° CS (100 sec.), the skin was hypoalgesic for up to 4 min., with DT and PT elevated to 1.2°C and 9°C, respectively; but by 10 min after this CS, the skin became hyperalgesic, and DT was lowered to 0.25° and PT to 0.5°C. A similar lowering of DTs and PTs were observed in skin made hyperalgesic by a topical application of 1% capsaicin (Sigma Chem. Corp.). Thus, in normal skin, the DT is lower for painful than for nonpainful base temperatures and may serve as an objective test of thermal pain sensitivity. Furthermore, following injury to the skin, a lowered DT is an objective indicator of the presence of hyperalgesia.

92.7 THE EFFECTS OF MORPHINE ON EXPERIMENTAL PAIN RESPONSE IN CHRONIC PAIN PATIENTS. Patricia J. Wolskee* and Richard H. Gracely* (SPON: Catherine Bushnell) Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205 USA.

Noxious thermal stimuli were delivered to 5 patients suffering from chronic low back pain to assess the effects of morphine on experimental pain responsivity. Forty-two noxious thermal stimuli ranging from 46-51°C were delivered via a contact thermode to the volar surface of the forearm of 5 chronic pain patients before and after the administration of morphine or saline placebo. Subjects assessed sensory intensity and unpleasantness of the stimuli by cross modality matching to handgrip force and by choosing verbal descriptors from randomized lists. The dose of morphine (mean = 12.2 mg) was determined individually to produce clinical pain relief without significant respiratory or cardiovascular depression. In comparison to placebo, morphine reduced verbal descriptor responses of sensory intensity ($t = 4.10$, $p < .01$) and unpleasantness ($t = 2.47$, $p < .05$). In contrast, handgrip measures of sensory intensity and unpleasantness were not significantly reduced by morphine in comparison to placebo.

Spatial variability of cutaneous thermal sensitivity was assessed in a preliminary study by randomly presenting 6 stimuli ranging in intensities from 46-51°C to each of 8 sites on the volar surface of the forearm. Three-sec duration stimuli were presented at 30 sec intervals to successive sites; each site received a stimulus at 240 sec intervals. Five subjects rated the sensory intensity of the stimuli by choosing verbal descriptors quantified previously. Statistical analysis (ANOVA) showed that there were no significant differences in thermal sensitivity between sites.

These results support a previous study with normal subjects showing that in comparison to placebo, fentanyl, a narcotic analgesic, significantly reduced sensory intensity responses to painful electrical toothpulp stimulation. Unlike the finding in the previous study with pain-free subjects, morphine also reduced unpleasantness. This result supports the hypothesis that the effect of a drug on perceived unpleasantness is dependent, in part, on the side effects experienced. After narcotic administration, pain-free subjects usually experience dysphoria and nausea, while chronic pain patients, in contrast, experience euphoria, warmth, and relaxation. These results further support the utility of the verbal descriptor method for assessment of different dimensions of the pain experience. Our findings also suggest that the verbal descriptor scaling of contact heat may provide an experimental model for the evaluation of pharmacological and non-pharmacological pain control methods.

92.8 DOES NALOXONE ALTER EXPERIMENTAL PAIN PERCEPTION? Richard H. Gracely*, William R. Deeter*, Patricia J. Wolskee* and Ronald Dubner. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

The influence of the narcotic naloxone on the perception of pain sensations evoked by electrical tooth pulp stimulation was assessed by pain-free volunteers experienced with cross-modality matching techniques. Forty-six subjects matched handgrip force to the intensity or unpleasantness of sensations produced by 42 stimuli before and after the random, double-blind, intravenous administration of either 10 mg naloxone or placebo (naloxone vehicle). The stimuli were 1-sec trains of 1-msec, monophasic, cathodal pulses delivered monopolarly at 100 Hz. Stimulus intensity varied in 7 equal-log steps between pain threshold and pain tolerance.

Mean handgrip responses to sensory intensity or unpleasantness were not significantly altered after either naloxone or placebo. However, a non-probabilistic index of discriminability based on analysis of variance and independent of mean response ($r = .06$) showed that handgrip responses matched to the intensity of the sensations were significantly more variable after naloxone in comparison to placebo ($t = 4.08$, $df = 20$, $p < .001$). The variability of unpleasantness responses also was increased by naloxone in comparison to placebo, but this effect was not statistically significant. The unpleasantness effect was significantly less than that observed for sensory intensity responses ($t = 3.27$, $df = 22$, $p < .01$).

These results show that naloxone did not change mean pain perception but that it did increase response variability. The negative effect with mean response is consistent with previous evidence that naloxone does not alter mean pain response to electrical, ischemic, or cold-pressor stimulation. The significant difference found between naloxone's effect on the variability of sensory intensity and unpleasantness responses suggests that verbal instructions to attend to either sensory intensity or unpleasantness can influence the outcome of cross-modality matches to painful experimental stimuli. The significant increase in the variability of sensory intensity responses produced by naloxone suggests that naloxone degrades psychophysical performance. This hypothesis is supported by observations that subjects receiving 10 mg of naloxone become restless, agitated and irritable. Thus, studies that use response measures based on sensory discriminability may show a naloxone-produced change in response that reflects reduced psychophysical performance and not a change in the magnitude of pain perception.

92.9 SELECTIVE DEPLETION OF SPINAL CORD MONOAMINES FAILS TO ALTER STIMULATION PRODUCED ANALGESIA (SPA). J.N. Johannessen*, L.R. Watkins*, & D.J. Mayer, Dept. of Physiology, Medical College of Va., Richmond, Va., 23298.

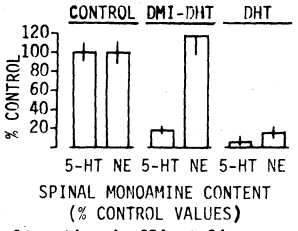
Striking parallels between SPA and morphine induced analgesia (MIA) have recently emerged. Both seem largely dependent on the integrity of central serotonergic (5-HT) systems and a descending inhibitory pathway within the spinal dorsolateral funiculus (DLF). Evidence suggests that monoamines may mediate this descending inhibitory control. Neurotoxins which destroy 5-HT terminals attenuate MIA. In addition, pCPA (a 5-HT synthesis inhibitor) reduces both SPA and MIA. To date, assessments of SPA or MIA after monoamine depletion have relied on systemic or ventricular drug injections - procedures which must necessarily affect supraspinal and spinal sites. Intrathecal (i.t.) administration of 5,7-dihydroxytryptamine (5,7-DHT) was therefore chosen to test the effect of spinal monoamine depletion on SPA.

Rats, implanted with stimulating electrodes in the dorsal raphe (DR) and with lumbosacral spinal catheters, were tested for SPA at one week intervals using the tailflick test. Results are given as % MPE (L. Grumbach, 1966). After two testing periods, rats received either i.t. saline (CONTROL), i.t. 5,7-DHT preceded by desipramine (DMI-DHT) or i.t. 5,7-DHT (DHT). In experiment 1, rats were tested 2 and 3 weeks post treatment. A second experiment tested rats at 24 hrs. to look for a transitory alteration in SPA. Spinal cords were assayed for 5-HT and norepinephrine (NE).

(Table 1)

	% MPE	CONTROL	DMI-DHT	DHT
EXP 1	PRE-	63±10	45±11	69±10
	POST-	64±11	65±11	44±12
EXP 2	PRE-	77±9	72±8	69±9
	POST-	76±9	52±17	69±15

(Figure 1)



Our results show no significant alteration in SPA at 24 hrs. or 2-3 weeks after treatment (table 1.). Chemical data (fig. 1) shows selective depletion of 5-HT or 5-HT and NE. These results suggest that the role of spinal monoamines in mediating SPA may be overemphasized. They are certainly not necessary for SPA. Supported by PHS Grant DA-00576.

92.10 ANALGESIC TOLERANCE TO CLONIDINE AND CROSS-TOLERANCE TO AUTOANALGESIA. William T. Chance. Department of Surgery, University of Cincinnati Medical Center, Cincinnati, Ohio 45267.

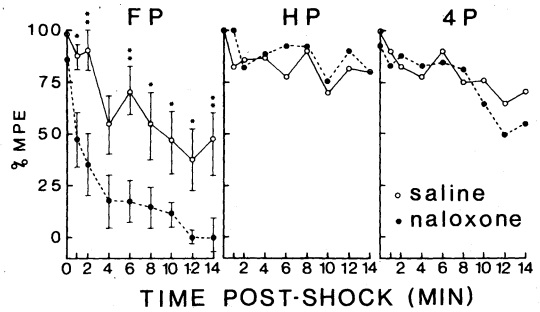
The antihypertensive drug, clonidine, has been reported to elicit analgesia across a wide variety of tests. Although this analgesic response appears to result from activation of descending inhibitory systems, it is not opioid in nature. In the present experiments, tolerance to clonidine-induced analgesia and cross-tolerance to autoanalgesia were investigated in adult, male, Sprague-Dawley rats. Analgesia was assessed using a radiant-heat tail-flick procedure with response latencies of approximately 3 sec in control rats and an 8 sec latency cut-off criterion. Initially, tail-flick latencies were determined prior to and 15, 30, 60, 90, 120 and 180 min following the injection (ip.) of 0.5 mg/kg (n = 8), 1.0 mg/kg (n = 8) clonidine HCl (free base, from Boehringer Ingelheim) or normal saline (n = 7). Each dose of clonidine elicited significant analgesia 15 min after injection, with peak analgesia occurring at 30 min (0.5 mg/kg = 6.59 sec, 1.0 mg/kg = 6.78 sec). Across the next 7 days, these treatments continued to be administered with tail-flick latencies being assessed prior to and 30 min after the injections. By the 8th drug administration, tail-flick latencies had significantly declined in both drug groups (0.5 mg/kg = 4.57, 1.0 mg/kg = 4.12 sec). To assess tolerance, on the following day, 2 mg/kg clonidine was administered to all rats. The reduced analgesic response revealed that tolerance had developed in both clonidine-treated groups (saline gp. = 7.04, 0.5 mg/kg = 5.00, 1.0 mg/kg = 4.17 sec). On the next day, the acute analgesic response to footshock (1.0 ma/15 sec) was assessed in each of these groups as well as in another experimentally-naive group (n = 6). An additional group (n = 6) served as non-shocked controls. Although significant analgesia was observed in the saline, 0.5 mg/kg and no-drug groups, the 1.0 mg/kg group exhibited a much attentuated response. Across the next 4 days, autoanalgesia was assessed in these groups by obtaining tail-flick latencies prior to the administration of footshock. Clonidine tolerance was maintained throughout this phase of the experiment. Within this paradigm, both clonidine-tolerant groups exhibited attenuated analgesia. To allow dissipation of clonidine tolerance, no further treatments were administered. Eight days after the last tail-flick-shock pairing, the rats were again placed on the grid and tail-flick latencies were determined with no shocks being administered. Although the clonidine-tolerant groups had previously exhibited very attenuated analgesia in this situation, the tail-flick latencies of all groups were over 7 sec. Thus, when tolerance to clonidine had been allowed to dissipate, the autoanalgesic response to conditioned fear was observed. These data suggest that clonidine and autoanalgesia may elicit analgesia through similar descending inhibitory mechanisms.

92.11 DISSOCIATION OF OPIATE AND NON-OPIATE FOOT-SHOCK PRODUCED ANALGESIA (FSA). D.A. Cobelli*, L.R. Watkins* & D.J. Mayer (SPON: R.L. Hayes) Dept. Physiol., Med. Coll. Va., Richmond, Va. 23298.

Aversive footshock has been shown to produce analgesia (Hayes et al., 1978). In this experiment we examined the effects of footshock applied to the front paws (FP), hind paws (HP) or four paws (4P) of rats. The effect of naloxone was examined to determine the involvement of endogenous opiates. The measure of analgesia was the tail flick (TF) test.

We studied 3 groups (20/group): FP, HP & 4P shock. Within each group, ½ received 2 i.p. injections of 10 mg/kg naloxone and ½ received equivolume saline. The first injection was given just prior to baseline (BL) TF testing & the second 5 min later, immediately post BL. Rats were then shocked for 90 sec (1.5 mA, rms).

Immediately post shock, TF latencies of virtually all rats increased to 100% MPE. TF latencies remained significantly elevated throughout the 14 min test for all groups except FP naloxone. At 1 min post-shock the FP naloxone rats were reliably less analgesic than FP saline rats ($p<0.02$). By 4 min, TF latencies of FP naloxone rats were not reliably above preshock values ($p>0.07$).



At all times tested, FP FSA was significantly attenuated by naloxone, indicating the involvement of an endogenous opiate-like mechanism. These observations suggest that noxious stimuli entering the cord at levels contiguous with that of the test area (ie. tail) result in potent non-opiate FSA. In contrast, input to cord levels distant from the test area elicit opiate FSA. We conclude that both opiate and non-opiate systems are involved in FSA. We propose that opiate FSA is more generalized both in production & effect. In contrast, non-opiate FSA may be highly specific in that zones of analgesia are confined to the shocked region. These results may have important implications for TENS & acupuncture theory & practice. Supported by PHS Grant DA-00576.

92.12 BEHAVIORAL RESPONSES TO DENTAL PULP STIMULATION IN PRIMATE-EFFECT OF TRIGEMINAL TRACTOTOMY. Ronald F. Young and Terrance D. Oleson, Division of Neurosurgery and Department of Anesthesiology, UCLA School of Medicine, Harbor/UCLA Medical Center, Torrance, CA 90509.

Macaque monkies were trained to press a bar to terminate a brief period of electrical stimulation of either the dental pulp, delivered via electrodes chronically implanted into the maxillary canine teeth, or facial skin delivered via intradermal electrodes. Unilateral trigeminal tractotomy was subsequently carried out and escape thresholds for dental and cutaneous stimulation were redetermined. Responses to facial pin-scratch were also observed following tractotomy. In two animals rhizotomy of the C 2-4 posterior cervical nerve roots was also accomplished, six weeks after tractotomy. Escape thresholds and responses to facial pin-scratch were again determined. Completeness of all lesions was histologically verified.

No animal was rendered analgesic to dental pulp stimulation after tractotomy. Slight, (mean 22%) but statistically insignificant elevations in dental escape thresholds were observed ipsilateral to tractotomy. On the other hand, marked (mean 124%) and statistically significant elevations were observed in escape thresholds for cutaneous stimulation ipsilateral to tractotomy. Responses to pin-scratch were absent in the peripheral portion of the face ipsilateral to tractotomy, however near the midline of the face and including the oral and buccal mucosa and tongue, aversive responses were either normal or slightly reduced when compared to the contralateral side. The addition of cervical rhizotomy had no effect on dental escape thresholds but further increases (mean 50%) were seen in escape thresholds for cutaneous electrical stimulation. In addition the zone of reduced or absent aversive responses to pin-scratch spread to include the side of the neck and shoulder.

The results suggest that trigeminal nucleus caudalis is not the exclusive brainstem relay for pain related information transfer from orofacial structures. Nuclear zones rostral to the obex, acting free of the influence of nucleus caudalis may process pain related information, particularly from the oral cavity and teeth. Results of cervical rhizotomy suggest that facial skin (exclusive of the paramedian area) is innervated by both the trigeminal and cervical nerve roots. Integrated processing of afferent input from these two pathways apparently occurs in trigeminal nucleus caudalis.

93.1 PRENATAL DEVELOPMENT OF CORTICOSTRIATAL PROJECTIONS IN THE RHESUS MONKEY. P. S. Goldman-Rakic, Sec. of Neuroanatomy, Yale Univ. School of Med., New Haven, Ct. 06510

In the adult rhesus monkey, prefrontal corticostriatal fibers are not uniformly distributed but form segregated clusters that surround round or elliptically shaped territories that are free of prefrontal afferents (Goldman & Nauta, J. Comp. Neurol. 1977 171: 369). To examine the time and mode of development of this pathway, a mixture of ^{3}H-leucine and ^{3}H-proline was injected into the prospective dorsolateral prefrontal cortex of eight embryonic (E) rhesus monkeys that had been temporarily removed from the uterus and then subsequently replaced in utero for 24-48 hours. Following delivery by Cesarean section, the fetuses were perfused intracardially and their brains prepared for autoradiography.

In the youngest fetus of this series, injected at E69, a light even spray of radioactivity was present over the appropriate area of the ipsilateral neostriatum, indicating that a small number of corticostriatal afferents have reached their subcortical target by this age. In a fetus injected at E85 and in two slightly older fetuses injected at E95 and E105, respectively, labeling over the ipsilateral neostriatum increases in density but continues to be uniformly distributed. The first indication of segregation of corticostriatal afferents appears in a fetus injected at E123. In this specimen, areas of higher and lower grain density begin to emerge and, indeed, ten days later at E133, ingrowing corticostriatal fibers assume the adult pattern of cortical fibers surrounding core territories devoid of cortical input. The configuration of the corticostriatal afferents at this stage are not very different from that observed in older fetuses (E151; E153) or postnatal monkeys (e.g. P1; P4; P60).

Thus, corticostriatal projections in the rhesus monkey are established within the first half of the 165 day gestation period in this species, expand throughout the middle of gestation and achieve the organizational features of the mature pathway a full month before birth. Throughout this period of fetal development, the prefrontal neostriatal pathway is well delineated ipsilaterally and there is no comparable contralateral component. The cortical innervation of the neostriatum displays a biphasic mode of developement proceeding from an overlapping, diffuse phase to a segregated and patterned phase similar to the transformation previously reported for the thalamocortical pathways of the primary visual system in the same species (Rakic, Nature, 1976 261; 467). This mode of development may therefore reflect a general rule governing the formation of long tract connections - one that applies to descending efferent fiber systems of association cortex as well as to ascending afferents of sensory systems. Supported in part by NS 16666.

93.2 THE ASSEMBLY OF THE RADIALLY STRIATED PATTERN OF THE NEOCORTEX: A GOLGI-EM ANALYSIS IN NORMAL MOUSE EMBRYOS. M.C. Pinto Lord*, P. Evrard*, V.S. Caviness, Jr. Department of Neurology, Massachusetts General Hospital, Boston, MA 02114 and Southard Laboratory, Eunice Kennedy Shriver Center for Mental Retardation, Inc., Waltham, MA 02154.

The cortical plate of the developing mammalian neocortex has a radially striated appearance in general cell stains. This reflects the assembly of neuronal somata into radially aligned groups, separated by intervals free of somata. The means of assembly of the somata and dendritic components of postmigratory cells into these general patterns has been examined in the cortical plate of normal E17 mouse embryos. The configurations of cells has been reconstructed from skip serial thin sections of tissue wherein radial glialfibers (RGF) are identified by the Golgi-gold toning method of Fairen et al ('77). The somata of neurons appear to be in contact with a single RGF. A radial assembly corresponds to somata associated with 3-4 adjacent RGF. The apical dendrites of cells are directed externally with respect to the somatic assembly. The dendrite of a cell contacts the cell soma immediately above its soma of origin but is progressively removed tangentially from successively more superficial somata. The dendritic ensheathments of adjacent somatic assemblies abut upon each other so that there is a continuous dendritic field throughout the cortical volume. The radial somatic assemblies are embedded as mosaic elements.separated from each other within the continuous dendritic field.

Supported in part by NIH grant 1-R01-NS12005-02

93.3 INTRACORTICAL MIGRATION OF NEURONS ALONG RADIAL GLIAL FIBERS. A GOLGI-EM ANALYSIS IN NORMAL MOUSE EMBRYOS. P. Evrard*, M.C. Pinto Lord*, V.S.Caviness, Jr. Department of Neurology, Massachusetts General Hospital, Boston, MA 02114 and Southard Laboratory, Eunice Kennedy Shriver Center for Mental Retardation, Inc., Waltham, MA 02154.

Neurons which form the mammalian neocortex migrate from the ventricular zone to the cortical plate along radial glial fibers (RGF) (Rakic, '72). They complete their migrations with their perikarya at the interface of the molecular layer and cortical plate. The ascent of migrating neurons through the cortical plate of N1 E17 mouse embryos has been examined in electronmicrographs of tissue in which RGF are impregnated by the Golgi-gold toning method of Fairen et al ('77). The configuration of migrating cells is reconstructed from skip serial thin sections. The migrating neuron is readily identified because its nuclear and cytoplasmic size and degree of differentiation are much less than those of adjacent postmigratory elements. The tapered leading process does not extend fully to the molecular layers. The intracortical migrating cell is invariably closely applied to a RGF throughout its length. It is coiled about the RGF with increasing tightness of coil at outer levels of the cortical plate. It is invariably interposed between RGF and postmigratory elements that it encounters in its ascent. These observations suggest that the surface of RGF is an obligatory corridor of ascent for migrating cells through the cortical plate and that their binding affinity for this surface is greater than that of postmigratory cells.

Supported in part by NIH grant 1-R01-NS12005-02

93.4 IMMUNOCYTOCHEMICAL STUDY OF RADIAL GLIAL CELLS AND ASTROCYTES IN THE DEVELOPING RHESUS MONKEY BRAIN. P. Levitt and P. Rakic. Sec. of Neuroanatomy, Yale Univ. School of Med., New Haven, Ct. 06510.

Gliogenesis in the central nervous system (CNS) of the rhesus monkey was examined at various embryonic (E) and postnatal (P) ages utilizing a specific antibody to the glial fibrillary acidic protein (GFA) and peroxidase-antiperoxidase immunohistochemical staining. Positive staining was noted by the presence of dark brown horseradish peroxidase (HRP) reaction product in the cytoplasm and processes of radial glial cells, Bergmann glial cells and astrocytes. The HRP product was conspicuously absent from all neuronal elements examined at the light microscopic level.

Radial glial cells are the first glial cells to appear, being present within the first quarter of the 165 day gestational period in the spinal cord and brainstem (E41), and the first third of gestation in the diencephalon (E45) and telencephalon (E47). In each of these areas, radial glial fibers fan out from the ventricular and subventricular zones, where their cell bodies reside, and course approximately 3-8 um apart through the developing mantle zone or cortical plate to terminate at the pial surface with conical endfeet. The Bergmann glial cell is the next glial cell type to appear. These cells, which are positively stained for GFA by E54, are located below the Purkinje cell layer. Evenly spaced parallel Bergmann fibers (3-6 um apart) run through the molecular layer to end along the pial surface. At specific times within each major subdivision of the CNS, there is an increase in the number of positively stained radial glial fibers. As tectogenetic changes occur, the massive number of elongated glial fibers alter their scaffolding patterns, but maintain constant ventricular-pial relationships. In all areas of the CNS, columns of unlabeled migrating neurons are seen juxtaposed to GFA-positive radial and Bergmann glial fibers in Nissl counterstained material. Radial glia undergo a variety of changes to assume transitional cell forms during the process of transformation into fibrillary and protoplasmic astrocytes. This transformation occurs at specific embryonic ages within each structure, usually commencing after neuronal migration has begun to subside.

The immunocytochemical localization of glial cells during embryonic development in the primate brain indicates that 1) a transient glial cell class, the radial glial cell, is present concominently with neurons during periods of neurogenesis and 2) two distinct cell precursor populations may compose the ventricular and subventricular proliferative zones during development. The close structural relationship between large numbers of migrating neurons and immunohistochemically identified radial glial fibers support the concept of a role for radial glial cells in migration guidance and compartmentalization of the brain during development. (Supported by NS 14841 and EY 02503).

93.5 MIGRATION OF EXTERNAL GERMINAL CELLS IN THE CEREBELLAR CORTEX OF NEONATAL RATS. I. S. Zagon and W. E. Rogers*. Dept. of Anatomy, The M.S. Hershey Medical Center, Hershey, PA 17033 and Dept. of Biology, Shippensburg State College, Shippensburg, PA 17257.

A close interrelationship between migrating external germinal cells and the Bergmann fibers of Golgi epithelial cells has been postulated by Rakic (1971) and others, with vertically oriented fibers thought to be imposing radial constraints and providing guidelines to facilitate the migration of young neurons. Evidence for this concept has been based largely on examination of animals at later stages of cerebellar development when a myriad of cells and processes are encountered in the molecular layer. The present study was undertaken in order to evaluate whether "glial guidance" is necessary at early developmental stages when the migration route is less densely packed with cell processes. Newborn Sprague-Dawley rats were fixed by intracardiac perfusion with 1% paraformaldehyde and 2% glutaraldehyde in 0.07 M phosphate buffer with 2% sucrose. Cerebellar were post-fixed in a 1% OsO_4 solution and embedded in Epon. A series of thin (700Å) sections were prepared in the sagittal (perpendicular to the long axis of the folia) and transverse (parallel to the long axis of the folia) planes and observed by electron microscopy; serial sections of at least 4 migrating cells/plane were examined. Migrating cells were often elliptical in shape, with both the perikaryon and the migrating cell process elongated in a plane parallel to the folium (i.e., transverse plane). Adjacent to migrating cells was a loosely fashioned network of processes from other germinal cells, as well as numerous areas of extracellular space; in some cases, these areas of extracellular space were quite extensive. Bergmann glial fibers were not observed in association with migrating cells, however, Bergmann glial fibers were occassionally noted in other areas of the cortex. These results suggest that, at least in the early stages of cerebellar development, germinal cells can navigate through the molecular layer without being dependent on glial fibers for guidance.

93.6 SENSORY INFLUENCE ON THE POSTNATAL RESHAPING OF THE CORPUS CALLOSUM - TEMPORAL FACTORS. G. M. Innocenti and D. O. Frost. Inst. of Anat., University of Lausanne, Switzerland.

Callosally projecting neurons, retrogradely labeled by horseradish peroxidase (HRP) were counted in areas 17 and 18 of 9 kittens deprived of vision by binocular eyelid suture performed on postnatal days 7-8 (prior to natural eye opening). Of these kittens, 7 were sacrificed on postnatal days 42-143 while 2 had their eyes reopened at the beginning of the second postnatal month and were allowed, respectively, 109 and 114 days of normal vision. In addition, a normal adult cat received 91 days of visual deprivation and two kittens were allowed normal vision for their first 29 and 32 postnatal days, prior to sacrifice.

In all but one of these animals 10 to 12, 0.5 µl injections of a 40 % HRP solution were injected unilaterally into areas 17 and 18 two days before perfusion with 3 % paraformaldehyde; in one animal deprived continuously from birth the solution was directly applied to cut callosal axons. The HRP was visualized with multiple substrates (diaminobenzidine, with or without cobalt intensification; tetramethylbenzidine) for each brain, according to standardized procedures. Charts of single coronal sections and reconstructions from serial sections, showing the distribution of labeled neurons, were made using automated procedures.

Binocular deprivation during the first two postnatal months or longer causes more than a 50 % decrease in the number of labeled neurons normally found in areas 17 and 18; it also narrows their mediolateral tangential distribution.

Deprivation during adulthood or restricted to the first postnatal month does not appear to have such an effect. Actually, the two kittens whose eyes were reopened after one month's deprivation showed a widening in the tangential distribution of callosally projecting neurons in area 17 similar to that previously observed in strabismic kittens (Innocenti and Frost, Nature, 280, 1979, 231-234). The widening is probably due to the persistence of juvenile callosally projecting neurons which at birth are distributed over the entire extent of areas 17 and 18 and which at the end of the first postnatal month, in both normally reared and binocularly deprived kittens, still occupy wider portions of both areas than in adults.

These results suggest the existence of a period during which juvenile callosal connections are sensitive to the stabilizing effects of visual experience. This sensitive period probably extends at least until the end of the second postnatal month.

93.7 EFFECTS OF AXOTOMY ON DEVELOPMENT OF PYRAMIDAL TRACT NEURONS. L. Ramirez*, K. Kalil and T. Reh (SPON: M. Javid). Dept. of Surgery, Dept. of Anatomy, and Neurosciences Training Program, Univ. of Wis., Madison, WI 53706.

Previous experiments have shown that when the pyramidal tract is severed in the adult hamster there is severe cell shrinkage but not cell death in the neurons of origin in layer 5 of the sensorimotor cortex (Kalil and Schneider, 1975, Brain Res. 89). In the present experiments, unilateral lesions of the medullary pyramids were carried out on infant hamsters to determine the effect of axotomy on developing cortical neurons.

Animals ranging from 2 days of age to adulthood received a unilateral lesion of the medullary pyramid and were allowed to survive for periods ranging from 4 days to several months. The fixed brains were embedded in celloidin and 20µ coronal sections were Nissl stained. Histograms of cell sizes were based on drawings made under 100X oil immersion and traced with an electronic planimeter of 100 cells in layer 5 of the sensorimotor cortex of each operated animal. The corresponding region of the contralateral cortex served as the normal control in all cases.

The results showed that, as previously reported in the adult lesioned animals, there is no significant cell loss after infant lesions. Rather, infant lesioned animals show a severe cell shrinkage such that the size of axotomized cortical neurons is reduced to 65% of normal controls. Moreover, an examination of pyramidal tract neurons one week after the lesion indicates that the neurons react quite rapidly to axotomy by a temporary shrinkage or, alternatively, by simply lagging behind in development.

These results suggest that the cortical neurons do not have an independent program of development, at least with respect to the size of the cell body, but one that can be severely disrupted by damage to their efferent fibers.

93.8 REGENERATIVE CHANGES IN COUPLING OF AMBYSTOMA BLASTOMERES MEDIATED BY VOLTAGE DEPENDENT JUNCTIONS, M.V.L. Bennett, A.L. Harris and D.C. Spray, Div. Cellular Neurobiology, Dept. Neuroscience. A. Einstein Col. Med., Bronx, New York 10461.

The junctional conductance between coupled Ambystoma blastomeres is strongly voltage dependent as characterized under voltage clamp (Spray et al., Science 204: 432,'79). This analysis was used to calculate steady state and transient potentials during current injection into one cell of a coupled pair. The predicted coupling shows hysteresis for slowly increasing and decreasing ramp currents. As applied current increases a voltage is reached where a further increase in voltage decreases junctional conductance and thereby increases voltage in the injected cell and decreases voltage in the coupled cell. The transjunctional voltage is increased and junctional conductance is further decreased. Thus, the transition is regenerative and a state of reduced coupling and higher input resistance is reached. As current is decreased again, the cells remain "uncoupled" to a lower current level because the transjunctional voltage is greater for a given applied current when the junctional conductance is low. Eventually a lower transition voltage is reached where a further decrease in voltage decreases junctional conductance and thereby decreases the voltage in the injected cell and increases voltage in the coupled cell. The transjunctional voltage is decreased and the junctional conductance is further increased. Again, the transition is regenerative. The calculations also predict that over a range of constant currents applied in one cell superimposed pulses of appropriate sign will cause transitions between stable states of more and less close coupling with lower and higher input resistances respectively. These predictions are readily verified experimentally. Furthermore, calculations predict that if the resting potentials of the cells are different, currents of one polarity will uncouple the cells at a lower level than currents of the opposite polarity; the junctions rectify under these conditions. Large differences in resting potentials (including those produced by a non-specific leak in one cell) can allow pulses to produce transitions between coupled and uncoupled states without maintained current application. Still larger differences can cause transition to the uncoupled condition without application of pulses. Bistability due to differences in resting potentials is readily demonstrated experimentally and can last for many minutes. This mechanism may cause rapid and sustained changes in intercellular communication during development, although longer term changes must involve growth and dissolution of junctions. In any case an unexpected plasticity of coupling can arise from voltage dependent junctions between amphibian blastomeres.

93.9 QUANTITATIVE ANALYSIS OF ELECTRICALLY COUPLED CELLS. N.G. Publicover* (SPON: D.G. Lawrence). Microsurgical Laboratories, McGill University, Montreal, P.Q. Canada, H3A 1A1

The transient response of an electrically coupled network of cells can be approximated with passive electrical components. A capacitance in parallel with a resistance may be used to represent the cell body. Communication with other equivalent cells via electrical synapses can be treated as purely resistive. The responses of this system can be described mathematically in terms of a pair of simultaneous differential equations and can be solved numerically by computer simulation.

The validity of the model has been assessed using standard intracellular recording techniques in identified pairs of electrically coupled neurons (L4 and R4 of the buccal ganglion) in the freshwater snail Helisoma trivolvis. A microprocessor-based computing system has been developed to 1) inject hyperpolarizing steps of current, 2) monitor the cells' voltage responses, and 3) perform all of the subsequent analysis using non-linear curve-fitting algorithms.

Two exponential decay modes are found in both the injected neuron and in the coupled cell responses. As seen in the model, the amplitude of one mode of the coupled response may be inverted, depending on the relative magnitudes of the membrane and coupling resistances. The presence of these two decay modes in the coupled response changes our interpretation of coupled cell behavior. For example, the prolonged latency of the appearance in a coupled neuron of an injected pulse of current is explicitly a function of the coupling circuit and not due to an excessive propagation along an axon. This accounts for the observation that action potential latency from one coupled cell to the next is related to the degree of coupling.

The two time constants of the injected cell response and the magnitude of the response in the injected neuron and one coupled cell provide enough information to calculate the values of each of the components in the equivalent circuit. This can be used as a mathematical foundation to describe neuronal responses mediated by electrical synapses.

93.10 POSSIBLE ELECTROTONIC EPSPs IN DYE-COUPLED NEOCORTICAL NEURONS. M.J. Gutnick* and D.A. Prince. Dept. of Neurology, Stanford University Medical School, Stanford, CA 94305.

Recent demonstrations of electrotonic coupling in a variety of subcortical mammalian CNS structures raise the possibility that this form of intercellular communication may be a general feature of the brain's neuronal connectivity. In the present experiments we obtained anatomic and physiologic evidence for electrotonic coupling in mammalian neocortex. In several systems, electrotonic coupling is associated with "dye-coupling", the cell to cell diffusion of an intracellularly injected, low molecular weight dye, presumably through gap junctions. Intracellular iontophoretic injections of the fluorescent dye Lucifer Yellow CH were made in 17 neurons in slices from guinea pig sensory-motor cortex maintained in vitro. Each of 6 injections at a depth greater than 1.2 mm below the pial surface caused staining of only one neuron. However, 10 of 11 superficial (< 0.4 mm beneath the pial surface) injections resulted in a staining of aggregates of 2-7 neurons. In 5 slices, injection of a single Lamina III cell caused staining of 3-6 pyramidal type neurons organized in columnar-shaped clusters oriented perpendicular to the pial surface. These dye-coupled neurons had extensive overlap of their dendritic arborizations. Dye-coupling with complete filling of the dendritic trees of all stained cells was observed as soon as 5 min after the end of the 5-8 min injection period. It was not dependent on evoked chemical synaptic activity, since it was present in slices bathed in a solution containing 3 mM Mn^{++}. Injection of superficial neurons never caused staining of deeper cells.

In parallel experiments, intracellular recordings were obtained from 14 superficial neurons which had membrane potentials of 65-76 mV and input resistances of 28-42 MΩ. In bathing medium containing 3 mM Mn^{++} and 1 mM Ca^{++}, all evidence of chemical synaptic transmission disappeared, and low intensity (< 100 μA) stimuli applied deep in cortex, near the subcortical white matter, evoked only antidromic activity. In 4 of these cells, subthreshold stimulation evoked small (< 4 mV) all-or-none depolarizing potentials at a fixed latency of 1-2 msec. These rose to peak within 1 msec and decayed over 10-20 msec. Their amplitudes and latencies were not affected by intracellularly applied depolarizing or hyperpolarizing currents. They were clearly distinguished from M or IS spikes by their different waveform and by failure to collide with intracellularly evoked spikes. These Mn^{++}-resistant potentials may reflect passive propagation of antidromic spikes that actively invade other, electrotonically coupled neurons. Thus, both the morphological and the electrophysiological evidence is consistent with the hypothesis that superficial neocortical neurons are electrotonically coupled.

93.11 CRYOPRESERVATION AND TRANSPLANTATION OF EMBRYONIC RAT NEOCORTEX: PARAMETERS INFLUENCING ITS SURVIVAL AND GROWTH. J. D. Houle* and G. D. Das* (SPON:J.A. Altman). Dept. Biol. Sci., Purdue University, W. Lafayette, IN. 47907.

It has been demonstrated that embryonic neural tissues can be successfully transplanted into the brains of neonatal and adult animals. Tissues for these studies have always been fresh and transplanted with minimal delay following dissection of the donor embryos. A recent study in our laboratory showed that neocortical tissue from 16-day-old rat embryos could be frozen and stored at -95°C, then thawed and used for transplantation. This prompted a more detailed study of various parameters related to the freezing of neural tissue, media and cryopreservative used, storage of tissues, and rates of thawing prior to transplantation.

Neocortical tissue was dissected from 17-day-old rat embryos. Individual hemispheres were placed in micro test tubes containing either Eagles' MEM, lactated Ringer's solution, or amniotic fluid obtained at the time of embryo dissection, and with DMSO added to a final concentration of 10% or 2%. Tissues were frozen and stored at -90°C for 21-35 days before thawing at either room temperature (slow) or by immersion in a 37°C water bath (fast) and washing with Ringer's solution. One entire hemisphere was transplanted into the cerebellum of a 10-day-old rat. Animals were sacrificed 30 days post transplantation and their brains processed for Golgi-Cox impregnation, cresyl violet and Bodian staining.

Qualitative and quantitative analyses were performed to define the conditions of cryopreservation which provided for optimal survival and growth of the transplanted tissue. In general it can be stated that the concentration of DMSO was most crucial to the survival of the neural tissue. Use of 10% DMSO in combination with any of the 3 media and employing either fast or slow thawing gave the most desireable results, i.e., all the transplants appeared as normal, healthy cortical tissue, occupying a volume of 1/3 to 1/2 of the host cerebellum. The transplants contained fully differentiated pyramidal and stellate neurons and normal neuropil. Anatomical integration of the transplants and host cerebellum was demonstrated by sharing of neuropil and presence of fibers crossing at the interface. In no combination was a concentration of 2% DMSO found to adequately protect the tissue during freezing and thawing as demonstrated by small transplants, if present at all. The use of amniotic fluid resulted in fragmented tissue after thawing which adversely affected the transplantability though apparently not the survival of the tissue.

93.12 ORNITHINE DECARBOXYLASE ACTIVITY IN THE DEVELOPING RAT CEREBELLUM: BIOCHEMICAL AND CYTOCHEMICAL STUDIES. G.M. Gilad and V.H. Gilad* Dept. Isotope Research, Weizmann Institute of Science, Rehovot, Israel.

We have recently characterized the developmental pattern of ornithine decarboxylase (ODC) activity, the enzyme catalyzing the first step in polyamine (PA) biosynthesis, in the rat cerebellum (Gilad & Kopin, J. Neurochem., 33:1195-1204, 1979). A transient increase with a sharp peak at 7d after birth occurs in ODC activity over the first two weeks after birth. Thereafter, the activity declines to very low levels which persist throughout adult life. This transient elevation in ODC activity coincides with the period of major cell proliferation, migration and beginning of differentiation in the cerebellar cortex. In the present study, therefore, we sought to determine if ODC activity is associated with a specific cell population. In order to do this, we had developed a new technique for cytochemical localization of ODC, using labelled α-difluoromethylornithine, an enzyme activated irreversible inhibitor (i.e. suicidal inhibitor) as a marker. Both rhodamine for fluorescence cytochemistry and biotin labelled inhibitor for biotin-avidin-horseradish peroxidase light microscopical studies were used. Using this technique, we have localized ODC, both in proliferating cells of the external granular layer of the developing cerebellar cortex at 6-10d after birth, and in the developing internal granular layer. No staining was observed in the molecular layer or deeper structures of the developing cerebellum. Adult cerebellum was also devoid of staining. We conclude that ODC activity and therefore, most probably, PA themselves, are associated both with neuronal proliferation and early stages of differentiation in the cerebellar cortex. Further studies are in progress to determine the subcellular localization of ODC.

93.13 AXOLOTL PROSPECTIVE FOREBRAIN-MIDBRAIN CAN BE REPROGRAMMED TO DIFFERENTIATE AS MAUTHNER CELL-CONTAINING MEDULLA. Pat G. Model. Depts. Neuroscience and Anatomy, Albert Einstein Coll. Med., Bronx, N.Y. 10461.

In premetamorphic amphibians, the Mauthner cells (M-cells), a single pair of large neurons, are present in the medulla at ear level. M-cells develop early and are easily recognized morphologically.

That the major axes of the CNS in the axolotl (Ambystoma mexicanum) are labile through mid-neural plate stages (Model, 1978, Brain Res. 153:135-143) suggests that regionalization of the CNS does not occur prior to that time. Prospective forebrain-midbrain from early midneurulae was unilaterally substituted for prospective hindbrain in hosts of the same stages. LM examination of feeding larvae showed that the implanted tissue differentiated as hindbrain and, in addition, produced an M-cell. EM examination of the M-cell surface revealed normal localization of vestibular input. Proof that the graft itself actually differentiated as medulla was obtained through implantation of H^3-thymidine labelled tissue into unlabelled host embryos and through implantation of pigmented tissue into albinos. That prospective forebrain-midbrain taken from early midneurulae is competent to produce medullae as well as M-cells indicates that regionalization of the developing CNS has not occurred by this stage and that regulating factors from the surrounding tissues can override the original fate of the graft to bring it into accord with the system as a whole.

94.1 STRUCTURAL ASPECTS OF THE 66,000 DALTON SUBUNIT OF THE TORPEDO MARMORATA ELECTROPLAQUE ACETYLCHOLINE RECEPTOR ANALYZED BY LIMITED PROTEOLYTIC DIGESTION. R.E. Oswald, L.P. Wennogle*, T. Saitoh* and J.P. Changeux*. Neurobiologie Moléculaire, Institut Pasteur, 75015 Paris, France.

Preparations of purified Torpedo acetylcholine receptor (AChR) contain peptides of molecular weights 40,000 (40K), 50K, 60K, and 66K. The 40K peptide can be affinity labeled by acetylcholine analogs and thus carries the acetylcholine binding site (rev. by Heidmann & Changeux, Ann. Rev. Biochem. 47, 317, 1978). Recently (Oswald, et al., FEBS Lett. 111, 29, 1980), the 66K peptide has been labeled with a photoaffinity local anesthetic analog, 5-azido ^{3}H-trimethisoquin (5AT). The labeling has all of the characteristics of noncovalent local anesthetic binding, indicating that the 66K chain may carry the local anesthetic binding site. The 66K chain also carries binding sites for lectins (Wennogle & Changeux, Eur. J. Biochem. 1980, in press), a specific site of phosphorylation by an endogenous kinase (Saitoh & Changeux, Eur. J. Biochem. 105, 51, 1980), and a disulfide which crosslinks two 66K chains (Hamilton, et al., Biochem. 18, 155, 1979). We have used trypsin digestion of the 66K chain to determine the relative positions of the specific sites mentioned above.

When 5AT is used as a specific marker for the 66K chain, SDS gel electrophoresis (in the presence of β-mercaptoethanol) of a series of samples containing increasing quantities of trypsin (15 min at 25°C) indicates that the 66K chain is degraded first to a 50K fragment, then to a 48K chain, and finally to a 47K chain. With concentrations of trypsin up to 3 mg/ml, no further degradation is observed and the 5AT and lectin binding sites are conserved. When β-mercaptoethanol is omitted from the electrophoresis sample buffer, a dimer of the 66K chain is observed. The dimer is cleaved by trypsin to 50K chains going through an 82K intermediate which corresponds to a 66K chain crosslinked to a 16K fragment. The loss of this fragment does not correlate to a conversion of the AChR complex from a 13S to a 9S species. When the 66K chain is labeled with ^{32}P by an endogenous kinase and subjected to trypsinization, the phosphate label is lost during the degradation of the 50K fragment to the 48K fragment. Finally, N-terminal analysis of the 66K chain and the 47K fragment demonstrated that both have valine as the N-terminal amino acid, suggesting that the tryptic cleavages are made closer to the C-terminal.

We conclude that the cysteine involved in the disulfide bridge resides between the C-terminal and the 50K cleavage, that the phosphorylation site is between the 50K and 48K cleavages, and that the 5AT and lectin binding sites are between the 47K cleavage and the N-terminal.

94.2 DOPAMINE RECEPTORS: TEMPERATURE EFFECTS ON ^{3}H-SPIPERONE AND ^{3}H-N-n-PROPYLNORAPOMORPHINE BINDING. D.L. Niehoff, J.M. Palacios, and M.J. Kuhar. Depts. of Pharmacology and Psychiatry, Johns Hopkins Univ. Sch. of Med., Balto., MD 21205.

^{3}H-spiperone (^{3}H-SP) has been widely used to study dopamine receptors in in vitro binding assays. Recently, ^{3}H-N-n-propylnorapomorphine (^{3}H-NPA), a novel dopamine agonist, has also been used by several investigators to characterize dopamine receptors in vitro; however, this ligand appears to label at least some receptors which differ pharmacologically from those labeled by ^{3}H-SP. Experiments in our laboratory with both homogenates of rat striatum and slide-mounted tissue sections revealed temperature-related differences in the kinetics and pharmacology of ^{3}H-NPA binding. Further investigation of both ^{3}H-SP and ^{3}H-NPA binding in tissue homogenates indicated that the binding of both ligands is temperature sensitive and that subpopulations of the receptors labeled by each are differentially affected by temperature.

The binding of ^{3}H-SP and ^{3}H-NPA was performed according to published procedures (Creese, et al., Europ. J. Pharmacol., 56, 1979; Creese, et al., Europ. J. Pharmacol., 46, 1977) at 37°, 25°, and 0° with homogenates of rat striatum. Association of both ligands at all three temperatures was complete at 45 min. Binding at equilibrium was reduced at 0°, suggesting either a K_d or B_{max} change. Kinetic experiments supported this observation. Scatchard analysis of ^{3}H-SP binding revealed a fourfold increase in K_d and 30% decrease in B_{max} at 0°. ^{3}H-NPA binding was more complex, revealing 2 components of binding at 37° and 25°, but probably only 1 at 0°, due to the apparent progressive loss of low-affinity sites with decreasing temperature. The K_d of the high-affinity site appeared to increase with decreasing temperature. Displacement experiments with (+)-butaclamol and dopamine revealed that agonists become increasingly potent or are unchanged in potency with decreasing temperature, while antagonists become less potent. All temperature-related effects have been shown to be independent of pH and tissue concentration, and occur at equilibrium. Thermodynamic analysis of ^{3}H-SP and high-affinity site ^{3}H-NPA binding according to Weiland, et al. (Nature, 281, 1979) showed that the binding of dopamine antagonists is entropy-driven, while the binding of agonists in enthalpy-driven. These results are similar to those obtained for the beta-adrenergic receptor.

Models for the binding of ^{3}H-SP and ^{3}H-NPA based on the selective effects of temperature on the kinetic parameters of the multiple sites labeled by these ligands will be presented.

Supported by USPHS grants MH25951, DA00266, MH00053, TW02983, and an NSF Pre-doctoral Fellowship.

94.3 SOLUBILIZATION OF γ-AMINOBUTYRIC ACID (GABA) AND BENZODIAZEPINE (BZ) BINDING-SITES BY DETERGENTS. F. P. Bymaster* and D. T. Wong. Lilly Research Laboratories Indianpolis, IN 46285.

In order to separate the molecular entities involved in the interaction between the receptors of GABA and BZ we have compared the effects of the detergents Triton X-100 (TX), deoxycholate (DOC), and lysolecithin (LLC) on the solubilization of components responsible for the binding of GABA and BZ. As previously reported (Wong and Horng, Life Sci. 20, 445, 1977), treatment with TX at concentrations up to 0.1% increased the binding of ^{3}H-GABA to the synaptosomal membranes of rat cerebral cortex, up to 5 times the levels found in native tissue, but higher concentrations increased the binding only 1- to 2-fold as expressed in pmole/gm tissue. However, the binding of the BZ, ^{3}H-flunitrazepam (FLU), to membranes was decreased at concentrations of TX greater than 0.01%, but FLU binding and protein were recovered in the soluble fraction. The rank of inhibition of FLU binding by 3 BZ (lorazepam, diazepam, chlordiazepoxide) in the soluble fraction paralleled that in FLU binding to cortical membranes. The soluble fraction of 0.2% DOC-treated membranes exhibited monophasic saturable binding of FLU with a dissociation constant (Kd) of 1.69 ± 0.06 nM and number of binding sites of 600.7 ± 14.5 fmoles/mg protein. Similar values were obtained on saturation binding of FLU to the soluble fraction of 2% DOC-treated membranes. Characteristics of FLU binding in membrane, such as stimulation by GABA agonists and rank order of inhibition by BZ drugs, were retained in DOC-solubilized fractions. Saturable and monophasic binding of FLU was also observed in fractions solubilized by 0.4% LLC. GABA agonists stimulated FLU binding to the soluble fraction and BZ had the same rank order of potency as in membranes. GABA agonists and bicuculline, a GABA antagonist, inhibited the binding of ^{3}H-muscimol to LLC-solubilized fractions. Scatchard analysis revealed the possibility of two components with similar affinity as seen in membranes. Thus the binding of BZ and GABA in the DOC or LLC-solubilized preparation retains some characteristics of the membrane bound receptors and the differential solubilization by TX suggested the involvement of separate molecular entities in binding of GABA and BZ.

94.4 CHARACTERIZATION OF ALPHA ADRENERGIC INHIBITION OF PROSTACYCLIN-STIMULATED ADENYLATE CYCLASE IN THE HUMAN PLATELET. Robert H. Lenox, C.L. McMains* and D.A. VanRiper*. Dept. of Psychiatry, Univ. of Vermont College of Med., Burlington, VT 05405

The prostaglandins E_1 (PGE_1), D_2 (PGD_2)and prostacyclin (PGI_2) have been shown to inhibit human platelet aggregation while stimulating adenylate cyclase (AC) activity. Alpha (α) adrenergic agonists, e.g. norepinephrine (NE), are potent stimulators of platelet aggregation and inhibit PGE_1-stimulated AC. Pharmacological studies of this response indicate that it is mediated by α adrenergic receptors with characteristics similar to the α_2 subtype. Since PGI_2 is reported to be one of the most potent endogenous stimulators of human platelet AC, we have proceeded to examine more closely the characteristics of the α adrenergic inhibition of PGI_2-stimulated AC in an intact platelet preparation.

Human platelets for these studies were obtained from volunteer subjects. Blood was collected and centrifuged to separate platelet rich plasma (PRP). AC activity was determined using a modification of the pulse labelling technique with [^{3}H] adenine developed by Kuo and DeRenzo (J. Biol. Chem., 224, 1969). Following termination of the reaction, the [^{3}H] cyclic AMP (cAMP) formed was assayed using two-stage column chromatography (Salomon et al. Anal. Biochem.,58, 1974). Recovery of cAMP ranged between 70-80%.

Maximal stimulation of AC was 32-fold over basal levels for PGI_2 (1μM) but only 7-fold for PGE_1 (1μM). The conversion of [^{3}H]ATP to [^{3}H]cAMP in the platelet in the presence of PGI_2 was found to be linear with time during the reaction period, over a wide range of platelet concentrations. NE inhibition of PGI_2-stimulated AC was found to be concentration dependent with the IC_{50} for PGI_2 at 0.5μM NE compared to 10μM for PGE_1-stimulated AC. NE inhibition of PGI_2 stimulation was effectively blocked by the α antagonist phentolamine and the selective α_2 antagonist yohimbine but not by the α_1 antagonist prazosin. Clonidine inhibited the PGI_2-stimulated AC to a lesser extent than NE, and its action was also antagonized by yohimbine. Beta adrenergic agonists and antagonists were not significantly active in this AC system.

Pharmacological characterization of NE inhibition of PGI_2-stimulated AC in the human platelet was consistent with the modified α_2 subtype demonstrated for PGE_1-stimulated AC. The increased sensitivity and range of response to NE inhibition of PGI_2-stimulated AC results in a more statistically reliable detection of changes in slope and IC_{50}, indicative of an alteration in α adrenergic receptor activity. Current studies are underway to determine whether altered α adrenergic receptor activity may be related to biochemical processes underlying various neuropsychiatric disorders.

94.5 RECEPTORS FOR α-AND β-BUNGAROTOXIN IN CHICK EMBRYO RETINA. Heinrich Betz* and Hubert Rehm* (SPON: H. Holländer). Max-Planck-Institute of Psychiatry, 8033 Martinsried, Germany.

^{125}I-labelled α-Bungarotoxin (α-BTX) binds with apparent nicotinic-cholinergic specificity to membranes of chick embryo retina (Vogel and Nirenberg (1976) PNAS 73, 1806). In primary cultures of retinae from 8 day old embryos, a large portion of the neurons present (20 to > 60% depending on culture conditions) develops cell surface receptors for this toxin. Despite α-BTX is ineffective in blocking carbamylcholine-induced ^{22}Na uptake in these cultures, it may be a selective ligand for the nicotinic acetylcholine receptor (AChR) present in this tissue: i) preincubation with carbamylcholine decreases the initial rates of α-BTX binding in the presence of this agonist, suggesting that the toxin receptor is susceptible to cholinergic desensitisation; ii) 30 to 60 % of the detergent solubilised α-BTX binding sites are precipitated by antisera to Torpedo or Electrophorus AChR. The accumulation in culture of α-BTX receptors is increased by 0.1 to 1 mM 8-Bromo-cAMP and different steroid hormones, whereas dibutyryl cGMP (0.1 to 0.5 mM) and veratrine (o.Ol to O. M) inhibit receptor appearance. In the absence of external Ca^{2+}, the latter compounds are ineffective.

ß-Bungarotoxin (ß-BTX) is thought to selectively bind to and destroy the retinal ganglion cells in 18 to 20 day-old chick embryos (Hirokawa (1978)J.Comp. Neurol. 180, 449). ^{125}I-labelled ß-BTX binds in a specific and saturable manner to P2 membrane fractions isolated from retinae of 17 to 20 day old chick embryos. Binding is Na^+-sensitive and completely abolished by 0.25 mM Ca^{2+}. Saturation of specific binding sites is reached within 1 to 3 min depending on temperature; dissociation of the ß-BTX-receptor complex, however, proceeds only slowly ($t_{1/2}$ > 10 min). Scatchard analysis reveals one class of binding sites with approximately 10^3 to 10^4 receptors per retina cell. Supported by the Deutsche Forschungsgemeinschaft.

94.6 C6 GLIOMA CELLS GROWN WITHOUT SERUM HAVE INCREASED β-ADRENERGIC RECEPTOR NUMBERS. Mark D. Dibner and Paul A. Insel*
Div. of Pharmacology, UCSD, La Jolla, CA 92093

The β-adrenergic receptor system was compared in rat C6 glioma cells grown in serum and in a serum-free defined medium. In parallel cultures, cells were grown in a DME:F-12 medium with 5% fetal bovine serum or with a defined mixture of 5 hormones in the absence of serum. These include insulin, transferrin, fibroblast growth factor, linoleic acid and serum spreading factor. (R. Wolfe, D. McClure and G. Sato, J. Cell Biol., in press) Cell growth was similar under both conditions. β-Adrenergic receptors were measured in cells dissociated from the dish by incubation with the antagonist radioligand [^{125}I]iodohydroxybenzylpindolol (IHYP). All studies were carried out in washed cells in the absence of serum or hormones. Several IHYP binding properties were similar with cells grown under both conditions such as association rates for IHYP and stereospecific affinities of the (+) and (-) isomers of isoproterenol and propranolol. In spite of these similarities of IHYP binding in cells grown under both conditions receptor numbers were increased by approximately 50% in cells grown without serum. Scatchard analysis of specific binding data (1.0 μM propranolol used to define specific binding) showed that there were approximately 9,500 receptors/cell with serum growth for 7 days and 14,000 receptors/cell with the defined medium ($p<0.01$). This increase in receptor number was even greater when expressed as receptors/μm^2 surface area. This effect took more than 3 days to occur and was not readily reversible by changing back to serum-containing medium. We also found that serum added to our in vitro IHYP binding assay led to a decreased affinity of the receptor for isoproterenol. Thus, our studies demonstrate that C6 cells grown in serum-free media have an increase in receptor number and that serum added to our IHYP assay decreases the affinity of β-adrenergic receptors for agonists.

94.7 IDENTIFICATION AND CHARACTERIZATION OF AN INVERTEBRATE ACETYLCHOLINE RECEPTOR. W.E. Thomas* and J.G. Townsel (SPON: R. Greenberg). Dept. of Physiol. Biophys., Univ. of Illinois Medical Center, Chicago, Il. 60612

The snake venom neurotoxin α-bungarotoxin has been used to investigate an acetylcholine receptor in the central nervous system of the horseshoe crab, Limulus polyphemus. Levels of α-bungarotoxin binding of 500-700 pmoles/mg of protein were detected in the subesophageal ganglia, ventral nerve cord and cardiac ganglion. This binding was inhibited by greater than 80% by 100 μM d-tubocurarine. The level of toxin binding in nonneuronal tissues was less than 10% of that observed in central nervous system tissues. The physiological specificity of α-bungarotoxin in Limulus nervous tissue was accessed by recording spontaneous activity from the dorsal root of the ventral nerve cord. In those cases where the spontaneous activity was stimulated by μM concentrations of nicotine, α-bungarotoxin caused a reduction in spontaneous activity and a pronounced inhibition of the stimulation by nicotine. Autoradiographic studies have shown the neuropil regions and longitudinal connectives to be the major sites of localization of toxin binding in the abdominal ganglion. Subcellular fractionation of the subesophageal ganglia revealed the greatest enrichment of toxin binding in the mitochondrial fraction. This fraction also displayed the greatest enrichment of acetylcholinesterase activity. Sedimentation studies of toxin binding in solubilized extracts of the subesophageal ganglia resulted in the identification of three α-bungarotoxin binding proteins. The approximate sedimentation coefficients of these proteins were 9S, 15.4S and 17.4S. Acetylcholinesterase and choline acetyltransferase from the same tissue had approximate sedimentation coefficients of 6S and 5S, respectively. The formation of the 15.4S and 17.4S toxin binding proteins from isolated fractions of the 9S protein was observed. Therefore, the 15.4S and 17.4S proteins are suggested to be aggregates of the 9S protein. This 9S protein is proposed as an acetylcholine receptor from the central nervous system of Limulus polyphemus. (Supported by NIH Grant HL 24140)

94.8 SNAKE α-NEUROTOXINS ANTAGONIZE CHOLINERGIC AND NONCHOLINERGIC Cl^--MEDIATED RESPONSES IN APLYSIA CNS. P.M. Salvaterra, J.K. Ono and R.E. McCaman. Div. of Neurosciences, City of Hope Research Institute, Duarte, CA 91010

Neurons in the CNS of the marine mollusc, Aplysia californica, may respond to acetylcholine (ACh) and other transmitters and agonists with a conductance increase (↑g) to Na^+, K^+, Cl^- or a combination of these ions. Confirming the observations of Kehoe et al. (Brain Res. 107:527, 1976), we find that α-bungarotoxin (αBTX), as well as α-naja toxin (αNTX), will block only the ↑gCl ACh response. In addition, our observations indicate that the α-neurotoxins also block ↑gCl responses mediated by noncholinergic agonists and transmitters. We have observed that responses involving an ↑gCl induced by the iontophoretic application of histamine, and in some cases glutamate, are reversibly antagonized by the perfusion of saline containing the α-neurotoxins at a level comparable to that affecting the ACh response of the same neuron. The α-neurotoxins also antagonize certain synaptically induced ↑gCl responses mediated by identified, noncholinergic, presynaptic neurons. Characterization of [^{125}I]αBTX binding to Aplysia CNS membranes indicates a single toxin binding site (Kp≈3nM) which is competitively antagonized by cholinergic ligands (nicotine, carbachol, curare). Noncholinergic ligands (glutamate, histamine) and Cl^- channel blockers (picrotoxin, penicillin) were without significant effect on toxin binding.

We believe that toxin binding in the Aplysia CNS is confined to a nicotinic cholinergic receptor mediating the ↑gCl ACh response. Despite the observation that toxin antagonizes noncholinertic ↑gCl responses, we do not believe that the α-neurotoxins are generally blocking Cl^- channels because: a) they do not antagonize all ↑gCl responses, e.g., GABA and in certain cells glutamate and histamine ↑gCl responses are not blocked by toxin; and b) the α-BTX binding is not antagonized by Cl^- channel blockers. Rather, we have formulated a working hypothesis that several neurotransmitter recognition sites may share the same ionophore. The α-neurotoxins block noncholinergic ↑gCl responses in cells where the recognition sites for these agonists and transmitters share the same Cl^- ionophore with cholinergic receptors. Experiments testing this hypothesis will be presented. [Supported by NS 13813 (PMS) and NS 15583 (REM & JKO).]

94.9 MULTIPLE AFFINITIES FOR MUSCARINIC ANTAGONISTS IN THE RAT BRAIN. J. Ellis* and W.Hoss, Center for Brain Research, University of Rochester, Rochester, NY 14642

Gallamine, a cholinergic antagonist at the (nicotinic) neuromuscular junction, possesses antimuscarinic potency in several systems. We report here that gallamine inhibits the binding of [^{3}H]-quinuclidinyl benzilate (QNB) in a competitive manner in several regions of the rat brain. The occupancy curves derived from these studies suggest that gallamine has widely varying affinities for different subpopulations of muscarinic receptors, a finding which sets gallamine apart from classical muscarinic antagonists such as atropine and QNB. The greatest difference in affinities for gallamine occurs in the brainstem, where the data can be satisfactorily fit to a two-site model, with 78% of the receptors having high affinity (K_d =20nM) and 22% low affinity (1mM) (a 50,000-fold difference). Further, these affinities display rank order correlation with those of carbachol (an agonist), although gallamine has so far displayed no agonistic (or partial agonist) activity. For example, carbachol, but not gallamine, enhances the turnover of phosphatidyl inositol in brain slices. We have also found that another antagonist, scopolamine, has a significantly higher affinity in the forebrain than in the brainstem, in contrast to the higher affinity of most muscarinic agonists for the brainstem (forebrain ID_{50} 0.2nM; brainstem ID_{50} 1 nM). The finding that certain antagonists, as well as agonists, display more than one affinity for muscarinic receptors suggests that there are fundamental differences among subpopulations of these receptors.

94.10 CHARACTERIZATION OF THE GLUTAMATE RECEPTOR-LIKE PROTEIN RECONSTITUTION INTO LIPOSOMES. Robert D. Grubbs and Elias K. Michaelis Dept. of Human Development and Family Life, Neurobiology Section, Univ. of Kansas, Lawrence, KS. 66045.

Initial attempts at the reconstitution of a glutamate binding glycoprotein into liposomes were reported at this meeting last year (Grubbs & Michaelis, 1979). The continued effort to reconstitute this protein isolated from rat brain synaptic membranes (Michaelis, 1975) has allowed for a preliminary characterization of the effects of this procedure on the specific, high-affinity L-[^{3}H]-glutamate binding of the protein.

The reconstitution procedure utilized for these experiments is based on the method of Epstein & Racker (1978) in which the protein, liposomes, and buffer are incubated together at room temperature for 30 minutes (total volume 0.5 ml). This mixture is then transferred to a short column (0.8 x 2.0 cm) of Bio-Beads SM-2 for 4 hr. at room temperature to remove Triton X-100 from the mixture. The columns are then centrifuged in a table-top clinical centrifuge at 1000 x g for 4 minutes. The eluate recovered from each column is centrifuged at 38,000 x g for 30 minutes. The pellet, which contains the reconstituted system, is resuspended in 0.5 ml of 50 mM Tris-HCl buffer.

The Bio-Beads incubation step in this procedure was found to reduce by 80% the Triton X-100 concentration of liposomes prepared in 0.5% Triton X-100 / 50 mM Tris-HCl buffer. This removal was monitored as the absorbance decrease at 280 nm, the peak absorbance wavelength of the detergent. This step was also observed to quantitatively remove the soluble, non-reconstituted binding protein from solution. The eluate of a column incubated with 30 µg of the binding protein has consistently yielded negligble amounts of binding activity and protein.

Using this reconstitution procedure, the effect of the liposome composition on the L-[^{3}H]-glutamate binding of the protein has been examined. The addition of Triton X-100 to the reconstituted system was found to enhance glutamate binding at low concentrations (20-40 µM), while higher concentrations had no effect. Data will be presented concerning the effects of Na^+ and Ca^{++} on the kinetics of L-[^{3}H]-glutamate binding.

This research was partially supported by DHEW Research Service Award HD 7066 from NICHHD to the Kansas Center for Mental Retardation and Human Development, by a grant from NIGMS, GM 22357, and grant #DAAG29-79-C-0156 from the Army Research Office.

94.11 INTERACTION OF CARDIAC NEUROTRANSMITTER RECEPTORS WITH A GUANINE NUCLEOTIDE BINDING SITE. T. K. Harden. Dept. Pharmacology, Univ. North Carolina School of Medicine, Chapel Hill, NC 27514.

Guanine nucleotides, which are obligatory for hormone effects on adenylate cyclase, have been shown to influence the interaction of muscarinic and β-adrenergic receptor agonists with their receptors. To date it is unclear whether a single nucleotide binding site is responsible for these effects. The present series of experiments was initiated to examine the interaction of guanine nucleotides with rat heart muscarinic cholinergic receptors. The muscarinic receptor antagonists, atropine and scopolamine, inhibited the binding of ^{3}H-quinuclidinyl benzilate (^{3}H-QNB) to a washed cardiac membrane preparation with K_I values of 0.6 and 1.3 nM, respectively. GTP exhibited no effect on the binding affinities of ^{3}H-QNB, atropine, or scopolamine. The K_I values for oxotremorine and carbachol for inhibition of ^{3}H-QNB binding were 15 nM and 42 nM, respectively. In the presence of GTP the concentration effect curves for these two agonists were shifted 1.0 to 1.5 orders of magnitude to the right. $K_{0.5}$ values for the effects of guanine nucleotides on agonist binding were generated for a series of nucleotides by incubating ^{3}H-QNB in the presence of a fixed concentration (0.1 µM) of oxotremorine and various concentrations of nucleotides. The $K_{0.5}$ values determined in this manner for GTP, Gpp(NH)p, GDP and GMP were 8, 72, 84, and 5000 µM, respectively. The sulfhydryl reagent, N-ethylmaleimide (NEM), was employed to probe potential differences in sensitivities to inactivation of components of the muscarinic receptor system. ^{3}H-QNB binding was not affected by concentrations of NEM less than 30 µM. In contrast, concentration effect curves for oxotremorine were shifted to the right by 1.0 to 1.5 orders of magnitude following preincubation of membranes with 10 µM NEM. GTP had no effect on apparent agonist affinity in NEM-treated membranes. Thus, high affinity cholinergic agonist binding and the effects of GTP appear to be lost in concert as a result of inactivation of NEM-reactive groups in cardiac membranes. The relationship between the effects of guanine nucleotides and NEM on muscarinic receptors versus β-adrenergic receptors in rat heart will be discussed. (Supported by USPHS HL22490 and the American Heart Association, North Carolina affiliate.)

94.12 RECEPTOR-MEDIATED INCREASE IN PHOSPHATIDYLINOSITOL TURNOVER IN CLONED CELL LINES. D.M. Schmidt, R.C. McGlennen, and W.L. Klein. (Biological Sciences, Northwestern University, Evanston, IL 60201).

Activation of muscarinic ACh receptors of cultured N1E-115 neuroblastoma and NG108-15 hybrid cells by 10^{-3} M carbachol causes a 60-100% increase in incorporation of $^{32}P_i$ into phosphatidylinositol (PI) during a 15 minute period. Enhancement of turnover can be observed within one minute after adding carbachol to cultures, and little or no desensitization occurs for at least 30 minutes. Stimulation of opiate, alpha$_2$, or serotonin receptors of NG108-15 cells does not increase PI turnover. Measurements of the specific activity of $^{32}P_i$ in PI have been facilitated by use of one-dimensional TLC for the rapid separation of phospholipids (butanol:acetone:acetic acid:water:: 5:5:1:1 on Whatman LK5D plates).

Because the muscarinic receptor-mediated increase in intracellular cGMP in N1E-115 cells appears dependent on calcium gating (R.E.Study, et al., Proc. Natl. Acad. Sci. 75: 6295,1978), it was of interest to examine the effect of changing the concentration of extracellular ions on the receptor-mediated stimulation of PI turnover in these cells. When Na^+ is replaced by choline or K^+, total incorporation of $^{32}P_i$ into PI is reduced by 90% and 50%, respectively. In contrast, removal of extracellular K^+ or Ca^{++} has little or no effect on $^{32}P_i$ incorporation. In all four cases, addition of carbachol increases PI turnover, although the percentage increase in the absence of K^+ or Ca^{++} is somewhat smaller than when these ions are present.

This work represents the first use of cloned cells to study receptor-mediated increases in PI turnover. In cloned neuroblastoma and neuron-like hybrid cells, muscarinic ACh receptors can mediate increases in PI turnover independently of the presence or absence of specific extracellular cations. The data are consistent with a possible role for enhanced PI turnover in the receptor-coupled calcium gating proposed to regulate intracellular cGMP. (Supported by NIH grant 5 R01 NS15299-02 to WLK.)

94.13 PURIFICATION OF THE SOLUBILIZED BENZODIAZEPINE RECEPTOR, J. Fong* and M. Goldstein (SPON: R. U. Margolis). New York Univ. Med. Cntr Dept. of Psychiatry, Neurochemistry Lab., New York, N. Y. 10016

Recently several methods for the solubilization of the benzodiazepine receptor from cerebral cortical membranes were described. We have attempted to purify the solubilized benzodiazepine receptor, using 1% Triton X 100 as a detergent. The solubilized membrane proteins were dialyzed against 0.1% Triton X 100 and 10 mM K-phosphate (KPi) buffer pH 6.3. Following dialysis and centrifugation at 100,000xg for 1 hr., the adsorption of the solubilized benzodiazepine receptor on different resins was tested. Chromatography on Concanavlin A- Sepharose 4B resulted in a 95% adsorption and 25% recovery following elution with 0.5 M α-methyl-D-mannoside. Chromatography on phosphocellulose resulted in a 75% adsorption and 25% recovery following elution with a gradient of 0.01-0.4 M KPi buffer (pH 6.3). Chromatography on hydroxylapatite(HA) resulted in a 95% adsorption and 40% recovery following elution with a gradient of 0.01-0.5M KPi (pH 7.0) + 0.1% Triton X 100. The solubilized benzodiazepine receptor was eluted from the HA column in two separate peaks. The first peak was eluted with 0.2 M Pi buffer and contained approx. 20% of the receptor, and the second peak was eluted with 0.35 M KPi buffer and contained also approx. 20% of the receptor. Scatchard plot analysis of H^3-flunitrazepam binding to the receptor isolated in the first peak revealed a Kd of 1.4 nM and that isolated from the second peak of 6.8nM. The binding of ^{3}H-flunitrazepam to the solubilized receptor obtained from both peaks was stimulated by GABA (approx. 90% stimulation at 10 μM GABA). Bicuculline at a concentration of 50 μM inhibited the stimulation elicited by 1μM GABA. The properties of the solubilized benzodiazepine receptors isolated from HA column are now being further studied.

94.14 INTERACTIONS BETWEEN THE BENZODIAZEPINES AND ALPHA-MELANOCYTE STIMULATING HORMONE (α-MSH). E. Matthew, D.L. Engelhardt*, J.D. Laskin*, and E.A. Zimmerman. College of Physicians and Surgeons, Columbia University, New York, N.Y. 10032.

High affinity binding sites for benzodiazepines (BDZ) have been demonstrated in the nervous system and in other organs, but no functional effects of these compounds have been established outside the nervous system. In earlier reports, we described melanotropic effects of benzodiazepines and high affinity binding sites (K_D=1.8±0.7nM) in the cell line B16/C_3 derived from a spontaneous melanoma in a C_{57} BL/6JAX mouse. These cells are of neural crest origin and are probably part of the APUD system. The combination of high affinity binding sites and a biological effect permits the study of the 'benzodiazepine receptor' in relation to other cell components. We now report the effects of alpha melanocyte stimulating hormone (α-MSH) which shares sequences 1-13 with ACTH. As with the benzodiazepines, α-MSH induced melanogenesis and differentiation in these cells in culture. However, the addition of α-MSH to radioreceptor assay for diazepam caused a two-fold enhancement of 3_H diazepam binding in cells at 70-90% confluency. When the cells were in stationary phase, this effect was not evident. Thus, although the benzodiazepines and α-MSH have similar melanotropic effects, they apparently do not act at the same binding sites. There are, however, significant modulatory influences between these substances which are most evident during cell growth and differentiation. This is the first demonstration of an association between the benzodiazepines and a peptidergic system. It emphasizes the value of the melanoma cell as an effective and accessible model in which to study benzodiazepine compounds.

94.15 ASCORBIC ACID INHIBITION OF DOPAMINE AGONIST BINDING IN STRIATUM T.N. Thomas, C. Koteel*, L.D. Middaugh and J.W. Zemp. Departments of Biochemistry, Psychiatry and Behavioral Sciences, Medical Univ. of S.C., Charleston, SC 29403.

Ascorbic acid (vitamin C) is a normal constituent of the brain and has long been known to be an important biological catalyst. Concentration of the vitamin in the brain of several mammalian species, including man, is higher than that of any other organ except the adrenal cortex, but the significance of ascorbic acid in brain function is yet to be realized. Recent findings in this laboratory indicate a role for ascorbic acid in regulating dopaminergic transmission. We have previously reported that ascorbic acid, like other known dopamine receptor blockers inhibited the dopamine-sensitive adenylate cyclase in rat striatum at physiological concentration. Subsequent studies revealed that elevation of ascorbic acid in rat and mouse brain specifically altered a variety of neurochemical, behavioral and physiological systems mediated by dopamine. This report is a further attempt to characterize the action of ascorbic acid on postsynaptic dopamine receptors in rat and bovine striatum.

Rat and bovine striata were removed and synaptic membranes were isolated using standard procedures. The membranes were washed thoroughly and the binding of the dopamine agonist, 8 nM ADTN (2-amino-6,7-dihydroxy-1,2,3,4-tetrahydronaphthalene) and the antagonist, 0.2 nM spiroperidol were studied by published procedures, in the absence of ascorbic acid. Nonspecific binding of the ligands to membranes were estimated by parallel incubation in presence of excess agonist apomorphine or dopamine (for ADTN) and antagonist + butaclamol (for spiroperidol).

In both rat and bovine striata, ascorbic acid specifically inhibited ADTN binding, with no evident effect on spiroperidol binding. In both species, a 50% reduction in ADTN binding was observed at a concentration of less than 5 μM ascorbic acid. The antioxidant properties of ascorbate have resulted in extensive use of this compound in studying the binding of ligands to neurotransmitter receptors. At 1 mM concentration normally used in dopamine receptor binding studies, there was 80% reduction in ADTN binding. Scatchard analysis of binding data in presence of varying concentrations of ADTN (0.1 to 8 nM) indicated that ascorbic acid caused a significant reduction in ADTN binding sites.

These results support our previous reports showing the ability of ascorbic acid to block the dopamine receptor and the effect seems to be on the agonist state of the dopamine receptor. Ascorbic acid might be thus useful in probing the agonist binding site of the dopamine receptor. This report questions the validity of previous dopamine receptor studies in presence of high concentrations of ascorbic acid.

94.16 GUANINE NUCLEOTIDES MODULATE RECEPTOR BINDING FOR TRH IN PITUITARY BUT NOT IN CNS. D. R. Burt and R. L. Taylor*. Dept. Pharmacol. Exp. Ther., U. Md. Sch. Med., Baltimore, MD 21201.

Guanosine-5'-triphosphate (GTP) and related nucleotides have been shown in vitro to lower the affinity of agonist binding for a variety of receptor types. This phenomenon is thought to reflect the existence of receptor-linked GTP-regulatory proteins as intermediates in the coupling of agonist binding to an adenylate cyclase or other response mechanism (Rodbell, 1980, Nature 284: 17). We report the detection of guanine nucleotide effects on receptor binding for thyrotropin releasing hormone (TRH) in membranes of sheep anterior pituitary gland and the inability to detect such effects in membranes from sheep retina or nucleus accumbens. Tissue resuspensions (100-200 mg wet weight/ml) in 20 mM $Na\text{-}PO_4$ buffer, pH 7.4, were incubated with 1-1000 μM GTP, guanyl-5'-yl imidodiphosphate (Gpp(NH)p, a nonmetabolizable analog), and other nucleotides for 5-20 min at 37°C, chilled, and diluted with an equal volume of 0.5-20 nM ^{3}H-TRH or ^{3}H-[3-Me-His^2]TRH with or without added nonradioactive TRH or [3-Me-His^2]TRH. The mixture was incubated for an additional hour on ice and filtered as previously described (Burt, 1979, Exp. Eye Res. 29:353). Gpp(NH)p, 100 μM, added to pituitary membranes during the 37° preincubation, increased the apparent K_D of ^{3}H-TRH binding from 27 ± 1 nM (6) to 47 ± 6 nM (4) with no effect on the B_{max} (13.1 ± 1.6 and 14.2 ± 1.7 pmol/g wet weight, respectively). Similar effects were observed with lower concentrations of Gpp(NH)p, with GTP and GDP (but not GMP, ATP, etc.), and with the new ligand for TRH receptors, ^{3}H-[3-Me-His^2]TRH (Taylor and Burt, 1980, Proc. Endocrine Soc., 62nd meet., in press). However, with neither ligand were we able to demonstrate nucleotide effects on TRH receptor binding in the retina and nucleus accumbens. This lack of effect was shown not to be due to soluble factors present in the central nervous system incubations by the ability of supernatant solutions from such incubations still to produce an effect when incubated with pituitary membranes. The apparent difference between brain and pituitary receptors for TRH in their response to guanine nucleotides is surprising in view of the close similarity of receptors in the 2 tissues in their kinetic properties and specificity for TRH analogs (Burt and Taylor, 1980, Endocrinology 106, in press), but is not unprecedented, e.g., for muscarinic (Ehlert et al., 1980, Life Sci. 26:245) or β (Hegstrand et al., 1979, J. Pharmacol. Exp. Ther. 210:215) receptors in certain rat brain regions as opposed to other tissues. It is not yet known whether such differences in nucleotide response among receptor binding sites in different tissues reflect actual differences in the binding proteins or rather differences in other components involved in coupling to a response. (Supported by grant MH-29671)

94.17 SOME STEREOCHEMICAL PROPERTIES OF THE 1-17 N-TERMINAL SEGMENT OF THE α-SUBUNIT OF THE ACh PROTEIN IN RELATION TO THE ACTUAL ACh BINDING SITE. J.R. Smythies. Neurosciences Program, UAB Medical Center, Birmingham, Alabama 35294.

The amino acid sequence of the 1-25 N-terminal segment of the α-subunit of the AChR protein is H - ser - glu - his - glu - thr - arg - leu - val - ala - asn - leu - leu - glu - asn - tyr - asn - lys - val - ile - arg - pro - val - glu - his - his - A Chou and Fasman analysis indicates that the segment from ser(1) to tyr(15) will probably be in the α-helical conformation and the segment from lys(17) to his(25) in the β-sheet conformation. Such an α-helix will be amphoteric with the array of hydrophilic amino acids down one side: glu(2), arg(6), asn(10), glu(13). This can be completed by lys(17) to form a regular array with the charge distribution - + ± - + . There are 4!/2 = 8 possible combinations of (+ or -) x 4 of which two are self-complementary. This sequence is one of these two. The α-subunit of the AChR exists as a dimer and is known to bear the actual ACh binding site. Thus two such (1-17) segments laid anti-parallel can form a four-runged grid made up of ionically linked complementary amino acids as follows: glu(2) to lys(17'); arg(6) to glu(13'); asn(10) and asn(10') (broken rung); glu(13) to arg(6') and lys(17) to glu(2'). This forms a symmetrical complex of two pairs of ionically bound rungs on either side of a central hole left by the short residues asn(10) and asn(10'). Experiments with CPK molecular models show that such a grid is highly complementary to a wide range of ACh agonists and antagonists. There are two pairs of potential ACh binding sites as follows. Site 1 (x2): lys(17) h bond to CO; asn(14) h bond to ether O; onium head in pocket between asn(10) and glu(13). Site 2 (x2): arg(6) to CO: his(3) to ether O: onium head to glu(2). The hypothesis is that ACh molecular binding in this manner would disrupt these ionic links and allow the two segments to separate, thus opening an ionic channel between them. Molecular model building experiments show that the separated segments (R1) are now complementary to antagonists such as curare, decamethonium, histrionicotoxin and snake neurotoxins. The closed conformation (R) is complementary to β-erythroidine. The hypothesis may be experimentally verified since it predicts that each α-subunit may be cross-linked by a covalent bond (using an agent such as carbodiimide) to its partner α-subunit via lys(17) to glu(2) (x2). Molecular models demonstrating these relationships will be presented.

94.18 DETERGENT SOLUBILIZATION OF AGONIST AND ANTAGONIST DOPAMINERGIC BINDING. E. Stefanini*, E. Suen* and Y. Clement-Cormier. Department of Pharmacology, The University of Texas Medical School, Houston, Texas 77025.

The binding of a radiolabelled agonist and antagonist have been used to characterize brain receptors solubilized with selected detergents. An extract, which binds (^{3}H) Spiroperidol exhibits stereoselectivity for (+) and (-) Butaclamol but does not bind the agonist (^{3}H)N-propyl-norapomorphine, was isolated from the dog striatal microsomes using the detergent digitonin. Conversely, the detergents deoxycholate and octyl-B-glucosylpyranoside solubilized receptor sites with a high affinity for (^{3}H)N-propylnorapomorphine but with a low affinity for (^{3}H) Spiroperidol. The extract that was solubilized with octyl-B-glucosylpyranoside was found to have essentially the same biochemical and pharmacological properties for (^{3}H)N-propylnorapomorphine as the native membrane bound receptor. Moreover, the site labelled with (^{3}H)N-propylnorapomorphine was heat stable up to 60 C whereas that for (^{3}H) Spiroperidol was heat labile. The results demonstrating both the differential solubilization of agonist and antagonist dopaminergic binding sites and the selective thermolability of the antagonist binding site, suggest that multiple binding sites may be involved in dopamine receptor responses in the brain. (This work was supported by grants from the Pharmaceutical Manufacturer's Association and the National Science Foundation).

94.19 SOLUBILIZATION AND PURIFICATION OF THE DOPAMINE RECEPTOR FROM CALF STRIATAL MICROSOMES: MULTIPLE BINDING SITES. Yvonne Clement-Cormier and Andrew McIsaac*. (SPON: B. T. Ho) Department of Pharmacology, University of Texas Medical School, Houston, Texas 77025.

Specific dopamine binding sites were solubilized from calf striatum using potassium chloride. The solubilized salt extract was found to have the same properties as the native membrane preparation including binding affinity and stereoselectivity. Gel filtration chromatography of the salt extract on Sephadex G-100 Superfine revealed the presence of multiple binding sites for the dopamine antagonist (^{3}H) Spiroperidol and the dopamine agonist (^{3}H) N-propyl-norapomorphine (NPNA). Some components bind only (^{3}H) Spiroperidol indicating a distinct and exclusive antagonist binding site and some components can bind both ligands indicating that a conformational change may occur to accomodate both antagonist and agonist drugs. The predominant site labelled by both (^{3}H) Spiroperidol and (^{3}H) NPNA had a calculated molecular weight of about 50,000 daltons as calibrated for globular proteins. Hill coefficients for selected agonists and antagonists of the dopamine receptor confirmed the presence of more than one population of agonist binding sites. Furthermore, the presence of high salt concentrations such as sodium chloride or potassium chloride can increase the affinity of (^{3}H) NPNA for the agonist binding sites but not the antagonist sites. These data support the existence of multiple binding sites of the dopamine receptor in the central nervous system. (This work was supported by grants from the Pharmaceutical Manufacturer's Association and the National Science Foundation).

94.20 LIGAND BINDING TO ACETYLCHOLINE RECEPTORS IN WILD TYPE AND ACETYLCHOLINESTERASE-DEFICIENT STRAINS OF THE NEMATODE C. ELEGANS W.M. James, C. DeCrease*, J.G. Culotti* and W.L. Klein. (Biological Sciences, Northwestern University, Evanston IL 60201)

Crude homogenates of the nematode worm C. elegans bind the cholinergic antagonists (^{3}H)QNB and (^{125}I)alpha bungarotoxin with high affinity. Specific binding sites are saturated by 10^{-9} M (^{3}H)QNB and by 2.5×10^{-9} M (^{125}I)toxin. In wild type strains, the maximum number of specific binding sites for (^{3}H)QNB is 15 fmols per mg total worm protein and for (^{125}I)toxin is 7 fmols per mg total worm protein. Competition experiments using unlabeled atropine, oxotremorine, carbachol, nicotine, and d-tubocurarine indicate that (^{3}H)QNB binding is to muscarinic ACh receptors and that (^{125}I)toxin binding is to nicotinic ACh receptors. The presence of acetylcholine receptors in C. elegans is in harmony with previous experiments showing locomotor deficits due to mutations in genes for acetylcholinesterase (J.G. Culott, et al., submitted to Genetics). Locomotor deficient ace-1 ace-2 double mutants have the same levels of acetylcholine receptors as wild type, although the locomotor normal ace-1 single mutant has only half the specific binding of the wild type when assayed using 10^{-9} M (^{3}H)QNB.

This is the first report of identification and quantification of any neuroreceptor in the nematode worm, an organism with a simple nervous system particularly amenable to genetic and developmental studies. The ability to measure acetylcholine receptors in this system suggests that it is possible to use the genetic advantages of C. elegans to assess the role and mechanism of action of specific neuroreceptors in neural development and also in simple behavioral traits. (Supported by NIH grant 5 R01 NS15299-02 to WLK.)

94.21 REGULATION OF β-ADRENERGIC RECEPTOR SUBTYPES IN RAT CEREBELLUM, CEREBRAL CORTEX, AND CAUDATE. B.B. Wolfe, K.P. Minneman*, M.D. Dibner and P.B. Molinoff. Dept. of Pharmacology, Univ. Colo. Health Sci. Ctr., Denver, CO 80262.

The effects of chronic alterations in β-adrenergic receptor stimulation on the densities of β_1 and β_2-receptors in regions of the rat CNS have been investigated (see Table). Noradrenergic stimulation was decreased by the chronic administration of the β-adrenergic antagonist propranolol or the neurotoxin 6-hydroxydopamine (6-OHDA). Both treatments led to increases in the density of β_1-receptors in the cerebellum and cerebral cortex without affecting β_2-receptors. To study the effects of increased norepinephrine availability, desmethylimipramine (DMI) or pargyline was administered. In the cerebral cortex these drugs decreased the density of β_1-receptors without changing β_2 receptors. In the cerebellum, on the other hand, administration of these drugs led to decreases in the the density of β_2-receptors. Decreases in the density of β_1-receptors were not observed, but since this receptor subtype comprises only 2-3% of total cerebellar β-adrenergic receptors, small decreases would have been difficult to detect. The administration of either propranolol or pargyline led to changes in the density of β_1-receptors in rat caudate.

	CORTEX		CEREBELLUM		CAUDATE	
	β_1	β_2	β_1	β_2	β_1	β_2
6-OHDA	↑59%	NS	↑250%	NS	NS	NS
PROPRANOLOL	↑51%	NS	↑150%	NS	↑11%	NS
DMI	↓42%	NS	NS	↓20%	NYD	NYD
PARGYLINE	↓23%	NS	NS	↓12%	↓22%	NS

Data are presented as % change from control values. All changes are significant ($p<0.0\%$). NS = $p>0.05$. NYD= Not yet determined

The data suggest that β_1-receptors in the cerebral cortex normally have a neuronal input. Interruption or facilitation of neurotransmission leads to reciprocal, compensatory changes in the density of these receptors. β_2-Receptors, on the other hand, are not regulated by these manipulations and may not receive a neuronal input. The density of cerebellar β_1-receptors increased as a consequence of manipulations that cause decreases in noradrenergic input, suggesting that these receptors also receive a tonic innervation. The decrease in the density of β_2 receptors in the cerebellum following DMI or pargyline suggests that drug induced increases in catecholamines released from the adrenal medulla or from nerve terminals have access to these receptors. Since chronic propranolol administration had no effect on these receptors they are unlikely to have a neuronal input under normal conditions. Surprisingly, some of these manipulations altered the density of β_1-adrenergic receptors in the caudate. These findings were unexpected since there does not appear to be a noradrenergic input to this brain region. These receptors may be on vascular elements affected by catecholamines released from the adrenal medulla. Supported by HL 24353, NS 13289.

94.22 BARBITURATES, BENZODIAZEPINES AND PURINES INHIBIT THE BINDING OF [^{3}H] α-DIHYDROPICROTOXININ. M.K. Ticku, T.P. Burch* and W. Davis*. Department of Pharmacology, University of Texas Health Science Center at San Antonio, Texas 78284.

[^{3}H] α-Dihydropicrotoxinin (DHP), a GABA synaptic antagonist having biological activity similar to picrotoxin, binds to rat brain membranes with an apparent K_D of ~2μM and a B_{max} of 5 pmol/mg protein (Ticku et al, Mol. Pharmacol. 14:319, 1978). The DHP binding sites are distinct from the GABA receptor sites and appear to be associated with the GABA receptor-ionophore system. Besides picrotoxin analogues, DHP binding is inhibited potently by depressant and convulsant barbiturates, benzodiazepines and purines. Depressant barbiturates inhibit DHP binding with IC_{50} values of 5-50μM. Stereoisomers of barbiturates which differ in pharmacological activity also inhibit DHP binding potently. In the case of depressant barbiturates like pentobarbital, the (-) isomer was three to four-fold more potent than its (+) isomer. Displacement curves with some barbiturates deviated from the law of Mass Action. Displacement curves with the (+) and (-) isomers of 1-methyl-5-phenyl-5-propyl barbituric acid, which show opposite pharmacological activity, were biphasic with a distinct plateau. These data suggest heterogenity of DHP binding sites. DHP binding was also inhibited by various benzodiazepines, including RO5-3553, with IC_{50} values ranging from 0.1-20μM. DHP binding was also inhibited by purines like inosine, hypoxanthine and adenosine, albeit with low potencies. It is interesting that purines inhibit the binding of DHP, GABA and diazepam to three distinct sites; nonetheless, all of these sites appear to be associated in the synaptic membranes. DHP binding was also inhibited by some of the fractions obtained by gel filtration of the supernatant of 100,000g rat brain pellet. Our preliminary studies indicate that deoxycholate extract of rat brain membranes binds [^{3}H] DHP with the expected properties. The DHP binding to deoxycholate extract was inhibited by picrotoxinin, DHP and pentobarbital.

94.23 DIFFERENTIAL SENSITIVITY OF MOUSE BRAIN SEROTONIN RECEPTORS TO ETHANOL IN VITRO. James D. Hirsch. Dept. Bio. Res., G.D. Searle & Co., Chicago, IL 60680.

During in vitro screening of drugs dissolved in ethanol it was observed that serotonin (5HT) receptors in whole mouse brain membranes labeled with [^{3}H]LSD were more sensitive to the alcohol than those labeled with [^{3}H]5HT. Further work revealed that versus [^{3}H]LSD in the presence of 1μM pimozide and 10μM dopamine (DA) to block [^{3}H]LSD binding to DA receptors, ethanol in the range of .054 to 2.17M had an IC_{50} of .63M. Versus [^{3}H]5HT, ethanol had an IC_{50} of 1.8M. These IC_{50}'s represent 2.7% (v/v) and 8.1% (v/v) ethanol respectively. With both ligands, non-specific binding was determined ± 10μM unlabeled 5HT. In the presence of 1μM pimozide and 10μM DA, [^{3}H]LSD labeled a single site noncooperatively (n_H=.95) and binding was saturable with a K_D of 13.8nM and a B_{max} of 86.3 fmol/mg protein. When assayed under identical conditions in the presence of .543M ethanol, binding was still saturable and noncooperative (n_H=.91), but had a K_D of 7.8nM and a B_{max} of 46.3 fmol/mg protein. Thus, ethanol caused a 46% decrease in the number of binding sites and a 43% increase in affinity. Double reciprocal and Scatchard plot analysis revealed that ethanol acts as an uncompetitive inhibitor of [^{3}H]LSD binding to 5HT receptors. In the presence of 10μM unlabeled 5HT, [^{3}H]LSD also labels DA receptors. In these experiments, non-specific binding was determined ± 100μM DA. Under these conditions, ethanol had an IC_{50} of .96M. Benzodiazepine, GABA, opiate and muscarinic receptors were not sensitive to the ethanol concentrations used here. These results lend support to the hypothesis that [^{3}H]LSD and [^{3}H]5HT label different populations of brain 5HT receptors and suggest that 5HT receptors labeled by [^{3}H]LSD are particularly sensitive to membrane perturbation by ethanol.

94.24 ADENOSINE RECEPTORS: ELECTROPHYSIOLOGICAL ACTIONS AT PRE- AND POSTSYNAPTIC SITES ON MAMMALIAN NEURONS. Barbara K. Henon, Diane K. Turner*, and Donald A. McAfee, Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

Our studies suggest that adenosine specifically antagonizes Ca^{++}-dependent processes in the rat superior cervical sympathetic ganglion in a receptor-mediated fashion. Postsynaptic effects were determined by intracellular potential measurements from single postganglionic neurons. These neurons show three Ca^{++}-dependent potentials: the Ca^{++} spike, the shoulder on the falling phase of the Na^+ spike, and the hyperpolarizing afterpotential (HAP). Presynaptic effects were determined by measuring synaptic depression. Repetitive preganglionic stimulation results in compound action potentials whose amplitudes depress as a function of time and stimulus frequency. This synaptic depression is decreased in lowered external [Ca^{++}], presumably by reducing depletion of readily releasable ACh.

Adenosine antagonizes these pre- and postsynaptic processes in a dose-dependent fashion. The EC_{50} for its effect on the HAP was 10 μM with maximal inhibition of 35% at 100 μM adenosine. Adenosine was less efficacious at 1 mM than at 100 μM. Other evidence for specific receptor-mediated action of adenosine is the observation that the enzyme, adenosine deaminase (10 μg/ml), blocks the effect of adenosine (250 μM) on the HAP and on synaptic depression. Cyclic AMP (250 μM) also decreased the pre- and postsynaptic signals, but this action was blocked by adenosine deaminase. It is possible that cyclic AMP must be metabolized to adenosine in order to antagonize the Ca^{++}-dependent responses. Theophylline (1 mM), an adenosine receptor antagonist, reduced by 85% the inhibitory effect of adenosine (100 μM) on the Ca^{++} spike. Theophylline alone had no effect on the Ca^{++} spike or on the shoulder of the Na^+ spike, two signals thought to be a direct result of the inward Ca^{++} current. Dipyridamole, which specifically blocks the uptake of adenosine in other cells, doubled the inhibitory effect of 10 μM adenosine in 3 of 4 cells tested. The response to 100 μM adenosine was unaffected by dipyridamole. This observation is consistent with the idea that adenosine acts on extracellular adenosine receptors.

The effects of adenosine are similar to those observed with α-adrenergic agonists. However, the effects of adenosine on synaptic depression were not altered by the α-antagonist, phentolamine. In addition, the postsynaptic effects of adenosine (10 μM) were additive with noradrenaline (1 μM). These results suggest that discrete pre- and postsynaptic receptors exist for both adenosine and catecholamines to control Ca^{++} influx and thus neuronal excitability. Supported by NSF Grant BNS 79-12394.

94.25 BINDING AND INTERNALIZATION OF ^{125}I-TETANUS TOXIN IN CEREBRAL CELL CULTURES. E. Yavin*, Z. Yavin*, W. H. Habig*, M. C. Hardegree* and L. D. Kohn* (SPON: J. W. Daly). Section on Biochem. of Cell Regulation, Lab. of Biochem. Pharmacology, and Bacterial Toxin Branch, Division of Bacterial Products, Food and Drug Administration, NIH, Bethesda, MD 20205

Tetanus toxin is a potent neurotoxin which is presumed to affect transmitter release at the nerve terminals and cause a syndrome of dysinhibition. The putative receptor for toxin binding has been postulated to be a polysialoganglioside. Studies with cultured cells of neural origin have established that tetanus toxin can be used as a highly specific neuronal marker because of its binding properties and its ability to alter the electrophysiology of these cells. There is currently no evidence whether and how the toxin is taken up by nerve cells, and whether uptake is important in its pathologic action. This concern is relevant given the ability of the toxin to undergo retrograde axonal transport. In the present report we document receptor mediated internalization of tetanus toxin by neuronal cell preparations grown for long terms in the absence of serum.

Dissociated rat embryo cerebral cells maintained in monolayer cultures in the presence of a mixture of 6 hormones to permit expression of neuronal characteristics and prevent glia proliferation, incorporate ^{125}I-tetanus in a time and ligand concentration-dependent fashion and with properties of a receptor mediated process. Uptake occurs equally effectively at 0° as at 37°C. Uptake can be partially prevented by the presence of 3×10^{-7}M unlabeled toxin or by a goat antitoxin. It is also inhibited (50%) by 5 mM EDTA. Pulse-chase studies in which radiolabeled toxin is exposed to cells and then chased with unlabeled tetanus toxin (25 µg/ml) tetanus toxoid (50 µg/ml) or tetanus antitoxin indicate that after 2 h radioactivity released in the medium approaches similar steady state levels irrespective of the compound added. This finding suggests a receptor-mediated process for uptake. The nonchased radioactivity associated with the cells can be completely extracted by sequential treatment with 5 M acetic acid or 0.5 N NaOH. About 25 to 35% of the radioactivity associated with the cells after chase can be extracted by either 0.1% Nonidet P-40 or 0.1% Triton X100. The bioactivity of this fraction is entirely preserved. The localization of the detergent-resistant toxin has been monitored by indirect immunofluorescence technique. Preliminary evidence suggests that it is associated with the cytoskeleton proteins.

95.1 PRELIMINARY OBSERVATIONS ON THE RELEASE OF LHRH FROM ISOLATED STORAGE GRANULES UNDER IN VITRO CONDITIONS. G.H. Burrows, J.C. Porter, and A. Barnea. Depts. Ob-Gyn and Physiology, Univ. of Texas Southwestern Med. Sch., Dallas, TX 75235.

Luteinizing hormone releasing hormone (LHRH), released from the hypothalamus, is involved in the regulation of the secretion of gonadotropins from cells in the pituitary gland. Although it is known that LHRH is stored in granule-like particles in hypothalamic neurons, the mechanism of release of LHRH from these granules is not known. In order to elucidate this mechanism, we have investigated under in vitro conditions the release of LHRH from LHRH-containing granules. Granules containing LHRH were isolated from homogenates of hypothalami obtained from adult male rats, employing differential centrifugation. After incubation, LHRH released into the medium was separated from the LHRH-containing granules by means of affinity chromatography. The LHRH that was released and the LHRH in the granules were quantified by radioimmunoassay. The granules were incubated for 1 hr at 22°C in a phosphate-buffered (10 mM, pH 7.8) solution of 320 mM sucrose. Of the total LHRH recovered, 7% was present as free LHRH in the medium and 93% was present in the storage granules. In the study of the effect of KCl on the release of LHRH, storage granules were incubated in a buffered (pH 7.8) solution of KCl (40, 80, 120, or 160 mM) for 1 hr at 22°C. The osmotic strength of the medium was adjusted to approximately 330 mOsm with sucrose. Twice as much LHRH was released in the presence of 160 mM KCl as in the absence of KCl. This small KCl-induced release of LHRH was found to be linear within the range of 40 to 160 mM KCl. The effect of H^+ concentration on the release of LHRH in the presence of 160 mM KCl was investigated. Incubation of granules at pH 7.8 resulted in a release of 14% of the stored LHRH, whereas incubation at pH 6.2 resulted in a release of 30% of the stored LHRH. This increased release of LHRH appears to be a saturable function of the H^+ concentration with maximal release occurring near pH 6.2. The effect of Mg^{2+} on the release of LHRH from LHRH-containing storage granules was also investigated. The presence of Mg^{2+} in buffered KCl (150 mM) solution at pH 7.8 enhanced the release of LHRH in a dose-dependent manner; at 10 mM $MgCl_2$, 25% of the stored LHRH was released. It is concluded that KCl, H^+, or Mg^{2+} induced the release of LHRH from its isolated storage granules under in vitro conditions. Based on these results, we speculate that these ions participate in the release of LHRH in the intact hypothalamus.

95.2 MECHANISM OF MONOVALENT IONOPHORE INHIBITION OF ACETYLCHOLINESTERASE SECRETION. Henry Smilowitz, Dept. of Pharmacology, U. Conn. Health Center, Farmington, CT 06032.

The monovalent ionophores nigericin and monensin inhibit acetylcholinesterase (ACHE) secretion from cultured chick embryo myotubes at 10^{-8}M to 10^{-7}M concentrations (Smilowitz, Molec. Pharm. 16:202-214, 1979). Our recent evidence suggests that K^+ transport is principally involved in the inhibition. Valinomycin inhibits ACHE secretion; half maximal inhibition is obtained at 10^{-8}M. Hence valinomycin is more potent (>) than nigericin > monesin. Concentrations of ionophore which lead to maximal inhibition of ACHE secretion do not result in net potassium loss from the cells or cell membrane depolarization. Nigericin at 10^{-8}-10^{-7}M does not alter intracellular K^+ and Na^+ after three hours; yet μM nigericin decreases intracellular K^+ and increases intracellular Na^+ 40%. Substitution of culture medium NaCl by KCl inhibits ACHE secretion while substitution of culture medium NaCl by potassium isethionate does not. The use of H^3 TPP (tetraphenylphosphonium) supports the conclusion that membrane depolarization is not involved as does direct electrophysiologic measurement of the resting potential in the presence and absence of nigericin. Additionally: (1) A23187 cannot overcome the effects of the monovalent ionophores, and (2) both monensin and nigericin can inhibit ACHE secretion in the absence of external sodium.

Ouabain mimics the effects of the monovalent ionophores. ACHE secretion and Rb^{86} uptake are both inhibited by ouabain; half maximal inhibition is obtained at 2 x 10^{-6}M ouabain at 4.5 mM external potassium, 10^{-7}M ouabain at 1.5 mM external K^+ and 10^{-4}M ouabain at 40 mM external K^+. ACHE secretion is inhibited by low external KCl and NaCl as is the Na^+, K^+ ATPase (Rb^{86} uptake). ACHE also accumulates on perinuclear intracellular membrane vesicles after ouabain or monovalent ionophore treatment as viewed by histochemical staining. Hence the Na^+, K^+ ATPase is involved in ACHE secretion. Since vanadate has no effect on ACHE secretion at concentrations which inhibit Rb^{86} uptake, these two processes are not obligatorily coupled.

We propose that potassium transport by the monovalent ionophores directly affects a putative regulatory site on the Na^+, K^+ ATPase which affects ACHE secretion. The monovalent ionophores inhibit Na^+, K^+ ATPase activity (hydrolysis of γ-P^{32} ATP) of aged red cell ghosts by 50% at .05-1.0μM levels. Rb^{86} uptake of cultured chick myotubes is twofold more sensitive to ouabain in the presence of 0.1μM nigericin. Hence we propose that ouabain affects both the ATP hydrolysis and the putative regulatory component of the Na^+, K^+ ATPase; monovalent ionophores primarily affect the regulatory component and vanadate inhibits ATP hydrolysis without an effect on the regulatory component. (NIH NS13860)

95.3 CONTRACTILE PROTEINS IN CHROMAFFIN CELLS IN CULTURE. D. AUNIS* (SPON : J. BABITCH). Ctr. Neurochem., U-44 Unit, F-67085 Strasbourg Cedex (France).

Isolated bovine chromaffin cells were plated on collagen-coated glass slides. After 2-4 hr, chromaffin cells started to attach and 12 hr later 50 % of the attached cells adopted an elongated bipolar shape. 24 hr later, up to five neuritic-like expansions could be observed on each individual cell. Cells cultured for more than 72 hr formed fine, colchicine-sensitive, neuritic extensions with numerous varicosities along their length and terminal growth cones. Anti-α-actinin, anti-actin and anti-myosin antibodies, together with anti-dopamine-β-hydroxylase (DBH) antibody, were used to localize homologous antigens by indirect immunofluorescence in parallel cultured of chromaffin cells. Staining with antiDBH antiserum showed a bright fluorescence, with a punctate distribution. Neurite-like elongations, varicosities and terminals were fluorescent. Labelling with anti-myosin antiserum was diffuse in cytoplasm and no fibrillar arrangement could be observed ; myosin was detectable in neurite-like elongations. Labelling with anti-actin displayed a punctate distribution : a fluorescent, granular pattern was visible in the cytoplasm and in neurite-like elongations. Faint, thin fibrillar structures, particularly in neurite-like expansions were also visible. Staining with anti-α-actinin was found in a punctate, fluorescent pattern ; fluorescence was detectable in neurite-like outgrowths and terminals where it was found to accumulate.

Chromaffin granules, the catecholamine-storing organelles, were isolated from intact bovine adrenal glands and the limiting membrane was isolated and solubilized with 2 % sodium docecylsulphate. Solubilized polypeptides were submitted to 4-30 % polyacrylamide gel electrophoresis under limiting pore size conditions. 37 bands with M.W. > 27,000 could be identified ; an actin-like and an α-actinin-like components (comprising, respectively, 0.5-1.5 % and 4 % of recovered proteins) were found to comigrate with actin and α-actinin. The α-actinin-like component was extracted from the granule membrane with low ionic strength buffers used to solubilize α-actinin from myofibril Z-lines and partially purified by chromatography on DEAE-cellulose. This component was enriched 3-fold and found to cross-react with anti-α-actinin antibody. External lactoperoxidase-coupled iodination of intact granules resulted in incorporation of radioactivity into the α-actinin-like component, an indication that this polypeptide is facing the cytoplasmic side of the granule.

These data show that the contractile machinery is present in chromaffin cells and its close relation with secretory vesicles suggests the contractile apparatus may be involved in granule transport and/or the release of stored material.

95.4 ADAPTIVE REGULATION OF PROLINE TRANSPORT IN MUSCLE CELLS. W.J. Logan, A. Klip*, E. Gagalang*. Neuromuscular Research Laboratory, The Hospital for Sick Children, University of Toronto, Toronto, Ontario. M5G 1X8.

L-proline (Pro) is accumulated by L-6 rat muscle cells in culture by a sodium dependent process. In other cell lines the transport of Pro and several other amino acids which utilize the A system adapt to substrate deprivation by increasing transport activity. In the present study we demonstrate the adaptive regulation of Pro uptake by L-6 muscle cells and further investigate its mechanism.

L-6 cells were incubated in a buffered solution with or without Pro (10 mM). Initial rates of pro uptake were then determined. Cells deprived of Pro for different periods of time showed a steady increase in initial velocity of uptake. After 6 to 7 h the maximum stimulation (4 to 6 fold) was attained. Under these conditions Vmax was 1.38 fmoles/cell/min and Km was 0.38 mM. This represents a 2 to 3 fold increase in Vmax and a 2 fold decrease in Km relative to basal uptake. Uptake of tryptophan was not enhanced by either tryptophan or Pro deprivation.

The stimulation of Pro uptake observed after 6 h of Pro deprivation could be reversed by a further 30 min incubation in 10 mM pro prior to uptake determination. This decrease in transport coincided with the build-up of free Pro concentration inside the cells. The stimulation was also reversed by loading the cells with other amino acids transported by the A system but not by those which are preferentially transported by other transport systems.

The decreased uptake rate in Pro loaded cells cannot be explained solely by the possible efflux of the accumulated amino acid, which could in turn dilute the external radiolabeled Pro during the uptake assay. This event would result in an apparent increase in Km, but Vmax should not be affected. The observed change in Vmax induced by Pro can be explained by the following mechanisms: (a) Decreased translocation rate (e.g. as a result of transinhibition). (b) A change in the number of transport sites. These possibilities are being tested by means of chemical and kinetic approaches. Differences in sensitivity to inhibition by SH-group reagents and in pH dependence suggest that the basal and stimulated transport may be mediated by two different populations of transport entities.

95.5 Na^+,K^+-STIMULATED ADENOSINETRIPHOSPHATASE IN THE CNS OF THE HAWK MOTH, MANDUCA SEXTA. A. L. Rubin*, A. F. Clark*, and W. L. Stahl. Depts. of Physiology, Biophysics, and Medicine, Univ. of Washington Sch. of Med., and the Neurochemistry Laboratory, VA Med. Ctr., Seattle, WA 98108.

Hemolymph from certain phytophagous insects has a low Na^+/K^+ ratio, and it has been postulated that for the nervous system to be functional, hemolymph Na^+ must be concentrated five- to ten-fold. To better understand the role of the Na^+,K^+-ATPase in insect nervous system homeostasis of Na^+ and K^+, we have studied the nerve cord and brain of M. sexta. Ventral nerve cords from immediately pre-emergent pupae were homogenized, briefly sonicated, and centrifuged to yield microsomes. Beef brain microsomes were used for comparative studies. The mammalian and insect Na^+,K^+-ATPases had similar pH optima and K_m values for Mg^{2+} and ATP. However, in M. sexta much higher levels of K^+ are required for full enzymatic activity. In the moth, a Na^+/K^+ ratio of 0.6 to 1.7 supported optimum enzymatic activity, whereas in beef brain optimum activity occurred with ratios between 1.3 and 10.8. Scatchard plots of ^{3}H-ouabain binding to nervous tissue in both species also yielded markedly biphasic curves under certain conditions. This different ion sensitivity of the Na^+,K^+-ATPase in M. sexta may reflect an adaptation for the high K^+ content in this insect's hemolymph. Additional studies demonstrated that inhibition of the M. sexta and mammalian Na^+,K^+-ATPase by cardiotonic steroids is complex and apparently biphasic (each prep. had I_{50} values of 10^{-6}M and 10^{-4}M with strophanthidin). Significant differences in sensitivity to K^+ and ^{3}H-ouabain binding to the enzyme were also noted. Finally, the enzyme was labelled with ^{32}P from AT^{32}P and was separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis. Two phosphorylated large subunits of the enzyme were observed in both the M. sexta and mammalian Na^+,K^+-ATPase. These results are consistent with the presence of two distinct Na^+,K^+-ATPases in the two preparations studied. The relative simplicity of the moth CNS compared to the mammalian CNS may provide a good model for direct study of the localization and role of these different Na^+,K^+-ATPases.

95.6 EFFECT OF DIETHYLDITHIOCARBAMATE ON BRAIN UPTAKE OF CADMIUM. L. Cantilena*, G. Irwin,* C. Klaassen* and S. Preskorn (SPON: E. Othmer). Depts. of Pharmacology and Psychiatry, University of Kansas Medical Center, Kansas City, KS 66103.

The element, cadmium (Cd) is largely excluded from the central nervous system by the blood:brain barrier (BBB). In a study of chelating agents to treat Cd poisoning, Cd (1 mg/kg) was administered intravenously 24 hours prior to measuring tissue concentration; the chelators were given intraperitoneally (i.p.) within a few minutes of the Cd. DDC, the metabolic product of disulfiram, produced a twenty-fold increase in the brain concentration of Cd while all other chelating agents tested decreased or had no effect on brain Cd concentrations. The effect of DDC on brain uptake of Cd following a single cerebral transit was then tested. DDC (10 mg/kg i.p.) given thirty minutes prior to intracarotid Cd administration caused a 6-fold increase in the single pass extraction of Cd into the brain.

Two mechanisms could explain this effect. First, DDC blocks norepinephrine synthesis by inhibiting dopamine-beta-hydroxylase. Since the central adrenergic system may act to modulate BBB (Preskorn et al., JPET, 1980), DDC might increase brain uptake of Cd by altering cerebral capillary permeability (CCP) or cerebral blood flow (CBF). Second, DDC might chelate with Cd to form a product which is more permeable across BBB.

To distinguish between these two mechanisms, a series of studies have been undertaken. The effect of this i.p. dose of DDC on CCP, ^{14}C and CBF was assessed. CBF was determined from the ratio of ^{14}C-butanol taken up by the brain to the ^{14}C-butanol in an arterial blood sample withdrawn at a constant rate following intravenous injection of a tracer bolus. Cerebral capillary permeability was determined as E_w (the extraction fraction of water) by the double diffusion tracer technique (Preskorn and Hartman, Biol. Psychiat., 1979). DDC did not alter either parameter, suggesting that the second mechanism--the formation of a more permeable product--accounts for the increase in brain uptake of Cd. Supported by USPHS grants GM 15956, ES 01142 and MH 27201.

96.2 QUANTITATIVE MEASUREMENT OF LOCAL METABOLIC RATE FOR GLUCOSE UTILIZING TRITIATED 2-DEOXYGLUCOSE. G. M. Alexander*.R. J. Schwartzman, R. D. Bell*,J. Yu and A. Renthal*. Lab. of Neurology, The University of Texas Health Science Center, San Antonio, Texas 78284.

The ^{14}C-deoxyglucose (2DG) technique has been widely utilized for the quantitative measurement of cerebral metabolism (ℓCMRG) in animals. This technique as presently used is limited by the energy of the ^{14}C B-particles, which can travel relatively great distances in tissue. This results in limited autoradiographic resolution and in computed ^{14}C concentrations which are a function of tissue section thickness. ^{3}H-2DG has less energetic B-particles; hence, the autoradiographs have better resolution and the optical densities are independent of tissue thickness for thicknesses greater than 5μ. We have recently developed a method for the quantitation of ℓCMRG in the rat using ^{3}H-2DG and a newly-developed ultrasensitive X-ray film. Autoradiographic tissue standards were prepared by injecting 8 rats with ^{3}H-antipyrine so that brain tissue concentration varied between 900 and 15,000 nci/g.

The antipyrine brains were cut in half, along the sagital plane. One half was cut into 20μ sections and used as tritium tissue standards; the other half was assayed for its tritium concentration in nci per gram of brain.

Four male wistar rats 250-350 g were used in this experiment. They were fasted for 16 hours; the femoral vein and artery were cannulated under light barbiturate anesthesia. The rats were allowed 24 hours to recover from the anesthesia, while the catheters were kept patent by slow continuous infusion of heparinized saline (1 ml/24 hr).

The animals were injected with a bolus of ^{3}H-2DG 200μci/g. Arterial blood samples were obtained, the animals sacrificed, and the brains frozen, sectioned and plated, along with the antipyrine tissue standards, for 20 days on LKB Ultrofilm. Tissue ^{3}H concentration was obtained autoradiographically; computation of the ℓCMRG gave values for the rat which were similar to those reported by Sokoloff et al, (J. Neurochem. 28:897-917, 1977) and Hawkins et al. (Stroke 10:690-703, 1979). The ℓCMRG from brain structures of adjacent sections showed no variation due to inadequate microtome precision. The resolution of discrete nuclei and particularly of fiber tracts is greatly enhanced, as compared with ^{14}C-2DG or ^{14}C glucose.

96.3 An autoradiographic analysis of ^{3}H-2-D-deoxyglucose uptake in the hippocampal region of the rat. J.P. Lund, J. Courville and J.J. Miller. Centre de Recherche en Sciences Neurologiques, Université de Montréal, Montréal, Québec, H3C 3J7.

Two series of experiments were carried out to examine a) the effects of various drug treatments on the uptake of deoxyglucose in the hippocampal region and b) to compare the relative distribution of radioactivity over cell bodies and neuropile.
a) 5 male rats (180-200 gm) were divided into 5 groups, one control and 4 others which received:
(1) chlorpromazine (12.5 mg I.M.); (2) ketamine (35.0 mg I.M.); (3) urethane (1.8 gm I.P.); (4) eserine (0.35 mg I.P.).
Ten minutes after injection of the drug, 1 mCi of ^{3}H-2-D-deoxyglucose was given I.P. and animals were killed by decapitation 30 min later. The whole brain was quickly dissected free and frozen in 2-methylbutane kept at -40°C in liquid nitrogen. Sections were cut at -18°C, dried and placed in contact with tritium-sensitive film for 3 weeks. Ketamine was found to increase deoxyglucose uptake above control levels in the molecular layer of the dorsal and ventral CA1 regions of the hippocampus and the ventral anterior nucleus of the thalamus (VA). Urethane reduced it markedly, while chlorpromazine and eserine had no effect. In the hippocampus, the labeling was heaviest in a band which appeared to cover the distal portion of the CA1 dendritic tree. The dendritic trees of the dentate granule cells were also densely labeled.
b) Blocks of tissue including the hippocampus and VA were removed from control and ketamine treated rats and frozen at -120°C in liquid nitrogen, cut in the dark at -30°C and placed in contact for 1 week with slides previously coated with NTB2 emulsion. Grain counts were carried out at consecutive positions across sections of the hippocampus and dentate gyrus and analyses of variance were used to evaluate the distribution of grains across the section. In the dorsal hippocampus, counts were approximately equal in strata oriens, pyramidale and radiatum, but were significantly higher in stratum lacanosum-moleculare. Ventrally, the heavily labeled band was wider, covering the distal half of the dendritic trees. Within stratum lacanosum-moleculare grains were equally numerous over neuropile and scattered cell bodies. Counts were higher over the molecular layer of the dentate granule cells than over their perikarya. In VA, the regions of highest grain density were also in the neuropile.

97.1 RESPONSE PATTERNING, T-MAZE ALTERNATION AND SEPTO-HIPPOCAMPAL CIRCUITRY. G.N.O. Brito and G. J. Thomas. Center for Brain Research, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

Four experiments investigated the ability of rats to discriminate a brain-built "cognition" of spatial (T-maze alternation) and temporal ("patterning") events as affected by small septo-hippocampal lesions inflicted before (acquisition) and after (retention) learning. In the T-maze hungry rats received 13T/day (12 opportunities to alternate) with a brief ITI under conditions of contingent reinforcement for alternating. Reinforcement consisted of about 10-sec access to wet mash introduced into the goal boxes after the rat had entered. In the runway rats also received 13T/day with a brief ITI, but they received similar reinforcement only on odd numbered trials. Under these conditions normal rats rapidly learn spatial alternation in the T-maze in few sessions, and in the runway normal rats learn to "pattern," i.e., to alternate running fast and slow. After behavioral testing, the lesions were evaluated histologically.

Small electrolytic lesions in posterodorsal septal area interfered significantly with acquisition of spatial alternation in a T-maze when the lesions were inflicted prior to learning. When the lesions were inflicted after learning and the animals were tested postoperatively (retention), they dropped to chance levels, but they recovered to normal levels within 9 sessions. The effects on temporal alternation in the runway were similar. Animals with lesions inflicted prior to learning acquired speedy running as quickly as controls, but they did not learn to pattern as well. When the rats had learned prior to surgery (retention) they dropped to chance levels of temporal alternation, i.e., they did not pattern, but by 15 training sessions they were patterning again, but not as well as controls.

The data suggest that interference with septo-hippocampal circuitry (some extrinsic afferent and efferent connections of the hippocampus) temporarily reduces the ability of rats to discriminate a brain-built cognition of where and when they last received reinforcement, a capability presumed to depend on "working memory."

97.2 REDUCTION OF THE SPATIAL REVERSAL DEFICIT IN MICE WITH SEPTAL LESIONS BY DISTRIBUTION OF TRIALS. C. R. Goodlett*, R. G. Burright* and P. J. Donovick. Dept. of Psychology and Center for Neurobehavioral Sciences, SUNY Binghamton, Binghamton, NY 13901.

The deficits in learning and performance following destruction of the septum have been shown to depend on task-specific parameters. For example, 24 hour spacing of trials eliminates the typical passive avoidance deficit of rats with septal lesions, indicating that deficits in response inhibition may result from disruption of temporal integration processes. Since spatial reversal is also known to reveal behavioral deficits in animals with septal damage, a water maze was used to assess the effect of distribution of trials on reversal performance.

Adult, male Binghamton-Heterogeneous mice were given large, bilateral septal lesions or control surgery, and were tested for position preferences in the water maze on the ninth post-operative day. Each surgical group was then randomly sub-divided into massed practice and distributed practice groups, and spatial discrimination to their non-preferred side was begun the next day. The mice in the massed practice groups were given 5 trials per day, with a 30 second inter-trial interval, while the distributed practice groups were given only 1 trial per day. A correction procedure was employed, and after reaching a criterion of 9 correct choices over 10 consecutive trials on the original spatial discrimination, the mice were reversed under the same training conditions to the 9/10 criterion.

There was no effect of surgery or training procedure on acquisition of the original spatial discrimination. For reversal, mice with septal lesions exhibited deficits only in the massed practice procedure. Control mice had similar trials to criterion (TTC) scores on reversal learning for massed and distributed practice (medians 26.5 and 24, respectively). The lesioned mice had significantly elevated TTC scores in the massed regimen (median 42), but were similar to controls when the trials were distributed (median 23). This pattern was also seen for initial errors to criterion, with controls having equivalent scores for massed and distributed practice, and lesioned mice having elevated initial errors with massed practice but not with distributed practice. In general, the distribution of trials dramatically improved reversal performance of the brain-damaged mice for measures taken across trials, but it did not affect their tendency to make repeated errors on the early trials during reversal training.

The results support the contention that septal lesions disrupt temporal integration processes. Factors contributing to the improved performance of brain-damaged animals with temporal spacing of trials will be discussed.

97.3 HOME ENVIRONMENTAL STIMULI ATTENUATE PERFORMANCE DEFICITS RESULTING FROM SEPTAL BRAIN DAMAGE. Gregory J. Smith*and Charles R. Goodlett* (SPON: Norman E. Spear). Department of Psychology, Case Western Reserve University, Cleveland, Ohio 44106 and State University of New York at Binghamton, Binghamton, New York, 13901

Previous reports have indicated that learning and performance deficits common to immature organisms may be attenuated if training occurs within the context of stimuli associated with the home nest environment.This effect,however,appears to disappear sometime between the ages of 20-30 d. postpartum in rats. The present series of experiments examined whether performance deficits following septal damage in adult rats (60-100d) might also be attenuated by the presence of home environmental stimuli during training. This hypothesis stems from the growing body of data suggesting that infantile behavior patterns may reappear following damage to the hippocampus or hypothalamus and neural degeneration accompanying normal aging.

The first experiment examined the spontaneous alternation behavior of septal lesioned female Sprague-Dawley rats and sham-operates in the presence of 7-day vintage litter shavings removed immediately prior from their nest cage (LS) or unsoiled,clean wood shavings (CS). The shavings were spread evenly beneath the wire mesh floor of an adult-size T maze during training. To assure a blind experimenter condition, another worker handled and gentled both lesioned and control groups for 7 days prior to training.

The results of Experiment 1 indicated that adult rats given septal lesions and trained in the presence of LS alternated in the T maze reliably more than lesioned rats trained in the presence of CS. Furthermore,septal rats trained in the presence of LS did not differ from controls trained in the presence of either LS or CS treatments. The presence or absence of litter shavings had no affect on the normal alternation behavior observed in sham control rats.

A second experiment examined the effects of home environmental stimuli on two types of passive-shock-avoidance behavior in septal lesioned adult rats.

These data suggest that performance deficits accompanying septal damage may be due to the stress of the test condition which can be attenuated by providing familiar home environmental stimuli in the test environment.

97.4 STRAIN DIFFERENCES IN THE BEHAVIORAL EFFECTS OF SEPTAL LESIONS IN MICE. R. J. Fanelli, P. J. Donovick, R. G. Burright* and W. J. Engellenner*. Dept. of Psych., Center for Neurobehavioral Sciences, SUNY Binghamton, Binghamton, NY 13901.

Over the past several years we have examined the behavioral effects of septal lesions in different strains of mice. We started with the assumption that destruction of the septal region enhances acquisition of two-way active avoidance tasks and impairs performance on passive avoidance tasks. We found that both of these brain damage effects are dependent upon the genotype of the animal. In attempts to explain these interactions between genotype and lesion effects, neurochemical analyses were performed, as well as batteries of tests designed to measure motor behavior and sensory reactivity. While genotype, lesion and interaction effects were present, they were not simply related across measures. The present investigations were designed to examine whether post-surgery and motivational reactivity might help clarify our previous findings.

C57BL/6J, RF/J or Binghamton Heterogeneous (HET) mice received either control operations or bilateral electrolytic lesions of the septal region. All animals were handled daily for a seven day recovery period during which reactivity (to handling) measures were taken. Then half of the animals were placed on a 23 1/2 hr water deprivation schedule and trained for acquisition and reversal of a spatial discrimination in a dry T-maze reinforced by water. The remaining animals were trained for acquisition and reversal of a spatial discrimination in a water maze placed in cold water. Following training, all animals were examined for shock sensitivity.

The results from the dry T-maze task further indicated the limitation of utilizing a single strain when examining the behavioral effects of brain damage. While the HET lesioned mice showed a clear decrement in performance relative to HET controls on acquisition of the discrimination, there was no difference between the lesion and control mice of the C57 strain on this measure, and in the RF strain, the lesioned animals actually performed better. In contrast, the three strains of mice performed relatively alike on the water maze task. There was no major differences on the acquisition of the spatial discrimination among any of the groups in the water maze but there was a lesion decrement on reversal of the discrimination. The results of the handling reactivity and shock reactivity measurements indicate significant strain by surgery interactions and seem to provide a possible explanation for some of the above findings. Thus, the need for a multifaceted approach to the study of the behavioral effects of brain damage, using a variety of tasks and genotypes, is indicated.

97.5 PARADOXICALLY ENHANCED LEARNING IN SEPTAL RATS: EFFECT OF NUMBER OF NONREINFORCED TONE PREEXPOSURES. H.A. Burton* and A.W. Toga (SPON: C. Tamminga). Neuroscience Program, Maryland Psychiatric Research Center, P.O. Box 3235, Baltimore, MD 21228, Neurology Department, Washington University, St. Louis, MO 63110.

Discrimination performance of rats with bilateral destruction of the lateral septal nuclei was enhanced by nonreinforced tone preexposure. Nonreinforced preexposure to a stimulus normally makes more difficult subsequent use of that stimulus for learning. The effect of this preexposure on learning is termed latent inhibition and was demonstrated in sham operated animals. Prior to surgery all animals were trained by appetitive conditioning to press a bar upon illumination of a cue (S^+) but not to the house light. Neither was lit during the intertrial intervals. The criterion for entering the second phase of the experiment was 80% response to S^+. Upon reaching this level subjects were divided into 8 groups matched for response rate. Four of these groups were assigned to the brain lesion and four to the sham condition. Bilateral ablation of the lateral septum was accomplished stereotactically. The sham controls underwent similar surgery except that the electrodes were lowered to just above the septum. Each operate and each sham group was assigned to a preexposure phase in which they received 0, 90, 180, or 270 presentations of a 1000 Hz tone within 60 minutes. The operate and sham groups receiving 0 preexposures sat in an identical training box without tone for 1 hour. Immediately following preexposure all animals were subjected to the first of four daily successive discrimination training sessions. S^+ now consisted of a simultaneous 5 sec. exposure to the tone, house and cue lights, and S^- the latter two alone. Latent inhibition or a delay in the initial learning following preexposure was less pronounced in operates. After testing the animals were killed by formolsaline infusion and the brains were removed for verification. The septal operate group receiving 0 preexposures exhibited the poorest discrimination performance as was evidenced by a high rate of S^- responding. A response perseveration model seems appropriate. Sham discrimination performance decreased with greater numbers of preexposures (latent inhibition effect), however septal discrimination performance was paradoxically enhanced. The septal operate group which received 270 preexposures exhibited discrimination performance significantly superior to all other groups. One may conclude that septal lesions have a disruptive effect upon the occurrence of latent inhibition, possibly by the release of behavior from those mechanisms which normally link it to appropriate stimuli, and that the lesion-preexposure compound appears to result in enhanced stimulus saliency such that successive discrimination performance can be controlled, and even made superior to that of controls.

97.6 EFFECT OF EARLY BRAIN DAMAGE TO HIPPOCAMPAL CONNECTIONS ON ACQUISITION OF A SPATIAL WORKING MEMORY TASK IN THE RAT. John A. Walker, Lydia E. Skinner*, and Eva S. Hersh*. Department of Psychology, Reed College, Portland, OR 97202.

In the adult rat, damage to the hippocampus or its extrinsic connections results in a severe and apparently permanent loss of ability to solve tasks requiring working memory, such as spatial alternation tasks. Animals with damage induced in adulthood perform at levels expected by chance, with no improvement with extensive testing for periods up to at least several months after surgery. However, the hippocampal circuitry is capable of remarkable plasticity. Moreover, in humans early brain damage results in little loss of certain kinds of abilities, while equivalent damage in the adult results in a profound and permanent loss. The present experiment investigated whether brain damage in young rats resulted in a deficit in working memory equivalent to that seen after adult brain damage, or whether there was a sparing of function as a consequence of the age at which the damage was induced.

The task was a spatial alternation test conducted on an elevated two-arm maze. At the beginning of each test, both arms contained a single 190 mg Noyes pellet in an opaque food cup at the end of the arm. After the rat had chosen one arm, only the choice of the other arm was rewarded (a correct choice). If the rat instead returned to the previously chosen arm (an incorrect choice), the test continued until the rat either chose the remaining arm, or had rechosen the first arm on six consecutive choices.

Rats were given bilateral fimbria-fornix lesions or control operations at either 7, 45, or 90 days of age. Rats were tested at about 90-120 days of age. Rats with control operations at any age learned the task to a criterion of 19/20 consecutive correct tests within an average of about 30 tests. Rats given fimbria-fornix lesions at 90 days showed the expected pattern of performance: their performance remained at chance levels up to the end of testing (150 tests, 30 test days). The pattern of errors made by the 90 day rats indicated no evidence of perseveration within a test: the rat was as likely to return to the already chosen arm as to choose the unchosen arm. In rats given fimbria-fornix lesions at 7 or 45 days, some but not all of the rats were able to learn the task, though not as efficiently as controls. In part, the ability of a rat to meet the criterion was a function of the extent of brain damage, and also a function of the age at surgery. These results suggest that, under certain circumstances, sparing of function after hippocampal system damage is possible. The mechanisms which underly this sparing are not yet known.

97.7 RATS WITH FIMBRIA-FORNIX LESIONS CAN USE A COGNITIVE MAPPING STRATEGY. J.T. Becker & D.S. Olton, Dept. Psych., The Johns Hopkins University, Baltimore, Maryland, U.S.A.

In order to determine the role of the hippocampal system in cognitive mapping, rats with lesions in the fimbria-fornix were trained to discriminate between two three-dimensional objects based on the location of these objects in the test environment. The rats were then given a series of transfer tests to determine: 1) the extent to which the rats used cognitive mapping strategies, and 2) the nature of the stimuli which controlled the rats' choice behavior.

The location discrimination was designed so that a rat could not predict the correct response based on either the stimulus characteristics of the objects themselves, or the location of the objects relative to himself as he entered the test arena. Only the location of the objects in the test environment accurately predicted the correct object.

The rats in the operated control group learned the discrimination in a mean of 50 trials, making 14 errors prior to reaching criterion performance. In contrast, the rats with fimbria-fornix lesions required 81 trials, and made 30 errors to criterion; both values significantly more than those of the rats in the control group.

The rats performed a series of transfer tests, called new door transfer tests, which required the rats to approach the goal locations from a new starting location, and travelling on a new path. The ability to perform accurately on the transfer trials is a critical test of the ability of the rat to use a cognitive mapping strategy. All of the rats, including those with lesions in the fimbria-fornix performed accurately on these transfer tests indicating that they were able to use a cognitive mapping strategy

A second series of transfer tests, called stimulus control transfer tests, was designed to determine the nature of the stimuli which controlled the rats' behavior. The rats with lesions in the fimbria-fornix differed from those in the operated control group in that these rats rarely (1 of 11) used the stimuli outside the arena to guide their choices.

These data demonstrate that although the rats with lesions in the fimbria-fornix were able to use a cognitive mapping strategy, the nevertheless used different cues to identify the correct location than did rats in the operated control group. These data are discussed in terms of the role of the hippocampal system in spatial information processing.

97.8 DELAYED RESPONSE (DR) PERFORMANCE OF FERRETS WITH FRONTAL LESIONS. Ausma Rabe, Yvette Zatz*, Raef Haddad and Donna Snow*. New York State Institute for Basic Research in Mental Retardation, 1050 Forest Hill Road, Staten Island, NY 10314.

Adult male ferrets with bilateral aspiration lesions in the dorsolateral frontal area (n=6) and sham operated controls (n=6) were trained in a Nencki box to select one of two positions signalled by a tone. They were food deprived and learned for a food reward (canned cat food), at the rate of 10 to 20 spaced noncorrection trials a day, five days a week. (1) Discrimination or predelay training: the ferrets were trained to choose the position at which the tone was sounded while the tone was on. The criterion was 45 correct responses in 50 consecutive trials (90%). (2) Delay training: the ferrets were permitted to make their choice following a 0,3,9 and 27 second delay after the presentation of the tone. The delays were randomized within the daily trials. Seventy trials were given with each delay interval. (3) Delay with distraction: an opaque cover was put over the restraining cage during the delay periods. Thirty six trials were given with each the 9 and 27 second delay.

The frontal ferrets mastered the initial discrimination at the same rate as the controls. The frontals were significantly poorer than controls at 0 delay (76% vs 85%, $p < .01$), but were not significantly impaired at 3,9, and 27 second delays; their performance did not deteriorate with the longest delay (76%, 79%, and 77%), while that of the controls dropped slightly (82%, 82%, and 77%). When distraction was introduced during the 9 and 27 second delays the performance of the controls, as compared to their own performance at these delays without distraction, showed only a small and statistically insignificant drop from 78% to 76%, while the performance of the frontal ferrets deteriorated appreciably from 81% to 62% ($p < .001$). The performance of the frontals was also significantly worse when compared to that of the controls (76% vs 62%, $p < .02$).

97.9 EFFECTS OF US PARAMETERS ON CLASSICAL CONDITIONING OF CAT HIND LEG FLEXION. A. G. Romano*, J. E. Steinmetz* and M. M. Patterson (SPON: M. P. Charlton). Dept. of Psych., Ohio Univ., Athens, OH 45701.

Using a new restraint system, we recently found rapid and stable conditioning of cat nictitating membrane and hind leg flexion responses which was relatively free of nonassociative responding. Brain correlates of cat nictitating membrane conditioning have already been examined. A comparison of brain correlates of conditioning for the two different response systems will be undertaken after identifying those parameters which produce similar conditioning performances in both response systems. Thus, two US parameters, intensity and duration, were manipulated to determine the minimal shock parameters necessary for reliable hind leg conditioning. Seventy-two cats were randomly distributed among nine experimental groups in which US intensity was either 2, 3, or 4 mA and US duration was 25, 50 or 100 msec. The CS was a 77 dB, 1000 Hz tone. The CS-US interval was 300 msec with the CS overlapping and coterminating with the US. The intertrial interval (ITI) was randomly varied among 50, 60, or 70 sec and averaged 60 sec. Nonassociative responding was assessed in eight additional cats who received unpaired presentations of the CS and the most severe US (4 mA, 100 msec), at an average 30 sec ITI. Each cat was placed in a plexiglas restraining device that allowed the hind legs to hang down. Conditioning took place in a converted, ventilated refrigerator shell. Two wound clips affixed to the right hind leg delivered the US while a third wound clip allowed the leg to be mechanically coupled to a potentiometer. All leg movements were transduced to dc signals and recorded on a polygraph. Time intervals and stimulus control were programmed by standard behavioral equipment. One day of adaptation to restraint, seven days of acquisition and two days of extinction were run. Acquisition for the experimental groups consisted of 45 CS-US paired trials and six CS-alone test trials while the control group received 51 CS trials randomly intermingled with 45 US trials. For all groups, no USs were administered during extinction.

Over the seven days of acquisition, the control group evidenced no reliable increase in their low level of responding while the experimental animals demonstrated significant conditioning with the level of conditioning increasing with increasing US duration. Although a significant US intensity effect was not observed, the level of conditioning appeared to increase with increasing US intensity at the 100 msec US. In general, the minimal shock level necessary for reliable conditioning appeared to be dependent upon shock duration rather than intensity with the 50 msec US producing the most consistent results.

98.1 ALGORITHMS FOR THE CHARACTERIZATION OF PULSATILE HORMONE SECRETION
G. R. Merriam and K. W. Wachter*, Developmental Endocrinology Branch, NICHD, Bethesda, Maryland 20205; and Dept. of Statistics, Univ. of California, Berkeley 94720.

The secretion of most anterior pituitary and many other hormones is episodic; for some hypothalamic peptides, such as LHRH, pulsatile secretion may be necessary to maintain agonist effects. The detailed cybernetics of pulsatile hormone levels have not been extensively studied, in part because objective criteria for identifying secretory pulses have been unavailable. We have developed algorithms for carrying out this process. There are three steps in the procedure: removing long-term baseline trends, such as diurnal rhythms, from the series of points; selecting secretory peaks in the residual series; and resolving each peak, if appropriate, into overlapping secretory episodes.

In the first step, we have employed a robust smoothing technique, using the method of Cleveland (J Am Stat Assoc 74: 829, 1979). This generates a smoothed series which omits peaks or trends with time constants less than 8-12 h; the characteristic smoothing time can be set freely. The smoothed series is subtracted from the original, and in the second step, their difference, the residual series, is examined for the presence of pulses. A robust estimate of the variance of the residual series is calculated, and points are rescaled in terms of variance units; if desired, the variance of the assay can be used as the criterion instead. Peaks are identified as individual sub-series elevated above the baseline, of duration t, all the points of which have magnitude at least G_t, where the G_t are cutoff criteria based upon the width of the peak. Thus the algorithm will select both narrow, high peaks, and broader peaks which may be lower. The user selects the G_t for each hormone based upon its half-life and other criteria. For example, for bovine growth hormone data collected at 15 min intervals, criteria of G_1=3.4 for peaks 1 point (15 min) wide, G_2=2.7 for 2-point peaks, G_3=1.7, G_4=1.33, and G_5= 0.55 have been used. Points which meet these criteria are identified as belonging to peaks and flagged. In order to assure that the smoothing process is not influenced by long runs of closely spaced peaks, these flagged points are then temporarily removed from the series, and the smoothing is repeated; the revised residuals are then re-examined. After these two steps are iterated until there are no further changes, each peak is examined in the third step, to determine whether it can be resolved into more than one overlapping peak. Finally, the process collects statistics on the average frequency and amplitude of the peaks in the series. This method appears to offer the flexibility to deal with a variety of kinds of episodic secretion. Computer programs to carry out this process have been developed.

98.2 ACCENTUATION OF THE DIURNAL PERIODICITY OF SLEEP AND ACTIVITY IN ADRENALECTOMIZED RATS BY CORTICOSTERONE REPLACEMENT.
D.J. Micco, Jr., Jerrold S. Meyer and Bruce S. McEwen. The Rockefeller University, New York NY 10021.

Glucocorticoid hormones have been reported to modify the temporal distribution of specific sleep sub-stages and activity. Previous work failed, however, to use the predominant glucocorticoid of the species being examined or else administered hormones by injections so as to produce fluctuating hormone levels. In the current study, we employed the predominant glucocorticoid for the rat, corticosterone (Cort), in s.c. pellet implants in order to produce constant serum levels of the hormone in previously adrenalectomized (ADX) rats. These implants produced plasma Cort levels comparable to normal resting afternoon levels (19 g%). Recording of sleep stages and activity was done automatically (Winson, Electroenceph. Clin. Neurophys. 41:179, 1976). Rats were maintained in an isolation chamber on a 12:12h light: dark cycle. In ADX subjects, the peak and trough of sleep and activity within the 12h day and 12h night were not pronounced although a definite 24h rhythm was observed. With Cort replacement therapy, a conspicuous enhancement of the amplitude of the daily rhythms in paradoxical sleep (PS) and activity occurred. In particular, Cort enhanced activity in the last 3h of dark and produced a greater change in PS during the first 3h of the lights-on period. The Cort effect on activity is reminiscent of the action of hippocampal ablation to increase activity during the last 3-4h of the dark phase (Iuvone and van Hartesveldt, Behav. Biol.19: 228, 1977). The results are consistent with our working hypothesis that the hippocampus, a primary cephalic target of glucocorticoids, may figure prominently in Cort effects on the brain. The notion of a net inhibition of the hippocampus by Cort is also consistent with previous work from our laboratory demonstrating a rather subtle modulating influence of glucocorticoids (in the same direction as the effects of hippocampal ablation) on behaviors believed to involve the hippocampus for normal expression (Micco, McEwen and Shein, J., Comp. Physiol. Psych. 93: 323, 1979, Micco and McEwen ibid. 94, in press, 1980). The current findings provide additional evidence for a modulatory, rather than determinant, role of glucocorticoids on neural activity and behavior. (Supported by grants from NSF GB43558 and NIH (NS07080). J.S.M. was a USPHS Postdoctoral Fellow (NS05040) and D.J.M. has received support from theAlfred P. Sloan Foundation.)

98.3 EFFECT OF SURGICAL OR PHOTOPERIODIC CASTRATION, TESTOSTERONE REPLACEMENT OR PINEALECTOMY ON MALE HAMSTER WHEELRUNNING RHYTHMS
L. P. Morin and L. A. Cummings*. Department of Psychology, Dartmouth College, Hanover, NH 03755.

1) Hamsters which had spontaneously recovered gonadal function after prolonged exposure to constant darkness (DD) achieved by blinding were castrated or sham operated. Half the castrates were given testosterone in a silastic capsule. All animals were then given access to running wheels. 2) Spontaneously recovered blind hamsters with access to wheels received the following treatment sequentially: sham operation; castration; blank capsule; testosterone capsule. 3) Photosensitive hamsters were pinealectomized or sham-P_x and placed in DD for 6 wks, to induce gonadal regression in to the sham-P_x animals. Animals were then given free access to running wheels. 4) Photosensitive hamsters were castrated or sham-operated, then placed in DD with access to running wheels. Subsequently, the animals received serial treatment of castration or sham-operation, blank and testosterone capsules. 5) Photosensitive animals were pinealectomized or sham-P_x, then placed in DD with access to running wheels.

The results showed that photoperiodic or surgical castration of animals prior to wheel access induced large increases in the variation of wheelrunning onset, a decrease in the number of wheel revolutions or minutes of running per day, a decrease in the number of activity bouts longer than 60 min, an increase in the number of activity bouts less than 6 min in duration, an increase in the number of total activity bouts and an increase in length in the active phase of the circadian locomotor rhythm compared to results from groups of animals with mature testes or testosterone replacement. Pinealectomy prevented DD-induced gonadal atrophy and the associated behavioral changes seen in sham-pinealectomized DD-exposed animals, changes which are best explained by the loss of testicular androgens in the latter animals. When the endocrine manipulations were performed sequentially in animals with prior access to wheels the effects of castration or hormone therapy on the above measures were not as clean as when the manipulations occurred prior to wheel access. The data suggest that access to wheels may influence the behavioral response to hormones, with animals tending to persist in the pattern which existed at the time of manipulation. There was no evidence that testosterone affected the circadian period of wheelrunning. The data suggest that if testosterone affects the circadian system of male hamsters, it does so by tightening the constraints on the activity phase, perhaps by slight changes in the phases of multiple oscillators regulating the locomotor rhythm.

98.4 THE RELATIONSHIP BETWEEN CORTICOSTERONE AND AVOIDANCE LEARNING.
J. H. Peck, S. Girelli* and M. Cohen*. Dept. of Psychology, Ithaca College, Ithaca, N.Y. 14850.

Some years ago a relationship was suggested between shuttle box avoidance and adrenal steroids such that as avoidance learning increased, blood levels of corticosterone decreased (Coover, et.al. JCPP, 1973, 82, 170-174). This study is an attempt to determine if there is a causal relationship between the levels of corticosterone and avoidance learning.

Avoidance rats (A) received 10 trials/day with a 60 second ITI. Each trial consisted of a tone followed 5 sec. later by 1 ma of scrambled foot shock. For each A rat which was trained in the shuttle box, there were 4 controls: 1) A yoked (Y) rat which received the same shocks as the avoidance rat, but with no opportunity to escape or avoid. 2) An all-shock (AS) rat which received 5 sec. of shock on each trial. 3) A handled rat (H) which was placed in a strange cage. 4) A basal rat (B) which was left in its home cage. The A rats (and their controls) were sampled after day 1 or upon reaching a 50%, 90% or overtrained (OT, 90% for 5 consecutive days) criterion. Upon reaching criterion, the rats were immediately decapitated, trunk blood was collected and corticosterone was later measured using a competitive protein binding assay. The first replications were run at the trough of the adrenocortical rhythm.

The greatest problem with the study was the failure of the rats to reach criterion and the replications were terminated after 30 days of training. This produced a new group of rats, the no-criterion rats (NC). Of the rats who reached criterion (about 30% beyond day 1) there was no evidence of a decline in corticosterone as a function of learning. Additionally, there was no decline in the NC rats nor any differences between the A and Y rats. All the control groups had about the same corticosterone values as rats killed on day 1.

Another set of replications was done at the peak of the adrenocortical rhythm. In fact about 50% of the rats reached criterion at the peak and adrenocortical values declined as the rats reached stricter criterion levels. But NC rats also showed a significant decline and there were no differences between A and Y rats.

Because of the small number of rats reaching criterion, no causal inferences can be drawn from these studies. It appears, however, that the decline in adrenal steroids is not related to learning because of the similarities of the A, Y, and NC groups at both the peak and trough of the adrenal rhythm.

98.5 CYCLIC NUCLEOTIDE LEVELS IN THE PITUITARY, HYPOTHALAMUS, PINEAL AND CEREBELLUM OF FEMALE RATS DURING THE ESTRUS CYCLE. G. Rufus Sessions, G. Jean Kant, Robert H. Lenox and James L. Meyerhoff. Depts. of Microwave Rsch and Med. Neurosciences, Walter Reed Army Institute of Research, Washington D.C. 20012 and Dept. of Psychiatry, Univ. of Vermont College of Medicine, Burlington, VT 05405

Current research has suggested that adenosine 3'5' monophosphate (cyclic AMP) and guanosine 3'5' monophosphate (cyclic GMP) function as "second messengers" in the CNS, mediating the effects of neurotransmitters. In several studies involving drug administration or certain types of stress, we have remarked on the exceptional responsivity of the pituitary cyclic AMP system (Kant et al. Biochem. Pharmacol. 29, 369-373, 1980). Since neurotransmitter turnover has been shown to change dramatically during proestrus in the female rat, we hypothesized that hypothalamic and pituitary cyclic nucleotide levels might fluctuate during the estrus cycle in response to these neurotransmitter changes. Changes in pituitary cyclic nucleotide levels might then have functional significance as regards pituitary hormone output during the cycle.

Forty-five female rats were maintained on a 14-10 hr light-dark cycle. Vaginal smears were obtained daily and rated by 2 observers to determine stage of estrus. Rats were sacrificed by microwave irradiation on the morning and afternoon of proestrus, at night during estrus and diestrus and the morning or afternoon of metestrus, diestrus 1, and diestrus 2. Cyclic AMP and cyclic GMP were measured by radioimmunoassay in the anterior and posterior pituitary, the hypothalamus, pineal, and cerebellum (Lenox et al, Neuroendocrinology, in press).

Cyclic AMP and cyclic GMP levels did not vary in any region examined as a function of the stage of the estrus cycle. However, the time of day at which the animals were sacrificed affected levels of cyclic AMP in the hypothalamus and cerebellum and levels of cyclic GMP in the cerebellum. Levels of cyclic AMP were as follows (pmoles/mg wet weight $\pm$ SEM): cerebellum 10 AM (.463 $\pm$ .037), 5 PM (.664 $\pm$ .033), 11 PM (.677 $\pm$ .064); hypothalamus 10 AM (.615 $\pm$ .029), 5 PM (.793 $\pm$ .037), 11 PM (.896 $\pm$ .055). In contrast anterior pituitary cyclic AMP levels were similar regardless of time of sacrifice: 10 AM (1.027 $\pm$ .051), 5 PM (.983 $\pm$ .071), 11 PM (1.057 $\pm$ .057). Cerebellar cyclic GMP levels (pmoles/mg wet weight $\pm$ SEM) were: 10 AM (1.338 $\pm$ .173), 5 PM (1.662 $\pm$ .154), 11 PM (2.257 $\pm$ .274). The increased nocturnal levels of cerebellar cyclic GMP may be a result of increased nocturnal activity (Meyerhoff et al., Life Sci 24, 1125-1130, 1979).

Cyclic nucleotide levels in the brain of female rats appear to be more influenced by circadian rhythms than by the estrus cycle.

98.6 THE EFFECTS OF ACUTE AND CHRONIC OVARIECTOMY ON PITUITARY-ADRENAL FUNCTION ON PROESTRUS IN RATS. S. Baron* and F. R. Brush. Psychology Research Lab., Syracuse Univ., Syracuse, NY 13210.

Female Long-Evans hooded rats were subjected to bilateral ovariectomy, sham ovariectomy, or no surgical manipulation between 0900 and 1100 hours on diestrus-2. Twenty-four hours or 21 days later, all rats were exposed to a 2-minute ether stress between 0900 and 1100 hours on proestrus (as determined by controls). Blood samples were collected from the external jugular vein within 3 minutes of onset of ether for the determination of resting concentrations of plasma corticosterone and by decapitation at 15 minutes after the onset of ether for the determination of stress-induced concentrations of plasma corticosterone.

The normally elevated resting concentrations of plasma corticosterone seen in proestrus rats were decreased 24 hours and 21 days following ovariectomy. However, a reduction in the stress-induced concentrations of plasma corticosterone was only observed at 21 days following ovariectomy.

Because ovariectomy resulted in a decrease in resting concentrations of plasma corticosterone, a subsequent study was designed to determine whether ovariectomy results in the elimination of A.M.-P.M. differences on proestrus. Using procedures described above, it was found that while ovariectomy resulted in a decrease in resting concentrations of plasma corticosterone in both the morning (1000 hours) and evening (1730 hours) of proestrus , the evening concentrations were higher than those observed in the morning. Therefore, the diurnal excursion of plasma corticosterone, while reduced, was not abolished by ovariectomy.

It appears that the ovarian hormones are responsible for the elevated resting concentrations of plasma corticosterone seen in the morning and evening of proestrus. Furthermore, the ovarian hormones contribute to the elevation of plasma concentrations of corticosterone observed in response to stress on proestrus, although ovariectomy does not affect the adrenal response to stress immediately. Therefore, the effect of ovariectomy on the pituitary-adrenal axis can be seen as a function of time after the removal of ovarian hormones.

98.7 A RETINAL PROJECTION TO THE LATERAL HYPOTHALAMUS IN THE RAT. J.N. Riley, J.P. Card, and R.Y. Moore, Dept. Neurology, State Univ. New York, Stony Brook, NY 11794.

A retinohypothalamic pathway terminating in the suprachiasmatic nucleus (SCN) of the hypothalamus is a consistent feature of the mammalian visual system. Although the existence of this pathway to the hypothalamus had been suggested in earlier studies, this pathway was not established until the development of newer anatomical methods, such as the autoradiographic method and electron microscopy of degenerating terminals. However, each of these methods is limited in its capacity to trace axonal connections. The autoradiographic method defines the course of a pathway but terminals occurring along the course of a pathway may not be identified. Electron microscopy is limited in its usefulness in screening for terminal fields. Usually other methods must be used to define areas of probable axonal termination prior to ultrastructural study.

During the course of a study of the organization of the hypothalamus neurons with dendrites extending into the optic tract were observed in Golgi-Kopsch material. In addition to neurons in the SCN and anterior hypothalamic area (Silver and Brand, Am. J. Anat., 155, 1979), some neurons in the lateral hypothalamic area (LHA) had dendrites extending into the optic tract. We have supplemented these observations with electron microscopy of normal material and experimental material prepared following enucleation or intraocular injection of horseradish peroxidase (HRP).

The presence of dendrites of LHA neurons in the optic tract was confirmed by electron microscopy. Axon terminals making conventional synaptic complexes with dendritic profiles were found within the optic tract. Following enucleation, some of the preterminal axons and terminals in synaptic contact with dendrites in the optic tract demonstrated dark degeneration. Intraocular injection of HRP resulted in the labeling of preterminal axons and synaptic terminals in the optic tract. Both Gray Type I and Type II synapses were observed.

These observations indicate that some LHA neurons receive a direct retinal projection from terminals making synaptic contact with LHA neuron dendrites that extend into the optic tract. The functional significance of this additional retinohypothalamic pathway remains to be determined.

Supported by USPHS Grant NS-16304 and USPHS Postdoctoral Fellowships NS-05732 and NS-06247.

98.8 RETINAL AND CNS INPUT TO THE SUPRACHIASMATIC NUCLEUS OF THE GOLDEN HAMSTER. A.J. Silverman and G.E. Pickard, Department of Anatomy, Columbia University, P&S, New York, NY 10032.

The temporal organization of hormonal secretions and behavior is the consequence of a neural timekeeping process. Numerous lesion studies have suggested that the suprachiasmatic nucleus (SCN) represents the endogenous clock responsible for maintaining hormonal and behavioral circadian rhythms. A direct retinal projection to the SCN photicly entrains these rhythms. To complete our understanding of the other neural inputs to the SCN a horseradish peroxidase (HRP) tracing study was undertaken.

HRP (30% solution in 0.05 M Tris, pH 7.6) was iontophoretically injected unilaterally into the SCN through 15-35 um (o.d.) micropipettes using positive current of 2uA for 2 min. After survival periods of 24-72 hrs the animals were perfused with 0.9% saline followed by 2.0% glutaraldehyde. During the saline perfusion both eyes were removed and the retinae were dissected free from the pigment epithelium. The retinae were fixed briefly in 1.5% glutaraldehyde; the brains were fixed overnight. HRP in the retinae and 60 um brain sections was demonstrated histochemically using the TMB procedure.

HRP labeled retinal ganglion cells were identified in retinal whole mount preparations. 85% of the 160 labeled ganglion cells measured after HRP injections into the SCN were classified as "large" (11-17um diameter). The number of labeled ganglion cells observed in each retina was equal; there was no tendency for the contralateral retinae to be more heavily labled.

Labeled neuronal perikarya were found throughout the diencephalon and midbrain. Neurons of the vLGN afferent to the SCN were principally located in the most dorsal aspect of the nucleus clustered beneath the fiber plexus separating the ventral and dorsal LGN. A few labeled neuronal perikarya were observed in the region of the vLGN-zona incerta and in the lateral terminal nucleus. A large descending ipsilateral input from the lateral and medial septal nuclei and the medial preoptic area was noted. Scattered cells were also found throughout the anterior hypothalamic area, the periventricular region, the ventromedial nucleus and the arcuate nucleus. A reciprocal connection to the contralateral SCN was also observed. A large number of labeled cells were found in the parasubiculum and the contiguous ventromedial portion of the subiculum, bilaterally. Labeled cells in similar numbers were seen in the dorsal raphe nucleus and in the nucleus centralis superior. Labeled cells were also seen in the dorsal and ventral tegmental nuclei and in the dorsal nucleus of the lateral lemniscus. Knowledge of the input to the SCN will aid in the understanding of the neural substrate underlying circadian rhythms. (Supported by PMAF (GEP) and HD-10665 (AJS).

99.1 MANIA: CONTINUOUS AND CATEGORICAL MEASURES OF SEVERITY. R.C. Young*, R.W. Nysewander*, M. Schreiber* (SPON: C. Shamoian). Dept. of Psychiatry, Cornell Univ. Med. Coll., Westchester Division, White Plains, NY 10605.

Forty hospitalized psychiatric patients who on admission fulfilled diagnostic criteria for mania (Feighner, J.P. et al., Arch. Gen. Psychiat., 26:57, 1972) were each studied twice. On each occasion, severity of illness was judged independently by two interviewers based on a brief semistructured joint interview using a rating scale of established reliability, validity, and sensitivity (Young, R.C. et al., Brit. J. Psychiat., 133:429, 1978). The scores assigned by the two interviewers were averaged. The assessments were done within the first week after admission and again two weeks thereafter. Treatment consisted of neuroleptics and lithium carbonate, usually in combination.

The initial median total score was 26.2 out of a possible 60 (range 9.3 - 45.0); the median total score on the second rating was 16.1 (range 2.0 - 31.5; $p < .001$). There was also a significant decrease between the first and second rating on each of the eleven item scores ($p < .05$).

Item scores were converted to categorical data by considering as "positive" those values ≥ 1.0 (≥ 2.0 for items 5,6,8,9). The most frequently positive ($\geq 80\%$) items on initial rating were "mood," "energy," "speech," "language-thought disorder," "content," and "insight." The least frequently positive ($\leq 40\%$) items were "disruptive-aggressive behavior" and "appearance." At the second rating, the "mood" and "insight" items were still frequently positive. Psychotic mental content (≥ 7.0 on item 8) was present in 25% on initial rating and 5% on the second rating ($p < .05$). When selected categorical data were examined with respect to criteria for mania, 95% of patients were manic at the first rating, while 48% were manic at the second rating ($p < .001$). Total rating scale scores were significantly different in the manic and hypomanic groups at both the first ($p < .05$) and second ($p < .001$) ratings. At the first rating, 63% of patients were categorized both euphoric and irritable.

99.2 LITHIUM ACCUMULATION IN VITRO: EVIDENCE FOR POSSIBLE NEURON-GLIA INTERACTION. R. P. Saneto*, S. K. Srivastava*, J. R. Perez-Polo (SPON: J. S. Kittredge). Dept. Hum. Biol. Chem. & Genet., Univ. Tex. Med. Br., Galveston, Texas 77550.

Lithium (Li) accumulation and the components of Li influx in cultured clonal cell lines of human neuroblastoma (SY5Y) and human glioma (A_1B_1) were studied to determine possible neuron-glia interaction. The probable target tissue for the efficacious effect of Li in manic depression is neuronal tissue. On the other hand, glia may play an important role in the regulation of Li concentration within the neuron by acting as an ion buffering system for neuronal tissue. To better understand this interrelationship, we used the ion transport inhibitors ouabain and phloretin to dissect Li influx components in neuroblastoma and glioma cells. Neuroblastoma cells have a ouabain but not a phloretin-sensitive component of Li influx; 0.1 mM ouabain significantly inhibited the influx ($n = 6$, $P < 0.005$) while 0.1 mM phloretin had no effect. Since inhibition by ouabain was only partial (49%), probably neuroblastoma have other component(s) of Li influx. In contrast, glioma does not have either a ouabain or phloretin-sensitive influx components; both 0.1 mM ouabain and phloretin have no effect on Li influx. However, since the accumulation of Li influx is saturable, it is likely that an active component(s) of Li influx exists. Glioma cells accumulated about 4-fold more intracellular Li ($n = 6$, $P < 0.001$) than the neuroblastoma cells. In addition, the affinity of entry was 3-fold and velocity of entry was 2-fold greater in the glioma cell. Although our studies are with glioma cells in culture the data suggest that glia may regulate the level of Li by preferentially accumulating and establishing the level of Li in the extracellular environment of neurons. Thus, the glia may play an important role in therapeutic action of Li.

99.3 THE EFFECTS OF THE PARASITE TOXOCARA CANIS ON BEHAVIOR IN THE MOUSE. Z. S. Dolinsky, R. G. Burright*, and P. J. Donovick. Dept. of Psychology and Center for Neurobehavioral Sciences, SUNY Binghamton, Binghamton, N.Y. 13901 and L. T. Glickman*, R. H. Cypess*, and J. Babish*. Dept. of Preventive Med., Cornell Univ., Ithaca, N.Y. 14850.

Toxocara canis, a parasitic roundworm commonly infects dogs. The eggs of the parasite are excreted in the animal's feces and may be ingested by children. The consequent symptoms include fever, leukocytosis, eosinophilia, hypergammaglobulinemia, and hepatomegaly. In addition, this parasite is known to migrate to the central nervous system in humans.

We examined the behavioral effects of the parasite Toxocara canis in mice. Binghamton Fuller Heterogeneous stock (HET) adult male mice were intubated with 1000 eggs (one gram of canine feces contains between 50-60 thousand eggs) of the parasite Toxocara canis. Control animals were intubated with an equal volume of physiological saline. Seven weeks later a battery of behavioral tests were begun. Tests included: home cage behavior; open field and water dip activity; performance on a passive avoidance task; ability to remain on a rotorod; and activity in running wheels. These tests required 8 weeks. Animals were then sacrificed and brains examined for larvae.

Through most of the behavioral testing there was no evidence of body weight or gross physiological disturbance as a result of Toxocara administration. However, Toxocara mice were less likely to explore the vertical aspects of their environment than controls as measured by ascending to another cage by chain or by standing up in an open field. Toxocara mice also exhibited altered behavior in water and dry open fields. Furthermore, Toxocara animals required more trials to learn a shuttle passive avoidance task.

Not until 11 weeks post-intubation did the Toxocara animals begin to lose weight relative to controls and continued to do so through the remainder of the behavioral testing. Behavior continued to reflect the effects of Toxocara. These mice left the rotorod sooner than controls. In addition, Toxocara animals were less active in the running wheels than controls.

Histological examination revealed larvae in cerebellum, brain stem, hippocampus, basal ganglia, colliculi and cerebral cortex. The number of larvae per weight of region was greater in these areas than in olfactory bulbs or hypothalamus.

These results suggest that Toxocara canis can alter motor activity in mice and may have important implications for children who have a known history of pica for dirt.

99.4 HOST DETERMINANTS OF THE BEHAVIORAL EFFECTS OF HERPES ENCEPHALITIS IN THE LABORATORY MOUSE. D. McFarland* and J. Hotchin. Division of Laboratories and Research, New York State Department of Health, Albany, NY 12201.

Previous work in this laboratory (McFarland, Baker, and Hotchin, Physiology and Behavior, in press) has indicated that host and viral genetic factors greatly influence the nature of the behavioral effects of scrapie viral encephalopathy. In order to determine whether similar dependencies exist with other forms of viral encephalitis, the influence of host genetics on the behavioral consequences of experimental herpes encephalitis was examined in the present investigation. Nylar and Swiss mice were given immunizing footpad inoculations followed two weeks later by intracerebral herpes inoculations. The effects of the viral infection on open field and Y-maze exploration were subsequently examined. A significant interaction between host genotype and the effects of viral infection was obtained. These results suggest that organismic factors may be important determinants of the effects of CNS viral infections and suggest one possible source of the diversity of sequela observed in clinical populations.

99.5 DOUBLE-BLIND EVALUATION OF THE POTENTIAL THERAPEUTIC EFFECTS OF HEMODIALYSIS IN SCHIZOPHRENIA. D.P. van Kammen, S.C. Schulz*, J.E. Balow*, G. Mundinger*, W. Flye*, W.E. Bunney, Jr. *Biological Psychiatry Branch, NIMH, Bethesda, MD 20205.*

INTRODUCTION: To evaluate the reported improvement in schizophrenia with hemodialysis (Wagemaker and Cade, 1977), we designed a double-blind, sham-dialysis-controlled protocol to study the effects of hemodialysis on healthy, well-diagnosed schizophrenic patients. METHODOLOGY: 3 male and 5 female schizophrenic patients (RDC) (average age 30 yrs.) who had been ill for an average of 9 yrs. completed 20 weekly dialysis sessions: 10 consecutive active dialyses and 10 sham dialyses. They had signed informed consent forms prior to participation and formation of the arteriovenous fistula needed for blood access. We used an opaque EX-23 dialyzer coil with a cuprophan membrane of 18μ thickness and a surface area of 0.8 m^2, identical to the dialyzer used by Dr. Wagemaker. Blood-flow rate was maintained at 200 ml/min. and a dialysate-flow rate of 300 ml/min. Sessions lasted for 5 hrs. The double-blind was maintained by using an identical-looking opaque dialyzer containing tubing rather than a membrane and by administering fluids intravenously and orally. Double-blind behavioral evaluations were performed extensively by psychiatrists and nurses using the Brief Psychiatric Rating Scale (BPRS) and the Bunney-Hamburg Global Behavioral Rating Scale. RESULTS: Analysis of the double-blind psychiatrists' ratings revealed that there was no significant difference for the patient group between active and sham dialysis. No single patient responded to 10 wks. of active dialysis with a decrease in global psychosis or in affective symptoms. The double-blind nursing ratings corroborated the psychiatrists' observations. No individual symptoms such as hallucinations or thought disorder were decreased by active hemodialysis; 4 patients showed unequivocal worsening at the end of their active trial; complications and side effects were minimal. DISCUSSION: These data will be compared to other negative and positive reports of nonblind evaluations in the literature since 1960. At this time hemodialysis cannot be recommended as a treatment for schizophrenia. Inasmuch as only 8 patients completed the trial, further double-blind evaluations of other schizophrenic patients are needed to determine the effects of hemodialysis in schizophrenia.

100.1 COLLATERAL ARBORIZATION OF AXONS OF RAT STRIATAL NEURONS IN THE GLOBUS PALLIDUS STUDIED BY INTRACELLULAR HORSERADISH PEROXIDASE LABELING. H. T. Chang, C. J. Wilson* and S. T. Kitai, Dept. of Anatomy, Michigan State University, E. Lansing, MI 48824.

Studies employing retrograde axonal transport of horseradish peroxidase (HRP) have established that the majority of striatal neurons are projection neurons. Combined electrophysiological studies and intracellular labeling have further demonstrated that medium spiny neurons are striatal projection neurons and in some cases their axons could be traced to the globus pallidus (GP). In order to determine more precisely the pattern of termination of striatal efferents, we have examined in detail the collateral arborizations of striatal axons in GP.

Following intracellular recording of striatal neurons in the rat, cells were labeled by intracellular injection of HRP. After fixation in aldehydes, sagittal sections containing striatum and GP were processed for demonstration of HRP and prepared for light and electron microscopic analysis using the section-embedding procedure of Wilson and Groves (1979). After giving off numerous local collaterals, the axons of some very heavily stained medium spiny neurons could be followed for distances of several millimeters and were traced into GP. In all these cases, the main axons did not appear to end in GP, but were seen to give off various patterns of collateral arborization in GP. In some cases, the axons of the medium spiny neurons appeared to be unbranched throughout their course in striatum and gave rise to only a few collaterals terminating in GP. In other cases, axons from medium spiny neurons divided within striatum to form two or three branches which took a parallel course toward GP. These branches gave rise to extensive and highly overlapping axonal arborizations which involved large areas of GP and were oriented primarily in the rostro-caudal and dorso-ventral planes. These striatal efferent plexuses in GP consisted of thin unmyelinated fibers and boutons packed with large and moderately pleomorphic vesicles resembling to those formed by the intrinsic collaterals of spiny neurons within striatum. These terminals formed symmetrical synapses on dendritic shafts and somata of GP neurons and were similar to those described by Kemp (1970).

These observations indicate that: 1) At least some strio-pallidal projection neurons are medium spiny neurons, 2) The pattern of strio-pallidal terminal arborization is highly organized and involves a large area of GP, and 3) Individual striatal projection neurons may vary in their patterns of collateral arborization in their target areas. (Supported by USPHS Grant NS 14866).

100.2 PROCESSING OF SOMATOSENSORY INFORMATION IN THE GLOBUS PALLIDUS OF CATS. T. I. Lidsky and J. S. Schneider, SUNY at Stony Brook,N.Y.

Several different investigators have reported that high proportions of neurons in the globus pallidus (GP) changed firing rate during eating and drinking. However, the functional significance of these neural responses remains obscure. In an effort to better understand the nature of pallidal involvement, a series of experiments was begun with the general aim of assessing the role of the GP in the various sensory and motor processes which are important in ingestion. This abstract presents data concerning information processing in the GP with specific reference to those sensory stimuli important for ingestion.

Units were recorded from awake, partially restrained cats. Von Frey hairs,blunt wooden probes and an electromechanical device (that produced events of reproducible magnitude and duration) were used to present somatosensory stimuli.

48% of sampled GP cells responded to somatosensory stimulation of the face. Receptive fields varied from moderate in size (e.g. a vibrissa field) to quite large (e.g. the entire face). 68% of receptive fields were confined to areas served by one branch of the trigeminal nerve, 16% were from areas innervated by two branches and 16% from areas innervated by all three branches. 65% of the receptive fields were contralateral, 6% ipsilateral and 29% bilateral.

Response latencies were short (mean, 10.2 msec) and thresholds were quite low. The majority of cells were activated by Von Frey hairs calibrated at 1 gram. Increasing response magnitude resulted in more vigorous neuronal responding. However, given the variability in unit response on successive trials, only gross differences in force were being encoded.

42% of responsive cells were solely or best activated by rapid brushing of the hairs rather than indentation of the skin. Half of these cells responded primarily to stimuli moving in a particular direction.

Several aspects of GP sensory responses seemed particularly relevant for the control of ingestional behavior. 53% of the receptive fields included perioral tissue. Moreover, when stimuli were applied within various portions of the receptive field, the most pronounced responses were evoked from zones closest to the mouth. Finally, the majority of directionally sensitive neurons responded best to stimuli moving along a path directed toward the mouth.

(Supported by USPHS grant NS15328 from the NINCDS)

100.3 STRIATAL NEURONAL ACTIVITY AND THE CONTROL OF HEAD MOVEMENT IN CATS. J.S. Schneider and T.I.Lidsky, SUNY at Stony Brook,N.Y.

Previous work from this laboratory has shown that neurons in the head of the caudate and the putamen are involved in ingestive behavior. The present work was intended to further analyze the properties of cells in these areas with respect to sensory and motor processes which are components of ingestion.

Striatal neurons were recorded from chronically prepared cats. During testing, animals were restrained in a device which allowed rotational head movements in the horizontal plane.

37% of striatal cells changed firing rate in relation to some aspect of head movement. These movement-related cells could be grouped into one of three categories based on response characteristics. Type 1 (21% of movement units) fired only if postural fixation of the head was disrupted. When rotational force was applied to the cat's head by the experimenter and the animal resisted displacement, firing of these cells increased. However, type 1 cells did not change firing rate during self-initiated movements.

Types 2 and 3 movement cells (respectively 54% and 25% of movement cells) fired in relation to self-initiated head movements. Type 2 changed firing rate at the onset of head displacement and well after onset of neck muscle EMG activity. Type 3 cells changed firing rate before onset of EMG response. Lead times as long as 1200 msec were encountered although these latencies varied considerably on successive movements. While all type 2 and type 3 cells fired in relation to movements in either direction, roughly half of these cells showed augmented responding to particularly directed movements. Unit activity did not relate to other parameters of head movement such as magnitude, velocity or absolute position. No striatal cells were found which fired in specific relation to jaw or tongue movements.

24% of striatal cells (both those related and those unrelated to head movement) were responsive to cutaneous somatosensory stimuli. Receptive fields were moderate to large but always included perioral tissue. When stimulation was applied within various portions of the receptive field, the largest responses were evoked at the front of the mouth. Some cells were only responsive to moving tactile stimulation; stimuli which moved along a path directed to the front of the mouth evoked enhanced responding.

The sensory properties of striatal cells suggested the encoding of a tactile stimulus' position with respect to the front of the mouth. The motor concomitants of striatal activity suggested a role in the control of axial muscles. Taken together, these data indicate striatal involvement in the somatosensory control of head positioning.

100.5 TOPOGRAPHICAL STUDY OF THE STRIATOFUGAL PATHWAYS IN THE CAT AND THE MONKEY. M. Giguère and L.J. Poirier. Centre de recherche en neurobiologie, Hôpital de l'Enfant-Jésus, Québec, Qué. G1J 1Z4.

The organization of the striatofugal fibers was studied with the autoradiographic technique. The course and distribution of these fibers were compared in different animals following the injection of ^{3}-H leucine in various parts of the caudate nucleus and putamen. Their course and pattern of distribution are to a certain extent different in the two species.

In the monkey, the striatal efferents are topographically related to the corresponding parts of both divisions of the pallidum along the dorsoventral and rostrocaudal axes. In the sagittal plane, however, the caudato-pallidal and putamino-pallidal fibers end in the dorsomedial and the ventrolateral parts of both divisions of the pallidum, respectively. The striatopallidal fibers represent the most important projection from these structures. The striato-nigral fibers terminate in the substantia nigra in a reversed dorso-ventral pattern. The caudato-nigral fibers reach approximately the medial half of the substantia nigra and terminate in both the pars compacta and reticulata along the whole rostrocaudal extent of this structure. The putamino-nigral fibers follow a more lateral course and terminate more laterally and also over the entire rostrocaudal extent of the substantia nigra. Striatal efferents however do not apparently reach the most lateral part (pars lateralis) of the substantia nigra in the monkey.

The striatopallidal efferents have a similar topographical distribution in the dorsoventral and rostrocaudal axes in the cat and monkey. Caudato- and putamino-pallidal fibers, however, overlap at the level of the pallidum in the sagittal plane of the cat brain. In this species the entopeduncular nucleus receives fibers from the caudate nucleus but not from the caudal part of the putamen. Putamino-nigral fibers from the caudal part of the putamen, however, end in the most lateral part (pars lateralis) of the substantia nigra. Therefore the caudal half of the putamen end exclusively in the pallidum and the pars lateralis of the substantia nigra. Caudato-nigral fibers end over the whole pars compacta and reticulata of the substantia nigra. Fibers originating in the rostral part of the caudate nucleus project more medially in the substantia nigra and those originating more caudally terminate more laterally in this same structure. Moreover the pattern of distribution of the caudato-nigral fibers in the substantia nigra is more diffuse along the rostro- caudal or sagittal plane. (Supported by grant MT-732 of the Med. Res. Council of Canada).

100.6 CELLS OF ORIGIN AND AXONAL BRANCHING PATTERNS OF THE CORTICO-STRIATE PATHWAY IN RAT. S.E. Knowles*, C.S. Lin, J.K. Chapin and D.J. Woodward. (SPON: D.C. German). Dept. Cell Biology, Univ. of Texas Health Science Center, Dallas, Texas 75235.

The aim of this study was to determine the organization of neural projections from the cerebral cortex to the striatum of rat and in particular to establish: a) which cortical layer(s) project to the striatum; b) the soma size and axonal morphology of corticostriatal cells, and c) the degree of overlap of the striatal projections from different cortical areas.

HRP uptake and transport as a method for study of pathways was augmented by adding 1-3% lysophosphatidyl choline to a 20-30% solution of HRP prior to injection (2-3 μA, 15 min). The DAB reaction was enhanced by preincubation in 0.5% $CoCl_2$. In addition to retrogradely labeling cell somata, this technique also permitted visualization of the morphology of the somata, dendritic trees, axons and axon collaterals of both ortho- and retrogradely filled cells.

Small groups of retrogradely labeled cells were observed in cortex after discrete (usually less than 1 mm diam) HRP injections into striatum. A topographical organization was observed, with each cortical area examined (prefrontal, MI and SI) projecting to its striatal target. HRP filled corticostriatal cell bodies were found mainly in ipsilateral layer V. Most corticostriate cells fell within the small to medium size range (5-15 μM diam).

HRP injections were also made into electrophysiologically identified MI and SI forepaw and vibrissae areas and anterogradely filled axons in the striatum were examined. Termination zones found in the lateral striatum were clearly distinguished from larger mediodorsal areas containing heavy parallel bundles forming the internal capsule. Axon collaterals branched from the major corticofugal bundles and traveled for 500 to 1000 μM before arborizing into diffuse networks which contained varicosities. Major termination sites from the MI forepaw area were ~ 1mm rostral to those of the SI forepaw area. Overlap was observed in the peripheries of the striatal projection zones of these homotopic cortical regions.

In summary, a heterogeneous population of cortical layer V cells project to the striatum of rat. At least some of their axons are collaterals of projections to other subcortical sites. A topographical organization with a small degree of overlap between somatic sensory and motor areas is present in the corticostriate pathway.

100.7 MONOLAYER CULTURES OF NEWBORN RAT CORPUS STRIATUM by Anne Messer, Div. of Labs & Research, NYS Department of Health, Albany, NY 12201.

Monolayer cultures of corpus striatum cells from newborn rats have been established using techniques similar to those previously described for rat and mouse cerebellum. Cells can be grown on media supplemented either with horse serum, or with an "artificial serum", a modification of the hormone mix first described by Bottenstein and Sato, and seem to exhibit a variety of rather similar neurochemical properties under the two conditions.

Striata dissociated with trypsin at room temperature are plated on to polylysine coated glass coverslips and incubated with 10% horse serum for 24 hours; then the coverslips are inverted and the media is changed to include either 10% horse serum or an artificial serum containing insulin, transferrin, progesterone, putrescene and selenium.

After 21 days in vitro, the majority of the cells have rounded, 9-12μ cell bodies, with scant cytoplasm and 2-5 processes. A few larger neurons and a substantial number of flatter cells (probably atrocytes) are also observed in all cultures.

Biosynthesis of γ-aminobutyric acid (GABA) and acetylcholine has been demonstrated by incubating whole cells with precursors, and measuring products using high voltage electrophoresis. Differences in transmitter synthesis between horse serum and artificial serum-grown cultures are not significant.

Thirty to 50% of the neuronal-looking cells in the culture, as well as many of the flat cells, show high-affinity uptake of GABA. Quantitatively, both the levels of GABA uptake, and the proportion of the total uptake which can be inhibited by the glial uptake inhibitor β-alanine are similar under the two culture conditions.

The presence of leu-enkephlin in the serum-free cultures can be demonstrated by immunocytochemistry.

100.8 ENTOPEDUNCULAR NUCLEUS PROJECTIONS TO THE POSTERIOR MESENCEPHALON. E. Garcia-Rill, Dept. Anatomy, Univ. Arkansas for Medical Sciences, Little Rock, AR 72205.

We reported previously the existence of a small projection from the entopeduncular nucleus (EN) to the mesencephalic locomotor region (MLR) (Skinner et al., Neurosci. Abst. 5, 1979). We were able antidromically to activate EN neurons (less than 6%) from the same mesencephalic site stimulation of which, following precollicular-postmamillary transection, elicited locomotion on a treadmill in the same animal. This site was invariably located in the postero-medial cuneiform nucleus (CF). Recent studies reported similar (Larsen and Sutin, Brain Res. 157, 1979) and much greater (Filion and Harnois, J. Comp. Neurol. 181, 1978) numbers of antidromically activated EN neurons by stimulation of more anterior mesencephalic sites, from which locomotion cannot be induced.

In order to determine the synaptic effects of EN terminals on neurons in the posterior mesencephalon, intracellular recordings of neurons in CF and posterior nucleus tegmenti pedunculopontinus (NTPP) were carried out in locally anesthetized, paralyzed cats after suction ablation of the occipital cortex and removal of the tentorium. Stimulating electrodes were placed in EN (n=3), caudate nucleus (CN) (n=4), internal capsule (IC) (n=2) and motor cortex (n=4). Almost 10% of neurons in CF and posterior NTPP were found to respond to EN stimulation. Only cells which were driven from EN and, at longer latency, from CN, and did not respond to IC stimulation, were included in this group. All of the responses elicited in this area following EN stimulation were EPSP or EPSP-IPSP sequences. The mean latency to the beginning of the EPSP was 6.8 ± 1.7 (S.D.) ms following EN stimulation, and 11.2 ± 1.2 (S.D.) ms following CN stimulation. A similar proportion (10%) of neurons which responded to EN stimulation, but not to CN or IC stimulation, showed a mean latency of 12.5 ± 6.02 (S.D.) ms. These longer latency effects could be mediated in CF and NTPP via the substantia nigra. Although a large portion (30%) of neurons in the posterior mesencephalon responded to IC stimulation, none of these were found to respond to motor cortex stimulation. These results support our previous report describing terminal labeling only anterior to the MLR following injections of tritiated amino acids into motor cortex.

These findings support the suggestion that the EN-MLR pathway may be involved in the triggering, via the MLR, of locomotion generators. In the diseased state, lack of activity along this pathway may be partly responsible for the inability to initiate sequences of movements in which locomotion is necessary.

100.9 PALLIDAL AND HYPOTHALAMIC INFLUENCES ON LATERAL HABENULAR NUCLEUS. Russell L. McBride. Dept. Anatomy, Emory Univ. Sch. of Med., Atlanta, GA 30322.

The entopeduncular nucleus (feline homologue of the primate medial segment of globus pallidus) and lateral hypothalamus-preoptic region project to the lateral habenular nucleus (LHB). While this indicates the LHB is a site of convergence of basal ganglionic and limbic system output, retrograde transport studies have shown that the region of LHB receiving pallidal input projects to the ventral tegmental area, while the region receiving hypothalamic input projects to raphe, paramedian reticular formation and central gray. This study was designed to determine the influences of pallidal and hypothalamic activation on the activity of LHB projection neurons in different regions of the nucleus.

In barbiturate anesthetized adult cats, bipolar stimulating electrodes were placed in the lateral hypothalamus and entopeduncular nucleus to orthodromically influence LHB neurons, and in the fasciculus retroflexus to antidromically activate LHB projection neurons. Extracellular recordings were made from LHB neurons with micropipettes filled with 4 M NaCl. Neurons were considered to be antidromically activated if they followed high frequency stimulation with constant latency and showed collision. Latency of antidromic activation of LHB neurons averaged 5 msec. Locations of stimulating and recording electrodes were verified histologically.

Both hypothalamic and entopeduncular stimulation resulted in inhibition with short latency and long duration of antidromically identified LHB neurons. Stimulation completely inhibited the activity of LHB neurons for 75 to 300 msec, with most neurons inhibited for about 150 msec. Some neurons responded with a single 3 to 5 msec latency spike followed by inhibition. The short latency spike followed high frequency stimulation with constant latency and therefore may be an antidromic response.

While a few LHB cells responded only to lateral hypothalamic or entopeduncular stimulation, most responded in the same manner to both stimuli. The similarity of responses from the two stimulation sites may be due to activation of entopeduncular axons as they pass through the lateral hypothalamus. Since entopeduncular stimulation should not activate lateral hypothalamic neurons, however, these studies indicate the entopeduncular nucleus influences LHB neurons in the same manner regardless of the location of the neurons.

100.10 EFFECT OF CORTICAL ABLATION AND OF TEGMENTAL MIDBRAIN LESIONS ON HEAD TURNING INDUCED BY ENTOPEDUNCULAR AND BY NIGRAL STIMULATION IN THE CAT. R. Hébert* and M. Filion. Lab. Neurobiologie and Dépt Physiologie, Fac. Méd., Univ. Laval, Québec, Qué., Canada G1K 7P4.

In previous studies we have shown that the majority of medial pallidal (entopeduncular) neurons in the monkey and in the cat send branches of their axon to the ventrolateral thalamus and to the midbrain pedunculopontine nucleus. Nigral neurons also branch to the thalamus and to the midbrain. This suggests that pallidal and probably nigral activity can use thalamocortical as well as midbrain pathways to control motoneurons. To clarify this point, the entopeduncular nucleus and the substantia nigra were stimulated unilaterally with bipolar concentric electrodes in cats. Pulses of current of 0.1 ms duration were delivered in trains of 40 pps during 3 s. The stimulation was applied when the animal was sitting quietly and looking straight ahead. A light emitting diode was fixed to the head of the animal and filmed from above to record horizontal head movements. The intensity of the light was increased at the time of stimulation to measure the latency of the response.

Unilateral entopeduncular and nigral stimulation elicited contraversive head turning as described in the litterature. Threshold intensities were in the range of 0.05 to 0.5 mA. The latency of the movement was around 1000 ms at threshold and never shorter than 100 ms at maximum intensity of stimulation. When the responses to stimulation were stable, as shown by latency/intensity curves, two operations were performed under anesthesia at a month interval: 1) the rostral portion of the stimulated hemisphere (including frontal, somatosensory, motor and parietal cortical areas) was completely disconnected from the brain by suction of a slab of tissue in an oblique plane from above the rostral thalamus to the middle of the olfactory tract; 2) electrolytic lesions were made in the midbrain to destroy the pedunculopontine nucleus and tectal efferent fibers on the stimulated side. To date, our largest midbrain lesion destroyed these structures extensively but not completely. Yet, after these large cortical and midbrain lesions, the threshold and the latency of head turning were similar to those recorded before the lesions. Therefore, extensive lesions of cortical and of tectal efferent fibers and of the pedunculopontine nucleus spare a sufficient number of efferent fibers for head turning to be produced by entopeduncular and by nigral stimulation as easily and as rapidly as in intact animals. The effect of more complete midbrain lesions and of commissural lesions is under study.

100.11 THE RAT OLFACTORY TUBERCLE: ITS CONNECTIONS AND RELATION TO THE STRIO-PALLIDAL SYSTEM. Richard B. Goldschmidt* and Lennart Heimer (SPON: M. West). Anatomy Inst. B, Univ. of Aarhus, 8000 Aarhus C, Denmark.

The olfactory tubercle is a heterogenous structure in the basal forebrain containing several different cell groups which are more or less intermixed. Although the rat olfactory tubercle is typically divided into layers like a cortical structure, Heimer and Wilson (1975) have suggested that many connections of this region are unlike any other cortical region and that some of its connections seem to resemble those of the striatum and globus pallidus. This suggestion was examined in more detail by comparing the experimentally observed projections of the olfactory tubercle with those of the striatum, nucleus accumbens, globus pallidus, and the neighboring pyriform cortex.

Connections of the superficial part of the tubercle were studied using laminar heat lesions. Degeneration was stained with the deOlmos cupric silver method. Medium-sized cells of the "pyramidal" layer project dorsally and caudally to terminate in the polymorph layer of the tubercle and more dorsally in the area called "ventral pallidum". In contrast to neighboring allocortical areas, no association pathways from these "pyramidal" cells to other cortical areas have been identified.

The suggested "ventral pallidal-thalamic" projection originates from neurons deeper in the tubercle, in the polymorph layer and "ventral pallidum". These large neurons were retrogradely labeled after injections of HRP or fluorescent tracers into the mediodorsal thalamic nucleus. Injections of fluorescent tracer into the subthalamic nucleus were used to evaluate the pallidal nature of this region. Many neurons were labeled in the main, dorsal part of the globus pallidus (external segment), but very few neurons were labeled in the "ventral pallidum". Since the "ventral pallidum" shares a common iron positive neuropil (Switzer & Hill, 1979) and is continuous with the external segment, and like the internal segment (entopeduncular n.) has a thalamic projection and no subthalamic projection, it shares some features of both these parts of globus pallidus. It should also be emphasized that there are important differences between the main, dorsal parts of the striatum and pallidum and the "ventral strio - pallidal system" to which the olfactory tubercle contributes.

Supported by NIH Grant NS15510-02

100.12 WIDESPREAD PROJECTIONS TO THE STRIATUM FROM THE LIMBIC MESOCORTICES IN THE MONKEY. C.L. Barnes,* G.W. Van Hoesen and E.H. Yeterian (SPON: A. Applebaum), Depts. of Anat. & Neurol., Univ. of Iowa, Iowa City, IA 52242.

The identification of structures responsible for the initiation of motor behavior has been elucive. In terms of cortex, early thinking assumed that motor cortex was connected directly to sensory cortex and that this linkage provided a means for triggering motor movement. With the exception of somatic sensation, anatomical results have not supported this seemingly logical supposition. In fact, physiological studies suggest that cortical influences on motor cortex may be channeled through the basal ganglia and cerebellum. Their influence on the thalamus then heralds a response in motor cortex. Thus, corticostriate and corticopontine projections may be viewed as early components in multisynaptic pathways enabling widespread parts of the cortex to influence motor behavior. Corticostriate projections are thought to arise from all parts of the cerebral cortex. However, little information is available on corticostriate projections from the cortical areas that constitute the limbic lobe. We have observed that the cingulate, retrosplenial, parahippocampal, temporal polar and orbitofrontal cortices all have powerful projections to the caudate nucleus and putamen, and thereby, provide a limbic influence on the striatum in consort with the more well-known sensorimotor influences. The brains of 25 rhesus monkeys were available for study. In each, tritiated amino acids (^{3}H-leucine, lysine and proline) had been injected into the various areas of the limbic lobe. Autoradiography was used to assess terminal labeling. It was observed that all limbic cortices project to the striatum, and in particular, to the caudate nucleus. Projections from the parahippocampal cortices terminate over all parts of the caudate nucleus (head, body, bend and tail). Cingulate projections terminate over the head, body and tail as well, with anterior areas (areas 24 & 25) projecting in addition to the putamen. Temporal polar and posterior orbitofrontal areas project mainly to the head and tail of the caudate nucleus, although orbitofrontal projections also terminate over the anterior part of the putamen. Overlap in topography has been observed, and in general, the heaviest projections are directed toward the periphery of the striatum. For all cases, terminal labeling was patchy, forming an overall mosaic-like pattern. These results provide evidence for a strong limbic influence on the striatum in the monkey, and may represent a structural basis for affect-related influences on motor behavior. (supported by grant NS 14944).

100.13 STRIATONIGRAL RELATIONSHIP IN MACAQUES. John Hedreen, Mahlon DeLong, and Glenn Holm. Departments of Cell Biology and Anatomy and Physiology, Johns Hopkins Medical School, Baltimore, MD 21205

According to current views of the striatonigral relationship in primates, derived principally from fiber degeneration studies, the striatonigral projection ends almost wholly in the pars reticulata of the substantia nigra (SN). The topographic interrelationships have not been completely worked out, although an exchange of connections between rostral striatum and rostral SN, and between caudal striatum and caudal SN, has been commonly accepted. Our studies with axonal transport methods require that these concepts be revised.

We made injections of combined tritiated amino acids and HRP, or HRP alone, into the neostriatum in 10 hemispheres of 5 Macaca cynomolgus monkeys. Stereotaxy was guided by multiple prior penetrations with a recording electrode.

The HRP-tetramethylbenzidine sections, and to a lesser degree the autoradiography + HRP-diaminobenzidine sections, revealed striatonigral terminals and nigrostriatal cells in the same sections. In many places the heavy terminal fields in the pars reticulata were seen to extend up and engulf groups of labeled pars compacta cells.

The labeled terminals occurred in dense patches within a broad strip extending the entire length of the SN, located along the medial edge after injections of rostralmost striatum, and more and more lateral with more and more caudal injections. The strips of terminals were not exactly parallel to the midline, especially more laterally, but paralleled instead the course of fibers in the underlying cerebral peduncle. The nigral projection fields from different regions of striatum showed considerable overlap, although whether there is convergence at the single cell level is not certain. Dense populations of labeled cells were seen in approximately the same longitudinal strips as the labeled terminals in the same case, and were sometimes immersed in a sea of such terminals. More scattered labeled cells extend medial to the terminal strip. Differences between dorsal and ventral, or medial and lateral injections were less apparent.

These findings provide anatomic evidence for a striato-nigrostriatal loop, and yield a new concept of the relationship between striatum and SN in primates.

100.14 GLOBUS PALLIDUS: NEURONAL RESPONSES TO ARM LOADING. M.H. Branch* M.D. Crutcher, and M.R. DeLong. Dept. Physiol., Johns Hopkins University Sch. Med., Baltimore, Md. 21205

Neurons in the basal ganglia of behaving primates have been shown to alter their activity in a variety of motor tasks. This study examines quantitative responses of neurons in the globus pallidus of monkeys to load pertubations of the arm. Monkeys were trained to grasp a torquable manipulandum and maintain a steady position using visual feedback of arm position. Step loads were then applied to the handle, displacing the limb either toward or away from the animal. The animals were required to recover and maintain their initial limb position against the sustained load.

Neurons were selected for study in the task only if their activity was correlated with movements or manipulations of the arm. 91% of the neurons studied (n=33, 2 hemispheres) responded vigorously to the application of the load; 80% of these cells altered their activity at latencies of less than 100 msec after load onset. The median latency was within 40-60 msecs, with less than 7% of the neurons responding at latencies in the 20-40 msec range. 73% of the activity changes consisted of increases in discharge rate. In some cases, reciprocal changes in rate were observed with load application of opposite direction. In addition to the short latency responses observed, 53% of the neurons maintained an altered discharge rate during the static phase of the task (i.e. after recovery of initial limb position) suggesting a tonic neuronal relation to muscle tension.

The response latencies observed in globus pallidus neurons were sufficiently brief to suggest a proprioceptive input. However, responses to limb pertubations at similar latencies (40 msec) in motor cortex (1) and dentate (2) appear to be related to the "motor set" of the animal rather than to the kinesthetic input. Therefore, the responses observed in globus pallidus neurons may be related to the ensuing movement rather than to the afferent input. We are currently investigating this problem in the putamen, subthalamic nucleus and globus pallidus in order to clarify the processing of proprioceptive input within the basal ganglia.

100.15 SINGLE UNIT ACTIVITY IN THE SUBSTANTIA NIGRA (SN) OF AWAKE RATS DURING CONDITIONED FORELIMB MOVEMENTS. Lawrence R. Huntoon and Samuel L. Liles. Dept. of Physiology, Louisiana State Univ. Med. Ctr., New Orleans, LA 70119.

Extracellular single-unit recordings were obtained using a chronic recording technique which has been previously described (Neurosci. Abstr. 3:40, 1977). Specially-designed concentric Pt-Ir microelectrodes were used to eliminate EMG contamination from orofacial muscles. A total of 218 cells were isolated in the ventral midbrain of 5 chronic rats: 26 in pars compacta region of SN, 115 in pars reticulata of SN, and 77 in regions adjacent to SN. All recording sites were verified histologically. Four categories of response types were found: (limb) movement-related, orofacial-related, modulated (e.g. related to posture or to a non-monitored movement), and cells which displayed a gating function (turned on or off during a series of limb movements). Within the (limb) movement-related category there were three subcategories of responses: (i) non-spontaneously firing cells that discharged only when the rat was making forelimb movements; (ii) spontaneously firing cells that were inhibited prior to the onset of forelimb movements; and (iii) spontaneously firing cells that increased their firing rate prior to the onset of movement. Analysis of limb EMG activity and peri-movement histograms of unit activity showed that many SN cells exhibited statistically significant firing changes more than 100 msec before the onset of limb movement. Present findings indicate that 10% of the cells in SN are related to contralateral forelimb movements and 4% are related to orofacial movements. The majority of the cells isolated in SN were small amplitude, rapidly firing cells which were predominantly located in pars reticulata. The very slowly firing dopaminergic nigrostriatal Type I cells, which are prevalent and easily isolated in acute preparations, were conspicuous by their absence in the awake rat.

The study concludes that there are cells in SN and in adjacent regions of the midbrain tegmentum of the rat which display movement-related activity, and that these cells play a role in the initiation of movement. Unlike in the monkey, however, where most of the cells in SN appear to be related to orofacial movements (Delong and Georgopoulos, Neurosci. Abstr. 4:42, 1978), most of the SN cells in the present study were related to limb movements. The great diversity of single cell responses reported in this study provides a basis for more specific examination of individual SN cells in relation to motor function. (Supported in part by NIH Grant NS-15485).

100.16 KITTENS: ONTOGENY OF EVOKED UNIT ACTIVITY IN THE SUBSTANTIA NIGRA. R.S. Fisher, M.S. Levine, N.A. Buchwald and C.D. Hull. MRRC and BRI, Sch. Med., UCLA, Los Angeles, CA 90024

Extracellular single unit recording was used to describe the ontogeny of the responses of units in the substantia nigra to stimulation of the caudate nucleus (CD) (monosynaptic input), the precruciate cerebral cortex (CX), and the dorsum of the central lateral forepaw (external sensory input).

Nigral units responded to each of these inputs at the earliest ages tested (2 days postpartum). There were, however, a number of significant indices of postnatal maturation; e.g., decreases in latency to response, increases in the proportion of units responding, and shifts in response type.

Recordings were obtained from more than 200 nigral units in 23 cats and kittens ranging from 2 days of age to adulthood. The results are summarized as follows: CD stimulation - 1) The proportion of units responding to CD stimulation increased from 29% (46/161) in the 1-40 day age range to 48% (14/29) in adults. 2) At all age ranges, CD stimulation predominantly evoked an initial inhibition in nigral units. There were, however, occasional instances of initial excitation in kittens. In adults, all initial responses were inhibitory. 3) Latency to onset of inhibition decreased with age ($\bar{X} \pm$ s.e.m. = 58 $\pm$ 14 msec (1-10 days) vs. 24 $\pm$ 3 msec (adults). 4) Postinhibition excitatory firings (rebound) occurred to a greater extent in adult nigral units (71%) than in kitten nigral units (25%). 5) Latency to antidromically activated spikes evoked by stimulation of CD or medial forebrain bundle decreased markedly with age (for CD stimulation, 40-60 msec (1-10 days) vs. 6-10 msec (adults)). CX stimulation - 1) At all age levels, about a third of the nigral neurons responded to CX stimulation. 2) At all age levels, CX stimulation produced a mix of initial excitation and inhibition in nigral units. 3) Latency to CX stimulation decreased with age (approximately 80 msec (1-10 days) vs. 17 $\pm$ 4 msec (adults)). 4) Rebound occurred more frequently in older cats (13% (1-40 days) vs. 67% (adults)). Forepaw stimulation - 1) As with CD stimulation, the proportion of nigral neurons responding to forepaw stimulation increased with age (48% (12/25) in adults vs. 30% (25/78) at 1-10 days). 2) Responses shifted from a predominant initial inhibition to a predominant initial excitation with age (16% (4/24) excitation at 1-40 days, 75% (9/12) excitation in adults). At all age levels, a high proportion of units responded to each of the three inputs tested (CX, CD, and paw). (Supported by USPHS HD 05958 and 1T32MH15345).

100.17 EFFECTS OF DOPAMINERGIC, CHOLINERGIC AND GABERGIC DRUGS UPON THE ACTIVITY OF RAT GLOBUS PALLIDUS NEURONS. D.A. Bergstrom* and J.R. Walters (SPON: D.B. Tower). NIH, NINCDS, Bethesda, MD 20205.

Dopamine (DA), acetylcholine (ACH) and GABA are known to be neurotransmitters in the basal ganglia. Extensive pharmacological studies have been performed on the effects of several agonists and antagonists of these transmitters upon the activity of neurons in the rat substantia nigra and neostriatum. The present study examines the responsiveness of cells in the globus pallidus (GP) to the effects of systemically administered pharmacological agents which are commonly used to explore DA, ACH and GABA influences.

Extracellular single unit recordings were made from GP cells in rats paralyzed with gallamine, locally anesthetized and artificially respired. Spontaneously active cells with biphasic action potentials in the frequency range of 10-140 spikes/sec were recorded. One cell was monitored per rat; drugs were given i.v. To investigate the effects of DA receptor stimulation and blockade, 3 doses of apomorphine (APO) were given at 3-5 min intervals; haloperidol (HAL) was administered alone or after APO. Five out of 15 cells showed a dose-related, HAL-reversible increase in firing to an average of 15%, 47% and 92% after 5, 35 and 280 µg/kg APO, respectively. The remaining 10 cells were not significantly affected. HAL (0.025-1.6 mg/kg), in rats pretreated with APO, produced a dose-related inhibition (90-100%) in 10 out of 11 cells. If HAL was given alone, however, a cumulative dose regimen of 1.6 mg/kg caused only a slight 13% decrease (n=8); a cumulative dose of 3.2 mg/kg HAL produced a maximum of 36% decrease in GP neuronal firing (n=6). Thus it appears that APO may be causing a subtle change in the modulation of dopaminergic influence on GP transmission that is greatly enhancing the ability of HAL to inhibit firing.

In 6 out of 8 cells recorded in atropine methyl nitrate pretreated rats, logarithmically increasing doses of carbachol (4 µg/kg to a total dose of 256 µg/kg) caused dose-related increases in firing (at 32 µg/kg: 50-100%). Two cells showed no change. The GABA agonist muscimol caused a dose-dependent, picrotoxin (PIC) reversible inhibition of the GP cells recorded (n=7). An average dose of 1.5 mg/kg muscimol produced a 50% inhibition in neuronal firing. PIC, given alone in 1 mg/kg increments every 2 min caused dramatic dose-related increases (4 mg/kg: 250%) in the firing of these cells (n=6).

These observations demonstrate that there are populations of neurons in the rat GP that appear to be sensitive to alterations in DA, ACH and GABA-related transmission. Whether these changes are direct effects on the neurons themselves or mediated indirectly through inputs to the GP remains to be determined.

100.18 d-AMPHETAMINE-INDUCED CHANGES IN NEURONAL FIRING IN RAT GLOBUS PALLIDUS. J.R. Walters and D.A. Bergstrom*. NIH, NINCDS, Bethesda, MD 20205.

Several investigators have shown that systemic administration of d-amphetamine (AMP) produces a decrease in the spontaneous firing rates of neurons located in the rat substantia nigra pars compacta (SNpc) and neostriatum. This effect has been shown to be reversed by haloperidol (HAL) and, in the SNpc, blocked by pretreatment with α-methyl-p-tyrosine (AMPT). We have been interested in determining whether AMP, administered systemically, affects the activity of cells in another nucleus of the basal ganglia, the globus pallidus (GP).

Extracellular single unit activity was recorded from spontaneously active cells in the GP of rats paralyzed with gallamine, locally anesthetized and artificially respired. AMP was given i.v. at 2 min intervals in logarithmically increasing doses (0.2 to 6.4 or 12.8 mg/kg). The firing rates of 17 out of 19 cells were significantly increased (>30%), one cell was unaffected (<30%) and one cell showed a dose-related decrease. Two types of AMP-induced increases were observed. Half of the cells showed a dose-related increase in rate and the rest responded markedly to the lower doses of AMP (0.8 m/kg or less) and maintained this enhanced rate throughout the remaining drug regimen. Lower frequency cells (<50 spikes/sec, n=13) were significantly more sensitive to the rate-increasing effects of AMP than were the higher frequency firing cells (>50 spikes/sec, n=4).

To examine the effects of HAL (i.v.) on AMP-induced increases in pallidal activity, rats were given AMP (cumulative dose: 0.8 to 3.2 mg/kg) until the monitored firing rate of the GP cell was 50-100% above baseline (n=5). HAL (0.2-0.4 mg/kg) antagonized the rate-elevating effect of AMP and returned the firing rates to baseline control. However, HAL, in doses up to 1.6 or 3.2 mg/kg, did not antagonize AMP's effect on 2 cells in rats given a cumulative dose of 12.8 mg/kg AMP.

To investigate the dependence of AMP's effect on catecholamine (CA) synthesis and release, GP cells were recorded in rats pretreated with reserpine and AMPT. Results (n=4) indicated that interruption of CA synthesis and release attenuated the rate-elevating effects of AMP.

This study indicates that systemically administered AMP can markedly enhance the firing rates of a population of GP cells in gallamine-paralyzed rats. This effect is reversed by HAL and attenuated by CA depletion. The effect of AMP differs from that of systemically administered apomorphine (Bergstrom & Walters, this vol.). AMP caused a greater and more consistent increase in pallidal firing rates and did not enhance the ability of HAL to inhibit pallidal firing to below predrug activity as did apomorphine.

101.1 MORPHOLOGY OF ELECTROPHYSIOLOGICALLY IDENTIFIED TYPES OF MYENTERIC NEURON: INTRACELLULAR RECORDING AND INJECTION OF LUCIFER YELLOW IN THE GUINEA-PIG SMALL BOWEL. S.M. Erde*, M.D. Gershon, and J.D. Wood. Dept. Anat., Columbia Univ. P.&S., New York, 10032. Dept. Physiol., Sch. of Med., Univ. Nevada, Reno, NV 89557.

The morphology of physiologically identified neurons of the myenteric plexus has not yet been described. Hodgkiss and Lees (J. Physiol. 285:19P, 1978) reported the intracellular injection of cells with Procion Yellow; however, they did not inject the dye through the electrode that was used for electrical recording but attempted to re-impale cells. In the present study electrical activity of myenteric ganglion cells was recorded intracellularly with glass microelectrodes filled with the fluorescent dye, Lucifer yellow, and beveled to resistances of 80 to 100 megohms. Presynaptic fibers and the processes of the neurons were activated by electrical shocks delivered by a 20 um Pt electrode positioned on an interganglionic connective. Neurons were identified electrophysiologically by their responses to injection of depolarizing current and to stimulation of their synaptic input. Lucifer Yellow was injected into the cells by iontophoresis from the recording electrode, and the morphology of injected cells was studied by fluorescence microscopy. Three types of neuron were identified on the basis of electrophysiological criteria. These were AH/Type 2 neurons, S/Type 1 neurons (Hirst et al., J. Physiol. 236:303,1974; Nishi and North, J. Physiol. 231:471, 1973) and a third type that had a relatively low input resistance, a resting potential of 65mV, but which did not discharge action potentials when injected with a depolarizing current. These latter cells showed large amplitude EPSPs (15mV) without spikes in response to stimulation of their synaptic input. There were two morphological classes of S/Type 1 neurons. One class had short club-like dendrites with a single long axon that projected via interganglionic connectives through two or more ganglia in the aboral direction. The second class of S/Type 1 neuron had oval somas with many fine, varicose processes that projected circumferentially around the bowel both inside and outside of the ganglion of origin. AH/Type 2 neurons had oval somas with two or more processes that projected both longitudinally and circumferentially. Processes ramified extensively within the ganglion of origin but also projected to other ganglia. Some of the processes of AH/Type 2 neurons did not exit the ganglion in fiber tracts; instead, they passed through the periganglionic sheath as single processes and terminated as swellings a short distance from the ganglion. These may be projections to other intestinal layers that were severed during the dissection of the myenteric plexus. The morphology of the third type of neuron was similar to that of AH/Type 2 neurons. Supported by NIH grants NS 12969, AM16813. NS07062.

101.2 ULTRASTRUCTURAL IDENTIFICATION OF NORADRENERGIC AXONS IN THE ENTERIC PLEXUSES OF THE GUINEA-PIG ILEUM. I.J. Llewellyn-Smith*, A.J. Wilson*, J.B. Furness*, M. Costa* and R.A. Rush* (SPON: P.R. Wilson). Centre for Neuroscience, Flinders Univ. Sch. of Med., Bedford Park, S.A. 5042 AUSTRALIA.

Noradrenergic axons in the myenteric and submucous plexuses of guinea-pig ileum were identified by electron-dense deposits in their vesicles after loading with 5-hydroxydopamine (5-OHDA; Tranzer, J.P. and Thoenen, H., Experientia 23:743, 1967), localization of dopamine-β-hydroxylase (DBH) with horseradish peroxidase-conjugated antibodies (Rush, R.A. et al., In Catecholamines:Basic and Clinical Frontiers, Usdin, E.et al., eds., p. 331, 1979) or the chromaffin reaction (Tranzer, J.P. and Richards, J.G., J. Histochem. Cytochem. 24:1178, 1976).

All three cytochemical techniques showed that noradrenergic axons in myenteric plexus contained many flattened vesicles (usually more than 30% of the total number of vesicles) in addition to oval or irregularly shaped vesicles. Cytochemically labeled profiles were absent in myenteric plexus from surgically denervated segments of ileum and pretreatment with 6-hydroxydopamine greatly reduced the number of labeled profiles.

In normal submucous plexus after the chromaffin reaction and 5-OHDA loading electron-dense deposits were found in the vesicles of some axon profiles which contained many small round and a few flattened and large round vesicles. Other profiles with similar types and proportions of vesicles were not cytochemically marked. After anti-DBH labeling, noradrenergic axon profiles contained more flattened vesicles than after the other treatments. All reactive axon profiles disappeared from the submucous plexus after extrinsic denervation. Axon profiles which contained small granular vesicles with rings of electron-dense material lining the inner aspects of vesicle membranes after conventional processing were not cytochemically labeled and persisted after extrinsic denervation.

In the myenteric plexus noradrenergic axon profiles were found frequently near the edges of ganglia, sometimes near nerve cell bodies and rarely in the internodal strands. In the submucous plexus noradrenergic profiles occurred randomly throughout submucous ganglia. No synapses between noradrenergic axons and nerve cell bodies or processes were observed in the myenteric plexus. Synapses between noradrenergic axons and nerve cell processes were occasionally found in the submucous plexus.

In conclusion, noradrenergic axons in myenteric plexus can be distinguished in conventionally processed tissue on the basis of morphological criteria alone whereas noradrenergic axons in the submucous plexus can only be identified by cytochemical staining procedures.

101.3 LONG TERM SURVIVAL OF SEROTONERGIC NEURONS IN TISSUE CULTURES OF MYENTERIC PLEXUS DISSECTED FROM GUINEA PIG ILEUM AND DUODENUM. M.D. Gershon, S.M. Erde and C.F. Dreyfus, Department of Anatomy, Columbia University, P&S, New York, NY 10032.

The enteric nervous system has been shown to contain serotonergic neurons. These neurons have been found to survive in organotypic tissue cultures derived from hemisections or muscularis externa of mouse intestine (Dreyfus et al., Brain Res.128: 109-123, 1977). The enteric serotonergic neurons are thus intrinsic to the gut. The present experiments were designed to determine if enteric serotonergic neurons would survive in cultures of longitudinal muscle with adherent myenteric plexus (LM-MP) stripped from guinea pig duodenum or ileum. Guinea-pig fetuses were removed just prior to the expected date of delivery; the gut was removed and the LM-MP was dissected. Flat sheets of tissue were explanted onto collagen-coated coverslips and grown as lying-drop preparations in Maximow depression slide chambers. After 2 weeks' growth in culture the cultures were exposed to glyoxylic acid for examination by histofluorescence, or incubated with ^{3}H-serotonin (0.9 uM; 60 min) and fixed (2.5% glutaraldehyde, containing 3% sucrose in 0.2M phosphate buffer at pH 7.4) for light and electron microscopic radioautography. Numerous cells were found showing the characteristic glyoxylic acid-induced fluorescence of serotonin. More such cells were found in cultures of ileum than duodenum. Uptake of ^{3}H-serotonin was found in axons and in some mast cells in all cultures. Ganglion cells survived well in culture and retained synaptic connections; however, after 2 weeks smooth muscle cells were no longer discernible. It is concluded that intrinsic enteric serotonergic neurons can be grown in culture even from relatively mature guinea pig small intestine. The presence of these neurons in cultured LM-MP strips confirms that the myenteric plexus contains serotonergic perikarya. As has been observed previously, the serotonin uptake mechanism in these neurons is probably confined to their axons. These long term cultures provide a stable preparation of myenteric plexus, devoid of inputs from the CNS or submucosal plexus, that should prove useful for further neurochemical or electrophysiological characterization of the myenteric plexus. (Supported by NIH grants NS12969 and NS07062.)

101.4 BIOSTRUCTURE AND BIOCHEMISTRY OF THE HAMSTER SUPERIOR CERVICAL GANGLION (SCG). A. C. Black, Jr., J. Jew, J. K. Wamsley, D. Sandquist*, J. R. West, and T. H. Williams. Department of Anatomy, University of Iowa College of Medicine, Iowa City, Iowa 52242.

Electronmicroscopy of the small, intensely fluorescent (SIF) cells of the hamster SCG indicates that they receive putative cholinergic afferent synapses. They also give rise to axodendritic and somatodendritic efferent synaptic contacts with the dendrites of principal ganglionic neurons (PGNs). Quantitative Fluorescence microscopy (FM) of five hamster SCG demonstrated that there were 223 ± 31 SIF cells per ganglion, equivalent to 140 ± 26 SIF cells per mg tissue (wet weight). SIF cells with long axons are found among clusters of SIF cells near blood vessels in hamster SCG, as in rat and guinea pig SCG.

Cyclic AMP has been shown to be a second messenger in SCG function. Incubation of hamster SCG in vitro with 50 μM L-isoproterenol under conditions producing maximal cyclic AMP production increased cyclic AMP values by 522% over controls, but no response to 50 μM dopamine (DA) was noted. Thus, like rat and guinea pig SCG, the hamster SCG contains a β-adrenergic receptor–adenylate cyclase complex, but lacks a dopamine receptor–adenylate cyclase complex. DA and norepinephrine (NE) levels were determined in hamster SCG. The ratio of DA to NE in the hamster SCG was 0.08. This low ratio is similar to values obtained in guinea pig SCG (where the SIF cells contain NE as a transmitter). By comparison, the rabbit SCG (where SIF cells contain DA as a transmitter) exhibits a DA to NE ratio of 0.678. Thus, while not conclusive evidence, the low DA to NE ratio in the hamster SCG suggests that NE may be the SIF cell transmitter in the hamster SCG. Comparison of these results with those obtained in other species suggests that the SCG of three rodents - the hamster, guinea pig, and rat - differ significantly from those of other species in their morphological and biochemical properties. (Supported by N.I.H. grants NS-11650 to T.H.W., HL-24351 to A.C.B., and HL-21914 to J.J.)

101.5 THE NUCLEUS TRACTUS SOLITARIUS OF THE CAT: A GOLGI ANALYSIS. T.J. Mullett*, B.E. Maley and R.P. Elde. Department of Anatomy, University of Minnesota Medical School, Minneapolis, MN 55455.

In a series of adult cats, the Golgi-Kopsch method was employed to impregnate a number of neurons within the nucleus tractus solitarius (NTS). Subsequent to routine histological procedures, representative cells from the commissural, intermediate, lateral, medial and ventrolateral nuclei of the NTS, which were named according to Loewy and Burton ('78), were drawn at a final magnification of 400x utilizing a drawing tube attached to a light microscope.

Cell soma size in most areas of the NTS ranged from 10-20 µm. In addition to the many small neurons, the ventrolateral nucleus contained a few large cells which measured over 25 µm in diameter. Most NTS neurons were multipolar and possessed short, proximal dendrites that were relatively smooth and most often lacked spines. These dendrites, in turn, gave rise to numerous secondary branches, which in many cases were longer than their parent structure. The dendritic arbor of most NTS neurons extended over 150 µm, while the dendritic spread of the large cells in the ventrolateral nucleus was greater. Although the majority of dendrites remained within the confines of the nucleus, a small number of peripheral neurons sent their dendrites outside the NTS into the surrounding areas. In addition, several NTS neurons bordering the tract of solitarius possessed dendrites which extended into the tract. These latter neurons were most often elongated and exhibited dendrites arising from the two opposite poles. Spines, when encountered, were restricted to the shafts of secondary dendrites and many times occurred in clusters at branching points of dendrites. The spine form included sessile, pedunculated and complex varieties. Somatic spines were not readily evident on NTS neurons. Axons of NTS neurons were found to arise from the cell soma and they could be followed for varying distances. Initially, these structures possessed a smooth contour, however, with increasing distance from their origin they became beaded. At no time could collaterals be seen arising from the parent axon.

The morphological aspects of this Golgi study will form a basis for analyzing the structure of neurons possessing one of the putative neurotransmitters within the NTS as visualized with immunohistochemistry. These studies should form a cytoarchitectonic basis for the neurotransmitter-specific synaptological studies now in progress.

R.P.E is a recipient of a Scholar in Neuroscience Award from the McKnight Foundation.

101.6 CAROTID SINUS NERVE AFFERENT PROJECTIONS TO THE NUCLEUS OF THE TRACTUS SOLITARIUS AND THE REGION OF THE NUCLEUS AMBIGUUS. R. O. Davies and M. Kalia. Dept. of Animal Biology, University of Pennsylvania, Philadelphia, PA 19104 and Dept. of Physiology, Hahnemann Medical College, Philadelphia, PA 19102.

As part of a study of peripheral sensory inputs to the pontomedullary respiratory complex we studied the distribution of carotid sinus nerve (CSN) afferent fibers (chemoreceptors and baroreceptors) using the transganglionic transport of horseradish peroxidase (HRP). The CSN was carefully dissected in anesthetized cats and a piece of parafilm was placed between it and the underlying tissue. 10 µl of 5-10% HRP solution in Triz buffer (pH 8.6) was injected into the uncut CSN using a 10 µ tip, glass micropipette coupled to a Hamilton Syringe. This procedure of "intraneural" injection of a peripheral nerve avoided problems associated with HRP application to a cut nerve: surreptitious uptake by surrounding nerve fibers and the effects of axonal degeneration on the transport process. Following a 48 hour survival period the brainstem and petrosal ganglion were removed and processed for demonstration of HRP reaction product using tetramethyl benzidine (TMB) as the substrate. HRP reaction product was visualized in sensory nerve terminals (extraperikaryal), nerve fibers (sensory and motor) and perikarya. Sensory nerve terminals were found in the nucleus of the Tractus Solitarius (nTS) bilaterally, with the ipsilateral side showing more intense labeling. Within the nTS the distribution of extraperikaryal labeling was non-uniform. The dnTS, dlnTS, mnTS and ncom showed heavy labeling. This corresponds to the general distribution previously reported (Neurosci. Lett. 14:153, 1979). Significant labeling was also seen in vlnTS, sg, nI and dorsal third of the area postrema. Another region showing moderate sensory nerve terminal labeling was identified ipsilaterally in the vicinity of the nucleus Ambiguus (nA) at the level of the obex to 2mm caudal to the obex. HRP labeled fibers from the nTS could be followed to this region of extraperikaryal labeling. HRP labeled perikarya were found in the rostral region of the nA (retrofacial nucleus) 5-6 mm rostral to the obex, thus confirming previous reports of brainstem efferents in the CSN. No sensory terminal labeling was found at these rostral levels. Furthermore the location of these efferent perikarya was congruent with the anatomically and physiologically identified Bötzinger Complex which projects to the vlnTS. (This research was supported by USPHS grants HL-17800, HL-23961, HL-08805 and RCDA HL-00103 to MK.)

101.7 BRAIN STEM CONNECTIONS OF GLOSSOPHARYNGEAL AND VAGAL AFFERENT FIBERS IN THE CAT. F. R. Calaresu, A. W. Hrycyshyn*, B. A. Flumerfelt and J. Ciriello. Departments of Physiology and Anatomy, University of Western Ontario, London, Canada N6A 5C1.

Brain stem projections of the glossopharyngeal and vagus nerves in the cat were studied by exposing these nerves to crystalline horseradish peroxidase for 4-10.5 hours. After a survival period of 24-120 hours transverse and horizontal frozen sections of the brain stem were processed according to the tetramethylbenzidine method. Labelled fibers from both nerves were found bilaterally in the solitary complex, and ipsilaterally in the ventral region of the external cuneate nucleus and in the medial portion of the nucleus praepositus hypoglossi. Within the solitary complex labelling was observed in the parvocellular, lateral, ventrolateral, medial, and commissural solitary nuclei. In addition, the glossopharyngeal nerve was found to project ipsilaterally to the rostral dorsal motor nucleus of the vagus, the nucleus insulae cuneate lateralis, the ventrolateral portion of the medial cuneate nucleus, the dorsal part of the nucleus interpolaris and caudalis of the trigeminal complex, and the dorsolateral nucleus medullae oblongata centralis. Finally, the area postrema was found to receive a distinct bilateral projection of vagal and an ipsilateral projection of glossopharyngeal fibers. These findings point to the existence of projections to the brain stem which are more widely distributed for the glossopharyngeal compared to the vagus nerve and provide useful information on the wiring diagram of visceral and tase projections to the central nervous system.

101.8 CENTRAL AFFERENTS TO THE INTERMEDIATE NUCLEUS TRACTUS SOLITARIUS AND THE COMMISSURAL NUCLEUS OF THE VAGUS: A RETROGRADE TRANSPORT STUDY IN RAT AND RABBIT. D.A. Ruggiero, C. Ross, and D.J. Reis, Laboratory of Neurobiology, Dept. of Neurology, Cornell University Medical College, New York, NY 10021.

Baroreceptor and other cardiovagal afferents terminate in the intermediate third of the nucleus tractus solitarius (NTS) and the commissural nucleus of the vagus (CNV). We sought to compare the central projections to both of the cardiovascular subdivisions of the solitary complex and to areas of the medullary reticular formation (RF) underlying NTS.

Fifty to 100 nl of a 40% HRP solution (0.9% saline) were injected in the medulla of rats and rabbits. After 24 to 48 hrs the animals were perfused with 1.25% glutaraldehyde and 0.4% paraformaldehyde followed by a 15% solution of sucrose in phosphate buffer. Brains and selected segments of the spinal cord were sectioned at 50 µ and processed using the Mesulam technique.

Afferents to NTS in rat are similar to those of CNV. Projections arise from the posteromarginal zone and lamina X of spinal cord (SC), lateral reticular nucleus, A5 area of Dahlstrom and Fuxe (Acta Physiol.Scand. 62, 1964), locus ceruleus, paraventricular hypothalamus (PVN), and parabrachial nucleus (PBN). Afferents from PBN to NTS and RF are, however, primarily derived from the medial PBN and Kollicker-Fuse nucleus--an area which projects to the spinal cord (Ross, Ruggiero and Reis, Neurosci. Abstr., 1979). Projections to RF are more widespread and, for most nuclei, quantitatively greater than those to the overlying NTS. Major afferents to RF arise from SC, other parts of RF, cranial nerve nuclei, deep cerebellar nuclei, zona incerta, PVN and the central nucleus of the amygdala. Projections into NTS and RF of rabbits were similar.

To control for diffusion of the enzyme, HRP was injected into the nucleus gracilis (NG). Afferents to NG are different from those to NTS and are derived from SC lamina IV and V, spinal trigeminal nucleus, ventral hindbrain RF, red nucleus and cerebral cortex.

Projections from NTS/RF identified by anterograde transport of HRP primarily ascend via the central and lateral tegmentum. Labeled efferents from NTS/RF to the PBN mainly terminate in the dorsal PBN in contrast to the major source of PBN afferents to the NTS.

We conclude that sites of baroreceptor projection in NTS and CNV, are richly innervated by projections from restricted regions of brain and spinal cord. Some of these projections may serve to modulate baroreflex activity.

(Supported by NIH grant HL 18974)

101.9 **Afferent Projections to the Dorsal Motor Nucleus of the Vagus; HRP and Electrophysiological Studies.** R.C. Rogers, H. Kita, S. Shibata and D. Novin. Center for Ulcer Res. and Ed., UCLA, Los Angeles, CA. 90073; Department of Physiol. Kyushu Univ. Sch. Med. Fukuoka,812 Japan.

The afferent projections to the dorsal motor nucleus of the vagus (DMN) of the rat were determined using a combination of HRP histochemical and electrophysiological techniques. With bipolar stimulating electrodes palced on the cervical vagus, the dorsal medulla was exposed by removing the occipital skull plate. Recording electrodes filled with 2% HRP (Sigma, type VI), .3M NaCl and .2M tris buffer (pH 8.6) were directed under visual guidance toward the DMN. When clear antidromic activation of neurons occured following cervical vagal stimulation, small amounts of HRP were iontophoretically ejected through the recording electrodes. Subsequent histological processing of the HRP-injected brains revealed bilateral projections from the nucleus of the solitary tract, the parvo- and giganto- cellular reticular nuclei of the medulla, the nucleus raphe obscuris and the paraventricular nucleus of the hypothalamus. A weak ipsilateral projection from the principal trigeminal sensory nucleus was also observed. Control injections of HRP into the solitary nucleus revealed only local reticular inputs. In seperate experiments, the physiological nature of projections from the paraventricular nucleus to the DMN was examined. Neurons in the paraventricular nucleus of the hypothalamus were antidromically activated by stimulating the DMN. Antidromic activation of the paraventricular nucleus followed the medullary stimulus with a latency of about 50msec. and these neurons would follow stimulus frequencies of up to 200/sec. Identified neurons in the DMN were, in turn, orthodromically activated by paraventricular stimulation with a latency of about 50 msec.

These data verify and extend the results of previous investigators (Saper, et al, Brain Res. 117:305,1976; Swanson and Hartman, Neurosci. Abs. 5:235,1979.) with regard to direct hypothalamic - autonomic projections.

This project was supported by NSF/JSPS exchange grant #NSF-INT 78-17733.

101.10 PROJECTION OF BUFFER NERVES TO THE SOLITARY COMPLEX IN THE CAT. J. Ciriello, A. W. Hrycyshyn* and F. R. Calaresu. Departments of Physiology and Anatomy, University of Western Ontario, London, Canada N6A 5C1.

Previous experiments have suggested that primary afferent fibers of the buffer nerves project primarily to the middle third of the nucleus tractus solitarius. However, the precise distribution of buffer nerves within this region remains controversial. The location of second order neurons of carotid sinus (CSN) and aortic depressor (ADN) nerves in the solitary complex of the cat was determined in this study using anatomical and electrophysiological methods. Using the anterograde transport of horseradish peroxidase it was found that both the CSN and ADN had a wider distribution in solitary complex than previously suggested. Within the solitary complex both buffer nerves projected bilaterally to the dorsal portion of the lateral and medial solitary nuclei, the commissural solitary nucleus and the medial aspect of the parvocellular solitary nucleus along the lateral edge of the area postrema, with a predominant ipsilateral projection. Exclusive projections of the CSN were found bilaterally to the intermediate solitary nucleus, and ipsilaterally to the ventrolateral solitary nucleus and the area just ventral to the solitary complex. These areas receiving primary afferent fibers within the solitary complex were explored for single units responding to stimulation of the buffer nerves in chloralosed, paralyzed and artificially ventilated cats. Of 177 responsive units, 80 responded only to stimulation of the carotid sinus nerve, 44 only to stimulation of the aortic depressor nerve, and 53 to both nerves. These data demonstrate that second order neurons have a wide distribution in the solitary complex and receive inputs from either one or both buffer nerves, pointing to the existence of separation of central pathways carrying CSN and ADN afferent information.

(Supported by MRC of Canada)

101.11 DISTRIBUTION IN THE BRAINSTEM OF NEURONS WITH EFFERENT PROJECTIONS IN THE CERVICAL VAGUS: AN HRP STUDY IN THE DOG. C.L. Chernicky, K.L. Barnes, J.P. Conomy and C.M. Ferrario. Division of Research and Department of Neurology, Cleveland Clinic Foundation, Cleveland, Ohio 44106.

The distribution of cell bodies with axons in the cervical vagi was examined in the brainstem of the dog using retrograde axonal transport of horseradish peroxidase (HRP). The sheath of the cervical vagosympathetic trunk was opened 3-4 cm distal to the nodose ganglion and the proximal cut end of the vagus was slipped into silastic tubing filled with 30% HRP (Sigma, Type VI) in acrylamide gel; the sheath was closed around the package with a continuous 6-0 suture. After 5-7 days the dogs (wt. 6-9 kg) were perfused for HRP histochemistry. Serial 60 µm sections from C_1 to the caudal pons were processed for HRP with the tetramethylbenzidine procedure (Mesulam, J. Histochem. & Cytochem. 26: 106, 1978) and examined for HRP reaction product using both bright and dark field illumination.

Only a few lightly labelled neurons could be found in the brainstem after 5 days survival. On the other hand, numerous cells containing HRP reaction product were observed after 7 days. Thus the rate of transport of HRP by axons in the dog's vagus appears to be slower than that reported for other species. Although heavy labelling was observed in neurons within the nodose ganglion, no evidence could be found within the brainstem of transganglionic transport of HRP.

Labelled neurons were seen in the brainstem ipsilateral to the HRP-treated vagus. The majority of cell bodies containing HRP reaction product were found in either the dorsal motor nucleus of the vagus (DMV) or the nucleus ambiguus (NA). Labelled cells were distributed quite homogenously throughout the rostral-caudal extent of the DMV. On the other hand, the majority of cells seen within NA were found between 0.5 and 3.0 mm anterior to the obex. In addition, a few labelled cells were observed in the intermediate zone between DMV and NA described by Geis and Wurster (Brain Res. 182: 19, 1980). A few small neurons containing HRP reaction product were also seen ventrolateral to NA, approximately 3 mm anterior to the obex.

These studies reveal that localization of neural pathways using HRP in the dog may require longer survival times than in other species. Nevertheless, the distribution within the dog's brainstem of neurons with axons in the cervical vagus appears similar to that previously reported in the cat (Geis and Wurster, 1980; Sugimoto et al, Neurosci. Lett. 12: 53, 1979).

Supported by grants from NHLBI #HL-6835, American Heart - Northeast Ohio, and the Reinberger Foundation.

101.12 SITES OF ORIGIN OF EFFERENT FIBRES OF VAGUS, GLOSSOPHARYNGEAL AND CAROTID SINUS NERVES IN THE CAT. A. W. Hrycyshyn*, J. Ciriello, B. A. Flumerfelt and F. R. Calaresu (SPON: J. Kiernan). Departments of Anatomy and Physiology, University of Western Ontario, London, Canada N6A 5C1.

Cells of origin of vagus, glossopharyngeal and carotid sinus nerves were localized utilizing the retrograde horseradish peroxidase (HRP) tracing method. Following application of crystalline HRP for 4 to 10.5 hours to the proximal end of cut nerves, cats were allowed to survive from 24 to 120 hours and their brain sections were processed according to the tetramethylbenzidine method. Following application of HRP to the left vagus transected at lower cervical levels, almost all the cells within the ipsilateral dorsal motor nucleus of the vagus nerve were labelled. No such labelling occurred on the contralateral dorsal motor nucleus. HRP labelled cells were also observed within the ipsilateral nucleus ambiguus and bilaterally within the retrofacial nucleus. When HRP was applied to the right cervical vagus, labelling of cells was observed bilaterally within the dorsal motor nucleus of the vagus and nucleus ambiguus with a predominant projection to the ipsilateral side. Labelling of cells in the retrofacial nucleus was similar to that seen when HRP was applied to the left vagus. Following application of HRP to the cut glossopharyngeal nerve at a level distal to the emergence of the carotid sinus nerve, labelled cells were found ipsilaterally within and about the rostral nucleus ambiguus and within the facial and retrofacial nuclei. A few labelled cells were seen within the ipsilateral gigantocellular-tegmental field. When only the carotid sinus nerve was exposed to HRP, cell labelling occurred bilaterally in the nucleus ambiguus, facial and retrofacial nuclei, with labelled cells predominating on the ipsilateral side. Few cells were also seen in the ipsilateral gigantocellular-tegmental field. These results demonstrate that the right vagus nerve contains preganglionic fibres originating from both dorsal motor nuclei of the vagus and nuclei ambiguus, while the left vagus nerve originates only from the ipsilateral side. Furthermore, the finding of labelled cells in the medulla after application of HRP to the carotid sinus nerve suggests a possible route by which brain stem structures may modulate activity of carotid baro- and chemoreceptors.

101.13 HISTOCHEMICAL ANALYSIS OF VAGAL EFFERENT NEURONS BY DUAL STAINING FOR HORSERADISH PEROXIDASE AND ACETYLCHOLINESTERASE.
D. B. Hoover, Dept. of Pharmacology, College of Medicine, East Tennessee State University, Johnson City, TN 37601.

Several recent studies have shown that the vagal innervation of the heart originates not only from the dorsal motor nucleus (DMN) but also from the nucleus ambiguus (AMB) and neurons located between these nuclei or ventral to AMB. Although it is well accepted that the DMN and AMB contain cholinergic neurons, the neurochemical characteristics of the extranuclear vagal efferents are not established. To examine this problem, rat vagal efferent neurons were labeled with horseradish peroxidase (HRP), and tissue sections through the medulla oblongota were subsequently stained for both HRP and acetylcholinesterase (AChE).

The loading of neurons with HRP was accomplished by sectioning the vagus nerve just below the larynx and placing the proximal end in a small trough containing 30% HRP (type VI) in 0.85% NaCl. After 45-60 min. the nerve was removed from the HRP solution, and the animal was allowed to survive for 24 h. The brain was then fixed and processed according to methods described by Mesulam (J. Histochem. Cytochem 24:1281-1286, 1976). The HRP was visualized as blue granules, and AChE positive neurons stained reddish brown. The vast majority of HRP-labeled neurons were found in the DMN, and these also contained AChE. Similar dual-labeled neurons were found in the nucleus commissuralis and nucleus intercalatus. The amount of AChE stain in all these neurons ranged from light to very dark. Several neurons within the AMB proper also stained for both HRP and AChE, and the AChE stain in these cells was quite dark. A few cells were found outside of the major nuclear groups. In general these stained only lightly for AChE or not at all. The absence of AChE stain in some of these neurons raises the possibility that they may not be cholinergic. The present findings indicate that cholinergic neurons constitute the vast majority of vagal efferents, but a small number of non-cholinergic medullary neurons may also contribute axons to the vagus nerve. (This study has been supported by a grant from the American Heart Association, Tennessee Affiliate.)

101.14 THE SEGMENTAL ORGANIZATION OF PARASYMPATHETIC PREGANGLIONIC NEURONS AND SOMATIC NEURONS IN THE SACRAL PORTION OF THE MAMMALIAN SPINAL CORD.
I. Nadelhaft, W. C. deGroat, C. Morgan, and S. Ames* VA Hosp. & Depts. of Neurosurg. & Pharmacol., Univ. of Pittsburgh Med. Sch., Pittsburgh, Pa.

What is the relationship between the location of a cell body within the spinal cord and the root through which its axon leaves the cord? In a recent study, Rubin and Purves (1) showed that, contrary to earlier reports, sympathetic preganglionic axons in the thoracic rami arise from cell bodies located in the corresponding cord segments. In the course of our study of the innervation of the pelvic viscera in the cat, we have attempted to increase the labelling efficiency of the sacral parasympathetic nucleus (SPN) by applying HRP to the central cut ends of sacral ventral roots. These experiments also allowed us to study the segmental organization of the SPN and the ventral horn motor nuclei. In adult cats anesthetized with dial-urethane, ventral roots (single or alternate on opposite sides of the cord) were exposed to HRP. Subsequently, appropriate lumbar, sacral, and coccygeal spinal cord segments were sectioned and processed for HRP reaction product. Labelled neurons were always located ipsilateral to the exposed root and, on the basis of morphology (size and shape) and position, could be separated into two major groups (parasympathetic and somatic) each of which was further divided into subgroups; parasympathetic: dorsal band, lateral band (2); somatic: lateral motor group, Onuf's group X, medioventral motor group. The rostrocaudal position of all those cells labelled via a particular root was found to be shifted in a rostral direction relative to the segmental boundaries (defined by gross spinal rootlet entry zones). On the average (16 cases) the cells first appeared 0.9 mm rostral to the caudal boundary of a segment and extended into the next rostral segment by 1.1 mm. We found no evidence that axons travelled more than one segment before exiting through a spinal root. Our results support the hypothesis that in the sacral region the spinal cord is organized so that cell bodies, whose efferent axons lie within a particular spinal root, are located ipsilateral to that root and, except for a slight rostral shift, within the cord segment associated with that root.

101.15 FLUORESCENCE MICROSCOPY/HORSERADISH PEROXIDASE HISTOCHEMISTRY: A METHOD FOR STUDYING TWO NEURONAL SYSTEMS IN THE SAME SECTION.
Bang H. Hwang* and Terence H. Williams. Department of Anatomy, University of Iowa, Iowa City, IA 52242.

Although fluorescence microscopy (FM) has yielded much information about the extensive projections of CA neurons in the CNS, it does not provide detailed information about distribution of CA terminals in relation to the innervated cell bodies. Retrograde axonal transport of horseradish peroxidase (HRP) can be used to visualize HRP-positive cell bodies whose terminals have taken up HRP. Using FM and HRP techniques together can be valuable for demonstrating the neuroanatomical relationships between CA terminals and the neurons innervated by these CA terminals.

The steps in this procedure are as follows: (1) 24 hrs. after HRP administration, rats are pretreated with Nialamide (500 mg/kg, i.p.) 2-5 hrs. before sacrifice; (2) the animals are perfused through the aorta with 250 ml of 2% glyoxylic acid in Krebs-Ringers solution containing 10% sucrose at pH 7.2, saturated with a $95\%O_2$-$5\%CO_2$ mixture; (3) after dissecting out the tissue, immersing for 10 min. in Krebs-Ringer solution containing 10% sucrose, transferring to a pre-cooled chuck without mounting medium, and putting the tissue in a cryostat set at -25°C until the tissue becomes solid, the tissue is cut into 20 μm sections; (4) after mounting on a glass slide, the section is immersed in the fixative (1.5% paraformaldehyde-0.025% glutaraldehyde in phosphate buffer, pH 7.3) for 20 seconds; (5) the slide is then run through 3 changes of 1% glyoxylic acid in phosphate buffer at pH 7.2, containing 6.8% sucrose (de la Torre, 1979), before drying for 5 min. under a hair dryer; (6) the slide is then placed in a pre-warmed beaker containing mineral oil in an oven at 95°C for 5 min.; (7) after mounting with fresh mineral oil and cover slip, the section is ready for FM observation; (8) after photographing CA terminals and recording coordinates, the slide is immersed in acetone to remove mineral oil, rinsed in distilled water and processed for HRP localization according to Mesulam (1978); and (9) with the aid of the coordinates, the locations of previously photographed CA terminals are observed for HRP localization in the cell bodies. By matching up the FM image and HRP localization in the same section, the precise anatomical relationships of CA terminals to target neurons are established.

102.2 EFFECT OF PHENYTOIN ON 2-DEOXYGLUCOSE UPTAKE AND IONIC CHANNELS. I. Yokoi* and T. Yanagihara. (SPON: M. D. Muenter). Dept. of Neurol., Mayo Clinic and Mayo Med. Sch., Rochester, MN 55901.

Phenytoin (DPH) is a commonly used anticonvulsant. However, the anticonvulsive mechanism is not clearly elucidated. Although DPH binds to various membrane structure, high affinity or saturable binding has not been demonstrated. In the present study, the effect of DPH on the uptake of 2-deoxy-D-glucose (2-DG) into isolated nerve endings was investigated with and without depolarization of membrane by 25 μM veratridine or 60 mM K^+. We also evaluated the contribution of Ca^{2+} for depolarization and/or the effectiveness of DPH. Since synaptosomes have a high affinity uptake system for 2-DG and our investigation has shown the alteration of uptake by membrane depolarization, this model will be useful for the above purposes. Synaptosomes were prepared by Ficoll density gradient ultracentrifugation from rat cerebral cortex (Cotman and Matthews, Biochim. Biophys. Acta 249:380, 1971) and were incubated in the presence of [^{3}H]2-DG (0.1-2 mM) under various ionic conditions for 5 min at 25°C. After incubation, particle-associated 2-DG was recovered on filter membrane, and the radioactivity was determined. The data was analysed using Lineweaver-Burk plot. The effect of DPH was evaluated in the presence of 100 μM DPH.

In the presence of 1.8 mM Ca^{2+}, the Km and Vmax of 2-DG uptake was 0.45 mM and 1.07 pmol/mg protein/min, respectively. The elimination of Ca^{2+} enhanced the uptake by 35%. Ca^{2+} and 2-DG appear to be competitive in this system. Uptake of 2-DG was inhibited by 60 mM K^+ (20%) and by 25 μM veratridine (40%) in the presence of Ca^{2+}. The inhibition was 25% by 60 mM K^+ and 30% by veratridine from the enhanced uptake level in the absence of Ca^{2+}. Uptake of 2-DG was inhibited by 15% in a competitive manner by DPH in the presence of Ca^{2+} and 20% in the absence of Ca^{2+}. Depolarization by veratridine was significantly suppressed by DPH but not by depolarization with 60 mM K^+. This was also true in the absence of Ca^{2+}. The present investigation suggested that DPH exerts its effect through sodium channel and that Ca^{2+} facilitates the effect of DPH on depolarization caused by veratridine. (Supported by the grant NS-52327 from NIH).

102.3 BINDING OF DIAZEPAM AND PHENYTOIN IN RABBIT BRAIN IN VITRO. T. Yanagihara and I. Yokoi*. Dept. of Neurol., Mayo Clinic and Mayo Med. School, Rochester, MN 55901.

Previous investigation from this laboratory demonstrated binding of phenytoin to many subcellular and cellular fractions after incubation with brain slices in vitro but the binding was not high affinity or saturable (Soc. Neurosci. 5:578, 1979). With diazepam, under a similar experimental condition, the binding was observed in many subcellular fractions, but displacement by clonazepam and saturable binding were observed only with the synaptosomal and microsomal fractions. In the present investigation, binding characteristics and drug interaction of these two anticonvulsants were evaluated using isolated subcellular elements from rabbit brain in vitro. For this purpose, nuclei, synaptosomal membranes and microsomes were prepared by sucrose or Ficoll density gradient ultracentrifugation. Synaptosomal membranes were prepared according to Whittaker et al (Biochem. J. 90:239, 1964) and Cotman and Matthews (Biochim. Biophys. Acta 249:380, 1971). The binding assay was carried out by incubation of a subcellular element in the presence of [^{3}H]diazepam or [^{3}H] phenytoin and subsequent membrane filtration. The results were analysed by Lineweaver-Burk or Scatchard plot.

With [^{3}H]phenytoin, there was no specific high affinity binding in any of these subcellular fractions investigated. With [^{3}H]diazepam, the binding in nuclei was nonsaturable and nondisplaceable by clonazepam. The binding to other subcellular fractions studied here was displaced by clonazepam. The synaptosomal membranes showed higher binding capacity than microsomes. The synaptosomal membrane fraction prepared by the method of Cotman and Matthews showed the highest specific activity. With the thoroughly washed membrane fraction, the analysis suggested the existence of two separate binding sites with different affinity. The dissociation constant was tentatively calculated as 10.3 and 82.2 nM respectively, and the corresponding maximum binding site was 0.46 and 1.45 pmol/mg protein. This finding may indicate the presence of benzodiazepine receptor in more than one subcellular location or the presence of more than one endogenous ligands for benzodiazepine receptor. Phenytoin (100 μM) inhibited binding of diazepam up to 25% but only at a low concentration (less than 5 nM) of diazepam. Phenobarbital failed to inhibit binding of diazepam. There is no evidence at present that phenytoin exerts anticonvulsant action through benzodiazepine receptor. (Supported by the grant NS-52327 from NIH).

102.4 HARMALINE-INDUCED TREMOR: INTERACTION WITH THE BENZODIAZEPINE RECEPTOR AS A POSSIBLE MECHANISM OF ACTION. H. A. ROBERTSON. Department of Pharmacology, Dalhousie University, Halifax, N.S., Canada B3H 4H7.

Harmaline (1-methyl-7-methoxy-3,4-dihydro-β-carboline), at doses of 10-30 mg/kg, i.p., produces tremor. Diazepam antagonizes both the tremorogenic effect of harmaline and the increase in cerebellar 3',5'-cyclic GMP elicited by harmaline. Inhibition of GABAergic neurotransmission also produces increases in cyclic GMP (Costa et al, 1975). I now report that harmaline displaces 3H-flunitrazepam from the benzodiazepine receptor. Furthermore, the concentration of harmaline in brain during tremor is sufficient to occupy at least some benzodiazepine binding sites.

3H-flunitrazepam binding assays were done in vitro on membrane fractions from mouse brain using 2nM 3H-flunitrazepam. Brain harmaline concentrations were determined by spectrophotofluorimetry. Although the affinity of harmaline for the benzodiazepine receptor is low (IC_{50}=600 μM), brain concentrations of harmaline produced by tremorogenic doses fali within a range (20-70 μM) where at least a small percentage (5-20%) of benzodiazepine receptors would be occupied. The time course of harmaline-induced tremor was also studied. A dose of 30 mg/kg i.p. produced tremor within 5 minutes at which time the brain concentration was 35 μM. Peak brain concentration (80 μM) was achieved at 30 minutes but tremor continued for more than 2 hours. At 4 hours the brain concentration had fallen to 12 μM and no tremor was evident. The results indicates that occupancy of only a small percentage of receptors may be necessary for production of tremor, suggesting either "spare receptors" or a specific population of receptors preferentially affected by harmaline. Paul et al (1979) have also shown that only a small fraction (25-30%) of benzodiazepine receptors need be occupied by diazepam to completely abolish pentylenetetrazol convulsions. These results suggest that harmaline might act by displacing an endogenous ligand for the benzodiazepine receptor, a ligand whose role is to facilitate GABAergic neurotransmission.

102.5 THE ACTION OF AVERMECTIN Bla ON THE NEMATODE ASCARIS. I. S. Kass*, A. O. W. Stretton and C. C. Wang. Dept. of Zoology, Univ. of Wisconsin, Madison, WI 53706 and Merck Inst., Rahway, NJ 07065.

Avermectin Bla (AVM) paralyzes nematodes without causing hypercontraction or flaccid paralysis. We have investigated the site of action of AVM in Ascaris by using selective stimulation and differential drug application techniques. When a single excitatory motorneuron is stimulated directly, AVM does not affect its activity; however if the motorneuron is stimulated indirectly through interneurons, AVM inhibits transmission between interneurons and the motorneuron and no activation of the motorneuron occurs. This inhibition is reversed by picrotoxin. We believe that AVM acts via a gabanergic mechanism. This is supported by the fact that muscimol and piperazine, GABA agonists in Ascaris, both mimic the action of AVM; furthermore the effects of muscimol and piperazine are reversed by picrotoxin. The site of action of these three compounds was investigated in experiments in which they were applied only to the ventral nerve cord. In each case the transmission between interneurons and the motorneuron was blocked, but could be reversed by picrotoxin. The effects of AVM in Ascaris are consistent with its action in other systems. In the lobster Fritz et al. (Proc. Nat. Acad. Sci., 76:2062, 1979) showed that AVM eliminated IPSP's; Pong et al. (J. Neurochem. 34:351, 1980) showed that AVM caused the release of GABA from mammalian synaptosomes. Our hypothesis is that in Ascaris AVM causes the release of GABA, causing an inhibition of the interneuron to motorneuron pathway.

102.6 TISSUE CULTURE STUDIES OF KAINIC ACID NEUROTOXICITY IN THE ABSENCE OF GLUTAMATERGIC FIBERS. F.J. Seil and W.R. Woodward. Neurology Research, V.A. Med. Ctr. and Depts. of Neurology and Biochemistry, Univ. of Oregon Health Sci. Ctr., Portland, OR 97201.

On the basis of results from both animal and tissue culture studies, it has been suggested that the presence of glutamatergic afferent fibers is necessary for the manifestation of kainic acid neurotoxic effects. Cortical glutamatergic afferent fibers can be eliminated in cerebellar cultures by exposing explants to cytosine arabinoside during the first 5 days in vitro. Such exposure results in destruction of cerebellar granule cells, whose axons (parallel fibers) normally contact all other cerebellar cortical neurons, and whose neurotransmitter is believed to be glutamic acid. The purpose of this study was to determine whether or not kainic acid neurotoxicity was expressed in granuloprival cerebellar cultures.

Cerebellar explants derived from newborn mice were exposed to 5 μg cytosine arabinoside per ml nutrient medium for 5 days after explantation and then cultivated in normal medium. After 16 days in vitro, granuloprival cultures were exposed for 6 days to nutrient medium incorporating either 10^{-4}M kainic acid or 10^{-3}M D-glutamic acid. The latter is a metabolically inactive excitatory isomer of L-glutamic acid that is not neurotoxic to normal cerebellar cultures. Granuloprival explants exposed to D-glutamic acid also demonstrated no neuronal destructive effects, and the cortices of such cultures contained abundant large neurons and numerous neurites. By contrast, large cortical neurons and their axonal processes were markedly reduced or absent in granuloprival cerebellar cultures exposed to kainic acid, and reactive gliosis was prominent. Effects were similar to those obtained by exposure of normal cerebellar explants to 10^{-4}M kainic acid, and were repeated upon application of kainic acid to granuloprival cerebellar explants cultivated in low-L-glutamate medium. The results of this study suggest that kainic acid neurotoxic effects can be manifested in the absence of glutamatergic afferent fibers.

102.7 SUBSTANCE P DECREASES MEMBRANE POTASSIUM AND SODIUM CONDUCTANCES OF MOUSE SPINAL CORD NEURONS IN CELL CULTURE. L. M. Nowak and R. L. Macdonald. Neurosciences Program and Department of Neurology, University of Michigan, Ann Arbor, MI 48109.

The undecapeptide, substance P (SP), is a neurotransmitter candidate for a subpopulation of small diameter dorsal root ganglion (DRG) neurons in which SP-like immunoreactivity has been localized in vivo and in vitro. We have examined the ionic basis of SP-produced depolarization of mouse spinal cord neurons grown in primary dissociated cell culture and report that SP decreased membrane conductance to potassium ions (g_K) and to a lesser extent, sodium ions (g_{Na}).

Spinal cords and attached DRGs were dissected from 12-13.5 day old fetal mice, mechanically dissociated, plated on 35mm collagen-coated dishes and grown in culture at 35° for 4-8 weeks prior to electrophysiological investigation. Intracellular recordings were made from neurons bathed in buffered saline on the heated (35-37°), modified, stage of an inverted phase-contrast microscope, using one or two 4M potassium acetate-filled micropipettes. Peptides were applied directly to the neuronal surface by pressure pulses (1 sec at .25-3.0 psi) from blunt glass micropipettes (2-10μ tips).

SP produced dose-dependent (.5-20μM), slow (.75 sec latency), reversible depolarizations accompanied by decreased membrane conductance. SP-response amplitude increased when membrane potential was depolarized and decreased when membrane potential was hyperpolarized with steady polarizing currents. SP-responses had reversal potentials (RPs) that were more negative than resting membrane potential, suggesting that SP reduced either g_K or chloride ion conductance (g_{Cl}). However, intracellular and extracellular tetraethylammonium, which blocks g_K, eliminated or reduced SP-responses respectively. Moreover, SP-responses recorded with 3M potassium chloride-filled micropipettes (which shift chloride equilibrium potential to about -20mV) were increased or unchanged. These data indicated that SP reduced g_K, rather than g_{Cl}, to depolarize membrane potential. This hypothesis was further tested by manipulating the extracellular potassium concentration ($[K^+]_o$). The RPs for SP-responses varied log linearly as a function of $[K^+]_o$ with a slope of -60 in high $[K^+]_o$ s (15, 20 and 40mM), however, in low $[K^+]_o$s (1, 5 and 10mM), RPs were more depolarized than predicted by the Nernst potential for potassium, indicating that another cationic conductance, probably g_{Na}, was also decreased.

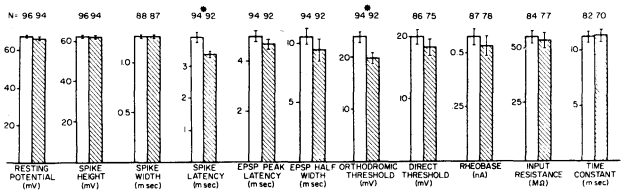
Thus SP depolarized membrane potential by reducing the univalent cation conductances of mammalian spinal cord neurons in cell culture.

103.1 COMPENSATION FOR LOSS OF SYNAPSES IN SENESCENT RAT HIPPOCAMPUS. C. A. Barnes and B. L. McNaughton. Institute of Neurophysiology, University of Oslo, Karl Johans Gate 47, Oslo 1, Norway.

Anatomical studies have revealed that the granule cells of the fascia dentata undergo a partial (27%) deafferentation as a result of senescence (Geinisman & Bondareff, Am. J. Anat., 145,129-136, 1976). The present report examines the physiological correlates of this process in order to determine how the input-output relations of the granule cells might be altered. The experimental techniques involved extracellular stimulation and recording in the awake unrestrained rat (male Long Evans; 31 aged 12 mo; 30 aged 30 mo), and both extra- and intracellular recording from granule cells in the in vitro transverse hippocampal slice preparation (male Wistar albino rats; 16 aged 10 mo; 16 aged 31 mo).

Compared with adult controls the senescent animals exhibited a significant reduction in both the perforant path excitatory synaptic field potential and in the afferent fiber response. Since there was no apparent change in the threshold for fiber activation these data support the anatomical literature indicating a loss of afferent synapses. For a given magnitude of afferent fiber response, however, the old animals exhibited a larger synaptic field potential, suggesting that the remaining synapses were in fact more powerful. Furthermore, the magnitude of the extracellular population spike was greater in the old animals when plotted as a function of extracellular EPSP amplitude.

Intracellular recording from a total of 190 stable cells revealed two statistically significant ($p < .05$) differences between age groups as seen in the Figure below (shaded histograms refer to the old population): a 17 percent reduction in the voltage threshold for synaptically elicited granule cell discharge, and a 13 percent reduction in the latency of the action potential. This pattern of results suggests that the locus of spike initiation may move into the proximal portions of the dendrites of old animals. Taken together these data indicate that the granule cells may compensate for a loss of synapses during senescence both by an increase in their electrical responsiveness to synaptic activation and by an increase in synaptic efficacy.



103.2 AGE-RELATED ELECTROPHYSIOLOGICAL CHANGES IN RAT CEREBELLUM. J. Marwaha, B. Hoffer*, R. Wyatt† and R. Freedman*. Departments of Pharmacology and Psychiatry, Univ. of Colo. Health Sciences Center, Denver, CO 80262, and †NIMH, St. Elizabeth's Hospital, Washington D.C. 20032.

The spontaneous discharge of cerebellar Purkinje neurons was studied in 3-, 12-, 15-, and 20-month-old rats. Fluphenazine and haloperidol administered intraperitoneally produced a dose-dependent increase in the spontaneous discharge in 3-month-old animals, but were ineffective in 12-, 15- and 20-month-old rats. Intraperitoneal administration of amphetamine resulted in a dose-dependent decrease in spontaneous Purkinje neuron discharge in 3-month-old rats without affecting neurons from the older animals. Disruption of norepinephrine afferents by 6-OHDA or reserpine increased spontaneous discharge rate in 3-month-old animals. This treatment did not affect Purkinje neurons in 12-, 15- and 20-month-old rats. Local application of drug with the same multibarreled electrode revealed that neurons from older rats were significantly less sensitive to inhibition by norepinephrine than were Purkinje neurons from 3-month-old animals. Similarly, application of GABA did not reveal a differential sensitivity (see figure). For locus coeruleus activation to produce 50% inhibition in Purkinje neuron discharge, significantly higher stimulation currents were required in 15-month-old rats than in 3-month-old animals. Our results suggest a decreased postsynaptic sensitivity to norepinephrine in 12-, 15 and 20-month-old rats as compared to 3-month-old animals.

103.3 A COMPUTER-ASSISTED STUDY OF NEURON NUMBER AS A FUNCTION OF AGE IN MOUSE BARREL CORTEX. C.A. Curcio* (SPONS: P.D. Coleman). Dept. of Anatomy, Univ. of Rochester Sch. Med. Dent., Rochester, N.Y. 14642

It is widely assumed that the aging process produces a substantial reduction of neurons in the brain. Studies showing cell loss in the cerebral cortex have actually demonstrated changes in packing density, since cortical volume changes with age are not well understood. The barrel is a unique feature of rodent somatosensory cortex, a morphological and functional subunit whose dimensions may be determined empirically; therefore cell counts in a barrel may indicate whether there is absolute cortical neuron loss with age. Thus, cells in one identified barrel, C3, have been counted in coded tissue from male C57Bl6 mice aged 4 to 30 months.

Barrels are most easily visualized in thick tangential sections at low power. In contrast individual cell types are best resolved in thin sections at high power. Therefore, a two-stage approach has been adopted in which data from a single barrel at different levels of histological processing and examined at different magnifications are integrated by a computer modelling and graphics system (Curcio and Sloan, in preparation).

Tangential 100 mu Vibratome sections through mixed aldehyde-fixed hemispheres are osmicated, dehydrated, and flat-embedded in plastic. Barrels are visible in these unstained preparations, and are photographed and mapped at low power. Barrel C3 is then resectioned at 1 mu for cell counts and is examined at high power. The barrel boundary seen in thick sections and profiles of neuronal nuclei drawn from thin sections are traced onto a digitizing tablet. The computer system then superimposes the barrel boundary on the cell map using common landmarks (blood vessels) and determines cell density within the barrel. Barrel cross-sectional area is also determined from the low power maps, and barrel height is determined from cortical tissue from the opposite hemisphere sectioned normal to the pial surface.

Supported by NIH training grant GM07136 to CAC and NIH grant AG1121 to PDC. Animals obtained from NIA colony.

103.4 FINE STRUCTURAL STUDIES ON THE AGING NEUROENDOCRINE AXIS: OBSERVATIONS ON THE PITUITARY AND ADRENAL. J.E. Johnson, Jr. Hitachi Scientific Instruments, Rockville, Md. 20850; Dept. Neurology, Johns Hopkins School of Medicine, Baltimore, Md. 21205; Section on Experimental Morphology, National Institute on Aging, GRC, NIH, Baltimore City Hospital, Baltimore, Md. 21224.

Several investigators have proposed that the hypothalamic-pituitary-target axis represents a key system in affecting the aging process. Dilman (1971) suggested that there is a gradual increase in the threshold of hypothalamic sensitivity to feedback suppression. A later study suggested that the pineal may modulate this feedback sensitivity (Walker and Bethea, 1977). If sensitivity loss as a function of age were affected by age related pineal deterioration, the pineal should have distinct morphological age changes which, indeed, it does (Johnson, 1980). Recently, Denckla (1974) proposed that the pituitary may modulate some aspects of aging by actively secreting a substance which decreases tissue response to thyroxine. Removing the pituitary (and thus removing the source of this unidentified hypothetical substance) has reduced age indices in the kidney (Johnson and Cutler, 1980). If the secretion of this substance is an actively maintained program for aging, one might predict that the pituitary would, itself, be protected from the more severe changes with age.

In the present study, male Fischer-344 rats, 4-36 mos of age were perfused with aldehyde fixative, the pituitary, adrenal and other tissues removed and processed for electron microscopy.

Cells in the adenohypophysis were found to show very little structural age change. Only occasional age pigment (probably lipofuscin) granules were seen. Cells in the neurohypophysis on the other hand, contained age pigments more frequently. In the aging adrenal gland, the situation appeared different. Both the adrenal cortical cells and the neuroectodermally derived cells of the medulla contained significant amounts of age pigment. Thus, the two glands, both containing hormone secreting cells as well as nervous tissue, show markedly different responses to age. The adenohypophysis, in fact, shows among the least structural age changes we have found in a variety of tissues examined.

103.5 CAN RETINAL CELLS AGE GRACEFULLY? Ruth A. Trachimowicz and James W. Hinds. Dept. of Anatomy, Boston University School of Medicine, Boston, MA 02118.

In earlier studies (Lai et al., Invest. Ophthalmol. 17: 634, 1978; Weisse and Stötzer, Virchows Arch. (Path. Anat.) 362: 145, 1974) retinal aging was characterized both by a generalized thinning of the photoreceptor layer (ONL) throughout the retina and, in the far periphery, a selective loss of entire retinal layers; specifically, receptor inner and outer segments (IS+OS), ONL, and outer plexiform layer (OPL). The present study describes retinal aging in an age-graded series of males from 3 rodent strains: C57BL/6 mice (2 - 31 mos., median life span 31 mos.), AKR mice (4 - 14 mos., median life span 11 mos.), and COBS rats (6 - 31 mos., median life span 26 mos.). In general, the changes noted are mild compared to those previously described. No cysts were observed in either the central (C) or peripheral (P) loci sampled, and all the retinal layers, though reduced in thickness, were still intact at both loci. All 3 strains exhibit the most pronounced changes in the ONL, as decreased layer thickness (AKR: 40% C, 35% P; COBS: 26% C, 17% P; C57BL/6: no significant change) and/or decreased rod planimetric density (AKR: 43% C; C57BL/6: 14% C). Rod planimetric density has not yet been measured in COBS rats. A thinning of IS+OS was observed only in AKR mice. In none of the strains examined do the OPL, inner nuclear layer (INL), or inner plexiform layer change with age, and in the AKR and C57BL/6 mice INL cell counts at the central locus show no change in the planimetric density of either bipolar or amacrine cells. INL planimetric densities have not yet been measured in the COBS rats.

Preliminary results of synapse counts in the OPL of 3 young (4 mos.) and 3 old (14 mos.) AKR mouse retinas suggest a loss of rod synapses with age (from 883/1000 μm^2 to 488/1000 μm^2), while the number of cone ribbon synapses appears to remain constant (119 - 131/1000 μm^2). As a model for aging the retina thus differs from the olfactory bulb in its response to receptor cell loss: postsynaptic mitral cells in the olfactory bulb undergo a pronounced atrophy with advanced age (Hinds and McNelly, Soc. Neurosci. Abstr., in press), while retinal bipolar cells appear unaffected by a loss of receptor input. OPL synaptology will be analysed to determine what, if any, compensatory changes occur in receptor - bipolar contacts to maintain the bipolar cells following receptor loss (Do the sizes of the remaining rod spherules increase with age? Do the number of ribbon synapses/ rod spherule increase with age?

This research was supported by NEI grants EY-07022 and EY-01398 and NIA grants AG-00001 and AG-00020.

103.6 PURKINJE CELL DENDRITES IN AGED RATS: A MORPHOMETRIC GOLGI ANALYSIS. Joseph J. Pysh and Michael D. Benson*. Department of Anatomy, Northwestern University Medical and Dental Schools, Chicago, Illinois 60611.

The affect of aging on the structure of the neuron is of considerable neurobiological interest. The objective of this study was to examine the structure of Purkinje cell dendrites in inbred aged rats as demonstrated in Golgi-Kopsh preparations. The isoplanar nature of the dendritic tree makes the Purkinje cell uniquely suitable for morphometric analysis.

Four 3-month old and four 33-month old Fisher 344 female rats were used in this study. A total of 115 complete Purkinje cell dendritic trees were obtained for analysis. Fifty-one Purkinje cells from young animals and 64 cells from aged animals were evaluated.

Body weight and cerebellar weight were significantly greater in aged compared to young animals by 37% and 17%, respectively. Histometric analyses of sagittal sections of the cerebellar vermis revealed that vermis sectional area was 8.6% larger in aged rats which correlated with a 12% larger area of the granular layer and white matter. No differences were found in the thickness or sectional areas of the molecular layers of aged compared to young rats. This suggests possible atrophy of the molecular layer since previous studies in mice demonstrated continual growth, attributed primarily to glial hypertrophy, of both the granular and molecular layers from 3 to 8 months of age. The qualitative appearance of Purkinje cells in young and old animals were similar. Morphometric analyses of Purkinje cells revealed no significant differences in dendritic field size, branching density, total branch length or spine density. An analysis of frequency distribution histograms of Purkinje cell dendritic field size did not reveal any evidence of atrophy or hypertrophy in aged animals. A reduction of 10% in total numbers of spines per cell in Purkinje cells of old compared to young animals was found not to be statistically significant.

In conclusion, the present study establishes that aging is not associated with significant alterations in the dendritic tree of rat Purkinje cells.

Supported by NIH Grant #NS 10657.

103.7 d-AMPHETAMINE BEHAVIORAL EFFECTS AS A FUNCTION OF AGE IN THE RAT M.M. Kilbey*, J.W. Moore, Jr.*, and W.C. Willson* (SPON: C.N. Jones). Psychology Dept., M.T.S.U., Murfreesboro, TN 37132. Behavioral effects of psychoactive drugs appear to be correlated with, and possibly to result from, action of drug upon neurotransmitter metabolism. Descriptive parameters of transmitter properties as a function of early development are relatively well known, and some recent work has begun to elucidate transmitter functions in aged animals. Differences in transmitter function might be expected to be expressed in differential behavioral effects in younger and older rats in comparison to those seen in young adult rats. In our laboratory, the effects of d-amphetamine upon general activity, startle response, stereotypy and stimulus properties have been measured in male and female Long-Evans rats as a function of age (3,12 and 24 months). Results from these experiments indicate a complex pattern of differences in d-amphetamine induced behavioral changes as a function of age. The degree of stereotypy induced by 8 mg/kg d-amphetamine was not found to vary as a function of age. Startle response to an air puff stimulus, in younger animals under drug conditions (0,4 and 3 mg/kg), were significantly augmented as a function of dose while aged animals showed no dose-response effect. Four mg/kg d-amphetamine significantly increased activity measures in aged animals, but not younger Ss. In the stimulus properties paradigm, age differences were found in the rate of acquisition of stimulus control of behavior by .5 and 1.0 mg/kg d-amphetamine as well as in generalization functions once stimulus control had been established. These results are discussed in terms of their implications for drug/behavior relationship differences in rodents as a function of age and the utility of age as a variable in animal models of abnormal behavior.

103.8 ELECTROPHYSIOLOGICAL ANALYSIS OF REACTIVE SYNAPTOGENESIS IN THE DENTATE GYRUS OF THE AGED RAT. E. W. Harris, S. W. Scheff and C. W. Cotman. Dept. Psychobiology, Univ. California, Irvine, CA 92717 and Dept. Anat., Med. Center, University of Kentucky, Lexington, KY 40536.

The hippocampal formation has been used extensively to study the response of the mammalian central nervous system to damage. After removal of the largest extrinsic input to the hippocampal dentate gyrus, arising from the ipsilateral entorhinal cortex, there is a pronounced increase in the terminal fields of remaining afferents. Using anatomical techniques, it has been shown that aged animals subjected to unilateral entorhinal lesion have a reduced capacity to sprout. The work presented here is an electrophysiological analysis of the normal and reorganized dentate gyrus in young adult compared to aged rats.

Conventional extracellular recording techniques have been used to examine two inputs to the dentate gyrus: the projection from the contralateral hippocampus (the commissural system) and the pathways arising from the ipsilateral and the contralateral entorhinal cortex (the ipsilateral and crossed temporodentate pathways). The maximum rate-of-rise and laminar distribution of the field potentials evoked by stimulation of each pathway have been determined in young (3 month) and aged (27 month) rats, and in animals with long-standing unilateral entorhinal lesions.

The commissural system of normal aged rats was not noticeably different from that in young adult rats, but the normal crossed temporodentate pathway was larger in the aged animals. Following entorhinectomy, both inputs exhibited an increase in evoked response amplitude in aged animals similar to that in young animals. However, the increase in commissural system response is less than that observed in young rats, in agreement with anatomical findings. The sprouted crossed temporodentate pathway is also smaller than in young animals. These data illustrate that there is a reduced functional reorganization of the fibers which are present in the aged animal. (Supported by NIH AG00538-04 and NINCDS NS06480-01.)

103.9 EFFECTS OF DIAZEPAM AND IMIPRAMINE ON BODY TEMPERATURE OF AGED SQUIRREL MONKEYS. S.M. Clark* and J.M. Lipton (SPON: J. Kirkpatrick), Depts. of Physiology and Neurology, University of Texas Health Science Center, Dallas, TX 75235.

Certain medications prescribed for elderly patients may increase their vulnerability to accidental hypothermia. We tested the effects of two drugs widely prescribed for the elderly, diazepam and imipramine, on rectal temperature of squirrel monkeys 2-16 yrs old. In a thermoneutral environment, diazepam (0.125-0.5 mg/kg, im) produced hypothermia in animals of all ages, with monkeys over 14 yrs showing a greater response with the highest dose. Hypothermia in the old monkeys was greatly augmented in a cold environment (15°C) but there was no difference between responses of old and younger animals in the heat (30°C). In initial studies, icv administration of diazepam in a thermoneutral environment produced hyper- rather than hypothermia in all animals, and the response was decreased in animals over 10 yrs of age. The responses of animals of all age groups to imipramine (1.5-12.0 mg/kg, im) given in a thermoneutral environment was variable, but animals over 14 yrs more consistently developed hypothermia. There was no clear age-related difference in response of old animals exposed to heat. Because of toxic effects, no experiments were carried out on imipramine in the cold. These results suggest that these commonly used drugs may increase the risk of accidental hypothermia in the elderly. Determination of the site of action of these drugs in producing hypothermia in aged primates (central vs peripheral site of action) must be determined in future experiments. (Supported by National Institute on Aging Grant AG 00109.)

103.10 AGING EFFECT ON THE NORADRENALINE CONTENT OF RAT BRAIN MICROVESSELS. Larry J. Embree, David W. Jackson*, Frederick Ordway*, and Isaac F. Roubein. Veterans Administration Medical Center and Department of Neurology, Louisiana State University Medical Center, Shreveport, Louisiana 71130.

There is both anatomical and physiological evidence that the intraparenchymal vasculature of the brain is innervated by noradrenergic nerve fibers. This noradrenergic system of vascular innervation has the potential for influencing cerebral blood flow and overall brain metabolism. Thus, its proper function would be critical to maintenance of normal neurologic activity, and derangements might correlate with aging and certain disease states, particularly those classified as metabolic or degenerative.

One aspect of the integrity of this central adrenergic system is the level of noradrenaline (NA) in the cerebral microvasculature, and while there are published studies on NA content of microvessels isolated from brains of young adult animals (Lai et al., Proc. Nat. Acad. Sci., USA, 1975, Reinhard, et al., Neusci. Abstracts, 1979), information is lacking on the effect of aging on the level of this monoamine in microvessels; hence this study was undertaken.

Aging male Sprague-Dawley rats (23-24 months old) were sacrificed by decapitation, the brains were removed immediately, stripped of meninges, choroid plexus, pineal body, and brain stem. Microvessels were isolated from forebrains and their NA content was determined using high pressure liquid chromatography and electro-chemical detector after homogenizing the tissues in 0.4 M perchloric acid. Protein levels were determined on the resolubilized pellet by the Lowry method. Microvessels isolated from young adult rat (10-12 weeks old) brains were used as controls.

Microvessel preparations from aging animals contained 128 ±17 pg NA/mg protein and similar preparations from young adult rats contained 243 ± 26 pg NA/mg protein. This difference was statistically significant ($P < .01$).

This decrease in microvascular related neurotransmitter may indicate a deficiency in the control of the cerebral vascular bed which could lead to metabolic disturbances of the neural tissues and clinical neurologic dysfunction. If similar changes in NA content of microvessels are found in aging human brain, the possibility exist for a pharamacological approach to ameliorate some of the signs and symptoms that are associated with aging of the brain.

103.11 ULTRASTRUCTURAL CHARACTERISTICS OF THE SUPRAOPTIC NUCLEUS (SON) OF THE AGED RAT. T.H. McNeill, C.L. Clayton, R.J. Joynt. Department of Neurology, University of Rochester, Rochester, N.Y.

The ultrastructural characteristics of the SON of the 30 mo. old rat were examined. Five young (3 mo.) adult male Fisher 344 rats and five senescent (30 mo.) rats of the same strain were prepared for electron microscopy. Brains were fixed under pentobarbitol anesthesia by a vascular perfusion with 2% paraformaldehyde-2% gluteraldehyde in phosphate buffer, pH 7.2. Tissues were post-fixed in 1% osmium tetraoxide for 1 hour, dehydrated in increasing consentrations of ethanol and embedded in Spurr low viscosity resin. Ultrathin sections were mounted on uncoated 200 mesh grids and stained with uranyl acetate and lead citrate. Sections were analyzed in a Zeiss EM 10A electron microscope at an accelerating potential of 60kV.

Electron microscopic examination of the stained tissue sections suggest that the ultrastructure of SON perikarya is not significantly altered with age. Perikarya had a well defined nucleus with a large nucleolus. Cytoplasm exhibited diolated arrays of perinuclear Golgi, parallel arrangement of short cisterna of rough endoplasmic reticulum, lysosomes and mitochondria. Large neurosecretory granules were concentrated along the periphery of the cell and in the proximal axon. In contrast to SON perikarya in the 3 mo. old rat "aged" perikarya had numerous large lipofuscin granules with associated lipid bodies and an apparent increase in cytoplasmic polyribosomes. Although a morphometric analysis was not undertaken, axosomatic synapses were identified on SON cell soma. These data suggest that unlike other neuronal systems (i.e. Purkinje cells, hippocampus, spinal cord etc.), the ultrastructure of SON perikarya is not significantly altered with age and may possibly reflect a cellular hyperactivity in the 30 mo. old rat.

Supported by USPHS Grants AG05175, AG01456 and AG01903.

103.12 ULTRASTRUCTURAL CHARACTERISTICS OF MEDIAN EMINENCE (ME) IN THE AGED MOUSE. Claudia J. Clayton,* David E. Scott and Tnomas H. McNeill. Dept. of Neurology and Anatomy. Univ. of Rochester, Rochester, N.Y.

Ultrastructural characteristics of the aged ME were studied in male C57BL/6 mice. Animals 4 months old and 29-30 months old were anesthetized with pentobarbital and perfused through the ascending aorta with 2% glutaraldehyde-2% paraformaldehyde, pH 7.2, in phosphate buffer. Medial basal hypothalami were blocked and post-fixed in 1% osmium tetroxide for 2 hours, dehydrated in graded ethanols and embedded in Spurr low viscosity resin. Ultrathin sections were mounted on uncoated 200 mesh grids and stained with uranyl acetate and lead citrate. Sections were analyzed on a Zeiss EM 10A electron microscope at 60 kV.

The fibrous zone of the aged ME demonstrated an increase in size and number of Herring bodies. These were usually unmyelinated or thinly myelinated and contained mitochondria, polymorphous autophagic granules, autophagic vacuoles and secretory granules of varying density. Glial elements in this zone often contained lipofuscin.

Several types of ultrastructural alteration were apparent in the external zone of the aged ME. Processes packed with clear microvesicles were common and were often very large,measuring up to 4.7um in diameter. Few dense core vesicles were observed in these processes. Other large processes exhibited lysosomes and mitochondria centrally which were surrounded by a dense accumulation of concentrically and longitudinally oriented microtubules. Unmyelinated Herring bodies were present and exhibited microtubule proliferation as well as autophagic granules and vacuoles, lamellar bodies and dense core vesicles. Other fibers contained numerous lamellar bodies in addition to mitochondria, microtubules and dense core vesicles. No degenerating fibers or terminals were observed. The majority of fibers in the external zone were normal in appearance.

Morphological changes in the aged ME may reflect an altered availability of releasing factors for transport to the pituitary. Immunocytochemical studies are underway to determine if these ultrastructural alterations are confined to distinct populations of fibers.

Supported by USPHS Grants AG 01903 and AG 05175.

103.13 INDUCTION OF PSEUDOPREGNANCY BY CERVICAL STIMULATION IN MINIMALLY ANDROGENIZED AND AGING FEMALE RATS. J.R. Lehman* and S. E. Hendricks, Department of Psychology, University of Nebraska at Omaha, Omaha, Nebraska 68182

The present study is a part of a series of experiments designed to assess the utility of using the androgenized female rat as a model system for investigating age related changes in reproductive function. Previous experiments have suggested that with increasing age, the capacity of cervical stimulation (CS) to induce a progestational response deteriorates; e.g., a greater number of intromissions are required for an aged female. Comparisons were made among groups of intact, multiparous females (3, 9, and 14 months of age) and adult female rats which were subjected to varying dosages of androgen during the neonatal period (oil, .05, .5, and 3.0 µg testosterone proprionate injected at five days of age). Two weeks prior to and following CS, vaginal smears were obtained daily. CS stimulation (30 sec. of 10, 30, or 50 V pulsed at 200/sec. with a duration of one msec.) was delivered during the evening of an estrous day. Increases in voltage of CS were consistently associated with an increasing tendency of the rat to exhibit a pseudopregnancy response within each of the age and androgenized groups. For androgenized females which were cycling prior to CS there was a negative correlation between rates of pseudopregnancy and dose of neonatally injected androgen. Aging female rats which were cycling prior to CS treatment did not reveal an age-associated difference in proportion of animals becoming pseudopregnant. However, for those aging females which were in a state of persistent vaginal estrus prior to treatment, there was an age-associated attenuation in tendency to exhibit pseudopregnancy in response to CS. These findings indicate that with respect to responsiveness of the neuroendocrine system to CS, the dosages of neonatally injected androgen given produce deficits which are not apparent in aging rats.

Supported in part by a Dissertation Fellowship from the University of Nebraska Center on Aging to JRL.

103.14 EFFECTS OF AGING AND ESTROUS CYCLE ON THE HYPOTHALAMIC-PITUITARY-THYROID AXIS IN THE FEMALE GOLDEN HAMSTER. H.J. Chen. Neuroendocrine Research Laboratory, Barrow Neurological Institute, Phoenix, Arizona 85013

The purposes of these studies were aimed at determining the effects of aging and estrous cycle on basal and thyrotropin releasing hormone (TRH)-induced thyrotropin (TSH) release and on serum Thyroxine (T4) and Triiodothyronine (T3) concentrations in the female golden hamster (Mesocricetus auratus). Unlike the old female rat which enters a period of constant estrus, pseudopregnancy, and finally anestrus beginning at 10-14 months of age, 70 - 80 percent of female hamsters maintain regular 4-day estrous cycles at an older age (16-18months). This ability of the older female hamster to maintain regular estrous cycles renders it an ideal animal for study of the effect of aging on various endocrine functions during the estrous cycle. Young (3-4 months) and old (16-18 months) cycling female hamsters were used in the present experiments. The animals were injected subcutaneously with a single dose of TRH (100 ng/100 g BW) between 9:00 AM and 10:00 AM on various stages of the estrous cycle. Blood samples were collected one hour before and 10, 30, and 60 minutes after TRH injections. Serum TSH, total and free T4, and total T3 were determined by radioimmunoassays.

TSH response to TRH (100 ng/100g BW) stimulation was significantly greater in the young than in the old female hamsters even though basal TSH concentrations were comparable. Different stages of the estrous cycle did not affect basal or TRH-induced TSH release in either young or old hamsters.

Basal total and free Thyroxine concentrations were significantly higher in the young (3-4 months old) than in the old hamsters at all stages of the estrous cycle. In young females total T4 concentration was significantly ($p<0.01$) higher on estrus than on any other stages of the estrous cycle. Such a difference in T4 serum concentrations was not observed in the old (16-18 month) female hamster. Serum T3 concentration was significantly higher in the young than in the old hamsters, although different stages of the estrous cycle did not affect T3 concentrations in both old and young hamsters.

These results indicate that aging decreases TRH-induced TSH release in the golden hamster just as has been reported in female rats with similiar gonadal steroid influences (Chen and Walfish, J. Endocrin. 78: 225-232, 1978). Thyroid functions as indicated by circulating T4 and T3 concentrations diminish with advancing age in the female golden hamster. There is an increase in T4 concentrations in young female hamsters on the morning of estrus as compared with any other stages of the estrous cycle.

103.15 ESSENTIAL,DIETARY METAL IMBALANCE AND ALUMINUM INTOXICATION IN DEMENTED ALZHEIMER PATIENTS: INTERACTION WITH THE CATECHOLAMINE SYSTEMS. G. Wenk, Kettering Institute, Univ. of Cincinnati, Cincinnati, OH, 45267.

The distribution of Aluminum (Al) to certain catecholamine (CA)-rich regions of the brains of Alzheimer, demented, and elderly patients may be influenced by other trace metals in the diet. Clinical symptoms of depression, memory loss, and tremor, parallel elevated Al levels in the cortex, hippocampus, and cerebellum. A possible interaction of Al with the catecholaminergic systems in these regions is suggested. The neurotoxic effects of Al on the CA systems, and the influence of a dietary trace metal imbalance on the brain-Al distribution were investigated.

The results indicated that Al accumulation can be influenced by an imbalance in dietary copper, zinc, iron, and magnesium levels. The norepinephrine concentration in the cortex and hippocampus are depressed in animals eating diets with suboptimal amounts of copper or zinc, who also show elevated Al levels in these regions. Dopamine in Al-rich cortexes was also found to be lowered in animals on certain suboptimal diets.

103.16 CHOLINE TRANSPORT ACROSS THE BLOOD-BRAIN BARRIER IN AGED RATS. P. B. HICKS, C. ROLSTEN* and J.C. SCHOOLAR. Texas Research Institute of Mental Sciences, Houston, Texas 77030.

Choline transport across the blood-brain barrier (BBB) can be adequately described as the parallel sum of facilitated transport and passive diffusion processes (Cornford, et al, J. Neurochem. 30:229, 1978). Because of the possible benefits from the pharmacological use of choline in disorders that increase in incidence in geriatric patients, it is of considerable importance to characterize choline transport at the BBB in aged animals. We have previously reported that the brain uptake index (BUI) of choline decreases in aged rats. In order to characterize age-related changes in the kinetics of choline transport across the BBB, male Fisher 344 rats obtained from the N.I.A. were used at 3, 9 and 24 months. Choline transport was measured by the method of Oldendorf using ^{14}C-tryptamine as the diffusible reference substance and Tc^{99m}-DTPA as the non-diffusible vascular space marker. Choline transport (nmol/g·min) was determined at choline concentrations from 0.125mM to 10mM in five brain regions (cortex, striatum, midbrain, hippocampus and diencephalon). The kinetic constants of facilitated transport and passive diffusion of choline were estimated by a nonlinear regression fit of the data to the following equation:

$$V = \frac{Vmax \cdot (C)}{Km + (C)} + Kd \cdot (C)$$

where V = choline transport rate (nmol/g·min), C=choline concentration (M) in the injection mixture, Vmax = maximal choline transport rate (nmol/g·min), Km = choline concentration (µM) at half-maximal transport, and Kd = diffusion constant (µl/g·min).

Vmax values were higher in the cortex ($\bar{X}$= 8.6 nmol/g·min) than all other regions ($\bar{X}$= 5.8 nmol/g·min). Km values did not show regional variation ($\bar{X}$= 285 µM). Kd values showed marked regional variation being highest in cortex ($\bar{X}$= 5.27 µl/g·min), intermediate in hippocampus and midbrain ($\bar{X}$= 2.76 µl/g·min), and lowest in striatum and diencephalon ($\bar{X}$= 1.89 µl/g·min). In comparison to the 3 month old rats the 24 month old rats had lower Vmax values in the midbrain, but higher values in both the cortex and hippocampus. Km values were lower in the 24 month old rats only in the midbrain. Kd values for the 24 month old rats were higher than the 3-month old rats in the diencephalon and higher than the 9-month old rats in the cortex and striatum.

The results suggest that only minor changes occur in choline transport with age between 9 and 24 months. However, the physiological significance of these changes has yet to be evaluated. It appears likely that the efficacy of choline in the treatment of mental and motor disorders in geriatric patients is not related to BBB function.

103.17 NEUROCHEMICAL STUDIES IN AGING BRAIN: A. PROTEIN ALTERATIONS IN MYELIN. M. Malone, J. Greaney* and M. Szoke*. Geriatric Research, Education and Clinical Center, Veterans Hospital, Bedford, MA 01730.

Simple brain atrophy with dementia is a degenerative disorder characterized pathologically by atrophy of brain white and grey matter, the presence of neurofibrillary tangles, senile plaques and deposits of lipofuscin. Atrophy is the most consistent age-related finding and there is strong evidence that primary loss occurs in white matter. Such loss involves the myelin sheath. Myelin is a lipid-protein complex elaborated from the surface membranes of oligodendroglia and developmentally sub-stages of myelin have been isolated and identified. Our present studies have been made to characterize biochemically changes with age in central myelin.

Myelin was isolated from the brains of old (13 mo.), aged (19 mo.) and mature (2-4 mo.) Sprague-Dawley rats by the method of Norton and Poduslo (J. Neurochem. 21, 749, 1973) as modified by Zimmerman and Quarles (ibid 25, 749, 1975) to yield Heavy, Intermediate and Light myelin forms. After delipidation and solubilization (Quarles, et al, J. Neurochem. 466, 176, 1977), myelin proteins were separated on an acrylamide gel slab (10%) (Chan and Lees Biochem. 13, 2704, 1974), stained with Coomassie Blue and PAS and studied by densitometer with applied reference standards.

We have found a major decrement in a high molecular weight myelin glycoprotein in old myelin and an absence of this material in aged myelin isolates. This is a major aging change in the structure of white matter.

103.18 NEUROCHEMICAL STUDIES IN AGING BRAIN: B. STRUCTURAL CHANGES IN MYELIN LIPIDS. M. Szoke*, M. Malone and J. Greaney*. Geriatric Research, Education and Clinical Center, Veterans Hospital, Bedford, MA 01730

Loss of brain weight is a prominent feature of aging and regional atrophy is the most consistent pathological change in senile dementia. This atrophic change involves white matter and E.M. studies (Terry, et al, Am. J. Path. 44, 269, 1964) have reported primary changes in the organization of myelin. Central myelin is a complex lipid bimolecular-protein structure elaborated through a series of transitional forms from the primary plasma membranes of oligodendroglia. Detailed changes in lipid structure and composition characterize the process of myelination in early development. We have studied these changes in myelin isolates from the mature (2-3 mo.), old (13 mo.) and aged (19 mo.) rat brain.

Myelin was isolated from rat brains by fractionation on discontinuous ultracentrifuge gradients in methods designed to yield compact mature myelin and pre- or protemyelin forms. Myelin lipids were extracted by the Folch procedure (Folch-Pi, J. et al, J. Biol. Chem 226, 497, 1957), separated by preparative TLC (Seminario de Bohner, L. et al: J. Chromat. 17 154, 1965) and the glycolipids subjected to hydrolysis and derivatization, followed by Gas Liquid Chromatography (Kishimoto, Y.: Res. Methods in Neurochem. 1978). We found that compact myelin isolates from aged rat brain showed a major increase in the ratio of unsaturated (mono-enoic)/saturated long chain (C18-26) glycolipid fatty acids compared to isolates from mature or older animals. Such age-related changes suggest fundamental instability at the molecular membrane level.

103.19 STRUCTURAL CHANGES ASSOCIATED WITH AGING IN THE FORNIX OF THE RAT AND MOUSE. P.A. Paskevich* and J.N. Naranjo*. (SPON: J.F. Lipinski). McLean Hospital, Belmont, MA 02178 and the Department of Anatomy, Harvard Medical School, Boston, MA 02115.

It has been known for some time that age-related changes occur in the central nervous system. Recent studies utilizing newer techniques have confirmed these findings, and have enabled more accurate description of neuronal and glial degeneration. The present study is a histological and electron microscopic examination of the fornix in aged and young Fisher-344 rats and C57/USC mice. The tissue of 10 aged (28-32 months old) and 10 young (8 months old) rats and 8 aged (24-28 months old) and 8 young (6 months old) mice were analyzed using the following techniques: i) a reduced silver stain method (Naranjo and Greene, 1977) to ascertain gross degenerative changes throughout the pre- and post-commissural fornix, and ii) electron microscopy to analyze ultrastructural changes as a result of age.

Fiber degeneration, slight argyrophilia and a proliferation of oligodendroglia were noted throughout the entire extent of the fornix in the aged animals. The descending columns of the fornix as well as the commissure of the fornix were particularly impregnated, with densely stained degenerating fibers being the predominant feature. An absence of degeneration was noted at every level of the fornix in all young animals.

An ultrastructural analysis was used to enhance and confirm our histological data and further clarify the morphological changes associated with cellular aging in the central nervous system. It was noted that perivascular astrocytes contain membrane bound inclusion bodies that have the characteristic lamellar appearance of myelin. Furthermore, an analysis of myelinated fibers show numerous degenerative axoplasmic profiles, with a typical breakdown of microtubules.

104.1 OSCILLATORY EYE MOVEMENTS IN STROBE REARED CATS. G. Mandl, G. Melvill Jones, M. Cynader and J.S. Outerbridge*. Dept. of Physiol. and Biomed. Eng. Unit, McGill Univ., Montreal; and Dept. of Psychology, Dalhousie Univ., Halifax, Canada.

INTRODUCTION. Kittens reared from birth in stroboscopic light develop spontaneous eye oscillations. The present experiments set out to characterize these abnormal eye movements as recorded in complete darkness, in strobe light of various frequencies, after exposure to normal light, after attenuation of the vestibulo-ocular reflex (VOR) gain (eye vel./head vel.) by vision reversal, and during optokinetic stimulation.

METHODS. 2 cats were reared from birth to one year in 8 Hz stroboscopic light of 5 μsec flash duration. One normally reared animal was used as a control. Horizontal movements of the right eye were measured by the scleral eye coil method (resolution 5-10 min arc, 3 db at 1 KHz). Head fixation was achieved by means of a conventional acrylic block fastened to the skull. Power spectral analysis, by a method of modified periodograms using a Hanning data window, was performed on sections of relevant eye movement records, to ascertain their frequency content. VOR gain was estimated by rotating the animal sinusoidally in the dark, at 1/8 Hz and 5^{o}/sec amplitude.

RESULTS. (1) With head fixed in the dark, both strobe reared cats generated spontaneous eye oscillations of about $0.5\text{-}1.0^{o}$ amp. with each of the 2 animals exhibiting a "fundamental" frequency close to that of their original rearing environment. (2) Strobe light exerted a strong modifying influence upon the spontaneous "dark" eye oscillations, with pronounced entrainment of eye oscillations at a given "forcing" strobe frequency. In some cases, power spectral analysis revealed the presence of more than one distinct frequency component, indicating a mixture of several harmonics. (3) In the presence of normal light, the frequency of spontaneous eye oscillations, as measured in one of the strobe reared animals, dropped from its characteristic "dark" value of 9 Hz, to a new maintained low of 2.7 Hz. (4) Adaptive attenuation of the VOR to some 40% of control value caused a virtually total abolition of regular spontaneous eye oscillations in the dark, although transient responses to single strobe flashes could still be elicited. (5) The abnormal spontaneous eye movements did not interfere with, and were not abolished by, normal oculomotor activity.

Supported by the Canadian Medical Research Council.

104.2 SEX DIFFERENCES IN 6-HYDROXYDOPAMINE INDUCED HYPERACTIVITY AND AMPHETAMINE RESPONSIVENESS IN DEVELOPING RATS. J.T. Concannon and M.D. Schechter, Dept. of Pharmacology, Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272.

In an attempt to produce hyperactivity in developing rats, we utilized neonatal intracisternal injections of 6-hydroxydopamine (6-OHDA) and measured activity across maturation using a time-sampling procedure described by Shaywitz et al. (Science 191: 305, 1976). At 5 days of age, rat pups from litters consisting of an equal number of male and female rats were randomly assigned to either 6-OHDA or vehicle treatment using a littermate control design. Behavioral activity was measured at 12, 15, 18, 21, 24 and 27 days of age after an IP injection of either 0.5 mg/kg d-amphetamine or saline. An age-dependent increase in activity between 12 and 21 days of age was found for vehicle-treated animals injected with saline. Thereafter, males showed a decline in activity, while females remained at their peak of activity. The 6-OHDA treatment produced hyperactivity in males at 18 and 27 days of age, although it did not significantly alter activity in females. Although there was never a "paradoxical" calming effect of amphetamine, amphetamine responsiveness was altered by 6-OHDA in a sex-dependent manner. That is, male 6-OHDA treated rats showed less of an increase in activity associated with amphetamine at 12, 18, 24 and 27 days of age. Female 6-OHDA treated rats also showed less of an increase in activity associated with amphetamine at 12 and 18 days of age, but displayed more of an increase in activity than vehicle-treated rats at 24 and 27 days of age. Whole-brain dopamine (DA), assayed at 35-36 days of age, was depleted 38%, while norepinephrine (NE) was not reliably depleted. Furthermore, the 6-OHDA treatment did not significantly alter body weight gain. At a basic level, these results suggest that the failure to produce hyperactivity by 6-OHDA treatments in rat pups may result from failure to consider sex of animals within treatment conditions. At a clinical level, these results may provide a starting point for the laboratory examination of the source of the higher incidence of diagnosis of hyperactivity in male pre-adolescent children.

104.3 CHRONIC MATERNAL ETHANOL CONSUMPTION THROUGH THE 2ND TRIMESTER OF GESTATION: SYNAPTIC PLASMA MEMBRANE PROTEINS & GLYCOPROTEINS IN OFFSPRING. A.B. Noronha* and M.J. Druse-Manteuffel Department of Biochemistry and Biophysics, Loyola University Medical Center, Maywood, Illinois 60153.

Female Sprague Dawley rats were pair-fed using either control or ethanol (6.6%) (v/v) liquid diets for 1½ months prior to conception and during the first two weeks of gestation. At 9,16 or 23 days of age, control and ethanol offspring were injected intraventricularly with 30 μCi ^{3}H-fucose. Eighteen hours later, the animals were sacrificed and synaptic plasma membranes (SPM) were isolated.

Body weights of control and ethanol offspring were comparable at all ages examined.

Although the total brain protein content of ethanol and control pups was similar at 10 to 24 days, the ethanol pups had less than 50% of the normal amount of SPM protein at 17 and 24 days of age. Similarly, total incorporation of ^{3}H-fucose into brain glycoproteins was normal in ethanol pups, although they demonstrated a significant decrease in fucose incorporation into SPM glycoproteins at all ages . Thus, it appears that SPM proteins and glycoproteins are severely affected by maternal ethanol consumption, despite the fact that the ethanol mothers terminated their consumption of ethanol after the 2nd trimester of gestation.

This research was supported by grants from NIH (SO1-RR05368), NIAAA (AA03490), The National Council on Alcoholism and The Schweppe Foundation. M. Druse-Manteuffel is the recipient of a Schweppe Foundation Career Development Award.

104.4 LEARNING DEFICITS AND BRAIN MONOAMINE LEVELS IN RATS WITH CONGENITAL HYPERBILIRUBINEMIA. R.M. Swenson, J. Jew and T.H. Williams. Department of Anatomy, University of Iowa, Iowa City, Iowa 52242.

Rats with congenital hyperbilirubinemia (homozygous Gunn strain) were tested at 28 days of age on an active learning task (2 way shuttlebox avoidance) and a passive learning task (step down avoidance) and compared with controls (i.e., their heterozygous littermates). Pain sensitivity was measured by testing jump thresholds to painful electric footshock. One week after the behavioral testing, eight portions of brain (hippocampus, caudate, remaining telencephalon, hypothalamus, remaining diencephalon, midbrain, pons-medulla, and cerebellum) were assayed for norepinephrine and dopamine according to the method of Jacobowitz and Richardson (Pharmacol., Biochem. & Behav., 1978, 8, 515).

When measured against performance of the control animals, the hyperbilirubinemic rats demonstrated significant learning retardation. The latter failed to learn the active avoidance task although there were given twice the number of trials needed by control animals for mastering the task. Similarly, hyperbilirubinemic rats failed to avoid shock in the passive avoidance task: compared with control animals, hyperbilirubinemic rats stepped down faster onto the grid on which they previously were shocked. These differences in learning ability were not due to differences in sensitivity to electric footshock since jump thresholds to shock were similar in hyperbilirubinemic animals and their controls.

Biochemical studies showed that, compared to controls, hyperbilirubinemic rats have higher levels of norepinephrine in cerebellum, hypothalamus, and hippocampus, whereas dopamine was significantly lower in cerebellum, pons-medulla, and caudate. This is the first study to show changes in putative neurotransmitter levels in brains of congenitally jaundiced rats. Further work will correlate these data with the learning measures and with morphological observations of the brain areas that show biochemical changes. These multidisciplinary studies carried out at different stages in development may indicate whether any recovery from hyperbilirubinemia occurs. (Supported by N.I.H. grant HD11800.)

104.5 PERMANENCE OF KINDLING IN DEVELOPING RATS. Solomon L. Moshe* and Bruce J. Albala. Dept. of Neurology and Dept. of Psychiatry, Albert Einstein College of Medicine, Bronx, New York 10461.

The kindling phenomenon consists of repeated applications of focal intracranial stimulations at low intensities that lead to the development of electrographic afterdischarges (ADs), behavioral automatisms and eventually generalized seizures. Kindling has been induced in suckling and young rats as well as in mature animals. However, although the suckling rats developed generalized seizures, the kindling patterns differed from those seen in young (35 days) and older rats. Since in mature animals, kindling has been reported to be permanent, the present study was designed to investigate whether the kindling changes produced in developing animals are also enduring.

Male suckling rats were chronically implanted with bipolar electrodes in the left amygdala. At 18 days of age they were stimulated every hour for 1 second (400 μAmps, 60 Hz); ADs were consistently elicited in all. Though all animals were given a fixed number of stimulations approximately one half developed generalized seizures while the remaining were only partially kindled. Subsequently, the electrodes were removed and the animals left to grow to 60 days of age. The mortality rate during this period was 30 %. The surviving rats were then reimplanted in the amygdala and divided into two groups. One group included those animals that had developed generalized seizures (Fully Kindled), while the other consisted of those that had shown little or no behavioral manifestations (Partially Kindled). They were then stimulated daily using the same parameters as before and compared to age-matched naive controls. Data analysis included only those animals in which the amygdala placements were histologically verified.

There were no differences in the weights and AD thresholds among the three groups. However, the duration of the first AD elicited was longer in the Fully Kindled rats as compared to Controls (63.7 sec vs 19.7 sec, $p<0.05$). Furthermore Fully Kindled rats required less stimulations to develop generalized seizures than the Partially Kindled rats (4.3 vs 7.0, $p<0.01$) and Controls (4.3 vs 14.1, $p<0.001$). The Partially Kindled rats also had significantly shorter kindling rates than Controls (7.0 vs 14.1, $p<0.001$).

The above data indicate that despite continuous changes in brain size and progression of synaptogenesis and myelinization kindling is long lasting in the immature rat and carries over into adulthood. The ease of mature animals to develop generalized convulsions correlates directly to previous neonatal seizure exposure. The results are indicative that kindling can be employed as a developmental model of epilepsy.

104.6 FAILURE IN DEVELOPMENT: RECEPTOR SENSITIVITY CHANGES FOLLOWING POSTNATAL X-IRRADIATION OF HIPPOCAMPUS. G. C. Palmer, R. B. Chronister and L. K. Gerbrandt. Depts. Pharmacol. and Anat., Univ. S. Ala. Col. Med., Mobile, Ala. 36688 and Neurosci. Res. Program, MIT, Boston, MA 02116.

Numerous approaches have been used to investigate mechanisms involved in neuronal plasticity. One of the more challenging techniques in this regard is x-irradiation applied to postnatal neurogenesis in the dentate gyrus of hippocampus. Here it has been shown that a redistribution of norepinephrine fibers occurs while the amount of norepinephrine remains constant. The purpose of the following experiments was to examine the receptor mechanisms associated with these norepinephrine fibers--specifically, the adenylate cyclase activation induced by norepinephrine.

Neonatal rats (Long-Evans derived hooded) of both sexes were irradiated either bilaterally (N=6) or unilaterally (N=12) between the 2nd and 15th postnatal days. Sham irradiated animals and the non-irradiated sides serves as controls. All comparisons were made using the Students *t* tests.

At maturity (at least 200 grams wt) the hippocampi were removed, homogenized and analyzed for either adenylate cyclase activity or cyclic AMP phosphodiesterase activities (both high and low Km). Cyclase activity was expressed as pmoles of cyclic AMP formed/mg protein/min and phosphodiesterase activities as nmoles (low Km) and μmoles (high Km) of cyclic AMP hydrolized/mg protein/min.

In all cases irradiation produced a dramatic decrease in cyclase activation. This diminished response was noted through dose response determination to norepinephrine, dopamine and histamine (10^{-6}-10^{-4}M). The comparisons were significant across animals (bilateral x-irradiation) or within animals (unilateral x-irradiation). Basal activities were not different between the controls and the x-irradiated animals.

The high Km phosphodiesterase levels (both calmodulin independent and dependent) were not altered. However, the low substrate moiety (low Km) displayed a significant increase in the ability to hydrolyze cyclic AMP.

The results of the present study show that the consequences of x-irradiation are mixed. First of all, there is a redistribution of norepinephrine fibers. Secondly, the enzyme-metabolic-receptor mechanisms of the postsynaptic cell are either altered (such as transcription changes) or never develop properly. This suggests that the determination of receptor plasticity changes requires careful scrutiny. Further work is in progress to elaborate these mechanisms. (Supported by Epilepsy Foundation of Amer. and Scottish Rite Schizophrenic Foundation.)

105.1 DEVELOPMENTAL CHANGE IN CO_2 SENSITIVITY OF CHICK LENS INTERCELLULAR COUPLING. Stephen M. Schuetze and Daniel A. Goodenough.* Dept. Anat., Harvard Medical School, Boston, MA 02115.

Adult lens cells are extensively interconnected by gap junctions. Freeze fracture studies show that lens junctions differ from those in other tissues in that the connexons (subunits) are more widely spaced and disordered. To investigate the functional meaning of this structural difference, we are studying gap junctions in early embryonic chick lens cells (Hamburger and Hamilton stages 12-22). During stages 12-14, the presumptive lens begins as a thickened region of ectoderm that subsequently invaginates. Freeze fracture replicas of these lenses fixed in glutaraldehyde reveal small, infrequent gap junctions that contain tightly packed, ordered connexons, unlike their adult counterparts. Between stages 14-18, the lens completes invagination and pinches off from the ectoderm to form a hollow, spherical lens vesicle. At these stages, freeze fractured gap junction plaques contain small islands of tightly packed connexons within larger regions of loosely packed connexons. Between stages 18-22, the lens increases in size and lens fiber cells begin to elongate. Junctions in these older lenses appear similar to adult lens junctions.

Lens cells are electrically coupled at all stages, shown by paired intracellular recordings. Typical resting potentials are -60 to -70 mV. The cells are also dye coupled. One minute after iontophoretically injecting a single lens cell with the fluorescent tracer Lucifer yellow (MW 443), dye can be found in dozens of adjacent cells. There is no striking change in dye coupling with age. Both dye transfer and electrical coupling occur via gap junctions and not via intercellular cytoplasmic bridges: When a single cell at any stage is injected with horseradish peroxidase (MW 40,000), the tracer is confined to the injected cell. Studies reported in the literature on other tissues suggest that increasing the CO_2 tension of the bath reversibly blocks intercellular coupling by lowering intracellular pH. We find that incubating stage 15-22 lenses for 20' in medium equilibrated with 50% CO_2/50% O_2 has no detectable effect on dye transfer. In contrast, incubating stage 12-14 lenses for 10' in the same medium appears to decrease dye coupling, since only a few cells near the injection site contain dye. The appearance of CO_2-resistant coupling may be correlated with the appearance of loosely packed connexons in freeze fracture replicas (cf. Raviola et al. (1978) JCB 79:229a). Supported by NIH grants EY03011 and EY05337. We thank W. Stewart for the generous gift of Lucifer yellow.

105.2 ELECTRICAL UNCOUPLING OF VERTEBRATE SPINAL CORD NEURONS DURING DEVELOPMENT. N.C. Spitzer, Biology Dept. UCSD, La Jolla, CA 92093

Low-resistance intercellular junctions demonstrable by electrical coupling are a common feature in the development of many tissues. Neuronal development involves the appearance of electrical excitability, chemosensitivity and electrical uncoupling. The 200 Rohon-Beard neurons in the spinal cord of Xenopus tadpoles are sufficiently large and accessible to be visualized and impaled with microelectrodes at very early stages of development, and are thus suitable for studies of neuronal differentiation.

These cells are electrically coupled and do not make action potentials or respond to a variety of putative neurotransmitters just prior to the closure of the neural tube, ~6 hrs after their birthdate in gastrula. Coupling coefficients as large as 0.5 are seen between adjacent cells, but the low resting potentials recorded (~-50 mV) suggest that the coupling in vivo may be larger. This coupling does not show rectification, but is voltage-dependent: current injection that causes sufficient polarization of one cell for several seconds uncouples it from other cells. The apparent input resistance of the first cell increases, and the coupling coefficient decreases to ~10% of its initial value. The cells are usually rapidly recoupled following the current pulse, and the phenomenon can be repeated many times. Cells occasionally remain uncoupled after termination of the current pulse, probably as the result of a leak current arising from the impalement: the difference in membrane potential between the injected cell and other cells may be sufficient to keep it uncoupled. The voltage-dependent uncoupling is unaffected by replacement of Na^+ with Tris, Cl^- with isethionate, high Ca^{2+}(40 mM), addition of 30 mM Co^{2+}, or high K^+ that depolarizes the cells by as much as 30 mV. Lowering the pH from 7.4 to 6.5 with HCO_3^- buffer does not abolish electrical coupling, but appears to eliminate the voltage dependence. Other cells in the spinal cords of the same embryos show coupling that is not voltage dependent.

Rohon-Beard cells begin to make action potentials at the time of closure of the neural tube. These depend on an inward Ca^{2+} current and are several hundred ms in duration. The depolarization of a cell by this action potential spreads electrotonically to nearby cells, causing them to fire action potentials. Individual Ca^{2+} action potentials are not large and long enough to uncouple the cells. Over the next few days the ionic dependence of the action potential shifts from Ca^{2+} to Na^+ and its duration decreases to 1 ms. These cells become electrically uncoupled around the time of appearance of the Na^+ component of their action potential. Other, unidentified cells in the spinal cord are still coupled and show voltage-dependent uncoupling at this time. Rohon-Beard neurons appear to remain uncoupled during further development.

105.3 AN ULTRASTRUCTURAL PROFILE OF DEVELOPING RAT SUBSTANTIA GELATINOSA. M. L. Kirby. Dept. of Anatomy, Medical College of Georgia, Augusta, GA 30912.

The substantia gelatinosa is involved in the central processing of nociceptive information. A study of the ontological development of the area should enhance our understanding of the adult morphology of the substantia gelatinosa and ultimately the complex processes involved in the perception of pain. Five Wistar rats were perfused and analyzed on each of the following days: 15, 17, and 19 through 22 day fetuses; 1, 3, 6, 10, 15, and 30 day neonates and > 90 day adults. All animals were perfused with 4% gluteraldehyde and the spinal cords were dissected from low cervical and upper thoracic regions and processed for electron microscopy. The neuronal cell body diameter and synaptic density in the substantia gelatinosa were analyzed from electron micrographs taken from 16 different fields in each section. Cell body areas in the micrographs were measured with a planimeter and converted to diameters. Synapses in each field were counted and multiplied appropriately to determine the number of synapses/1000μ^2. The cell body diameter increased from 5.5μ on day 15 of gestation to 9.7μ on day 15 postnatally and decreased thereafter to the adult mean diameter of 8.6μ. Synapses were seen first on day 17 of gestation. Synaptic density increased gradually to parturition. Between 1 and 3 days postnatally, synapses underwent a 2-fold increase from 23.5±1.8 to 41.3±4.6. A gradual increase occurred after day 3 and the adult synaptic density was 55.1±6.6. The population of synapses in the developing substantia gelatinosa was obtained by analyzing the synapses in 2 different fields averaging 7,000-10,000μ^2. The initial population of synapses at 17 days was 12.7% axosomatic, 81.7% axodendritic and 5.6% axoaxonic. Axosomatic and axodendritic synapses changed inversely in a generally linear fashion to reach the adult values of 1.3% axosomatic, 19.1% axoaxonic. The axodendritic presynaptic terminals were populated primarily by clear-spherical (CS) vesicles with very few clear-flat (CF) or dense-cored (DC) vesicles. However, the CF and DC containing terminals increased during development.

105.4 A GOLGI ANALYSIS OF NEURONAL RELATIONSHIPS IN THE SPINAL CORD OF THE MOUSE EMBRYO. L.E. Wentworth. Department of Anatomy, Univ. of California, School of Medicine, San Francisco, CA 94143.

The initial development of neurons in the cervical spinal cord of the mouse embryo of 9 to 11 days gestation (E9-E11; E0=vaginal plug) has been reported previously (Anat. Rec., 193:717-718, 1979). By E10 the central process of dorsal root ganglion (DRG) cells has entered the spinal cord and by E11 the anlage of the dorsal funiculus (DF), (oval bundle of His), is forming. By E12 the DF is a well formed fiber bundle located just dorsal to the entering dorsal root fibers. Branches of dorsal root axons can be seen entering the intermediate (mantle) layer, although they do not penetrate deeply into this zone. A few commissural neurons (CN) and ipsilateral association neurons (AN) begin to sprout dendrites by E11, but the dendritic processes of these cells are not seen to be closely approached by dorsal root axons. On E12 the CN's are mainly located along the interface between the mantle and ventricular layers; some of the CN's, with cell bodies located close to the DF, have dendritic processes entering the DF. The axon of CN's pass through or close to some of the dendrites of the medial motor column neurons.

The AN's and CN's intermingle on E11; by E12 the AN's are primarily located ventromedial to the developing dorsal funiculus and lateral to the CN's. Whereas Sims and Vaughn found that many interneurons of E13 send axons into the ipsilateral lateral marginal zone and appear to provide an early synaptic input to dendrites of lower motor neurons (Neuroscience Abst., III:119, 1977), the most advanced AN's at E12 (in the present study) have dendritic processes entering the DF and their axons enter the lateral funiculus, which also contains dendrites of some of the more advanced lateral motor column neurons.

Cells first appearing at E12 include multipolar neurons located along the border between the mantle layer and DF with processes branching into both areas. The ventricular layer, especially in the alar plate region, still contains radially oriented cells forming a pseudostratified columnar epithelium with an apical and basal process attached to the lumen and external limiting membrane respectively.

105.5 PRE-MIGRATORY MOTOR NEUROBLASTS HAVE AXONS IN THE PERIPHERY: AN HRP STUDY. Sally A. Moody and Marieta B. Heaton, Dept. Neurosci., College of Medicine, Univ. of Florida, Gainesville, FL 32610.

Pre-migratory trigeminal motor neuroblasts lie in a medial column near the developing MLF after leaving the mitotic cycle. At stage 14(Hamburger and Hamilton, 53 hours of incubation) a lateral migration is first observed. The cells are adjacent to marginal zone fibers and a small motor root is apparent.This lateral migration continues until day 6 of incubation when the main trigeminal motor nucleus is completed(Heaton & Moody,1980, JCN 189:61).

On incubation days 2.5,3,3.5,4,& 4.5, we have cut the motor root at the proximal edge of the V ganglion and applied crystalline horseradish peroxidase (HRP,Sigma type VI) to the wound in order to study whole-cell silhouettes during the temporal extent of this developmental process. In this experiment only those cells are labeled whose axons have been injured by the knife cut.

In day 2.5 embryos, V motor neuroblasts are labeled only if the cut is no more than 8μm from the brainstem. These cells are close to the pial edge and are without a primitive internal process. Migratory and lateral cells are labeled; medial column cells are not. In several embryos in which the cut is 10-12μm distant from the exit of the motor root, no metencephalic cells are labeled. In embryos which received HRP applications on days 3,3.5,&4, pre-migratory medial column cells, migratory cells and post-migratory lateral nucleus cells are labeled. Rarely are trailing processes observed. Medial cells exhibit only occasional somal filopodia and frequent axonal branches. As the cells progress laterally, somal filopodia increase. Lateral nucleus cells either have short stubby processes or only a long, slender one extending dorsally. Axonal processes are sinuous with frequent swellings. At day 4.5 of incubation only a few medial column cells are labeled; these are small with smooth perikarya. The number of migratory cells has decreased and the lateral nucleus cells morphologically resemble those of earlier ages.

Migrating cells are often labeled in groups, cell somas in intimate contact with axons of adjacent cells. Thus the fiber bundles on which these cells appeared to be migrating in Hematoxylin stained material(Heaton and Moody,ibid) were probably their own axons. In cases in which the ganglion sensory root is severed but not the motor root, the labeled fibers seen within the metencephalon, the central processes of the ganglion, are confined to the spinal tract of V. They do not extend into the migratory area.

These experiments demonstrate that axonal outgrowth and invasion of the periphery, at least to the level of the V ganglion, preceeds somal migration of the trigeminal motor neuroblasts in chick. This outgrowth may be important in the determination of the appropriate migration pattern of motor neuroblasts.

105.6 DEVELOPMENTAL CHANGES IN DEGENERATION ARGYROPHILIA OF MEDIAL PREFRONTAL CORTEX EFFERENTS IN THE GOLDEN HAMSTER. James E. Crandall and Christiana M. Leonard. Dept. of Neuroscience, Univ. of Florida, Gainesville, FL 32610.

The appearance of long lasting degeneration argyrophilia(LLDA) in retinal and olfactory bulb efferents has been previously suggested to be related to functional maturation of these systems. The development of reliable hoarding behavior between Day 21 and Day 25 in the hamster coincides with age related changes in mediodorsal thalamic and perirhinal cortical afferent input to medial prefrontal cortex as revealed by retrograde HRP methods. In order to test the hypothesis that the onset of LLDA in medial prefrontal cortex efferent output might also be related to the maturation of hoarding, lesions of medial prefrontal cortex were produced in hamsters ages 10, 21 and 25 days. Following survival times of either 24 or 72 hours, series of coronal 25 um sections were stained with a Fink-Heimer procedure for anterograde degeneration. In pairs of animals matched for lesion extent location, we found no differences between LLDA patterns in 21 and 25 day animals. LLDA was well established in major fiber tracts (internal capsule, cerebral peduncle and pyramidal tract) as well as principal terminal regions in the caudoputamen, mediodorsal thalamus and lateral tegmentum. Short survival degeneration argyrophilia disappeared by Day 21, but is clearly evident on Day 10. On the other hand, no LLDA was noticeable in Day 10 animals.

It appears that the occurrence of LLDA in medial prefrontal cortex efferents does not correlate with the ontogeny of reliable hoarding behavior. Dramatic changes in the afferentation of this region, by contrast, do coincide with the behavioral transition. These findings that efferent projections of a region are established before ingrowth is complete support a theory of the retrograde development of the neuron, i.e., axonal maturation precedes dendritic. Our HRP results suggest that between 21 and 25 days of age the afferent projections segregate while cortico-cortical input increases. Whether either of these changes is dependent upon or a stimulus for dendritic outgrowth remains to be determined.

This research supported by NIH grant NS31516 to CML and a NSF predoctoral fellowship.

105.7 A GOLGI STUDY OF THE DEVELOPMENT OF PYRAMIDAL NEURONS IN THE RAT VISUAL CORTEX AFTER EYE OPENING. Janice M. Juraska, Cynthia Elliott* and Janice Wesa*. Psychology Dept., Indiana Univ., Bloomington, IN 47405 and Psychology Dept., Univ. of Illinois, Champaign, IL 61820.

In previous work, the dendritic development of pyramidal neurons in the rat visual cortex was quantified through day 15 (Juraska & Fifkova, J. Comp. Neurol. 183:247, 1979). At day 15 dendritic branching appeared very similar to that seen in the adult. This observation is quantified in the present study. Hooded rats of both sexes were sacrificed at 15, 30 and 60 days of age. The 30 and 60 day rats had previously been weaned at 23-25 days and were group housed with same sex littermates until sacrifice. All rats were intracardially perfused with 4% paraformaldehyde and their posterior cortex was stained with the rapid Golgi method according to Lund (J. Comp. Neurol. 147:455, 1973). The basilar dendrites of layer V pyramidal neurons were traced with the aid of a camera lucida at 500X and analyzed for number and length of branches at each order from the cell body. Fifteen neurons per animal from four rats (two male and two female) at each age were sampled from areas 17 and 18. There were no differences in either number or length of dendrites among the three ages. Thus the dendritic branching pattern of layer V pyramidal neurons in the rat visual cortex at day 15 (one day after eye opening) is indistinguishable from the adult pattern in socially housed animals. Another cell population--layer III pyramidal neurons--is currently being quantified. Spine counts on both layer III and layer V pyramidals are also in progress.

105.8 ANATOMICAL EVIDENCE FOR DIFFERENTIAL RATES OF MATURATION OF THE MEDIAL DORSAL NUCLEUS PROJECTIONS TO PREFRONTAL CORTEX IN RATS. J.V. Corwin*, J.E. Crandall, C.M. Leonard, and T.A. Schoenfeld. Dept. of Neuroscience, University of Florida College of Medicine, Gainesville, FL 32610.

Previous anatomical research in the visual and olfactory systems has suggested that the presence of long lasting degeneration argyrophilia (≥ 72 hours: LLDA) may be a sign of functional maturation. We have attempted to relate the presence of LLDA as an anatomical marker of maturation to behavioral data derived from lesion studies of prefrontal cortex in infant rats. Sahley (1979) has found evidence that sulcal prefrontal cortex is functionally mature before medial prefrontal cortex. Sulcal prefrontal cortex lesions resulted in behavioral deficits as early as 14 days of age, whereas medial prefrontal cortex lesions produced no behavioral impairments at that time. We examined the projections of the medial dorsal thalamic nucleus to sulcal and medical prefrontal cortex in the rat to determine if these cortices differed in the age at which LLDA is first seen. The behavioral effects of prefrontal cortex lesions in infancy might predict that LLDA should be present in sulcal prefrontal cortex before being found in medial prefrontal cortex. To test this hypothesis, unilateral medial dorsal thalamic electrolytic lesions were produced in rat pups at 13, 20, or 25 days of age. The pups were sacrificed at either 24 or 72 hours post lesion. The brains were cut at 25μm and stained using the method of Fink-Heimer (Procedure I). The results indicate an age dependent pattern of LLDA in the sulcal prefrontal and medial prefrontal cortices. In the 13 day, 24 hours survival group (n=5), terminal degeneration was found in Layers 1 and 3 in both frontal subfields. By 72 hours survival (n=4), although LLDA was found densely distributed in layers 1 and 3 of sulcal prefrontal cortex, there was no discernable degeneration in medial prefrontal cortex at this survival time. In contrast, in the 20 and 25 day, 72 hour survival groups (n=6) LLDA was found densely distributed in layers 1 and 3 in both sulcal and medial prefrontal cortex. These anatomical results indicate a differential rate of maturation between the medial dorsal nucleus efferents to the two frontal subfields. The earlier presence of LLDA in sulcal prefrontal cortex (at 13 days) as compared to medial prefrontal cortex is anatomical evidence for the earlier maturation of the sulcal prefrontal system. With regard to the prefrontal system in rats, there is corresponding behavioral and anatomical evidence that the sulcal prefrontal system matures earlier than medial prefrontal system.

Supported by NIH grants NS 13516 to CML and NIH post-doctoral fellowship 1 F32 NS06402-01 to JCV.

105.9 A FREEZE FRACTURE STUDY OF THE DEVELOPING AXOLEMMA IN RAT OPTIC NERVES G.M. Bray and B.J. Oldfield* Neurosciences Unit, The Montreal General Hospital and McGill University, Montreal, Canada.

The nodal, paranodal and internodal portions of the axon membranes of myelinated fibers show distinctive intramembranous features which are presumed to relate to the specific roles of these regions in impulse conduction. Although each of these regions is characterized by different axon-sheath cell relationships, the extent to which the ensheathing cell influences the development of the axonal specializations is unclear. In this study, the intramembranous structures in the immature axons of rat optic nerves were examined by freeze fracture and thin-section electron microscopy.

Sprague-Dawley rats, 5 to 21 days of age, were perfused with phosphate-buffered aldehyde solutions. Both optic nerves were removed and immersed in fixative at 4° C. For freeze fracture, whole optic nerves were glycerinated, frozen on gold discs, fractured at -119° C and replicated with platinum and carbon. Portions of the optic nerves from each animal were also post-fixed with osmium tetroxide and embedded in epoxy resin.

On post-natal day 7, when optic nerve axons were unensheathed, both the inner (P-face) and outer (E-face) leaflets of the axolemma contained few particles (10-100/μm^2) of the type seen in mature axons. On day 14, many axons were ensheathed and thinly myelinated but others were still unensheathed. Both the P and E-faces of the unensheathed axons as well as the P-faces of the ensheathed axons showed particle densities which approached 1000/μm^2. Accummulations of particles resembling those seen at nodes of Ranvier were not observed along the unensheathed axons.

Assuming that the responses of axon membranes to fixative solutions were similar at different stages of neonatal development, there appears to be a marked increase in the densities of axolemmal particles in rat optic nerves between 7 and 14 days postnatally. Because these increased numbers of particles were present in both the ensheathed and unensheathed axon membranes at day 14, this phase of intramembranous development may not depend on contacts between axons and sheath cells.

105.10 MORPHOLOGY OF THE ACOUSTICOLATERAL AREA IN THE TADPOLE, RANA CATESBEIANA. J. Jacoby*, K. Rubinson and R.H. Browner. Dept. of Physiol. Biophys., New York Univ. Med. Ctr., New York, NY 10016 and Dept. of Anatomy, New York Med. College, Valhalla, NY 10595.

During metamorphosis, R. catesbeiana undergoes a degeneration of its lateral line system and the continued maturation of its terrestrial auditory system. The dorsolateral medullary tegmentum loses the lateral line input but remains the target of auditory input after metamorphosis. This study examines the changing morphology of the region during premetamorphic and metamorphic states. R. catesbeiana tadpoles were perfused with Heidenhain-Susa fixative, embedded, sectioned, and stained with toluidine blue. Through late stage 28 (referred to R. pipiens, Witschi, 1956), no magnocellular elements could be discerned in horizontal or transverse sections. The small (<than 10μ) cells which will constitute the dorsal acoustic nucleus are distinguishable at stage 25 and have migrated to the lateral surface by late stage 26. The longitudinal nucleus then lies lateral to a prominent cell-free area, the dorsal island of Kingsbury. By stage 28, the cells appear to have been displaced progressively deeper from the lateral surface while still maintaining a sharp medial border adjacent to the reduced dorsal island. The dorsalward displacement of the acoustic nucleus occurs later in metamorphosis as does the differentiation of the magnocellular nucleus.

105.11 CELL LINEAGE ANALYSIS OF PURKINJE CELLS OF C57BL/6J↔BALB/cByJ CHIMERIC MICE. M. L. Oster-Granite and J. Gearhart*. Dept. Anat., Univ. Md. Sch. Med., Baltimore, Md. 21201.

It is difficult to believe that a structure as exquisitely organized as the cerebellar cortex results from a random distribution of cells within each of its distinct cell populations. Several of the anatomic and physiologic properties which we observe in the development and organization of the mammalian cerebellum could be more readily explained if interconnected or contiguous cell populations shared a common or clonal origin.

To determine whether the cell populations of the mammalian cerebellum are randomly arranged or not, one must be able to follow unequivocally the fate of single cells or populations of cells throughout cerebellar development. To do this, one must use cell lineage analysis to construct fate maps for the various cerebellar cell populations.

We have adapted the cell marker system most commonly used for cell lineage studies in the mammalian embryo, the ubiquitous enzyme, glucosephosphate isomerase (GPI, E.C.5.3.1.9). We have purified the two most common electrophoretic variants of murine GPI, GPI-1A and GPI-1B. We have produced xenogeneic allozyme-specific antisera to one of these variants, GPI-1B. We use such antisera to visualize cells which contain the GPI-1B variant by immunocytochemical (PAP) staining techniques in histologic sections. We have produced murine chimeras between inbred mouse strains expressing different GPI variants (C57BL/6J(Gpi-1^b)↔BALB/cByJ (gpi-1^a)). We have examined the location and distribution of Purkinje cells which stain for the GPI-1B variant in the cerebella of a number of these chimeric mice. Other investigators, using different cell marker systems and different mouse strain combinations, analyzed a very limited number of chimeric mouse cerebella or only analyzed portions of one cerebellum. They found that Purkinje cell mosaicism was finely grained; the Purkinje cells tended to be randomly araanged.

In contrast, following extensive reconstructions of the cerebella of a number of our murine chimeras, we found that the Purkinje cells were not randomly arranged. Cells of like genotype tended to remain together in the adult cerebellar cortex. To determine how much randomization of the Purkinje cells does occur during the processes of cell migration and intermingling, cell selection, and cell death that occur during cerebellar development, we have examined progressively younger chimeric mice. We will discuss the developmental implications of our findings, as well as the chimerism exhibited by other cerebellar cell populations during cerebellar development. Supported by NIH (HD12685), NSF (PCM16763) the National Foundation-March of Dimes (JG), the Alfred Sloan Foundation (MLOG), and Paralyzed Veterans of America.

105.12 MORPHOLOGICAL ORGANIZATION OF PONTINE CATECHOLAMINERGIC NEURONS IN DEVELOPING RABBIT BRAIN. Christel Marschall. Abt. Molek. Gen., Max Planck Institut exp. Med., Gottingen, FRG.

The occurrence and distribution of catecholamine-containing (CA) perikarya in the pons of the rabbit during late gestation and at birth (gestation = 31 days) are described. CA perikarya were visualized with either the Falck-Hillarp paraformaldehyde method or with glyoxylic acid-induced fluorescence. Adjacent and serial sections were stained with luxol fast blue and/or cresyl violet.

CA perikarya form a bilateral rostro-dorsal continuum from the ventrolateral caudal pons medially to the aqueduct. Neurons are generally loosely arranged. In the developing rabbit the compact organization characteristic of the locus coeruleus (A6) CA neurons is limited to its dorsomedial extension. The locus subcoeruleus is composed of a widely circumscribed region in all gestational ages observed, extending from the ventrolateral pons and merging medially with the locus coeruleus. The scattered distribution of CA perikarya contrasts with the tightly-packed organization reported in the rat. This may, however, reflect a species - specific pattern rather than a developmental characteristic since Blessing, et al., (J. Comp. Neurol. 179: 407, 1978) have also pointed out the loose arrangement of CA neurons in older (4 mo.) rabbits.

The most ventrolateral extension of the CA continuum is found in the caudal pons. These CA perikarya probably represent the outermost aspects of the locus subcoeruleus rather than comprising a distinct cell group (M7, Garber and Sladek, J. Comp. Neurol. 159: 289, 1975) since they do not differ morphologically.

CA perikarya are generally bipolar, oval and oriented diagonally to the midline. This orientation is also apparent in cresyl violet sections. CA cells evidence a medium fluorescence intensity without drug pretreatment, however, the fluorescence is distributed unevenly in the cytoplasm. In sagittal sections CA fibers are seen to run both longitudinally and cross - wise, and are found both in areas containing CA neurons, as well as in CA neuron - free regions.Fiber tracts leaving the locus coeruleus and subcoeruleus were not visualized.

Although glyoxylic acid - induced fluorescence produces a sharper delineation of cell bodies and processes, general morphological relationships are retained preferentially with the Falck-Hillarp method.

Supported by a postdoctoral fellowship from the Max Planck Gesellschaft. Present address: Dept. of Zoology, Michigan State University, East Lansing, Michigan 48824.

105.13 PATTERNS OF SPONTANEOUS AND EVOKED DISCHARGES DURING PURKINJE CELL DEVELOPMENT IN CULTURE. M. C. Calvet and J. Calvet *. Lab. of Neurophysiology, INSERM U3, Hôpital de la Salpêtrière, 47 Bd. de l'Hôpital, 75651, Paris cedex 13, France.

Cerebellar explants from new-born rats and kittens were grown in Maximow assemblies with a drop of nutrient medium, renewed twice a week and which consisted of 30% Hank's BSS, 35% minimal essential medium (Eagle) and 35% foetal calf serum, supplemented with glucose (6mg/ml). After 8-66 days in vitro, extracellular recordings of the spontaneous and evoked discharges were taken from at least two neurons simultaneously. In some cases, the recorded neurons were stained by Horseradish peroxidase iontophoretic filling, in order to characterize their morphological features. Electrophysiological data from 95 Purkinje cells (Pc) and from 30 brain stem neurons were processed with a LSI 11 computer which was programmed to display standard interspike interval histograms and cross-correlograms.

The results statistically confirmed that Purkinje cells (Pc) and neurons from incorporated brain stem tissues had distinctive electrical patterns. When the P. cells developed in differently organized cerebellar explants, they showed different patterns of firing and two major types of histograms could be individualized. Cross-correlation analysis indicated that 80% of the Pc pairs had a tendency to fire synchronously when the cerebellar explant was grown with attached brain stem. No correlation could be evidenced between two Pc grown without their extracerebellar afferents. A high degree of synchronization of spontaneous firing was also found between Pc and brain stem neurons and between brain stem neuronal pairs from the same culture.

A comparable analysis was performed on the evoked activity recorded from the same neurons. Depending on the stimulating site, different types of Pc responses were individualized.

Our data suggest that the P. cell patterns of firing are modulated by the onset of synaptic connections arising from brain stem tissues and the role of climbing fiber function in Pc electrogenesis in vitro is specially discussed.

105.14 THE "MINI-LASER MICROELECTRODE": DETECTION OF CALCIUM SPIKES IN PROCESSES AND GROWTH CONES OF DIFFERENTIATED NEUROBLASTOMA CELLS UTILIZING FLUORESCENT VOLTAGE SENSITIVE PROBES. A. Grinvald* and I. Farber* (SPON: M. Devor) Dept. of Neurobiology, Weizmann Institute of Science, Rehovot, Israel.

Changes in fluorescence of neurons, stained with voltage sensitive dyes were used to record electrical responses in cell somata, processes and growth cones of neuroblastoma cells, N1E-115, grown in a monolayer culture. A 30μm microbeam from an inexpensive He-Ne laser, (5mW, H3025-P, Hughes Co.) was focused on the desired target. The cells were stained in normal medium containing 10μM oxonol dye WW-802,[1,3-dipentyl barbituric acid-(5)]-[p-sulfophenyl-3-methyl-5-pyrazolone-(4)]-pentamethin oxonol. Cells were stimulated either extracellularly or intracellularly with a microelectrode, and changes in fluorescence were recorded from the image plane of a 40X microscope objective with a photomultiplier. A fractional change of 5% in the fluorescence intensity was observed per 100 mV potential change. Action potentials were recorded from 3-6μm processes with a signal to noise ratio of ∿3-10 without averaging. A comparison of an electrical recording from the cell body with the simultaneous fluorescence change indicated that the optical response is linearly dependent on the membrane potential change. Action potentials in growth cones were recorded in medium containing 15mM TEA, 1μM TTX and 20mM Ca^{2+}. These spikes resemble the Ca^{2+} spikes recorded in neuroblastoma somata (Moolenaar and Spector, J. Physiol 292, 307, 1979). The following data suggest that active calcium channels are indeed present also in the processes: The spike in the growth cone is delayed by 2 to 6 msec compared to the one recorded simultaneously from the cell body with a microelectrode. The delay is a function of temperature. Frequently the different time course of the spike in the growth cone cannot be explained by different geometry or by passive conductance. Further evidence comes from an experiment in which the growth cone was at least 900μm away from the cell body. The amplitude of passively conducted 100 mV hyperpolarization was at least 3 times smaller than the amplitude of the Ca^{2+} spike both recorded in TTX-TEA medium. Unless the process had unusual rectification properties these results can be explained only if active Ca^{2+} spike zones exist in the process. The present technology is relatively simple, therefore, it should be useful in situations where the use of microelectrodes is difficult, especially for small or thin "targets" in monolayer cultures, where due to the absence of background fluorescence the signals are relatively large.

105.15 DEVELOPMENT AND TRANSMITTER SENSITIVITY OF DISPERSED FETAL HIPPOCAMPAL NEURONS IN CULTURE. S.M. Rothman* (SPON.:J. Sanes), Depts. Anatomy and Neurobiology and Pediatrics, Washington Univ. School of Medicine, St. Louis, MO 63110.

Cultures of dissociated hippocampal neurons from 18-day-old rat fetuses were examined by scanning electron microscopy after periods between one hour and 20 days following plating on a poly-L-lysine coated substrate. Cell attachment was virtually complete within one hour after plating, and at that stage many cells could be seen which had started to extend processes with growth cones. By four hours process formation was well advanced and some cells had assumed a pyramidal configuration. After 16 hours in culture numerous contacts were seen between neighboring growth cones, and this frequently led to fasciculation of the interacting fibers. During the next three weeks the cell bodies enlarged considerably, and two distinct types of processes became evident: large, rapidly tapering dendrite-like processes and finer, more uniform axon-like processes. A dense plexus of processes was formed and many of the finer processes had "bouton-like" swellings as they traversed the neuronal surfaces. Non-neuronal elements, which comprised only about five percent of the cells initially plated, eventually formed a confluent monolayer beneath the neurons.

The sensitivity of these cells to various neurotransmitters was examined during intracellular recording with high impedance (>150 MΩ) microelectrodes. All cells used for physiology had stable resting potentials in excess of 50 mV., and most had action potentials greater than 60 mV. Glutamate (.5M), a potent in vivo excitant depolarized almost all cells when applied by iontophoresis. GABA, applied by iontophoresis (.5M) or microperfusion (10^{-3}M) to cell bodies produced hyperpolarizing or depolarizing responses with approximately equal frequency. Virtually all cells responded to GABA. In contrast, cells seldom responded to acetylcholine or norepinephrine applied by iontophoresis (ACh 1.0;NE .5M) or microperfusion (10^{-3}M for both). These substances respectively excite and inhibit hippocampal neurons in vivo. We shall attempt to modify the transmitter sensitivity of these cells by co-culturing them with explants capable of providing adrenergic or cholinergic innervation.

105.16 RETINAL GANGLION CELL DEATH DURING NORMAL DEVELOPMENT IN THE SYRIAN HAMSTER. D.R. Sengelaub and B.L. Finlay Department of Psychology, Cornell University, Ithaca, NY 14853

Retinal ganglion cell death during postnatal development in the hamster was studied with light microscopy. Degenerating cell profiles were found throughout the retinal ganglion cell layer in the first 10 postnatal days. On the first postnatal day, degenerating cells were observed at a rate of 1-3 per 1000 live cells. This rate increased rapidly to 7-18 degenerating cells per 1000 live cells by postnatal day 5, and returned to the rate of 1-3 per 1000 by day 10. Although the cell death rates for both central and peripheral retina peaked on the same postnatal day, day 5, higher rates were found centrally for the first 4 postnatal days, and higher rates peripherally for days 5-10, suggesting either a central to peripheral trend in neurogenesis in retina, or a central to peripheral trend in the establishment of central connectivity. Degenerating cells were typically found in clumps rather than evenly distributed thoughout the retina.

The general time course of cell degeneration and its central to peripheral pattern corresponded to the pattern of cell degeneration seen in the superficial gray layer of the superior colliculus. In the superficial gray layer, cell death is also at a maximum on the 5th postnatal day, and the rate of cell degeneration is consistently elevated at the medial, caudal and lateral margins of the superficial gray relative to central superficial gray. The intermediate gray layer, not a target of retinal axons, does not show this central to peripheral disparity. Asynchony in the pattern of genesis of retinal ganglion cells and superficial gray neurons can account for this pattern of differential cell death.

105.17 ONTOGENY OF ANIONIC HERBICIDE TRANSPORT BY CHOROID PLEXUS AND BRAIN. C. S. Kim*, L. A. O'Tuama and J. R. Pick* (SPON: T. A. Reaves, Jr.) Dept. of Neurology, Pediatrics and Biol. Sci. Res. Ctr., Sch. of Med., Univ. of North Carolina at Chapel Hill 27514.

A distinctive transport system for organic anions has been described in the choroid plexus and the mechanisms of transport appear analogous to those involved in secretion of organic acids by the proximal tubule of the kidney (Pappenheimer et.al., Am. J. Physiol. 200:1-10, 1961). It has also been shown that the anionic herbicide, 2,4-dichlorophenoxyacetic acid (2,4-D) is actively transported on the organic acid system of kidney (Berndt and Koschier, Toxicol. Appl. Pharmacol. 26:559-570, 1973) and choroid plexus (Pritchard, J. Pharmacol. Exp. Ther. 212:354-359, 1980). The present study was undertaken to investigate whether the barrier system to anionic organic acid is functioning at an early stage of development. Albino rabbits of either sex (ages 3 days and 30 days) were sacrificed by decapitation. In each experiment, the brain was rapidly removed from the skull and the choroid plexus (CP) was dissected free. Brain slices were prepared from whole brain. CP and brain slices from both age groups were pre-incubated for 10 min in artificial CSF only and then transferred to experimental medium containing ^{14}C-2,4-D 0.02 μCi/ml (sp. act. 28 mCi/mmol). The initial uptake of ^{14}C-2,4-D at 5 min was reduced 28.55% in lateral ventricular CP (LCP) and 58.75% in fourth ventricular CP (FCP) of 30 day old rabbit incubated with 10 μM probenecid, classical inhibitor ($P < 0.005$) and 58.95% in LCP and 77.35% in FCP with 100 μM probenecid ($P < 0.001$). In the CP of 3 day old rabbit, the inhibition of uptake was 57.79% in LCP and 75.64% in FCP with 100 μM probenecid ($P < 0.001$) and 57.07% with 100 μM ouabain ($P < 0.001$) compared to controls. However, such treatment did not alter ^{14}C-2,4-D uptake or release by brain slices in either age group studied. The finding in this study of inhibition of ^{14}C-2,4-D transport by probenecid and ouabain suggests that the CSF-blood barrier to anionic organic acid transport systems are established at an early stage of development, as early as 3 days old. The active transport of ^{14}C-2,4-D in brain is limited to the CP and possibly similar structures. Early development of facilitated blood-CSF solute translocation is suggested by other studies. Thus the blood-CSF barrier to proteins functions by 18 to 20 days of gestation, the protein concentration of CSF approaches the normal adult value soon after birth (Ramey and Birge, Develop. Biol. 68:292-298, 1979). CP Na^+ -K^+ - ATPase levels remain stable between postnatal and adult rabbit (Mitchell et.al., Proc. Am. Acad. Neurol. 32nd Ann. Mtg., p. 36, 1980).

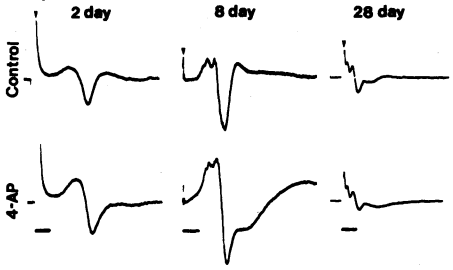
105.18 DEVELOPMENT OF CONDUCTION IN RAT OPTIC NERVE: PHYSIOLOGICAL AND PHARMACOLOGICAL OBSERVATIONS CORRELATED WITH MYELINATION. R. E. Foster, B. W. Connors and S. G. Waxman*. Dept. of Neurology, Stanford Med. Sch. and VA Med. Ctr., Palo Alto, CA 94304.

To study conduction in myelinating CNS axons, we examined the development of the compound action potential in rat optic nerve axons before, during and after myelination using in vitro methods. Myelination of optic nerve begins 6-8 days postnatal and 100% of the axons are myelinated in the adult. Our results indicate that the totally non-myelinated optic nerve (2 day) can conduct (cond. veloc., CV=0.2 m/s). The potential is blocked by application of 0.1 μM tetrodotoxin (TTX) and the amplitude is increased and recovery phase prolonged by application of 0.5 mM 4-aminopyridine (4-AP). These observations suggest that sodium and potassium conductances contribute to the optic nerve action potential prior to myelination. At the beginning of myelination (e.g. 8 days) the action potential exhibits two components (CV=0.4 and 0.6 m/s). Of these only the slower component is sensitive to 4-AP while both components are blocked by TTX. This suggests that, as myelination begins, voltage-dependent potassium conductance disappears. The slower component, presumably non-myelinated axons, retains sodium and potassium conductances. At 28 days (85% myelinated) the action potential has two fast (CV=3.9 and 7.3 m/s) and a slow component (CV=1.8 m/s). All components are TTX sensitive but only the slow component is affected by 4-AP.



(cal = 2 ms; conduction distance and gain not uniform; neg. down)

These observations suggest that during myelination the axon membrane reorganizes from a state where sodium and potassium channels are both present and functional to a state where sodium channels contribute almost the entire conductance which underlies the optic nerve action potential. (Supported in part by the VA, NIH, and NMSS).

105.19 MORPHOLOGICAL STUDIES OF NORMAL AND INDUCED ASTROCYTIC DIFFERENTIATION IN VITRO. P. Trimmer* P. Reier, and T. Oh. Dept. of Anat., Univ. of Md. Sch. of Med., Baltimore, MD 21201

The following study was undertaken 1) to establish the sequence of normal astrocytic maturation in vitro and 2) to compare these maturational events with the induction of process formation by dibutyrl cyclic adenosine monophosphate (dbcAMP) treatment. Tissue cultures consisting of immature glia were prepared from neonatal rat optic nerve as previously described (Trimmer, Reier and Oh, Neurosc. Abst., 5: 760, 1979). Cells at various stages of maturation were observed in vitro and their location was identified with a diamond marker objective. These identified cells were subsequently examined with either electron microscopy or immunocytochemistry. Cultured immature astroblasts are flat, polygonal cells which do not stain with the antibody to glial fibrillar acid protein (GFAP). With further maturation glial filaments gradually accumulated in the perinuclear region. In slightly more mature cells, distinct bundles of GFAP-stained glial filaments were distributed in radiating fascicles throughout the cytoplasm. The ultrastructure of these intermediate stage astroglia was characterized by regions of cytoplasm typical of astroblasts as well as discrete bundles of glial filaments characteristic of the mature cell. As maturation progressed, cytoplasmic vacuoles appeared between the fascicles of filaments. These vacuoles increased in number and coalesed. This results in a cavitation of cytoplasm between pre-existing bundles of glial filaments, giving rise to the mature, multipolar astrocyte. Following treatment with a 1mM concentration of dbcAMP, astroblasts were induced to form processes in a manner similar to the sequence of differentiation just described. A few hours after the addition of dbcAMP, vacuoles appeared in the cytoplasm of astroblasts. These vacuoles increased in number and size and ultimately the cytoplasm regressed leaving behind filament-containing cellular processes. From these observations of normal and chemically-induced astrocytic differentiation in vitro it appears that radial glial filaments play an important role in defining the distribution of astrocytic processes. The shape of the differentiated cell is more directly the result of cytoplasmic erosion around filament-rich areas of the astroblast rather than an active outgrowth of glial processes. (Supported by NIH Grant 13836 and The Paralyzed Veterans of America).

105.20 ULTRASTRUCTURAL CHARACTERISTICS OF MIGRATING MOTONEURONS. I-W. Chu-Wang, R. W. Oppenheim, and P. B. Farel. Neuroembryology Lab., Div. of Research, Dorthea Dix Hospital, Raleigh, NC 27514 and Dept. of Physiology, Univ. North Carolina Sch. Med., Chapel Hill, NC 27514

Migrating motoneurons, presumably destined to join the lumbar lateral motor column (LMC), of the tadpole (R. catesbeiana) can be retrogradely labeled by ventral root application of HRP (Farel and Bemelmans, Neurosci. Let., 1980). These motoneurons can be seen in all regions of the mantle layer as well as in contiguity with the ependymal zone. Migrating motoneurons are not retrogradely labeled when HRP is placed in the limb bud rather than in the ventral root. The present study examines the ultrastructural characteristics of these migrating motoneurons to determine their degree of differentiation compared to motoneurons that have completed their migration and joined the LMC.

Tadpoles of Stages VI-VII (Taylor and Kollros) were used in this study. HRP was applied to the ninth and tenth ventral roots and, three to four days later, the lumbar enlargement was removed and fixed by immersion in buffered 6% glutaraldehyde. Labeled motoneurons were located in 1 μm sections, and adjacent thin sections were examined under the electron microscope.

Motoneurons in the immediate vicinity of the ependymal zone were bipolar and appeared devoid of synapses. They were characterized by relatively sparse cytoplasm and organelles in an early stage of differentiation. Motoneurons midway between the ependyma and the LMC were either bipolar or monopolar, possessed synapses, and appeared cytologically indistinguishable from motoneurons in the LMC of the same animal.

Migrating motoneurons, then are highly differentiated both in terms of their organelles and in that they have synapses. These findings indicate that the mechanisms which specify the particular characteristics of a motoneuron may act before the motoneuron has reached its final location.

105.21 SURFACE SPECIALIZATIONS AT SITES OF CHOLINESTERASE ACTIVITY ON AMPHIBIAN EMBRYONIC MUSCLE CELLS CULTURED WITHOUT NERVE.
P. Weldon*, F. Moody-Corbett* and M.W. Cohen. Dept. Physiology, McGill University, Montreal, Quebec.

Patches of cholinesterase activity form on cultured myotomal muscle cells derived from Xenopus embryos. Such patches develop even though the muscle cells are cultured in the absence of nerve and overlap with sites of high acetylcholine receptor density (F. Moody-Corbett & M.W. Cohen, Proc. Soc. Neurosci. 5 486, 1979). In the present study, we have examined the fine structure of these areas of cholinesterase activity.

Most of the cell surface appeared morphologically unspecialized and was free of cholinesterase activity as indicated by the absence of histochemical reaction product. Discrete regions of reaction product extending for as much as 20 μm were observed on the lower (apposed to the culture dish) and upper cell surfaces and in the intercellular space between closely apposed cells. The majority of these regions were associated with sarcolemmal invaginations which varied considerably in size and depth ranging from shallow infoldings, similar in appearance to postsynaptic folds, to deep and sometimes branched invaginations some of which were similar to the invaginations characteristic of the amphibian myotomal myotendinous junction (T. Nakao, Cell Tiss. Res. 166 241-254, 1976). In cases where the reaction product was not so dense as to obscure other surface specializations, it was found to be associated with the presence of basal lamina and a "thickened" sarcolemma which are also characteristic of both postsynaptic membrane and myotendinous invaginations. These observations, taken together with our previous finding of a high incidence of overlap between cholinesterase patches and acetylcholine receptor patches, suggest that some of the sites of ultrastructural specialization of the cell surface contain high densities of acetylcholine receptors in addition to cholinesterase.

Supported by MRC of Canada.

106.1 QUANTITATIVE ULTRASTRUCTURAL ANALYSIS OF THE GOLDFISH OPTIC TECTUM FOLLOWING ENUCLEATION. Jeanette J. Norden and John A. Freeman, Dept. of Anatomy, Vanderbilt University School of Medicine, Nashville, TN 37232.

The morphological changes which occur in synapses as a function of innervation are of considerable interest in that they may reveal important aspects of underlying mechanisms of synaptogenesis. Of particular interest is whether removal of a major afferent pathway results in sprouting and reorganization of remaining synapses.

We have examined quantitatively the synaptic organization of the neuropil of the optic tectum in goldfish, using a new random sampling method developed for counting synapses (Freeman and Norden, in prep.). The number of synapses in the stratum fibrosum et griseum superficiale (SFGS) (the major target of retinal afferents in goldfish), and the fate of postsynaptic specializations has been followed in normal animals and in goldfish enucleated from 1-280 days. The number of synapses in the SFGS drops dramatically between 5-15 days post-enucleation and by 49 days, the SFGS is significantly reduced in volume. By 280 days post-enucleation, the SFGS is nearly non-existent. The number of synapses in tectal layers not receiving visual afferents, however, remains constant. Few vacated postsynaptic sites can be seen at any time following enucleation, suggesting that the postsynaptic area has been removed along with degenerating retinal afferents. We conclude that no significant sprouting or reorganization of tectal neuropil occurs following enucleation in goldfish.

The present results suggest that the loss of α-BTX binding sites following enucleation (Oswald, Schmidt, Norden and Freeman, Brain Res., 187:113, 1980) is due to the removal of the postsynaptic area containing the ACh receptor (Oswald and Freeman, J. Biol. Chem. 254:3419, 1979) along with degenerating retinal terminals, and that the gradual increase in the number of sites during regeneration (Schechter et al., Brain Res., 166:57, 1979) is due to the de novo synthesis of post-synaptic receptor or reorganization of remaining postsynaptic membrane.

Supported by URC Grant #3-60888, BRSG Grant #523766 and NIH Grant #EY01117.

106.2 IN VITRO SYNTHESIS OF A SPECIFIC PROTEIN IN THE DEAFFERENTED GOLDFISH RETINOTECTAL PATHWAY. Wolfgang Quitschke* and Nisson Schechter. Departments of Biochemistry, Psychiatry and the Long Island Research Institute, SUNY at Stony Brook, New York 11794.

The regenerating goldfish retinotectal pathway is a model system for the study of axonal outgrowth, nerve regeneration and neuronal specificity. A critical aspect of these phenomena is the study of unique proteins associated with the reconnection process. In a previous study utilizing two dimensional gel electrophoresis we identified specific endogenous proteins associated with the retinotectal pathway of goldfish (Brain Res., In press). In this study we report the synthesis of a ^{35}S-methionine labeled protein associated with tectal deafferentation.

Goldfish underwent enucleation of one eye or intraorbital optic nerve crush. Pooled control and experimental tecta were excised and incubated in HEPES minimal salts medium (pH 7.4) for 2 hr at 25°C in the presence of ^{35}S-methionine (50 μci/ml) (J. Neurochem. 22 (1974) 821-830). The tecta were subsequently frozen and lyophilyzed. The dry residue was solubilized in a lysis buffer containing 9.5M urea, 5% β-mercaptoethanol, 20% NP-40, Ampholines 1.6% pH 5-7, 0.4% pH 3.5-10. Protein separation patterns were obtained from experimental and normal tecta at various times after optic nerve crush or enucleation by two dimensional gel electrophoresis according to O'Farrell (J. Biol. Chem. 250, (1975) 4007-4021). Autoradiograms were obtained by exposing the stained and dried gels to x-ray film for 2-3 weeks.

The autoradiograms revealed an intensely labeled acidic protein spot in the 30K molecular weight range which was found in the experimental tectum 2-4 days after optic nerve crush or enucleation. This spot is undetectable in the ^{35}S-methionine labeled normal tectum and it cannot be detected with Coomassie blue staining either in the normal or experimental tectum. This protein is observed for about 12 weeks in the denervated tectum. The decrease in labeling intensity and the gradual return to control levels after optic nerve crush correlates with the time course of axonal regeneration.

These results suggest that the synthesis of at least one specific protein is induced in the optic tectum by disconnection of the optic nerve. The observation that it is highly labeled for a long period of time without ever reaching a level of detectability by Coomassie blue staining suggests a high turnover rate.

Studies are now in progress involving the synthesis of this protein and its detectability during the reconnection process under other conditions of optic nerve disconnection or tectal ablation.

106.3 DEVELOPMENT OF RETINOTECTAL CONNECTIONS. F. Levinthal* and C. Levinthal, Dept. of Biol. Sci., Columbia University, New York, N.Y. 10027.

In order to investigate the mechanism by which retinotectal connections are established we use serial section light and electron microscopy of optic nerves from the eye into the tectum of the Zebrafish. By studying animals from embryonic to adult stages one can observe the initial connection and the sequential growth and development thereafter. Previous reports of Bodick and Levinthal (PNAS 1980) demonstrated that there is in the embryo a well ordered mapping of retinal fibers from the ganglion cells to the optic nerve as it exits the eye. Observation of these fibers suggested that the mechanism by which the order can be established is based on the fact that growth cones of newly forming fibers are in contact with their more mature neighbors and with glia lining the lumen of the optic stalk. The order can be achieved by a simple following mechanism which translates time and position of ganglion cells differentiation into a well defined spatial organization within the optic nerve.

When the optic nerve of the newborn animal is followed from just behind the eye until it reaches the tectum, the growth cones are always found on the ventral portion of the nerve: thus the overall order of fibers everywhere in the nerve remains as it is when the nerve leaves the eye. The fibers in the newborn are not myelinated and they form a compact bundle over their entire path from the eye to the tectum.

In the adult, all of the optic fibers are myelinated and about 5% of them have areas some ten times larger than the majority. The fibers leave the eye as a compact bundle but between the eye and diencephalon they diverge into about 25 separate bundles which merge and rejoin as they proceed. Groups of fibers pass from one bundle to another. On reaching the chiasma the separated bundles come together into a single compact group before the fibers separate as they reach the tectum.

Shortly after hatching the single bundle behind the eye shows what appears to be the beginning of fragmentation into bundles. A large glial cell grows so as to separate the older fibers which lie on the dorsal side of the nerve from those on the ventral side where the fibers which have grown most recently are found. Details of the mapping, the formation of the bundles and the pattern of the nerves as they enter the tectum will be described.

This work was supported by grants from the National Institutes of Health (NS 09821 and RR-00442).

106.4 EFFECT OF THYROXINE ON RETINOTECTAL REORGANIZATION IN GOLDFISH. L.R. Marotte*, R.F. Mark* and J. Wye-Dvorak* (SPON: J.M. Wild). Dept. Behavioural Biol., R.S.B.S., ANU, Canberra, Australia.

After half tectal ablation in goldfish the retinotectal projection may undergo reorganization so that the whole of the visual field is represented on the remaining half tectum. There is an effect of season and lighting conditions on this (Wye-Dvorak, J., Marotte, L.R. and Mark, R.F., Neurosci. 4: 489-802, 1979). Compression of the whole visual field onto the remaining half tectum occurs in summer but not in winter in fish kept in normal light/dark (L/D). Constant light (C/L) conditions prevent compression (Yoon, M., J.Physiol., 246: 673-694, 1975). These results suggest a possible hormonal influence. The effect of thyroxine on reorganization was tested after removal of the caudal half of the left tectum in goldfish 6.5 - 9.0cm in body length. The results are summarised below.

Season of Year & Lighting conditions	Proportion of fish with reduplicated fields or partial compression		Time after operation of electrophysiological mapping
	Operated & Thyroxine	Operated	
L/D winter 4mgm/l thyroxine	6/7	2/8	41-65 days
L/D winter .006 mgm/l thyroxine	8/10	0/9	35-67 days
C/L summer 4mgm/l thyroxine	3/7	0/7	76-163 days

Both high and low doses of thyroxine induced some reorganisation particularly in fish kept in L/D during winter. Ultrastructural examination of tecta showed that this was not related to the amount of optic fiber sprouting. Less sprouting occurred in the L/D group receiving a high dose of thyroxine compared to its controls while no differences were seen in the other two groups. A hormonal influence on reorganization has been demonstrated and this may underlie the effects of season and lighting conditions which are both associated with changes in hormone levels.

106.5 THE ORGANIZATION OF RETINAL PROJECTIONS IN GOLDFISH. S. C. Sharma. Department of Ophthalmology, New York Medical College, Valhalla, New York 10595.

The retinal ganglion cell projections in goldfish were labelled by an injection of HRP solution into the vitreous of the eye. The pattern of optic axons in the optic tract was regular. The optic tract divides into lateral and medial tracts at the level of the anterior pole of the nucleus rotundus. The lateral tract curves around at the lateral and ventral aspect of the nucleus rotundus and divides further into two branches. The fibers in the extreme lateral position innervate the ventral lateral tectum directly, coursing in the SFGS. Fibers innervating the deeper tectal layer of the ventral and lateral tectum course through the tectobulbar tract to reach the tectum. The entries to the SFGS occur at various levels, hence a huge bundle gives the appearance of bending 90^{o} at the rostral pole. Fibers in the medial portion of the lateral tract course around the nucleus rotundus and turn dorsally before innervating the SFGS. Before entering the tectum, a few fascicles disassociate from the tract and innervate diencephalic areas.

Fibers of the medial tract travel medial to the nucleus rotundus, turn dorsally and form a 90^{o} curve from which eminate fascicles which enter the dorsal tectal SFGS. This crossover of fibers at the dorsal rostral pole of the tectum was well pronounced at the level of medial diencephalic target centers. Fibers terminating in the deeper tectal layers in the dorsal tectum separate from the ventral portion of the medial tract. This crossover of medial tract and the medial portion of the lateral tract at the level of the rostral pole of the tectum is similar to that suggested by Scholes in the Cichlid (Nature, 278: 620-624).

In addition, direct retinal projections were seen in the diencephalic centers which include the nucleus dorsolateralis, nucleus dorsomedialis, area pretectalis, nucleus pretectalis, preoptic nucleus, nucleus of the posterior commissure and lateral geniculate nucleus. Direct projection to the ipsilateral diencephalic centers was not observed. However, very few axons in the posterior commissure were labelled, suggesting fiber paths for the ipsilateral diencephalic target centers. In the tectum four different layers were labelled: stratum opticum, stratum fibrosum et griseum superficiale, stratum album centrale and stratum fibrosum periventriculare. In addition, large numbers of radial fibers were seen mostly originating from the deep fiber layer.

106.6 GOLDFISH OPTIC TECTAL EXPLANT AS A MODEL SYSTEM FOR NEUROPHYSIOLOGICAL AND BIOCHEMICAL STUDIES. T. J. Teyler, D. Lewis, V. E. Shashoua and C. G. Brogna*. Neurobiology Program, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272, and Dept. of Biological Chemistry, Harvard Medical School, Belmont, MA 02178.

We have developed methods for maintaining explants of goldfish optic tecta in a defined medium in vitro. Such cultures offer an excellent model system for studies of the neurophysiological and biochemical properties of an intact neural structure under controlled conditions. Because of the anatomical organization of goldfish tectum as a spheroid structure floating above the ventricular space, it can be removed almost intact by severing its three input and output systems, i.e., optic nerve, connections to dorsal tegmentum and commissural connections. This allows the removal of a 400u thick cortical structure with its laminar organization intact.

Using an incubation medium which approximates the ionic composition of goldfish brain CSF and a 95/5%, O_2/CO_2 atmosphere, we find that such explants can maintain a linear rate of RNA and protein synthesis at 22° C. for at least 17 hours and 24 hours, respectively. Protein synthesis can be inhibited by puromycin but not by chloramphenicol.

Electrophysiological stimulation of the severed optic nerve stump gives rise to short latency responses from widespread regions of the explanted tectum. Population responses to such stimulation at various recording depths display a field potential laminar profile indicative of source-sink relationships corresponding to the anatomical terminations of optic nerve fibers and are in agreement with similar in vivo profiles. A short-latency triphasic potential has been identified as a population fiber volley resistant to a high Mg++, low Ca++ incubation medium. A longer latency negative response centering on the stratum opticum displayed response jitter and variability, was abolished by a high Mg++, low Ca++ medium and followed moderately high (50 Hz) stimulation frequencies. Thus this potential was judged to be a monosynaptic response to optic nerve stimulation. Double-shock stimulation disclosed the nature of facilitation and recurrent inhibitory processes in this circuit. Stimulation at various intensities and locations indicated several additional, longer latency responses apparently mediated by pathways with lower conduction velocities.

These results demonstrate the biochemical and neurophysiological integrity of the system. Such cultures should be suitable for pharmacological and metabolic investigation.

106.7 ABERRANT RETINAL PROJECTIONS IN EARLY STAGES OF GOLDFISH OPTIC NERVE REGENERATION. A. D. Springer. Dept. of Anatomy, New York Med. Col., Valhalla, NY 10595.

The assumption that optic nerve fibers in goldfish regenerate only to appropriate targets and bypass inappropriate targets was examined by crushing one optic nerve behind the eye. Fish were maintained at 30°C following surgery in order to accelerate regeneration. Separate groups of 2-3 fish were injected intraocularly with 25μc of (^{3}H)proline 24 hr prior to being killed at either 2,4,8,16 or 32 day post-optic nerve crush. Subsequently, the brains were processed for radioautography.

Some fibers had regenerated to the chiasm within 4 days post-crush, but none had reached the diencephalon or tectum. At 8 days post-crush the contralateral tectum was densely labeled medially and laterally, as well as rostro-caudally. Other normal contralateral retinal targets that were labeled at this time included: nucleus dorsolateralis, nucleus dorsomedialis, area pretectalis, nucleus pretectalis, preoptic nucleus, nucleus of the posterior commissure and lateral geniculate nucleus. Several anomalous contralateral targets were labeled 8 days post-crush: nucleus rotundus, nucleus isthmi, torus longitudinalis, nucleus lateralis valvula and corpus cerebelli. In addition, the pituitary gland received fibers from both the contralateral and ipsilateral optic tracts. Furthermore, the ipsilateral optic tectum was extensively labeled. Fibers were observed in several anomalous tracts: ipsilateral optic tract, posterior commissure, intertectal commissure, horizontal commissure, tectobular tract and mesencephalo-cerebellar tract.

Aberrant fibers were only evident in the ipsilateral optic tract and in the stratum opticum of the rostral ipsilateral tectum at 16 days post-crush. By 32 days post-crush all label was confined to the normal contralateral and ipsilateral diencephalic retinal targets, as well as to the contralateral optic tectum.

The present study indicates that regenerating optic nerve fibers grow to extensive regions of the brain. Subsequently, they appear to retract or degenerate from anomalous structures. The occurrence of these aberrant projections was unexpected, as was their transience. An explanation of their transience assumes that the aberrant fibers are collateral branches rather than primary axons. Collateral fibers may fail to successfully compete with existing primary axons and therefore they either retract or degenerate. Previous evidence (Springer, Neurosci. Abstr., 5:684, 1979) suggests that competition between primary axons of different origins leads to fiber segregation, rather than to retraction of foreign fibers.

106.8 FURTHER RULES FOR ORDER IN THE GOLDFISH OPTIC NERVE. Anne C. Rusoff. University of Michigan, Ann Arbor, Michigan 48109

Axons from annuli of retinal ganglion cells are clustered together in the goldfish optic nerve. This raises the question: are the axons within such a cluster further ordered retinotopically? This question was answered by filling the axons of the ganglion cells from one half of the retina with horseradish peroxidase (HRP) and observing the distribution of axons filled with HRP reaction product in x-sections of the optic nerve and tract. HRP was introduced into the optic axons from half of the retina by cutting one brachium of the optic tract and coating it with HRP. (Axons from dorsal/ventral retina are in the ventral/dorsal brachium of the optic tract.) When the dorsal brachium alone was filled with HRP, a x-section from the optic nerve or distal portion of the optic tract had filled axons only around its outer edges; the central part was mostly free of reaction product. When the other brachium was filled, the converse pattern was observed. Thus, axons from the ventral and dorsal halves of the retina are segregated from each other; therefore, there is at least gross topographic order within the optic nerve.

A second question is: are adjacent clusters of axons in the nerve from adjacent retinal annuli? Since the retina grows by annular addition of ganglion cells, the axons in a cluster are from cells of the same age. A cluster of axons of one age might join the nerve near a slightly older cluster of axons. To test this idea, HRP was injected directly into a small spot on the retina, and filled axons were traced into the nerve. Each injection filled axons from ganglion cells peripheral to the injection site so that a central injection filled axons of both peripheral and central cells. All injections made into ventral retina filled axons around the outer edge of a x-section of the nerve, in agreement with the results above. A peripheral injection filled a short length of the edge, while a more central injection filled a longer length of it, rather than discontinuous clusters of axons. This result suggests that age-related clusters of axons do join the nerve next to slightly older clusters of axons.

In summary, axons in the optic nerve of goldfish appear to be ordered both by the age and position of their cell bodies. These results agree with suggestions of Bunt and of Dawnay and further suggest that axons in the goldfish optic nerve follow the same rules of ordering found in the ribbon-shaped optic nerves of perciform fishes (Scholes. Nature 278: 620, 1979). The "ribbon" is simply less obvious in the goldfish optic nerve. (Supported by PHS Grant # EY05294 to author and EY00168 to S. S. Easter, Jr.)

106.10 IN VITRO INTERACTION BETWEEN THE RETINAL TISSUE AND THE CO-CULTURED TECTAL TISSUE, EXPLANTED FROM ADULT GOLDFISH. Myong G. Yoon and Frank A. Baker* Department of Psychology, Dalhousie University, Halifax, Nova Scotia, CANADA, B3H 4J1.

The outgrowths of regenerating neural processes from the retinal tissue into the tectal tissue were studied in vitro under various experimental conditions by co-culturing the retinal and tectal tissues, explanted from the adult goldfish. An elongated rectangular piece of the retina was dissected free along the nasotemporal axis near the equator, and implanted on a culture dish in a predesignated orientation. The regenerating neurites from the retinal explant usually grew in the radial direction towards the phantom optic disc as reported by Johns, Yoon & Agranoff (1978). When the retinal explant showed vigorous outgrowth of neurites (usually 2-5 days after explantation), its topographically matching area of the optic tectum was dissected from the same experimental fish, and co-cultured later with the retinal explant in various geometric configurations. The patterns of neuritic outgrowth from the retinal explant into the co-cultured tectal explant were observed at different intervals in culture. The retinal neurites with bush-like growth cones which contained several philopodia at their advancing tips were firmly attached to the substratum on the culture dish before they grew into the tectal explant. When the retinal neurites successfully invaded the tectal explant, however, they tended to detach from the substratum, and appeared to form cables which linked the retinal and tectal tissues. In one case, the other retinal neurites which failed to invade the tectal explant were withdrawn and disappeared later. Further investigations on the trajectories of the retinal neurites within the co-cultured tectal tissue are in progress.

106.11 GLUTAMIC ACID BINDING TO GOLDFISH BRAIN:TECTAL ACTIVITY DURING OPTIC NERVE DEGENERATION AND REGENERATION. Andrew Francis*, Wolfgang Quitschke* and Nisson Schechter (SPON: B. Twarog)Cornell Medical School and Departments of Biochemistry, Psychiatry and the Long Island Research Institute, SUNY at Stony Brook, NY 11794

Regeneration of the goldfish optic nerve to optic tectum is a model system for study of axonal outgrowth and nerve reconnection. A critical aspect of reconnection is the analysis of neurotransmitter regulation and types of synapse in the tectum. We have previously shown that about 40% of the tectal nicotinic-cholinergic receptors are lost upon tectal denervation; both the number and concentration of receptors are restored during optic nerve regeneration. In contrast, tectal muscarinic-cholinergic receptors are stable in the denervated tectum (Brain Res 166 57; 185 161). We now report binding of L-Glu to goldfish brain membranes and changes in tectal binding following optic nerve denervation and regeneration. Equilibrium binding (at 21°) of ^{3}H-L-Glu was performed in Tris buffer according to Foster and Roberts (J Neurochem 31 1467). Saturable, reversible, and specific binding occurred to washed membranes from whole goldfish brain to a single population of sites having an apparent Kd of 4 uM and a capacity of 10 pm/mg original tissue. There was a 10-fold regional variation in specific binding (pm/mg original tissue) measured at saturation:cerebellum, 26; diencephalon, 8.4; telencephalon, 7.5; vagal lobe, 6.7; optic tectum, 4.8; spinal cord, 3.3. Specific binding was enriched 1.6 times in membranes derived from a crude synaptosomal (P2) fraction, prepared by differential centrifugation of brain homogenates in 0.32M sucrose. Pharmacological studies were performed by preincubating serial dilutions of drugs with membranes before addition of ^{3}H-L-Glu to a final concentration of 7 nM. The apparent protection constants (Kp) were defined as drug concentrations inhibiting binding by 50%:L-Glu, 4 uM; L-Gln, 30uM; L-Asp, 70 uM; kainic acid, $\gg$ 10mM; GABA, $\gg$ 10mM. Following eye removal, the total number of L-GLU binding sites was stable for 4 days, followed by a rapid loss in activity reaching 40 $\pm$ 12% at 24 days. At 70 days after optic nerve crush, when optic nerve regeneration had occurred, the number and concentration of L-Glu binding sites was not different from control. These observations suggest a delayed loss of L-Glu binding sites in the denervated tectum, which is reversed if optic nerve regeneration occurs. The delayed loss in these sites, compared immediate loss of nicotinic sites and stable muscarinic sites, suggest that these 3 sites are in differing tectal compartments. The L-Glu binding sites may be located on an intrinsic tectal system which is secondarily degraded during tectal denervation.

106.12 BANDED DISTRIBUTION OF RETINAL GANGLION CELL TERMINALS WITHIN THE STRATUM ZONALE (9A) LAYER OF THE FROG OPTIC TECTUM. Margaret I. Law* and Martha Constantine-Paton (Spon. D. Kelley) Princeton University, Princeton, New Jersey 08544

The existence of bands of retinal ganglion cell terminals within the stratum zonale (Potter's layer 9A) of the optic tectum were revealed through labelling with horseradish peroxidase (HRP) histochemistry. In normal postmetamorphic animals optic nerves were cut and HRP placed against the distal stumps. After two days survival the presence of HRP was detected through a $CoCl_2$-diaminobenzidine reaction. Layers 9B-F of the contralateral tectum contained the typical, uniformly labelled optic projection. Within 9A, however, 80-100μ wide bands of labelled neuropil alternated with 100-200μ wide terminal free areas.

This striped input appeared to develop in late tadpole life since no bands were observed in similarly labelled tadpoles. Serial reconstruction of postmetamorphic optic projections demonstrated that the bands extended in a rostral-caudal direction over the anterior 3/4ths of the tectal surface.

The interband regions are thought to be occupied by fibers originating in the nucleus isthmi. This nucleus mediates intertectal connections such that visual information from one tectal lobe is retinotopically mapped over the other lobe.[1,2] Thus, by way of a direct contralateral retinal projection and a poly-synaptic ipsilateral pathway both retinas are mapped within each tectum. Recent physiological and anatomical evidence located the isthmi's intertectal projection to be just below the pial surface, in layer 9A.[1,2]

We have previously reported the induction of periodic bands throughout layers 9B-E of the dually innervated tecta of 3-eyed and single tecta frogs.[3,4] The bands observed in normal animal's layer 9A are only half as wide and are not as regular as the induced bands of dually innervated tecta. Nevertheless, in both cases retinal ganglion cell axons terminate within similarly oriented bands of tectal neuropil receiving retinotopically organized visual information from two eyes.

106.13 CENTRIPETAL CELL LOSS IN THE RETINA OF RANA PIPIENS TADPOLES. Ricardo G. Cigarroa* and M. Constantine-Paton, Department of Biology, Princeton University, Princeton, New Jersey 08544

We have studied cell proliferation and cell loss in the retina of the larval leopard frog Rana pipiens. Frog embryos and tadpoles were multiply pulsed with ^{3}H-thymidine (NEN, specific activity 6.7Ci/mmole; 1μCi/gm) at Shumway[1] st. 21, Taylor and Kollros[2] st. 4,6,8,12,18 and 25. Two days after each pulse some animals were sacrificed to compare the initial location of labeled cells with their position at subsequent stages of development.

Our results confirm earlier observations on retinal histogenesis in this species in that new retinal cells appear to be generated only at the ciliary margin[3]. After a ^{3}H-thymidine pulse and a short survival all labeled retinal cells are located at the retinal perimeter. This labeled zone has an arrowhead shape with labeled cell bodies in the inner nuclear layer extending further toward the fundus of the eye than equally labeled cell bodies in the outer nuclear or retinal ganglion cell layers. The pattern of label suggests that for a given segment of retina, ganglion cells and receptors become post-mitotic before the inner nuclear layer.

Animals surviving for long periods of time showed a progressive and previously unsuspected absolute movement of the labeled cellular annulus toward the optic disc. For example, the labeled band of cells resulting from a pulse of thymidine at T & K st.IV will be completely absent from the ventral rim of the optic disc at T & K st. 18 and will be just discernable as a small band of labeled cells on the longer dorsal rim. By T & K st. 25 (total 131,000 ganglion cells) none of the retina generated before T & K st. VI (total 22,000 ganglion cells) is present. These cells have moved to the optic disc where they appear to die or migrate out of the eye.

This pattern of growth implies that none of the cells in the neuroepithelium that initially makes contact with the brain are present in the mature retina and that the position of each retinal ganglion cell relative to the visual world must change progressively during tadpole life.

Our analysis suggests that theories of retinotectal connectivity should be re-evaluated so that they take into account the fact that this anuran amphibian can generate an ordered topographic visual projection with a presynaptic cell population that is in a continual state of flux.

106.14 ORDERLY FASCICULATION IN THE EARLY OPTIC NERVE OF XENOPUS LAEVIS. Jacob A. Sapiro*, Jerry Silver and Marcus Singer. Dept. Anat., Sch. Med., Case Western Reserve U., Cleveland, OH 44106.

In an effort to elucidate the mechanisms which may be responsible for establishing the point to point specificity of retino-tectal projections, eyes and optic stalks of Xenopus laevis embryos at stages 31 to 39 were examined with transmission and scanning electron microscopy. Throughout early development, optic axons grew along the vitreal margin of the retina and the dorsal rim of the optic fissure. In the stalk, optic axons were grouped in a compact bundle, which was always located ventrally. Growth cones were observed with both transmission and scanning electron microscopy. They appeared as large bulbous neurite processes containing numerous vesicles, mitochondria, and other organelles. The growth cones were located primarily in the ventral part of the early nerve, usually in association with the glia limitans. The glia limitans was formed by processes of ventral stalk neuroepithelial cells that enwrapped the fascicle. Older axons, from more ventral regions of the posterior pole of the early retina, occupied a more dorsal position in the nerve. Scanning electron microscopy showed that optic axons tended to maintain their positions relative to their neighbors. It is therefore likely that the constant ventral accumulation of growth cones displaces older axons dorsally, thereby creating retinotopic order in the dorsoventral axis of the early nerve. This spatio-temporal sequence of orderly fasciculation onto the early optic nerve may, in turn, play a role in the establishment of ordered synapses in the tectum.

106.15 **ANOMALOUS IPSILATERAL RETINOTECTAL RESPONSE, FOLLOWING THE SELECTIVE ABLATION OF ONE CLASS OF RETINAL GANGLION FIBER IN THE CONTRALATERAL TECTUM OF THE FROG,** **S. Glasser and S.C. Sharma. Dept. Opthal., N.Y. Med. Col., Valhalla, N.Y. 10595**

The rostral tectum of the frog receives input from both contralateral and ipsilateral retina.

Fibers from the contralateral retina project directly through the optic chiasm to the tectum, whereas ipsilateral retinotectal input is relayed first through the contralateral tectum (Keating and Gaze, 1970).

We previously reported plasticity in the contralateral frog retinotectal projection following a partial ablation of only one class of retinal ganglion fiber. Class 2 fibers found just beneath the pia respond with a sustained discharge when a small black spot is brought in and stopped within their excitatory receptive field (ERF). Small, superficial, mediolaterally oriented cautery lesions in the rostral tectum were found to eliminate class 2 fiber activity in a region directly caudal to the burn. Such lesions, however, spare deeper class 3 fibers, which respond with a brief burst when an object is moved into their ERF. Three weeks following the lesion, in the region previously devoid of class 2 activity, class 3 responses were found at both class 2 and class 3 loci. The ERF's of the aberrant, superficial class 3 terminals completely overlap those of the normal, deeper class 3 terminals (Glasser, Sharma and Ingle: ARVO, 1979).

We now describe ipsilateral visuotectal response following superficial cautery lesions in the contralateral tectum.

Ipsilateral visually driven units in rostral frog tectum are characterized as class 2 or class 3 using the same criteria as for contralateral units. Superficial cautery lesions selectively abolish class 2 ipsilateral response in the tectum contralateral to the burn. Such lesions, however, have no effect on the density or response properties of the deeper, class 3 ipsilateral fibers. The class 2 scotoma in the ipsilateral tectum corresponds to that found in the contralateral tectum.

Three weeks postlesion, class 3 ipsilateral responses exactly mirror class 3 activity in the operated tectum. In the region of ipsilateral class 2 scotoma, ipsilateral class 3 units are found at both ipsilateral class 2 and ipsilateral class 3 loci. The ERF's of the aberrant, superficial class 3 terminals completely overlap those of the normal, deeper class 3 terminals.

The implications of these findings will be discussed

106.16 GROWTH AND DIFFERENTIATION OF THE OPTIC TECTUM OF PETROMYZON MARINUS. K. Rubinson, M.C. Kennedy and H. Cain*. Dept. of Physiol. Biophys., New York Univ. Med. Ctr., New York, NY 10016 and Dept. of Biology, New York Univ., New York, NY 10003.

The visual system of the sea lamprey, Petromyzon marinus develops slowly over the larval and transformation periods which encompass approximately five years of the seven-eight year life span of the animal. We have previously reported the presence of retinotectal projections throughout this period (Kennedy and Rubinson, 1977) although retinal differentiation and function are not accomplished until the middle of transformation (Rubinson, et al., 1977). Histological study shows that the differentiation of the laminae of the optic tectum reaches its adult character early in transformation (stage II). However, Golgi impregnations reveal that the tectal cells of the early transformer exhibit dendritic patterns comparable to those of the larva.

Planimetric analysis of the tectum from 10μ epoxy sections reveals a progressive increase in tectal surface area from early larval through young adult specimens. This growth pattern parallels the growth of the retinal surface and of the whole brain. From measurements of total tectal tissue volume and from surface measurements, an averaged index of tectal thickness was derived. This index shows an abrupt increase between stages II and V of transformation. The cellular laminae primarily responsible for this increase are the stratum cellulare externum and stratum marginale which are the site of retinal efferent fibers. This superficial zone grows during transformation to occupy nearly three-fourths of the tectal thickness. Thus, the increase in tectal thickness is contemporaneous with dendritic differentiation in the superficial laminae of the tectum and with the functional maturation of the retina.

106.17 REAGGREGATION OF CHICK RETINAL OR TECTAL CELLS CULTURED IN INTRACEREBRALLY IMPLANTED CAPSULES. E. Hibbard and B.L. Ruskin*. Dept. of Biol., Penn State Univ., Univ. Park, PA 16802.

A technique which has been developed to provide a functional artificial pituitary in rats (Hymer et al., Endocr. Soc. 61st-meeting [#231] P. 130, 1979) has been adapted to allow long term culture of embryonic neural cells as implants in the brains of chicks. Dissociated cells of neural retina and/or tectum of 7 day chick embryos were encapsulated in hollow H5P10 dialysis fibers (Amicon Corp.) and were inserted into the neostriatum of newly hatched chicks. Survival of the hosts was excellent and there was no apparent behavioral impairment. After varying survival times up to one month, the capsules were removed, fixed, critical point dried, opened and gold-coated for SEM. Cells cultured by this method reaggregated rapidly, developed neural processes, underwent a high degree of morphological differentiation, and showed apparent selective neuron to glia associations. Different developmental patterns were noted between retinal and tectal reaggregates. Retinal cells tended to aggregate into large masses and their well-developed processes appeared to preferentially associate with flattened epithelial-like cells which we interpret to be Mueller cells. Tectal cells form small aggregates which became interconnected by single neurites or fascicles. These fascicles of nerve fibers increased in complexity in older cultures. This method provides several advantages over conventional culture systems. The technique is simple and reliable and it provides the reaggregating cells with a constant, nearly normal cell environment at constant temperature. The 10,000 M.W. cut off of the fiber precludes invasion of the culture by phagocytes while permitting nutrient and gaseous exchange with the vascular or cerebrospinal fluid compartments of the host. There is little chance of contamination provided the capsules are prepared and implanted under aseptic conditions. The cultures are self-maintaining and when removed from the host are easily handled because the capsule need not be opened until processing has been completed. All cells are fixed in situ, even those which do not adhere to the substrate. The system provides a better environment than either plate or rotating suspension cultures because it provides a stable substrate while at the same time allowing the culture to develop three-dimensionally.

106.18 OBSERVATIONS ON THE EFFECTS OF MONOCULAR AND BINOCULAR EYE REMOVAL ON THE DEVELOPMENT OF THE CHICK VISUAL SYSTEM. D.D.M. O'Leary and W.M. Cowan. Dept. of Anatomy and Neurobiology, Washington Univ. Sch. Med., St. Louis, MO. 63110.

The effects of monocular and binocular eye removal, before and after the stage at which the retina is known to be specified with respect to its projection upon the optic tectum (i.e. stage 12/13 of the Hamburger and Hamilton series) have been studied in a series of chick embryos which were subjected to intraocular or tectal injections of ^{3}H-proline shortly before hatching (stages 43-45). We have confirmed that following the removal of one eye before stage 12, the surviving retina develops a substantial projection to the ipsilateral diencephalon and midbrain; in some cases the "aberrant" ipsilateral retino-tectal projection appears to be almost as substantial as the projection to the contralateral tectum, and it clearly persists throughout embryonic development. When the optic cup was removed after stage 12 (usually at stages 15-17) an "aberrant" ipsilateral retinotectal projection was usually present, but this was invariably less substantial than in those cases in which the eye removal had been done before stage 12.

In order to determine whether the topographically ordered projections of the optic tectum upon other brainstem structures can develop normally in the absence of retinal input, bilateral eye removals were carried out both before and after stage 12. Following bilateral eye removal, before stage 12, more than 90% of the embryos showed a fusion of the two tectal lobes, so that the dome-shaped single tectum closely resembled that seen after early mesencephalic alar plate ablations. Comparable tectal fusions were not seen when the optic cup removals were carried out after stage 12. By injecting ^{3}H-proline into different parts of the optic tectum in chick embryos which had earlier bilateral eye removals, we have been able to show that the projection of the optic tectum upon the nucleus isthmi pars parvocellularis and on the nucleus semilunaris is organized in a manner essentially similar to that seen in normal animals. This observation argues strongly for the view that the topographic specification of the connections of the optic tectum is not determined by its retinal input.

107.1 DIFFERENT CHOLINERGIC SYNAPSES CONVERGING ONTO NEURONS IN APLYSIA PRODUCE THE SAME SYNAPTIC ACTION. Michael Segal* and John Koester. Div. of Neurobiol. & Behavior, Dept. of Physiology, College of Physicians & Surgeons, Columbia University, New York, N. Y. 10032

If a neuron receives synapses from two different cells that use the same transmitter, can one cell depolarize and the other hyperpolarize by virtue of activating different types of postsynaptic receptors? In other words, when a postsynaptic neuron concentrates receptors at synapses, does it concentrate one type of receptor to a particular transmitter at one synapse and a different type of receptor to the same transmitter at another synapse?

To approach this question we have investigated neurons in the abdominal ganglion of Aplysia californica that receive inputs from more than one cholinergic interneuron. Two of the interneurons (L10 and Int XIII) have been shown previously to be cholinergic. Using both biochemical and pharmacological tests we have shown that a third interneuron, L24 (Int XI), is also cholinergic. We have compared the sign of the connection to seven postsynaptic cells (L10, L11, LD_{HI}, $L9_C$, R15, RB, L7). Some of these connections were previously known, and others we have recently identified.

For any given cell, we found that different cholinergic inputs converging onto the cell all produce the same sign of synaptic action. This finding holds even for L7, a cell known to have both depolarizing (D) and hyperpolarizing (H) ACh receptors; all three interneurons produce conjoint (D-H) PSPs in L7. These data are consistent with the hypothesis that a single postsynaptic cell does not segregate one type of ACh receptor to one type of synapse and a different type to other synapses.

If generally true, this lack of segregation may provide insights into some of the organizational principles of nervous systems. If all cholinergic inputs to a particular cell produce excitation, then inhibitory inputs to that cell must use a different transmitter. In addition, if two cells use the same transmitter and influence a particular cell in different ways, one would expect that at least one of the connections will be polysynaptic, involving an interneuron with a different transmitter. Thus, a lack of segregation of postsynaptic receptors for a particular neurotransmitter may help to explain why a nervous system uses many neurotransmitters as well as explain a need for certain interneurons. Supported by NIH Grant NS 14385 and NIH Medical Scientist Training Grant GM 0737-04.

107.2 TWO RELAXATION COMPONENTS ASSOCIATED WITH THE ENDPLATE CURRENT DECAY AND WITH THE CARBAMYLCHOLINE-INDUCED CURRENTS FOLLOWING A VOLTAGE JUMP. D.A.Farquharson*(SPON:F. C.G.Hoskin).Dept.Biol.,Ill. Inst. Tech.,Chicago,IL.

Some insight into the functioning of the acetylcholine receptor(AChR),has been gained by applying the methodology of chemical relaxation to chemically excitable membranes. This has usually involved either observing the decay of the endplate current(EPC)or observing the relaxation of the agonist-induced currents following a voltage jump. For either kind of relaxation experiment, results have shown that some component of AChR function is voltage sensitive. The relaxations themselves have been described as single exponential. There are occasional observations of a second relaxation component(e.g.Magleby & Stevens,J. Physiol. 223:173-197,1972) Also a wide range of endplate treatments have been reported to change single component relaxations of the AChR into relaxations with 2 or more components. This evidence suggests that under certain conditions more than one molecular process can be revealed(or produced) in an AChR relaxation. I find thatin the eel electroplaque,at temperatures above 20°C,AChR relaxations usually can be described as having 2 exponential components. This result was obtained both in voltage jump experiments with carbamylcholine(carb)as the agonist and in experiments involving the decay of the neurally evoked EPC. The faster component rate constant increases with membrane positivity. The slower component is less sensitive to membrane voltage and its rate constant increases with negativity when measured in voltage jump experiments. For EPC decay experiments, the voltage-sensitivity of the slow component is less clear. Ca^{++} has a differential affect on the 2 components of relaxation described here. With Ca^{++} in the bathing medium the slow component rate constant declines with time in carb. No statistically significant,similar decline is observed for the fast component.Also,when Mg^{++} is substituted for Ca^{++},no decline in the slow component rate constant occurs. When Ca^{++} is increased from 2mM to 4mM, the fast component rate constant increases, but the slow component rate constant is unaffected. Ca^{++} also has a separate affect on the relative current amplitudes of the slow and fast components. (Research supported by ARO grant DAAG29-78-G-0090)

107.3 QUANTITATIVE ANALYSIS OF THE ALTERATION OF FAST EXCITATORY POSTSYNAPTIC CURRENT DECAY BY ATROPINE. Elizabeth A. Connor*, Steven M. Levy*, and Rodney L. Parsons. Depts. of Physiol. and Biophys. and Anat. and Neurobiol., Univ. of Vermont, Burlington, VT. 05405.

Atropine decreases the amplitude of the fast excitatory postsynaptic current (EPSC) recorded at sympathetic ganglia and splits the current decay into at least two components; one faster and one slower than control (MacDermott et al., J. Gen. Physiol. 75:29, 1980). We have quantitated the concentration and voltage dependence of this action of atropine. Experiments were done on B cells in the IX and X sympathetic ganglion of the bullfrog, Rana catesbeiana, maintained in a HEPES-buffered solution at 21-23°C. In 18 control cells, the EPSC rose to a peak value of -7.4±4.0 nA (m±S.D.) within ∿2ms then decayed with a single time constant of 5.0±0.7ms. The concentration dependent reduction of the EPSC size and alteration of the decay time course by atropine in cells voltage clamped to -50mV is summarized below:

Atropine Conc.	Peak EPSC	EPSC Decay τ_2	EPSC Decay τ_1	#of Cells
($\times 10^{-5}$M)	(nA)	(ms)	(ms)	
1.0	-6.8±2.6	3.3±0.8	17.0±11.1	10
2.5	-4.1±1.8	2.3±0.6	16.3± 6.2	7
5.0	-4.0±1.7	1.7±0.7	21.0± 2.7	8
7.5	-1.7±1.0	1.7±0.4	16.4± 4.8	8

At a given atropine concentration, hyperpolarization markedly increases, τ_1 with no consistant effect on τ_2. The current-voltage relationship in the range of -20 to -100mV is linear in both control and atropine-treated cells. The concentration and voltage dependent alteration in the EPSC could be described by the following sequential scheme of channel blockade:

$$nA + R \underset{\text{closed}}{\overset{K_d}{\rightleftharpoons}} AnR \underset{\alpha}{\overset{\beta}{\rightleftharpoons}} \underset{\text{open}}{AnR^*} + Q \underset{F}{\overset{G}{\rightleftharpoons}} \underset{\text{blocked}}{AnR^*\cdot Q}$$

For simplification we have assumed that only the open state conducts ions, and that channels open instantaneously at the peak of the EPSC. For each concentration of atropine, the two decay rates and the ratio of their initial amplitudes uniquely determine the reaction rates α, G, and F. Our analysis indicates that α remains constant with increasing atropine concentration [α(-50mV, 10μM)= 211 sec; α(-50mV, 75μM)=202 sec] whereas, the equilibrium blocking constant G/F appears to decline with increasing concentration [G/F (-50mV, 10μM)=70833/M; G/F(-50mV, 75μM)=30609/M]. At a given concentration G/F is exponentially dependent upon voltage, changing e-fold for each 49.7±8 mV, which implies that ∿50% of the voltage is applied between the external solution and the atropine binding site. The results of this kinetic analysis are consistent with the view that atropine binds in the synaptic channel, blocking the passage of the ions. Supported by NIH Grant NS 14552.

107.4 INFLUENCE OF CALCIUM ON LIGAND BINDING TO THE ION CHANNEL ASSOCIATED WITH THE NICOTINIC ACETYLCHOLINE RECEPTOR. Dennis B. McKay*, Gerald O. Carrier and Robert S. Aronstam. Department of Pharmacology, Medical College of Georgia, Augusta, GA 30912.

Several conformations of the nicotinic acetylcholine (ACh) ion channel complex of Torpedo membranes can be detected by monitoring the binding of radiolabeled probes to the ion channel. The binding of two ion channel probes, tritiated phencyclidine ([^{3}H]PCP) and perhydrohistrionicotoxin ([^{3}H]H_{12}-HTX) is increased several fold in the presence of nicotinic agonists. This increase can be lessened in a time- and concentration-dependent manner by preincubating the membranes with a receptor agonist. The influence of calcium and other divalent cations on the binding kinetics characteristic of resting, "stimulated" and "desensitized" forms of the complex was determined.

Calcium inhibited the specific binding of [^{3}H]PCP and [^{3}H]H_{12}-HTX to the resting ion channel with ED50 values of 11 and 10 mM, respectively. However, the corresponding values for inhibition of binding to the stimulated receptor-ion channel complex (measured in the presence of 10^{-6} M ACh) were reduced to 0.7 and 1 mM, respectively. This increased inhibition was not due to inhibition of ACh binding to the receptor since [^{3}H]ACh binding was not decreased by calcium (10^{-4}-10^{-1} M). The sensitivity of [^{3}H]PCP and [^{3}H]H_{12}-HTX binding to "desensitized" receptor-channel complexes (measured after preincubation of the membranes with 10^{-5} M ACh) was the same as that of the stimulated binding. The chloride salts of several Group IIA cations inhibited ion channel binding. In terms of their inhibition of either [^{3}H]PCP or [^{3}H]H_{12}-HTX to the stimulated ion channel, Ba > Ca > Mg ≥ Sr. However, no ion selectivity was apparent with binding to sites on the resting ion channel (i.e., in terms of their ability to inhibit ligand binding, Ba=Ca=Mg=Sr). Double reciprocal plots of [^{3}H]PCP ion channel binding measured in the presence of various concentrations of calcium indicated a competitive inhibitory interaction. Removal of intrinsic stores of membrane calcium through prolonged incubation with EGTA decreased the affinity of both [^{3}H]PCP and [^{3}H]H_{12}-HTX for the ion channel, as well as the ability of ACh to stimulate channel binding. The amount of the inhibition was related to the calcium content of the membranes. (Supported in part by BRS-2S07-RR-05365-19).

107.5 PHENOBARBITAL ANTAGONIZES PENTOBARBITAL-INDUCED REDUCTION IN LIFETIME OF ACETYLCHOLINE-ACTIVATED SODIUM CHANNELS IN APLYSIA. Ruth E. Wachtel and W. A. Wilson, Dept. of Pharmacology, Duke Univ. Medical Center and Epilepsy Center, V.A. Medical Center, Durham, N. C. 27705.

In Aplysia, both pentobarbital and phenobarbital depress sodium-dependent excitatory responses to short iontophoretic pulses of ACh and GABA. Peak responses to both transmitters are reduced 50% by 75μM pentobarbital or 125μM phenobarbital (Cote and Wilson, JPET, in press).

The average lifetime of ACh-activated sodium channels has been determined from current relaxations in response to voltage jumps. During steady state current responses to ACh, hyperpolarizing voltage clamp commands produce an increase in current that consists of two components. After subtraction of capacitive transients, the current first appears to increase instantaneously due to a change in driving force on the ions, then relaxes to a new steady state level. This relaxation occurs because the channels remain open longer at hyperpolarized potentials. According to theory, the time constant of this relaxation reflects the average lifetime of an open channel.

We have previously shown that pentobarbital shortens the average open time of ACh sodium channels in Aplysia. In control, the current relaxations are a single exponential, with a time constant of ∿40msec at 90mv. In the presence of pentobarbital, however, current relaxations show an initial fast component which becomes faster at higher drug concentrations. At 75μM pentobarbital, the time constant of this fast component is ∿5-10msec.

In contrast, phenobarbital does not alter current relaxations at concentrations as high as 1mM. After exposure to phenobarbital, concommitant application of pentobarbital is then ineffective in reducing channel lifetime. Phenobarbital thus appears to be an antagonist of pentobarbital depression of ACh sodium channel lifetime in Aplysia.

107.6 CHLORISONDAMINE BLOCKS CRUSTACEAN MUSCLE GLUTAMATE AND SYNAPTICALLY ACTIVATED CHANNELS. E. Marder, C. Lingle, and J. Eisen. Biology, Brandeis University, Waltham, MA. 02254.

The excitatory innervation of the striated gm6 muscles of the decapod foregut is probably mediated by glutamate (Glu). We have studied the effects of chlorisondamine(CHL), a presumed nicotinic ganglionic antagonist, on neuromuscular transmission to gm6 muscle fibers from the crab, Cancer borealis, and the lobster, Panulirus interruptus. CHL reduced the peak amplitudes of intracellularly recorded excitatory junctional potentials and iontophoretic Glu responses in a dose-dependent manner; 50% block was seen at $2x10^{-4}$M CHL. Additionally, the time courses of both potentials were prolonged by CHL. Similar effects were seen on iontophoretic quisqualate responses. When synaptic transmission was blocked by 20 mM Mn^{++} saline, the effectiveness of the CHL block was unchanged. Dose-response curves done with iontophoretic Glu application suggested that the CHL block was non-competi tive. CHL produced no effect on muscle membrane potential or resistance. The effects of CHL on focally recorded extracellular excitatory junctional currents(f.ejcs) were examined. CHL reduced the amplitude of the peak of the f.ejcs. The block was more effective at hyperpolarized levels; 10^{-4}M CHL reduced peak f.ejcs about 50% at -120mV and about 25% at -60mV. The rate of decay of the f.ejcs approached a single exponential. Time constants were calculated from regressions over about 80 to 15% of peak amplitude. The f.ejc decay at resting potential (-60mv to -70mv) and at 14°C was substantially shortened from about 7 ms in normal saline to about 2 ms in 10^{-4}M CHL. Frequently the f.ejc decay in CHL was best fit by a double exponential where the slow decay was about 15-30 ms. The slow component was more evident at hyperpolarized levels than at rest. The data support the idea that at least part of the effect of CHL is to block open channels activated by either Glu or the natural excitatory transmitter. In contrast to these results, Glu-elicited Cl^- and K^+ conductance increases that are found on cells of the stomatogastric ganglion were unaffected by 10^{-4}M CHL. In addition to its effects on a glutamatergic excitatory process, CHL blocks excitatory ACh responses and f.ejcs at two orders of magnitude lower concentrations on acetylcholine-sensitive foregut muscles. Other pharmacological agents including many ganglionic nicotinic antagonists block foregut cholinergic responses, but not gm6 f.ejcs or Glu responses. Thus, CHL may help us directly compare the characteristic of ACh-gated and glutamate-gated excitatory conductances on similar muscles. CL is a postdoctoral fellow of the Muscular Dystrophy Assoc. 107.7 USE OF ARSENAZO III AS A MONITOR FOR CHANGES OF INTRACELLULAR FREE Ca^{++} AND pH IN ARCHIDORIS NEURONS DURING IONTOPHORETIC AND BATH APPLICATIONS OF NEUROTRANSMITTERS. P.E. Hockberger and J.A. Connor. Dept. of Physiology and Biophysics, and the Neural & Behavioral Biology Program, Univ. of Illinois, Urbana, IL 61801.

Recently, the dye Arsenazo III has been used for simultaneous measurements of intracellular changes in free Ca^{++} and pH under voltage clamping conditions in giant molluscan neurons (Z. Ahmed and J.A. Connor, J.Gen.Physiol., 75:403, 1980). This technique is very sensitive, has a time resolution in the millisecond range, and exhibits a steady baseline which can be monitored for hours. We therefore decided to examine the somata of some of the identifiable neurons in Archidoris *monteryensis* for possible changes in intracellular Ca^{++} and pH in the presence of particular neurotransmitters: acetylcholine (ACh), dopamine (DA), and serotonin (5-HT). In the course of these studies we also watched for changes induced by spontaneous synaptic activity.

Our results can be summarized as follows: (1) iontophoretic responses to DA and ACh which resulted in depolarization of the neuron did not yield a detectable change of either free Ca^{++} nor pH. No change was seen during or for many seconds after transmitter application even in high Ca (40mM) saline and at desensitizing levels of transmitter. (2) Spontaneous synaptic potentials exhibiting a wide variety of shapes were examined in many neurons. Again no correlation was found between the synaptic events and intracellular free Ca^{++} and pH levels. (3) Bath application of micromolar amounts of 5-HT, DA, or ACh did, however, result in an intracellular pH decrease in specific cells, although a corresponding change in free Ca^{++} has not been convincingly demonstrated. This pH decrease required exposure times in excess of two minutes, and it progressed throughout the exposure period (10-15 minutes). The response was usually reversible, although this required wash-out times greater than 20 min.

One possible source of this pH change may be the degradation of induced cyclic nucleotides, since bath applied 5-HT and DA have been shown to increase cyclic AMP levels in Aplysia ganglia (H. Cedar and J.H. Schwartz, J.Gen.Physiol., 60:570, 1972). This possibility is supported by two additional lines of evidence. We have injected cyclic AMP intracellularly and applied bath perfusion of 8-parachlorophenylthio-cyclic AMP (10^{-4}M) to our cells and observed a pH decrease using the dye technique. Both procedures resulted in larger and more rapid decreases than those evoked by the transmitters. Again these responses were reversible, with the injected response returning to baseline more quickly (i.e., within one or two minutes after termination of a 5 minute injection).

107.8 DISSOCIATION OF EXTRACELLULAR EPSP AND POPULATION SPIKE LONG TERM POTENTIATION IN THE RAT DENTATE GYRUS. R.C. Wilson, W. B. Levy and O. Steward. Depts. of Physiology and Neurological Surgery, Univ. of VA Sch. of Med., Charlottesville, VA 22908

A dramatic example of synaptic potentiation has been noted in the dentate gyrus of the hippocampal formation (Bliss, T.V.P. & Lømo, T., J. Physiol., 232: 331, 1973). Following conditioning stimulation of the dentate's perforant path input with several short (20 msec) bursts of high frequency (400 Hz) pulses, test stimuli generate an increased excitatory synaptic potential recorded extracellularly which is accompanied by a large increase in dentate granule cell discharge as evidenced by the population spike. The increased responsiveness persists for hours and in some cases days, hence its designation as long term potentiation (LTP). Previous investigators have, in certain instances, observed a disjunction in the occurrence of synaptic and population spike LTP. Since the results of synaptic processing in the dentate can only be expressed in terms of granule cell discharge, such a dissociation of synaptic change and population spike change might be of significance to dentate function as well as providing information concerning LTP mechanisms. We therefore analyzed the relationship between the extracellular population EPSP and the accompanying population spike before and after induction of LTP.

This relationship was illustrated by plotting population spike slope as a function of the slope of the EPSP which evoked it. Prior to potentiation, successive increments in the EPSP produced greater than linear increases in the population spike. Following LTP induction this relationship remained an increasing non-linear function but the rate of population spike increase over any range of EPSP values was greater than before potentiation. The net effect of this change was that an EPSP of a given size evoked a larger population spike following conditioning than a comparable EPSP did before. This result suggests that two processes may be involved in LTP; an increased synaptic drive and a separate factor or process which results in an additional increase in the population spike. Such factors as alterations in granule cell threshold or changes in inhibitory tone are considered.

107.9 A PICROTOXIN-RESISTANT HYPERPOLARIZING RESPONSE IS ELICITED BY ORTHODROMIC STIMULATION OF HIPPOCAMPAL NEURONS. R. H. THALMANN AND G.F. AYALA, Departments of Cell Biology and Neurology, and the Program in Neuroscience, Baylor Coll. Med., Houston, TX 77030.

When orthodromic pathways of the rat hippocampal slice were stimulated, a two-component hyperpolarizing response often followed the EPSP. The second component, or 'late hyperpolarizing response' typically became evident between 40-140mSec following the onset of the first hyperpolarizing component, the 'early IPSP', and was usually detectable for an additional 150-1,000mSec. The late hyperpolarizing response was accompanied by an increased conductance, and its reversal potential was negative to that of the 'early IPSP'. We have observed this response in CA1 and CA3 neurones following stimulation of Schaffer collaterals and mossy fibers, respectively; and in granule neurons of the dentate gyrus in response to stimulation of a) the perforant pathway, b) the molecular layer of the dentate g., and occasionally, c) in response to stimulation of mixed orthodromic and antidromic circuits in CA3. Although more intense stimulation increased the amplitude and duration of the late hyperpolarization, an action potential (AP) was not a necessary antecedent; the response occurred when the EPSP was below the threshold for elicitation of AP, and has been observed in granule neurons when Na-dependent AP were blocked by intracellular iontophoresis of a local anesthetic. We have not been able to establish whether the late hyperpolarization can be elicited in the complete absence of an EPSP since each of our attempts to elicit a pure recurrent IPSP has thus far elicited a small 'EPSP' in the initial 2-7mSec following the stimulus. Therefore this response may or may not correspond to one of similar appearance which follows an apparently pure recurrent IPSP in CA1 (Dingledine, 1980). It probably is equivalent to Fujita's (1979) 'dendritic' IPSP of CA1-CA3 neurons. Picrotoxin (PX) was applied either by pressure injection of $5X10^{-4}M$ PX near the observed neuron through a 10μ pipette tip, or by perfusion of $2X10^{-5}M$ PX. In each case the 'early IPSP' was reduced or blocked, but the late hyperpolarization was spared and often increased in duration. Intracellular injection of Cl failed to reverse the late hyperpolarization. In contrast, when K concentration in the perfusion medium was increased from 3.5 to 10.5mM (N=2 granule neurons), the reversal potential of the response became less negative. Thus far, then, neither Cl injection, nor the prelimary manipulations of K have been consistent with the existence of a major Cl component in the conductance increase of the late hyperpolarization. In addition, since it is thought that PX may act at or near a Cl ionophore, the failure of PX to block the response is also suggestive of an ionic basis other than Cl. Finally, AP are inhibited during the late hyperpolarization, even when PX has blocked the early IPSP which may overlap it. Supported by USPHS grants RR0425 and NS11535

107.11 MODULATION OF RHYTHMIC ELECTRICAL ACTIVITY IN AN ANTERIOR PITUITARY CELL LINE. M. Adler, N. Busis, H. Higashida*, S. Sabol*, A. Rotter*, and M. Nirenberg. Lab. of Biochemical Genetics, Natl. Heart, Lung and Blood Institute, NIH, Bethesda, MD 20205.

The electrophysiological properties of the clonal mouse anterior pituitary cell line AtT-20/D16-16, known to synthesize, store, and secrete ACTH and β-endorphin were studied by intracellular recording techniques at 37°C. Cells grown in Dulbecco's Modified Eagle's Medium and 5% fetal bovine serum had low resting potentials (-33 ± 2 mV, n=24). In cells held at -70 to -100 mV, depolarizing pulses elicited one or two brief spikes followed by a slower depolarization lasting 6-30 sec. The early spike had a threshold of ∿ -50 mV, varied with external $[Na^+]$ and was blocked by 1 μM tetrodotoxin (TTX). The slow component had a threshold of ∿ -30 mV, varied with external $[Ca^{2+}]$, and was blocked by the Ca^{2+} antagonists Ni^{2+}, Co^{2+}, and La^{3+}. A small proportion (13%) of the cells had irregularly occurring spontaneous depolarizations that resembled the evoked Ca^{2+} action potential. The voltage-sensitive Ca^{2+} permeability of AtT-20 cells was demonstrated also by $^{45}Ca^{2+}$ flux measurements. Depolarization of cells by 80 mM K^+ ions resulted in a 3.5-fold increase in cellular Ca^{2+} levels in 15 sec. Growth of the cells in medium supplemented with 1 mM dibutyryl-cyclic AMP for 9-12 days resulted in: 1) a 20 mV increase in resting potential; 2) an increase in rate-of-rise and overshoot of the Na^+ action potential; 3) an increase in rate-of-rise and shortening in the duration of the Ca^{2+} action potential; and 4) induction of rhythmic spontaneous action potentials in over 90% of the cells. The spontaneous responses were very regular and usually persisted for the duration of the impalement. A single spontaneous event consisted of several brief Na^+ spikes superimposed on the rising phase of a 50-200 msec Ca^{2+} spike that terminated in a 10-15 mV hyperpolarization. The frequency of events was sensitive to membrane potential, varying from 2 Hz at -50 mV to 8 Hz at -25 mV. Spontaneous activity was absent at potentials negative to -60 mV and was reduced to subthreshold oscillations at potentials positive to -15 mV. A similar rhythmic pattern could be evoked by long depolarizing pulses from cells held at -70 to -100 mV. Spontaneous responses generally persisted in the presence of TTX, although at a lower frequency, but disappeared after addition of 5-10 mM Co^{2+}. Brief focal application of norepinephrine (10 μM) by pressure ejection from micropipettes broadened spontaneous action potentials and induced spontaneous activity in quiescent cells. Since extracellular Ca^{2+} is required for the depolarization-induced release of ACTH and β-endorphin from these cells, changes in rhythmic Ca^{2+} influx may be important in modulating secretory activity.

107.10 DENDRODENDRITIC INHIBITION AND THE ACTIONS OF PUTATIVE CENTRIFUGAL TRANSMITTERS IN THE OLFACTORY BULB. C.E. Jahr and R.A. Nicoll, Depts. of Pharmacology and Physiology, UCSF, San Francisco, CA 94143.

Dendrodendritic reciprocal synapses have been demonstrated anatomically between dendrites of mitral cells (olfactory bulb relay neurons) and the gemmules of dendrites of the inhibitory interneurons, granule cells. Recent evidence obtained with intracellular recording indicates that synaptic inhibition of mitral cells is largely dependent on activation of this reciprocal pair of synapses (C.E. Jahr and R.A. Nicoll, Science 207: 1473, 1980). Mitral cell action potentials, whether spontaneous or evoked by injection of depolarizing current through the recording electrode, are followed by all-or-none bicuculline-sensitive chloride-dependent IPSPs.

Centrifugal fibers constitute an additional component of the reciprocal synapse since many of these fibers directly terminate onto the dendritic gemmules of granule cells. Mitral cells do not receive direct input from centrifugal fibers (J.L. Price and T.P.S. Powell, J. Cell Sci. 7:157, 1970). This centrifugal input can, therefore, only modify mitral cell excitability indirectly. We have examined the effects of norepinephrine (NE) and glutamate, two putative centrifugal transmitters, on mitral cell excitability. NE (10-50 μM) markedly decreases the size of the mitral cell IPSP. This decrease is due to an action on granule cells since NE has little effect on mitral cell V_m, R_m or Ca^{2+} spikes. Furthermore, the iontophoretic response to GABA was unaltered by NE. As a result of the IPSP attenuation, the frequency of spontaneous firing of mitral cells, which is governed in part by the size of the obligatory IPSP, increases. Thus, although the occurrence of the IPSP that follows individual spikes is all-or-none, its size can be altered in a graded manner by NE. Conversely, glutamate blocks spontaneous firing by hyperpolarizing mitral cells. Since Co^{2+} converts this response to a depolarization, we presume that glutamate is acting indirectly by depolarizing granule cells and releasing GABA. In summary, both NE and glutamate alter mitral cell excitability primarily by indirect actions; NE blocks GABA release from granule cells whereas glutamate induces GABA release. The granule cell, then, is the final common pathway on which the centrifugal fibers and their transmitter candidates exert presynaptic control and thereby modulate the flow of information through the olfactory bulb.

108.1 THE INTERACTION OF THE INSECTICIDE TETRAMETHRIN WITH THE NERVE MEMBRANE SODIUM CHANNEL. Albert E. Lund* and Toshio Narahashi. Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

We recently found that pyrethroid insecticide, tetramethrin, modifies a fraction of the sodium channels in crayfish giant axons in such a way as to drastically alter the channel gating kinetics. The modified channels activate with a time course of several hundred milliseconds and inactivate with a time course of several seconds. We now propose a kinetic scheme for the interaction of tetramethrin with the sodium channel. Crayfish and squid giant axons were internally perfused and bathed in K^+-free media at 10° C. Cs^+ and tetramethylammonium were substituted for K^+ in internal and external media, respectively. Internal application of 1-200 µM tetramethrin to the squid axons had little effect on the rising phase of the sodium current but dramatically slowed the falling phase and caused a large tail current to flow following repolarization, indicating that a second, persistent open state was produced by the insecticide. The falling phase of the sodium current and the decay of the tail current were second order. The time constants for the fast phase of inactivation and the tail current in the poisoned axon were identical to those of the normal inactivation and the tail current suggesting that only some of the channels were modified. The time course of the arrival of channels in this modified open state is clearly second order having a quickly developing phase with a time constant of about 8 msec and a slowly developing one with a time constant of about 80-100 msec. Thus there appears to be at lease two kinetic steps or pathways which lead to the modified open state of channels. It appears that some channels are modified in the resting state and then open and close in response to changes in membrane potential while others are modified only after they have been opened by the normal process. This second modification pathway is necessarily fast since it must compete for the normal state with inactivation. This model predicts that any treatment which interferes with the h process should potentiate the tetramethrin modification of channels. This has been shown to be the case: following pretreatment with pronase or N-bromoacetamide, the dose-response relation for the tail current amplitude was shifted in the direction of low dose and the maximum response was more than doubled. Supported by NIH grant NS 14143.

108.2 GENETIC ALTERATION OF TTX SENSITIVITY AND NERVE REFRACTORY PERIOD IN A MUTANT OF DROSOPHILA MELANOGASTER. C.-F. Wu, B. Ganetzky* and R. W. Joyner* (SPON: J. L. Denburg). Dept. of Zoology and Physiology, Univ. of Iowa, Iowa City, IA 52242 and Lab. of Genetics, Univ. of Wisconsin, Madison, WI 53706.

Single-gene mutations that disrupt axonal conduction provide one means to study the components and mechanisms that underlie membrane excitation. The recessive mutant nap^{ts} (no action potential, temperature-sensitive) is rapidly paralyzed at high temperatures (≥ 34°C) and recovers rapidly when temperature is lowered. It has been demonstrated in the larval preparation that nap^{ts} blocks the sodium action potential in nerves at high temperatures but synaptic transmission or the calcium action potential of muscle are unimpaired (Wu et al., PNAS 75, 4047, 1978). We have examined the tetrodotoxin (TTX) sensitivity of the nerve action potential in nap^{ts} and in normal individuals. The excitatory junction potential was recorded from larval muscle at different doses of TTX as a means of monitoring the activity of the motor axon at 23°C, a temperature at which nap^{ts} individuals behave normally. The concentration of TTX required to block axonal conduction is 9.8 ± 4.4 nM ($\bar{X}$ ± S.D.) in nap^{ts} and 40.3 ± 11.1 nM in normal larvae. This increase in TTX sensitivity is not restricted to the motor axon because similar results were obtained by monitoring the compound action potentials of larval segmental nerves.

A possible alteration in the density and/or kinetics of ionic channels in nap^{ts} is also suggested by an increased refractory period of the compound action potential. Twin pulses were used to stimulate the segmental nerve at one end and a suction electrode was used to record propagated responses. We defined $\tau_{\frac{1}{2}}$ as the interval between stimuli needed to obtain a second response with amplitude 50% of the first. At every relative stimulus strength, the mutant requires a longer interval for recovery than does the control. The minimum $\tau_{\frac{1}{2}}$ is about 4 msec in control larvae but is 10 msec in the mutant.

Computer simulations of active conduction in a Hodgkin-Huxley model axon of the size found in Drosophila showed that the observed increase in refractory period and the conduction block at high temperatures can be best accounted for by a decrease in Na conductance. Alteration of either K or leakage conductance can not satisfactorily explain the observed differences.

The above results are consistent with the idea that nap^{ts} alters the function and/or density of Na channels.

108.3 INTRACELLULAR RECORDING FROM VERTEBRATE MYELINATED AXONS: MECHANISM OF THE DEPOLARIZING AFTERPOTENTIAL. Ellen F. Barrett and John N. Barrett. Dept. Physiology and Biophysics, Univ. of Miami Med. Sch., Miami, FLA. 33101

Action potentials and afterpotentials were recorded intracellularly from peripheral myelinated axons (mainly motor) of grass frogs and lizards. Axons selected for study had resting potentials of at least -60 mV, and action potentials with peak amplitudes of at least 60 mV. All axons showed a prominent depolarizing afterpotential which decayed with a time constant of 50-150 msec. The peak amplitude of the depolarizing afterpotential was voltage-sensitive, increasing to up to 20 mV in axons more hyperpolarized than -80 mV, and virtually disappearing (but not reversing) in axons more depolarized than -55 mV. The amplitude of the depolarizing afterpotential was not affected by substituting a divalent calcium antagonist (2-10 mM nickel, cobalt or manganese) for bath calcium. The depolarizing afterpotential persisted during and after exposure to zero chloride (sulfate substituted) solutions. Reduction of bath sodium (to one-third normal, tetramethylammonium substituted) or addition of 1-10 uM tetrodotoxin decreased the amplitudes of both the action potential and the depolarizing afterpotential. The amplitude of the depolarizing afterpotential did not vary with bath potassium (range 0 - 7.5 mM), provided that the membrane potential was held constant, suggesting that the depolarizing afterpotential is not due to extracellular potassium accumulation. The time course of the depolarizing afterpotential was not slowed by reducing bath temperature from 20 to 10° C. The passive electrical response to subthreshold depolarizing and hyperpolarizing current pulses shows a prominent slow component kinetically similar to the depolarizing afterpotential. These results suggest that the depolarizing afterpotential is a passive capacitative discharge of the myelinated axon. We suggest that this heretofore unreported, long time constant current pathway results from discharge of the internodal membrane capacitance through an approximately 20 megohm resistance under or through the myelin sheath. (The voltage-sensitivity of the depolarizing afterpotential probably reflects the voltage-sensitivity of the nodal input conductance.)

Frog peripheral myelinated axons have a prolonged post-activation superexcitable period whose time course resembles that of the depolarizing afterpotential (see Raymond, J. Physiol. 290: 273, 1979). We suggest that the depolarizing afterpotential produces this superexcitability. Supported by NIH grants NS-12404 and NS-12207.

108.4 DEPRESSION OF EXCITABILITY FOLLOWING ACTIVITY SHOWS A WIDE RANGE IN FROG SCIATIC AXONS. Stephen A. Raymond and David A. Cohen*. Research Laboratory of Electronics, MIT, Cambridge, Massachusetts 02139

Depression of excitability follows impulse activity in peripheral nerve fibers, becoming quite pronounced after long tetani or high frequency bursts (Raymond, J. Physiol. 290:273-303,1979). Depression governs the periodicity of intermittent responsiveness observed in frog sciatic nerve fibers given long, regular trains of near threshold stimuli, and is implicated in the strongly periodic bursts associated with paresthesia recorded from single units in human median and ulnar nerves (Torebjörk, H.E. et. al. Acta Physiol. Scand. 105:518-520,1979)

Single fibers teased from frog sciatic nerve were recorded using flexible plastic suction electrodes. Conditioning trains were produced in the whole nerve by current pulses delivered 7 cm from the recording electrodes, and the threshold of the individual fibers was tracked by a threshold hunter.

Fibers depress to very different degrees. Some axons show less than a 5% change in threshold diminishing to control levels within two minutes after a burst of 20 impulses/sec fiven for one minute. Other fibers are so "depressible" that their threshold is raised dramatically by single pulses (200% following short bursts). Depressibility correlates with rapidity of recovery from depression, ie following a given level of activity axons that showed higher maximum thresholds also showed faster recovery to the control level.

Depression is completely inhibited by Ouabain, and is quite temperature sensitive. The process involved in depression and recovery is unknown in detail, but measures of threshold appear to provide an indication of the rate of metabolic ion pumping as it is altered by impulse conduction. Any one fiber shows consistent levels of depressibility over several days, and differences between fibers are much greater than the differences in conduction velocity or other parameters used to characterize peripheral nerve fibers.

These differences between fibers seem to reflect a wide range of pumping capability in axons of the same nerve.

108.5 FLUORESCENT DERIVATIVES AND A PHOTOACTIVATED FLUORESCENT DERIVATIVE OF TETRODOTOXIN TO LOCATE THE FUNCTIONAL SITES OF THE SODIUM CHANNEL OF RAT AXONAL MEMBRANES. Kimon J. Angelides* (SPON: P.E. Braun). Department of Biochemistry, McGill University, McIntyre Med. Sci. Bldg., 3655, Drummond Street, Montreal, Quebec CANADA, H3G 1Y6.

The permeability of excitable nerve cell membranes to specific ions is controlled by intrinsic membrane proteins which provide a channel through which these ions can pass. Over the years, considerable work has been directed towards a biochemical and electrophysiological description of their mode of action and regulation. The neurotoxin tetrodotoxin (TTX) has been used with considerable success to probe the extracellular face of the membrane and identify the sodium selectivity filter. The toxin eliminates the sodium current (the transient flow of Na^+ ions) while not affecting the gating current. We have synthesized three fluorescent and one photoactivated fluorescent derivative of tetrodotoxin. The three fluorescent compounds anthranilamide-glycine hydrazide (AG), N-methylanthranilamide-glycine hydrazide (NMAG) and anthraniloyl hydrazine (AH) were coupled to a ketone function at C_6 of TTX to form stable fluorescent hydrazones of TTX. Competitive binding with [^{3}H]-TTX for the TTX receptor on rat axolemma vesicles or from binding isotherms obtained by the fluorescence enhancement or polarization indicate a K_D=6.2 nM for AG-TTX; K_D=7.1 nM for NMAG-TTX; and a K_D=6.09 nM for AH-TTX, only about 5 times less active than TTX itself. The photoactivated fluorescent derivative of TTX, 2-azido-benzoyl-glycine hydrazone-TTX binds to the fast sodium channel of rat axolemma vesicles only 7 times less tightly than tetrodotoxin (K_D=16.8 nM) in the absence of light. Upon photolysis the association becomes irreversible and gives rise to a large fluorescent signal. These site-specific probes have been used to investigate the conformational dynamics of the toxin site, characterized by nanosecond lifetime and time-resolved anisotropy measurements as well as to locate the functional sites of the sodium channel by Förster singlet-singlet energy transfer. Supported by a grant from the Research Corporation.

108.6 SODIUM CURRENTS IN RABBIT SKELETAL MUSCLE FIBERS. G. E. Kirsch* and C. H. Wu. Dept. of Pharmacology, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Our progress in understanding the pathogenesis of membrane electrical events in human myotonic disorders has been frustratingly slow. Despite the availability of various voltage clamp techniques, it has not been easy to obtain adequate voltage clamp results in mammalian muscles. This is mainly because of the difficulties in dissecting single fibers and their relatively small sizes. Recent reports indicate the feasibility of obtaining satisfactory spatial voltage control and adequate temporal resolution of fast sodium kinetics in mammalian muscle fibers (Pappone, Biophys. J. 1977; Duval and Léoty, J. Physiol. 1978; DeCoursey and Bryant, Biophys. J. 1979). We now report our observations of the sodium currents in rabbit skeletal muscle fibers using the vaseline-gap technique of Hille and Campbell (J. Gen. Physiol. 1976).

Single fibers were dissected from the extensor digitorum longus muscle in the relaxing solution and the ends cut in 160 mM CsF. With the holding potential set at -90 mV, the peak sodium conductance reached 140 mS/cm^2. An occasional secondary current peak, probably originating from the currents in transverse tubule system, could be eliminated by maintaining the fiber at temperature below 16°C or applying 2 nM tetrodotoxin or bathing the fiber in the external solution containing 50% Na^+. At 14°C, half of the channel population was inactivated by conditioning depolarization to -80 mV (±7 mV S.D.). The time constant of fast sodium inactivation was 1.4-2.0 ms at E_m between 20-110 mV (5.5°C).

We have examined the effects of two aromatic monocarboxylic acids which are capable of inducing myotonia in mammalian muscles. 9-Anthroic acid at high concentration (0.1 mM) had no effects on the fast sodium kinetics other than shifting the current-voltage curve by 20 mV toward depolarization, probably resulting from changes in the surface potential. 2,4-Dichlorophenoxyacetic acid (1 mM) blocked the sodium conductance by 19%. We conclude that the repetitive discharges induced by these two drugs are not due to retardation of the fast sodium inactivation.

108.7 KINETICS OF Ca^{2+} CURRENT IN TWITCH MUSCLE FIBERS OF THE FROG. J.A. Sánchez and E. Stefani. Dept. Physiology and Biophysics, CIEA-IPN, A.P. 14-740, México 14, D.F.

Calcium current (I_{Ca}) kinetics in sartorius muscle of Rana temporaria was studied using the three microelectrode voltage clamp technique. Signals were digitalized and stored for analysis in a microcomputing system. Linear capacity and leakage currents were substracted. The saline contained (mM): 117 tetraethylammonium (TEA), 2.5 K^+, 10 Ca^{2+}, 350 sucrose and methanesulphonate as the anion. The temperature was 20°C. The membrane potential was clamped to -90 mV (E_h) and pulses to different potentials (E) were delivered. Remaining outward K^+ currents were blocked with 5 mM 3-4 diaminopyridine. In chloride saline, Ca currents could be recorded, but they were modified during depolarizing pulses by outward Cl^- currents. For a pulse to -10 mV, I_{Ca} decayed following a single exponential with a time constant of 540 msec. The time constant of decay of the amplitude of tail currents recorded at the end of pulses with different durations had a similar value of 590 msec. This indicates that I_{Ca} inactivates, since E_h=E_k. The steady state inactivation curve (9 sec. prepulses) was fitted to $h_\infty=|1+\exp(E-V_h)/k|^{-1}$ with k=5.9 mV and V_h=-31.7 mV.

I_{Ca} recorded with different pulse amplitudes were analyzed according to the Hodgkin & Huxley model. The records were fitted to the function: $A|1-\exp(-t/\tau_m)|^n|h_\infty-(h_\infty-h_o)\exp(-t/\tau_h)|$, where A is an amplitude factor. The best fitting for n was 3, therefore the values of A, τ_m and τ_h were computed. A, at potentials of -10 to +20 mV, and tail current amplitude had a linear relation with the voltage and subsequently m_∞ was calculated as a function of membrane potential from the expression: $A=\bar{g}_{Ca}(E-E_{Ca})m_\infty^3$. With the values of τ_m, τ_h, h_∞ and m_∞ the rate constants α_m, β_m, α_h and β_h were calculated for each potential value (E), and were fitted to the expressions: $\alpha_m(seg^{-1})=\bar{\alpha}_m(E-\bar{V}_m)/(1-\exp(-(E-\bar{V}_m)/V_{\alpha m}))$, $\beta_m(seg^{-1})=\bar{\beta}_m\exp(-(E-\bar{V}_m)/V_{\beta m})$, $\alpha_h(seg^{-1})=\alpha_h\exp(-(E-\bar{V}_h)/V_{\alpha h})$, $\beta_h(seg^{-})=\bar{\beta}_h/(1+\exp(-(E-\bar{V}_h)/V_{\beta h}))$. The values of the constants were: $\bar{\alpha}_m$=.29 sec^{-1} mV^{-1}, $\bar{V}_m$=-40.4 mV, $V_{\alpha m}$=1.4 mV, $\bar{\alpha}_h$=.34 sec^{-1}, $\bar{V}_h$=-29.2mV, $V_{\alpha h}$=13.3 mV, $\bar{\beta}_m$=2.2 sec^{-1}, $V_{\beta m}$=19.0 mV, $\bar{\beta}_h$=1.36 sec^{-1}, $V_{\beta h}$=3.2 mV. The calcium spike reconstructed with these values agreed reasonably well with the experimental ones.

108.8 LOSS OF MYOTONIA FOLLOWING DENERVATION OF GASTROCNEMIUS FIBERS IN THE MYOTONIC GOAT. K. Owenburg* and S.H.Bryant. Dept. of Pharmacol. & Cell Biophysics., Univ. of Cincinnati Col of Medicine, Cincinnati, OH 45267.

In the hereditary myotonia of goats Brown and Harvey (Brain 62:341,1939) reported that skeletal muscles continued to show myotonia through the eighth day following surgical denervation. Recently it has been reported by several laboratories that the abnormal repetitive firing of myotonia induced by chemical agents does not occur in chronically denervated fibers. We have re-examined the effect of denervation on myotonic goat fibers using microelectrode stimulating and recording from gastrocnemius fibers in vitro. We transected the tibial branch of the sciatic nerve in the thigh on one leg and after periods of 10, 14, 21 and 28 days the gastrocnemius muscle from both legs were removed, bundles of a few hundred fibers were cleaned from each biopsy and placed in normal goat ringer at 37°C. Electromyographic EMG recordings were also made from the exposed control and denervated muscles during biopsy. Excitability was monitored by passing constant current pulses into a fiber through one electrode while observing threshold for the action potential and ability to fire repetitively to super threshold pulses. Confirming Brown and Harvey we observed little change in the EMG and the abnormal excitability of myotonic fibers at 10 days of denervation. From 14 to 28 days of denervation marked changes occured in both myotonic and normal fiber excitability. Current threshold increased in myotonic fibers with decreasing number of action potentials in a repetitive train and absence of post stimulus discharge or myotonic EMG by the end of the period. In fibers from normal goats after 14 days, anthracene-9-carboxylic acid was unable to induce myotonic behavior, and myotonic and normal fibers had TTX resistant action potentials. Fibrillation was present in myotonic and normal denervated fibers after 14 days. In the myotonic fibers at 14 days fibrillation was present with diminished myotonia and could be distinguished from it. By 28 days only fibrillation activity was seen suggesting that fibrillation is not a consequent of increased excitability. By the end of 28 days of denervation, resting chloride conductance is low and potassium conductance is high for both myotonic and normal fibers. Their excitabilities have diminished to similar levels. Thus, these data suggest that loss of myotonia in congenitally myotonic fibers and the resistance of normal fibers to induction of myotonia by drugs after chronic denervation results from alterations in voltage dependent sodium and potassium conductances.

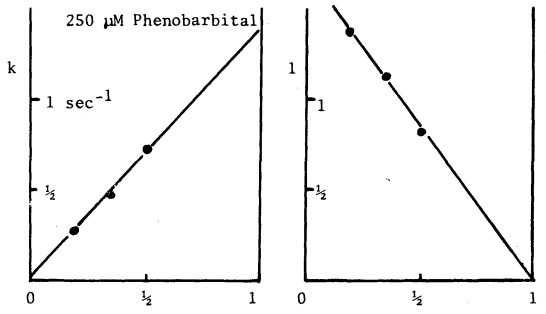
108.9 ABNORMAL ELECTRICAL PROPERTIES OF MYOTONIC MUSCULAR DYSTROPHY IN CULTURE OBSERVED WITH VOLTAGE CLAMP. Michael Merickel, Richard Gray, Priscilla Chauvin* and Stanley Appel. Dept. of Neurology, Baylor College of Medicine, Houston, Texas 77030.

We have approached the study of MyD by utilizing electrophysiological techniques to investigate the membrane properties of muscle fibers from normal and MyD patient biopsies grown in a primary tissue culture system. We have previously demonstrated that MyD myotubes in culture have abnormalities in some of their basic electrical properties compared to control myotubes. These include: 1) Decreased resting potential of approx. 10 mV; 2) Hyperexcitability, manifested as an increased tendency to fire multiple action potential (A.P.'s) in response to a single stimulus (i.e., myotonia); and 3) Decreased A.P. afterhyperpolarization (Merickel, M., Gray, R., Chauvin, P. and Appel, S., (1979), Soc. for Neuroscience Abstracts, 5, 378).

Further comparison of control and MyD myotube firing characteristics and membrane currents with voltage clamp has provided a clearer picture of the membrane electrical events underlying myotonia, the hallmark of MyD. The A.P. of at least 50% of the MyD myotubes examined exhibited a depolarizing afterpotential (DAP) in contrast to the typically hyperpolarizing afterpotential of control myotubes. DAP's have been observed in a number of invertebrate and vertebrate nerve and muscle systems which exhibit repetitive firing. The occurrence of DAP's in MyD myotubes accounts for their decreased average A.P. afterhyperpolarization amplitude. The voltage clamp technique is required to examine the ionic basis of the repetitive firing, DAP's and other electrical abnormalities observed in MyD myotubes. Comparison of the slow membrane currents of control and MyD myotubes with the single electrode voltage clamp has demonstrated that the outward-going current of MyD myotubes, particularly in MyD myotubes exhibiting DAP's, activates much more slowly than in control myotubes. The steady-state outward-going current, however, has been found to be only slightly decreased in MyD myotubes. The slower activation time course of the MyD outward-going current is believed to underlie their DAP's and repetitive firing behavior. Experiments are in progress to identify and examine the shorter time course currents responsible for the delayed activation. These experiments demonstrate that the observed electrophysiological abnormalities in MyD myotubes can be detected and studied with voltage clamp and may provide important insight into the ionic basis of the MyD abnormalities in tissue culture. Support for this work is acknowledged from the Muscular Dystrophy Association, Jerry Lewis Neuromuscular Disease Research Center and the Kleberg Foundation.

108.10 APPLICATION OF THE MODULATED RECEPTOR HYPOTHESIS TO ANTICONVULSANT DRUG ACTIONS. K. R. Courtney . Palo Alto Medical Research Foundation, Palo Alto, CA 94301

Anticonvulsant drugs such as phenytoin and phenobarbital have been shown to block nerve sodium channels in a frequency-dependent manner. Such a drug action, which leads to greater blocking efficacy at higher nerve discharge rates, can be modeled using Hille's modulated receptor hypothesis first described for local anesthetics. In this study two anticonvulsants, phenobarbital and mexiletine, have been applied to voltage-clamped semitendinosis muscle fibers (of bullfrog) in order to more precisely determine the sodium channel states involved in closed channel blocking and unblocking reactions. The blocking (k) and unblocking (l) rate constants were determined as a function of channel inactivation by measuring the amounts of non-frequency-dependent block and the block relaxation rates at several different holding potentials.



fraction of inactivated channels, 1-h

Observed increases in k and decreases in l with small depolarizations lead to the conclusions that (a) primarily resting (non-inactive) channels are involved in the unbinding step and that (b) primarily inactive channels are involved in the binding step. Thus these two anticonvulsants may manifest frequency-dependent excitability block primarily via their selective affinity for inactive sodium channels.

109.1 THE RESPONSE LATENCY OF ELECTRICAL STIMULATION OF THE TONGUE OF THE RAT. Mohsen S. Nejad* (SPON : Fereshteh Motamedi). Lab. of Neurophysiology, National University of Iran, School of Medicine, Tehran - Iran.

The rat chorda tympani and lingual nerves offer excellent conditions for studying the sensitivity of the tongue to different kinds of stimuli. The rat's tongue may be stimulated with chemical solutions or electrical currents and afferent impulses may be recorded from the chorda tympani or the lingual nerve.

The purpose of this study was to obtain qualitative and quantitative information concerning the response and response latency of gustatory receptors and nerve terminals of the tongue of the rat due to electrical stimulation.

Integrated neural activities of the chorda tympani nerve when the tongue (10 rats and 5 runs on each animal) was stimulated electrically (0.035-0.68 milliamps/unit area of the tongue) were very similar to those occuring when the tongue was stimulated chemically (0.025-1.0 M NaCl). The threshold for the lingual nerve was greater (0.225 milliamps/unit area of the tongue) than that of the chorda tympani.

When the tongue was pulled in between the stimulating electrodes both anodal and cathodal currents elicited activities in the chorda tympani and the lingual nerves. However, when the indifferent electrode was placed somewhere on the jaw of the rat, anodal polarization of the tongue surface caused a discharge and cathodal current inhibited the existing spontaneous discharges in the chorda tympani.

The response latency of chorda tympani at the threshold (0.035 milliamps/unit area of the tongue) was 16 ± 1 milliseconds. The plot of latency versus stimulus intensity in the chorda tympani showed a sudden drop in latency at a current approximately 0.4 ± 0.05 milliamps at which the latency became about 4 ± 1 milliseconds. This value was close to the latency of the lingual nerve when the tongue was stimulated at the threshold with anodal current. The existance of a two-phase-mechanism may be suggested. The first phase has a long latency and a rather small threshold (taste receptors), and the second phase has a short latency and a relatively large stimulus threshold (the nerve endings).

109.2 SELECTIVE INHIBITION OF BINDING TO A TASTE RECEPTOR SITE. Robert H. Cagan and John H. Teeter. Veterans Administration Medical Center and Monell Chemical Senses Center, Philadelphia, PA 19104.

The cutaneous taste system of the channel catfish *Ictalurus punctatus* is sensitive to a number of amino acids. Previous work demonstrated that the initial binding interaction at the plasma membrane underlies recognition of taste stimuli (1-3). An electrophysiological study of single nerve fibers in the catfish barbel (4) suggested that at least two populations of taste receptors exist, one that is relatively specific for L-arginine and another that is broadly sensitive to L-alanine and several other amino acids. Because our studies (1) had shown significant levels of binding of L-alanine and L-arginine to the receptor preparation, they were studied as prototypical ligands. Studies with additional amino acid ligands are in progress.

In the present studies, β-chloro-L-alanine markedly inhibits binding of L-[^{3}H]alanine but is without effect on binding of L-[^{3}H]arginine. For example, 4 μM β-chloro-L-alanine inhibits binding of 0.4 μM L-[^{3}H]alanine by 58% but shows no inhibition of 0.4 μM L-[^{3}H]arginine binding. The inhibition is concentration-dependent, and its effect is reversible. Furthermore, it is stereospecific, as β-chloro-D-alanine shows no inhibition of binding of L-[^{3}H]alanine.

Summated electrophysiological recordings from multi-fiber nerve preparations in the maxillary barbel provide corroborative evidence. The summated response elicited by a mixture of 10^{-4} M β-chloro-L-alanine + 10^{-5} M L-alanine was decreased by 40-60% compared with L-alanine alone. Although 10^{-4} M β-chloro-L-alanine evoked a small response in the nerve, it appeared similar in magnitude to the response with a control pulse of water. The response to a mixture of 10^{-4} M β-chloro-L-alanine + 10^{-5} M L-arginine was the same or slightly larger than with 10^{-5} M L-arginine alone.

The selective inhibition by β-chloro-L-alanine therefore shows it to be an antagonist for L-alanine taste receptor sites but not for L-arginine sites. As previously suggested (4), the present studies demonstrate biochemically and physiologically that *at least* two populations of taste receptor sites exist in the catfish. β-Chloro-L-alanine should be extremely useful in further defining the specificity of the catfish receptor sites. [Supported in part by NIH grant NS-08775/NS-15740 from NINCDS].

109.3 A MODEL FOR ACTION OF THE GYMNEMIC ACIDS AND ZIZIPHINS ON TASTE RECEPTOR CELLS. L.M. Kennedy and B.P. Halpern*. Worcester Fndn. Exptl. Biol., Shrewsbury, MA 01545 and Dept. Psych. and Sect. Neurobiol. & Behav., Bio. Sci., Cornell Univ., Ithaca, NY 14853

The gymnemic acids (GA) and ziziphins (Z) (from G. sylvestre and Z. jujuba) selectively suppress human sweetness perception (Meiselman et al., Physiol. Behav., 17: 313, 1976; Warren and Pfaffmann, J. Appl. Physiol., 14: 40, 1959), inhibit fly behavioral responses to sucrose, and inhibit and stimulate fly taste receptor neural responses (Kennedy et al., Physiol. Behav., 14: 755, 1975; Kennedy and Halpern, Soc. Neurosci. Abstr., 5: 412, 1979; Physiol. Behav., 24: 135, 1980). GA and Z are saponins, amphipathic molecules with surface active properties, and data support the notion of a role for surface activity in their taste-modifying action (Kennedy and Halpern, Chem. Senses, 1980, in press).

We propose a biphasic membrane penetration process for the action of GA and Z on taste receptor cells. In our model, the penetrating GA and Z molecules interact first, with the receptor cell plasma membrane surface and second, with the lipid membrane interior. The initial interaction is postulated to involve a selective effect on processes functional in the transduction and quality specification of a sweet stimulus and the second interaction to involve a general membrane disruption and nonselective effects on taste perception. This hypothesis is consistent with, and/or can account for (a) data on GA and Z chemistry, (b) psychophysical and neurophysiological data on the duration and selectivity of the taste-modifying action of GA and Z, (c) neurophysiological effects of GA and Z on taste receptor cells, (d) thermodynamic and kinetic theory for cell membrane penetration and (e) knowledge about the action of saponins on cell membranes. It offers an explanation for the puzzling fact that amphipathic saponin molecules, which probably penetrate into and generally disrupt the receptor cell membrane, have a selective effect on taste receptor cell neurophysiology and on taste perception. In addition, the model makes explicit predictions which can be tested in future experiments.

If the model holds, it has important implications for the design and interpretation of psychophysical, neurophysiological and chemical experiments that use GA and Z as tools to study taste perception. Moreover, if the model holds, it places at least one process involved in the specification of a sweet stimulus at the surface of the receptor cell membrane.

109.4 **SINGLE UNIT TASTE RESPONSES FROM THE PETROSAL GANGLION OF THE MONGOLIAN GERBIL.** **M.A. Hosley* and B. Oakley, Div. Biol. Sci., Neuroscience Lab. Bldg., Univ. of Mich., Ann Arbor, Mich. 48109.**

Microelectrode recordings were obtained from single petrosal ganglion (C.N.IX) gustatory units of the Mongolian gerbil (Meriones unguiculatus) in response to gustatory stimulation by 0.3M NH_4Cl, 0.3M NaCl, 0.5M sucrose, 0.01M HCl, 0.01M quinine-HCl and a "white taste" solution consisting of all of the above solutions in their listed concentrations. Single units were resolved by the criterion of constant spike height using an electronic window discriminator. Responses were measured in impulses per second for the five second interval of maximal activity during taste stimulation.

Gustatory units were, in general, responsive to all taste stimuli and thus lacked specificity for individual taste solutions. Analysis of units categorized according to their most effective "basic taste" stimulus (NaCl, sucrose, HCl or quinine-HCl) provided no clear evidence for types or classes of units. The high correlation between responses to 0.3M NH_4Cl and 0.3M NaCl suggests that these chemicals have shared or co-occurring receptor sites. Complex neural interactions are indicated by the responses to the "white taste" solution, whose effectiveness varied among neurons from the least effective solution to the most effective solution of the six taste solutions employed. The present results are consistent with an across fiber pattern theory of neural coding for taste qualities among gustatory units in the gerbilline petrosal ganglion. **Supported in part by NIH grant NS-07072.**

109.5 ACCESS OF LOW-VOLATILE STIMULI TO THE RODENT VOMERONASAL ORGAN DURING SOCIAL AND FEEDING BEHAVIORS. C. J. Wysocki, G. K. Beauchamp*, J. L. Wellington* and S. Erisman*. Monell Chemical Senses Center, 3500 Market Street, Philadelphia, PA 19104

Access of low-volatile chemical stimuli to the vomeronasal organ of mice, rats, pine voles and meadow voles was assessed during one of the following behavioral situations: investigation of a social stimulus (urine); social grooming, stimulated by the application of a foreign substance (carboxymethylcellulose, CMC) to the fur of a stimulus animal; self grooming, stimulated by the application of CMC; drinking of a novel solution (saccharin) or a familiar solution; or eating. In all situations the stimulus was mixed with a nonvolatile fluorescent dye, rhodamine B, prior to its presentation or application. The animal was allowed to contact the stimulus ad libitum for a predetermined amount of time. Immediately thereafter the animal was killed and the vomeronasal organ was removed, sectioned and surveyed with epi-fluorescence microscopy for the presence of rhodamine specific fluorescence.

The results were clear cut. In the majority of animals, the nonvolatile fluorescent dye was observed in the vomeronasal organ subsequent to each of the behaviors. In the absence of rhodamine no fluorescence could be detected from the vomeronasal organ.

Thus, at least some low-volatile substances encountered in urine, a cellulose-based gum, novel or familiar solutions, or food have access to the vomeronasal organ. That this access occurs in a variety of contexts suggests that this receptor organ could be involved in the regulation of social behavior, ingestion and in "self-smelling", a much broader array of behaviors than has generally been presumed.

We interpret these results to indicate that, as is the case for olfaction, animals sample their chemical environment with the vomeronasal organ during a variety of behaviors. However, unlike the olfactory system, the vomeronasal system may provide the organism with access to the wealth of information which can be stored in large molecules.

Specific experiments designed to test these hypotheses are required. Furthermore, although stimulus access to a chemo-receptor is necessary for stimulation to occur, it is not sufficient. At present, we do not know the properties of molecules which may activate the vomeronasal organ.

Supported in part by NIH Postdoctoral Award 1 F32 NS 6421-01, USDI Award 14-16-0009-79-102 and NSF grant 79-06234.

109.6 ANATOMICAL FEATURES OF THE BOVINE VOMERONASAL COMPLEX. V.L. Jacobs, R.F. Sis,* P.J. Chenoweth,* W.R. Klemm, C.J. Sherry Depts. of Vet. Anat., Med. and Surg., and Biol. Texas A&M Univ. College Station, Tex. 77843.

The vomeronasal organ (VNO) has been considered an important sensory apparatus related to sexual behavior in animals. Our studies have shown that Brahman bulls produce rapid tongue compression strokes (TCSs) of the hard palate while investigating the vulva of females. We believed that TCSs compressed the incisive and vomeronasal ducts to produce movements of fluid into the vomeronasal organ for estrus detection.

The hard palates of ten animals were removed following head perfusion with 10% buffered formalin. Gross observations on 6 animals were made on 1 cm sections cut with a band saw. Four animals were used to examine 6 µm sections taken from each cm segment of the incisive duct and vomeronasal organ. Alternate histologic sections were stained with H and E, Verhoeffs, PAS, Masson or Van Giesson. One fresh head was used to produce a latex model of the vomeronasal duct and organ.

The gross and microscopic specimens demonstrated a slit-like incisive duct 1 cm above the palatal mucosa. A comma shaped cartilage protects the incisive duct laterally and dorsally. The vomeronasal duct leaves the dorsal part of the incisive duct 1.5 cm caudal to the incisive pit. An expanded mucosal swelling bulges into the incisive duct at this juncture. The vomeronasal cartilage is remodeled further caudally so that the vomeronasal duct is protected medially and ventrally by it. The incisive duct lies 1.3 cm above the palatal roof and beneath the cartilage.

The position of the ducts above the palate near the midline may be easily compressed and manipulated by the tongue during TCS. Urine or vaginal secretion samples may be drawn into the incisive duct by TCSs where estrus pheromones could gain access to the VNO.

109.7 AN EXAMINATION OF THE COLLATERALIZATION OF MITRAL CELL AXONS BY RETROGRADE DOUBLE LABELING TECHNIQUES. M.B. Luskin* and J.L. Price. Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110

The axonal projection from the olfactory bulb (OB) to the olfactory cortex is diffuse; i.e., small areas within the OB project to almost the entire olfactory cortex, and small areas of the olfactory cortex receive fibers from all parts of the OB. Mitral cell axons leaving the OB in the lateral olfactory tract have been observed to give off a number of collaterals (Cajal, 1911), suggesting that individual mitral cells also have a diffuse projection to separate areas of the olfactory cortex. In the present study we have used retrograde double labeling techniques in the rat in order to test this hypothesis.

Three pairs of tracers have been used: HRP and tritiated HRP (^{3}H-HRP), HRP and ^{125}I-wheat germ agglutinin (I-WGA) and the fluorescent dyes, bisbenzimide and true blue. The fluorescent dyes have been the most useful because of their sensitivity and their differential distribution to the nucleus (bisbenzimide) and cytoplasm (true blue), which facilitates the identification of double- and single-labeled cells. Non-overlapping injections were made into anterior and posterior parts of the piriform cortex at several dorsal-ventral levels. The survival times used were: 1-2 days for HRP, ^{3}H-HRP and I-WGA, 2-4 days for true blue, and 6-8 hours for bisbenzimide. Following fixation and sectioning, the tracers were demonstrated using the DAB P-cresol procedure for HRP, autoradiography for ^{3}H-HRP and I-WGA, and epi-illumination fluorescence microscopy for bisbenzimide and true blue.

With each pair of tracers, a substantial number of double labeled mitral cells were observed, as well as cells labeled singly with either tracer. There was considerable overlap in the distribution of single and double labeled cells throughout the OB, and there were no regions of the OB which possessed only one class of labeled cells. The concentration of labeled cells was variable in different areas of the OB, and in some cases clusters of single and double labeled cells were encountered. Usually the occurrence of double labeled cells was a function of the density of single labeled cells, such that an increase in the number of single labeled cells tended to coincide with an increase in the number of double labeled cells.

These experiments indicate that individual mitral cells have branching axons which terminate in widely spaced areas of the olfactory cortex.

(We are grateful to Drs. Larry Swanson and Paul Sawchenko for gifts of the fluorescent dyes and for helpful advice. Supported by NIH Grants NS-09518 and T32-NS-07057.)

109.8 AFFERENT AND EFFERENT CONNECTIONS OF THE OLFACTORY BULB IN THE SOFT-SHELL TURTLE (Trionyx spinifer spinifer). Ronda R. Rolon and Leslie C. Skeen. Department of Psychology and Institute for Neuroscience, University of Delaware, Newark, Delaware, 19711.

We investigated the afferent and efferent connections of the olfactory bulb in the soft-shell turtle. Horseradish peroxidase (Sigma Type VI + Boehringer, 1:1) was injected unilaterally into the olfactory bulb using either pressure (3.0-0.3 µl, 40%) or iontophoresis (3 µA, 10-15 min., pulsed) to obtain injection sites of varying sizes. After appropriate survival times (6-13d.), the animals were perfused and frozen sections (30-40 µm) from their brains were processed with a variation of the tetramethyl benzidine procedure (Mesulam, '78).

Three efferent pathways can be traced from the injected olfactory bulbs. One is a component of labeled fibers that courses medially from the injection site to cross the midline and ramify in all layers of the contralateral bulb deep to the glomerular layer. The remaining two are composed by labeled fibers which course caudally through the internal plexiform layer to form the medial and lateral olfactory tracts. The former spreads a component of fine fibers and sparse terminals superficially across the medial aspect of the anterior olfactory nucleus and olfactory tubercle, and more caudally, across the rostral most portion of the hippocampus and medial parolfactory nucleus. The lateral olfactory tract forms the largest component of labeled efferents. Some of these fibers course laterally and caudally through the plexiform layer of the dorsal pyriform cortex distributing, more superficially, a pattern of dense terminals. Additional fibers course laterally and caudally through the cell layers of the dorsal and ventral pyriform cortex to spread a sheet of coarse fibers most superficially across the ventral pyriform cortex. The terminations of these fibers are also dense, but in this area, are distributed immediately subjacent to the fibers. Some of these fibers continue their caudal course superficial to the olfactory tubercle and amygdala with no obvious terminations. At the level of the amygdala these fibers turn medially and then dorsally into the stria terminalis for a short distance before joining the stria medullaris. These fibers then cross in the habenular commissure and distribute in the same fashion to the contralateral pyriform cortex.

Afferent connections of the olfactory bulb were found to originate from a number of central structures. Retrogradely labeled neurons are present in the contralateral olfactory bulb and, ipsilaterally, in the anterior olfactory nucleus, in layers II and III of the dorsal and ventral pyriform cortex, and in the vertical and horizontal limbs of the diagonal band of Broca.

109.9 ZINC SULFATE TREATMENT AND 2-DEOXYGLUCOSE UPTAKE PATTERNS IN THE RAT OLFACTORY BULB. William B. Stewart and Charles A. Greer. Sections of Neurosurgery, Neuroanatomy & Gross Anatomy, Yale Univ. Sch. Med. New Haven, Conn. 06510

We have employed the 2-deoxyglucose (2DG) method of Sokoloff to examine the functional activity in the rat olfactory bulb following intranasal zinc sulfate treatment, which destroys olfactory receptor cells (Smith, 1938). As a part of a larger study examining the potential for return of olfactory function following regeneration of a new complement of olfactory receptor cells, we have examined the functional activity remaining one week after injury. Since this time period is too short for new connections to be formed in the olfactory bulb, activity present at this time should be due to an incomplete destruction of the mature olfactory receptors.

Thirteen twenty day old rats, anesthetized with ether, underwent intranasal irrigation, either retropharyngeally or in the external naris with one percent zinc sulfate. Several rats in the latter group were also pretreated with atropine sulfate. Following a week recovery the rats were injected with C^{14}-2-deoxyglucose (200 uCi/kg) and exposed in an odor chamber to a 10^{-1} flow dilution of amyl acetate. Prior to the 2DG experiment some rats were tested for their olfactory function by determining their latency to discovery of a hidden food reward.

There was considerable variability in the amount of odor-evoked 2DG uptake in the olfactory bulbs. In two rats there was no evidence of 2DG foci in the glomerular layer. In some rats there were a few small foci present while in others there were large regions of increased 2DG uptake. In general the medial portions of the olfactory bulb were the most likely to show activity following zinc sulfate treatment. The behavioral data correlated well with the 2DG data. Rats with no discernible 2DG foci were unable to find the hidden chocolate, while rats with only a few foci had latencies clearly longer than control. Those rats with substantial regions of 2DG uptake did not exhibit latencies different from control.

We conclude that intranasal zinc sulfate irrigation may produce highly variable amounts of olfactory receptor cell damage, as inferred from both the 2DG and behavioral assessments. The correspondence between the 2DG and behavioral data suggests that the 2DG technique is an extremely sensitive method for assaying the extent of neuronal damage and recovery following trauma in the peripheral olfactory system.

109.10 CORRELATION OF HISTOLOGY AND 2-DEOXYGLUCOSE UPTAKE IN THE DEVELOPING RAT OLFACTORY BULB. C.A. Greer, W.B. Stewart, M.H. Teicher, J.S.Kauer and G. Shepherd. Sections of Neuroanatomy, Neurosurgery and Gross Anatomy, Yale Univ. Sch. Med., New Haven, CT. 06510

Studies employing the Sokoloff 2-deoxyglucose (2DG) technique have been directed toward describing the sequence of appearance of odor-induced activity in the olfactory bulbs of developing rats (Teicher et. al., Neurosci. Abst. 5:134, 1979). Of particular interest has been the identification of a modified glomerular region located in the dorsal posteromedial region of the main bulb near its border with the accessory olfactory bulb, which appeared to be a site of increased 2DG uptake during suckling, a behavior which may be directed, in part, by pheromonal cues. To further our understanding of the developmental sequence of odor processing in the olfactory bulb we are conducting a parallel analysis of 2DG uptake in response to an odorant, amyl acetate (AA), and correlating these findings with the histological ontogeny of the olfactory bulb. Beginning within 12 hrs. of birth rat litter mates were either injected I.P. with 20uC/100 g body wt. of C^{14}-2DG, followed by a 1 hr. exposure to a 10^{-1} flow dilution of AA and conventional processing for autoradiography, or perfused with Bouin's solution for paraffin embedding and histological study.

Increased 2DG uptake following AA exposure was apparent in even the youngest (12 hr. postnatal) rats. The patterns of uptake in the glomerular layer, however, differed somewhat from those typical of the adult. Punctate foci were present but they were widely dispersed. In addition, relative to the adult, the number of foci was smaller. Finally, the foci, although discrete, did not exhibit the same clarity or definition usually found in the adult. In the course of development these observations became less applicable as the adult characteristics emerged clearly around 12-15 days postnatally. Our observations on the histological development of the olfactory bulb are generally consistent with previous investigations in rodents (J. Hinds, J.C.N. 134: 267 & 305, 1968). At 12 hr. postnatal the rats exhibited a very poorly defined glomerular layer. Indeed, the incidence of identifiable glomeruli was very low and they tended to be scattered. During ensuing development the glomerular layer increased in definition; this increase appeared to be approximately correlated with the increased frequency of 2DG foci in odor exposed rats.

In summary, these results demonstrate an ontogenetic correlation between odor-induced physiological activity and histological differentiation in the olfactory bulb. Further studies designed to clarify the interdependence of these variables are currently in progress.

109.12 INDUCTION OF NEURONAL DEGENERATION IN SECONDARY OLFACTORY AREAS BY OLFACTORY BULB LESIONS AND ITS USE IN THE TRACING OF TERTIARY OLFACTORY CONNECTIONS IN THE GUINEA PIG. J. de Olmos, J. Carlsen and L. Heimer. Inst. Invest. Medica "M.y.M. Ferreyra", Cordoba, Argentina, and Inst. of Anatomy, Univ. of Aarhus, Aarhus, Denmark.

In 22 young guinea pigs weighing 150-300 g "indirect Wallerian degeneration" was induced in the olfactory system by means of complete surgical transection or chemical destruction of one olfactory bulb. After postoperative survival times of 1-6 days the animals were anesthetized, perfused and the tissue processed according to an allantoin-cupric silver procedure developed recently in our laboratory. In order to verify the validity of the hodological information obtained by the study of "indirect Wallerian degeneration", an additional group of animals was prepared in which HRP or fluorescent compounds (Nuclear Yellow or Granular Blue) were injected either by hydraulic pressure or by iontophoresis in some of the apparent targets of axons emanating from the degenerating neurons.

Like in the rat, strongly argyrophilic degenerating neurons were observed in the primary olfactory cortex, the ventral part of the lateral entorhinal area and in the postero-lateral cortical amygdaloid nucleus. Degenerating neurons appeared already after 24 hours following the operation, and the number of heavily argyrophilic neurons reached a peak in animals with 3-4 days survival time.

At this time axonal and terminal degeneration could be identified throughout most parts of the anterior olfactory nucleus, the olfactory tubercle, the nucleus of the lateral olfactory tract and the anterior amygdaloid area. The distribution pattern and morphological characteristics of this type of degeneration could easily be distinguished from that related to the lateral olfactory tract. In addition, terminal degeneration was observed in part of the basolateral amygdaloid complex, in the basomedial amygdaloid nucleus, and the temporal parts of the subiculum and dentate gyrus. Control experiments by the aid of the HRP technique and the retrograde fluorescent method seem to support the presence of tertiary olfactory projections to the areas of terminal degeneration revealed by the indirect Wallerian degeneration. (Supported by NIH and the Danish Medical Research Council).

109.13 PHYSIOLOGICAL AND MORPHOLOGICAL ANALYSIS OF PYRAMIDAL CELLS IN THE PIRIFORM CORTEX WITH INTRACELLULAR RECORDING AND INJECTION TECHNIQUES. L.B.Haberly and J.M.Bower. Depts. of Anatomy and Neurophysiology, Univ. of Wisconsin, Madison, WI 53706.

Intracellular responses of pyramidal cells in the opossum piriform cortex to shock stimuli applied to the lateral olfactory tract (LOT) and association axons have been analyzed with the following methods: 1) analysis of responses to paired shocks, 2) application of steady de- and hyperpolarizing currents to study properties of synaptic potentials, 3) current pulses to measure threshold and impedance changes during synaptic potentials, 4) iontophoresis of Cl^- to invert IPSPs. After physiological study neurons are injected with HRP for morphological study.

Experiments thus far have concentrated on an analysis of events during period I of the response to LOT stimulation. Results are consistent with the hypothesis (Haberly & Shepherd, J. Neurophysiol., 36: 789, '73; Haberly & Price, JCN, 178: 711, '78) that pyramidal cells are monosynaptically excited during the A_1 time period by LOT axons, then re-excited via association axons from other pyramidal cells during the B_1 time period. Evidence from the present experiments supporting this hypothesis includes: 1) Analysis of the time course and other characteristics of the EPSP evoked by LOT sitmulation indicates that it is generated by membrane currents during time periods A_1 and B_1. 2) A direct demonstration that pyramidal cells give rise to association axons by intracellular injection with HRP. 3) Demonstration of antidromic activation and apparent monosynaptically evoked EPSPs in pyramidal cells from direct stimulation of association fibers through electrodes in layer III up to 1.4cm distant from recording sites. 4) In addition, preliminary results obtained with the EM-autoradiographic technique indicate that terminals of association fibers are morphologically similar to those thought to mediate excitatory effects in other cortical systems: round vesicles and asymmetrical contacts onto dendritic spines. An unexpected finding is that an IPSP resulting from LOT stimulation begins during the B_1 time period, thus overlapping the EPSP generated through the association fiber system.

Analysis of the morphology of intracellularly injected pyramidal cells in layer II has revealed several new features: 1) These cells give rise to multiple rostrally & caudally, dorsally & ventrally directed association axon branches, most of which are very small in diameter ($\bar{x}$ 0.3μm). 2) These branches generate a widespread matrix of varicosities and boutons (presumed terminals) in layer III. No evidence for a restricted, columnar organization has been obtained. 3) There is a great diversity in spine morphology including very long, small diameter, varicose spines on apical and basal dendrites. Supported by NIH Grant # NS 15004.

109.14 OLFACTORY NEOCORTICAL AREAS IN THE RAT. S.J. Wiegand and J.L. Price. Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110

Previous studies have shown that cells deep to the olfactory cortex project to the central segment of the mediodorsal thalamic nucleus (MDc), which in turn projects to two prefrontal cortical areas in the dorsal bank of the rhinal sulcus, the ventral agranular insular area (AIv) and the lateral orbital area (LO). AIv, at least, also receives a direct input from the piriform cortex (PC).

In the present experiments Holtzman rats were anesthetized with chloral hydrate and fixed in a stereotaxic apparatus. The right olfactory bulb (OB) was stimulated with bipolar tungsten electrodes 1-2 mm deep to the surface. Following single or short trains of electrical shocks (5-10 V, 100 usec) evoked field potentials and unit activity were recorded in the PC, AIv and LO with tungsten microelectrodes (3-5 MΩ). In the PC a large increase in unit activity was observed 4-14 msec after OB stimulation followed by a longer period (ca. 50-100 msec) of inhibition. In both the AIv and LO a less marked increase in unit activity was usually observed 8-20 msec after OB stimulation followed by a period (ca. 30-100 msec) of decreased unit activity. This suppression of unit activity was sometimes observed without an initial increase in unit activity.

In these same experiments small injections (10-50 nl) of HRP (10-20%) or HRP conjugated to wheat germ agglutinin (HRP*WGA) (0.05-0.1%) were placed in the AIv or LO to determine their connections with olfactory related structures. In both cases, retrograde cell labeling was observed in the MDc and in the PC. Anterograde axonal labeling was also observed in the MDc and, especially when the AIv was involved, in the olfactory tubercle, anterior cortical amygdaloid nucleus and, to a lesser extent in the PC. These experiments also suggest that there may be differential inputs to the AIv and LO. For example, the cells which project to the LO are concentrated in the anteromedial part of the PC, while those which project to the AIv are more widely dispersed in the PC and adjacent olfactory areas. Autoradiographic experiments also support this distinction; injections of ^{3}H-amino acids into the posterior PC, label axons in the AIv only, while injections which involve the anteromedial PC also label axons in the LO.

Therefore, on the basis of these and previous experiments, we suggest that the AIv and LO are specific neocortical olfactory areas which receive olfactory-related inputs directly from the PC and indirectly from the MDc. (Supported by NIH grants NS09518 and T-32-NS07057)

109.15 THERMAL SENSITIVITY OF PARABRACHIAL TASTE NEURONS IN THE HAMSTER. Susan E. Plock and David V. Smith. Dept. Psychol., Univ. Wyoming, Laramie, WY 82071.

Hamster chorda tympani (CT) fibers are responsive to both gustatory and thermal stimuli (Ogawa, Sato & Yamashita, 1968). As part of an investigation of the gustatory sensitivities of neurons in the hamster parabrachial nucleus (PbN), we have examined the responsiveness of 13 cells to thermal stimulation. The gustatory stimuli were: 0.1 M sucrose, 0.03 M NaCl, 0.003 M HCl and 0.001 M quinine hydrochloride (QHCl), presented at room temperature (24° C). These stimuli and the thermal stimuli followed preadaptation of the tongue to distilled water at 24° C. Thermal stimuli ranged from a mean of 16° C (cool) to a mean of 39° C (warm). Twelve of these neurons responded to at least one of the thermal stimuli, 5 excited by both warm and cool stimuli, albeit differentially, 5 excited by either warm or cool stimuli, and 2 excited by cool stimuli and inhibited by warm. The mean firing rates to these stimuli were: 64.7 impulses/5 sec to sucrose, 71.2 to NaCl, 19.2 to HCl, 41.9 to QHCl, 37.7 to cooling, and 50.2 to warming. The across-neuron correlations between the gustatory and thermal stimuli were positive between responses to sucrose and warming ($\underline{r}$ = +0.86) and QHCl and warming ($\underline{r}$ = +0.49), but there was no relationship between responses to NaCl ($\underline{r}$ = +0.20) or HCl ($\underline{r}$ = +0.01) and warming. Cooling the tongue produced responses that were correlated across neurons with those to NaCl ($\underline{r}$ = +0.45), HCl ($\underline{r}$ = +0.62), and QHCl ($\underline{r}$ = +0.47), but not to sucrose ($\underline{r}$ = -0.07). The spontaneous rate of discharge in these neurons was correlated with the response to cooling ($\underline{r}$ = +0.63), but not to warming ($\underline{r}$ = +0.20). These relationships are similar to those reported for peripheral taste fibers in the hamster (Ogawa et al., 1968), except for the positive correlation between the response to QHCl and warming, which was negative in peripheral fibers. The mean responses to these stimuli in sucrose-best cells ($\underline{n}$ = 4) in PbN were 113.3 impulses/5 sec to sucrose, 49.5 to NaCl, 12.8 to HCl, 19.0 to QHCl, 8.5 to cooling, and 102.3 to warming. In NaCl-best neurons ($\underline{n}$ = 6), these responses were: 36.8 impulses/5 sec to sucrose, 88.2 to NaCl, 3.3 to HCl, 11.3 to QHCl, 45.2 to cooling, and 0.5 to warming. In the rat PbN, excitatory responses to thermal stimuli occur mainly to cooling (Norgren & Pfaffmann, 1975; Perrotto & Scott, 1976), which reflects the sensitivity of peripheral taste fibers in this species (Ogawa et al., 1968). The thermal sensitivity of hamster CT neurons is maintained in third-order PbN cells, adding further to their already broad responsiveness to gustatory stimuli. Whether this sensitivity to temperature is greater or less than that of peripheral fibers is not certain without further parametric investigation.

109.16 ASCENDING GUSTATORY AND VISCERAL AFFERENT PATHWAYS IN THE MONKEY. J.R. Morse, R.M. Beckstead, T. Pritchard and R. Norgren. The Rockefeller Univ., New York, NY 10021.

The ascending efferent projections from the parabrachial area (PBA) and the parvicellular portion of the ventral posteromedial nucleus of the thalamus (VPMpc) were studied in cynomolgus monkeys using the autoradiographic anterograde fiber-tracing method. Previous investigations in the same species established that the nucleus of the solitary tract (NST) projects directly to both these areas (Beckstead, Morse & Norgren, J. Comp. Neurol., 1980, 190, 259-282). The predominantly viscerosensory, caudal third of NST sends axons to the PBA, while fibers arising from the predominantly gustatory, rostral third of NST bypass the PBA and ascend to the ipsilateral VPMpc. Neurons in the middle third of NST project to both the dorsal pons and thalamus. Current experiments involve characterizing the sensory input to the PBA and VPMpc by electrically stimulating the vagus and glossopharyngeal nerves and by applying mechanical stimuli to the intra- and perioral fields, as well as thermal and sapid stimulation to the tongue. When an appropriate response is obtained, the recording locus is infiltrated with tritiated amino acids applied microelectrophoretically. To date, data from three parabrachial and four thalamic cases have been analyzed. Deposits in the lateral PBA at sites responsive to vagal and glossopharyngeal nerve stimulation yield labeled fibers that can be traced to the amygdala and bed nucleus of the stria terminalis (BNST). These fibers ascend in the central midbrain tegmental reticular formation and through the medial subthalamic area, partly in Field H of Forel and partly intermingled in the dorsal part of the medial forebrain bundle. Some fibers diverge laterally dorsal to the rostral part of the substantia nigra and curve around the lateral edge of the cerebral peduncle to terminate in the central nucleus of the amygdala. Distinct axon labeling is also present in the supracommissural part of the BNST and probably arises from axons that take a dorsalward course parallel to the internal capsule. A few fibers can be traced into the supraoptic commissures, but cannot be followed to a contralateral target with certainty. Axons have been traced from the rat PBA to ventrobasal thalamus and far lateral hypothalamus (Norgren, J. Comp. Neurol., 1976, 166, 17-30), but these connections are not evident in our primate material. Isotope deposits in the monkey's VPMpc, where neurons respond to taste stimuli, label fibers that enter the thalamic radiations to distribute in the dorsal part of the rostral insular cortex ipsilaterally. In contrast, axons emanating from sites in VPM, where neurons respond to lingual tactile stimulation, project to the lateral convexity of the cortex. Supp. by BNS76-81408 and NS06301-01.

109.17 CHEMOSENSORY CONTROL OF FOOD-RELATED BEHAVIORS IN THE HAMSTER. Robert D. Sweazey* and David V. Smith. Dept. Psychol., Univ. Wyoming, Laramie, WY 82071.

Hamsters were placed for six days in a semi-natural environment, consisting of a sand-filled chamber maintained on a 12-hr light/dark cycle, from which a series of plastic tunnels projected "underground", in constant red light. Water was available ad lib in the sand-filled chamber and 5 gm each of 10 novel foods were placed in this area at the beginning of the six-day period. Twenty-four hours after injection of saline or apomorphine (30 mg/kg), either paired with a distinct gustatory cue or given alone, the hamster was introduced into the tunnel system and its nest location and food distribution were noted daily. At the end of the session, the animal was removed and the location and amount remaining of each food was measured.

The saline-injected control animals typically hoarded all the foods within the first day, storing them consistently near the nesting site, always at the lowest points in the tunnel system. Preference among the foods was remarkably consistent, peanuts being the most favored, followed by sunflower seeds, oats, rye, wheat, rice, soybeans, barley, corn and Great Northern beans. Eighty percent of the peanuts were consumed, but only sixteen percent of the Great Northern beans.

Animals injected with apomorphine prior to the six-day session did not show normal patterns of food consumption or hoarding behavior. If the animal was poisoned in the absence of a distinct gustatory cue, the consumption of all foods was reduced by 60-100 percent, the foods were not hoarded immediately, and were scattered throughout the tunnel system over the entire six-day period. Additional animals were given apomorphine paired with a distinct gustatory stimulus (sucrose, NaCl, HCl or quinine). Rather than a widespread aversion to all novel foods, these animals demonstrated consistent and unique patterns of food consumption, depending upon which taste quality was paired with the illness. For example, after sucrose aversion the most preferred foods (peanuts and sunflower seeds) were less avidly consumed, with concomitant increases in the consumption of other foods. Hoarding behavior tended to be even more consistent in animals with specific taste aversions than in saline controls. Thus, the gustatory (and possibly olfactory) cues provided by these taste stimuli have a very direct influence on food-related behaviors. In the absence of these cues, the animal develops a strong and persistent avoidance of all novel foods, even though these are all that is available over the six-day period. If the animal can associate the poison-induced illness with distinct oral cues, then its behavior toward novel food substances comes under oral control.

109.18 THE EFFECTS OF TEMPERATURE ON THE PERCEIVED SWEETNESS OF SUCROSE. L. M. Bartoshuk, K. Rennart*, J. Rodin*, and J. C. Stevens. J.B.Pierce Fndn. Lab and Yale Univ., New Haven, CT 06519.

Early studies of the effects of temperature on taste were done almost exclusively with threshold measures. Only one previous study (Moskowitz, 1973) evaluated a range of concentrations of a sweet substance (glucose) in order to assess possible effects of temperature on the perceived intensity of sweetness. Moskowitz reported that the exponents for the psychophysical functions (which were power functions) for glucose were invariant but that when the stimuli were at approximately the same temperature as the tongue (35°C), they all tended to be sweeter.

Three experiments presented here show different results for sucrose. All three experiments had these features in common: the sweetness judgments were obtained with the method of magnitude estimation, and each stimulus was tasted after a rinse with deionized water warmed to approximately mouth temperature (34°C).

In the first experiment, solutions were tasted with the "sip and spit" method. Solutions at room temperature (22°C) and body temperature (34°C) were compared. The room temperature solutions were less sweet at concentrations less than .3-.5 molar, but were equally sweet at higher concentrations.

In the second experiment, similar temperatures were compared but two tasting methods were used: "sip and spit" and "sip and swallow." The results for both tasting methods agreed with those in the first experiment. Lower concentrations were less sweet at the lower temperature.

In the third experiment, stimuli were tasted with the "sip and spit" method and the temperature range was expanded to include: 4, 12, 20, 28, 36, and 44°C. The results confirmed the first two experiments and showed even greater effects of temperature on sweetness with the more extreme temperatures. That is, around .3-.5 molar, solutions were perceived to be about equally sweet. For lower concentrations, the warmer stimuli were sweeter and for higher concentrations, the cooler stimuli were sweeter.

It should be noted that there may be chemical sources for effects of temperature on the perceived sweetness of sugars since temperature is known to affect molecular conformation.

110.1 EFFECT OF MORPHINE ON PREFERRED DURATION OF ELECTRICAL BRAIN STIMULATION IN THE MOUSE. Hugh E. Criswell and Debi M. Starnes*
Dept. of Psychol. East Tenn. St. Univ. Johnson City, TN 37601.

When rats or mice are allowed to control delivery of electrical brain stimulation(EBS) to the lateral hypothalamic area, in a shuttle-box paradigm, they rapidly acquire shuttling behavior which results in precise control of both the duration of the stimulation and the time between stimuli (on time and off time). Systemic morphine has been shown to have a selective effect on the preferred duration of EBS in the rat. Moderate doses(5-10mg/kg) increase on times while higher doses produce catatonia which is associated with an increase in both on and off times(Levitt, et al, Psychopharmacol., 1977, 54,307-311). Some strains of mouse do not become catatonic at high doses of morphine. Instead, as dose is increased, their activity level increases. To determine the relation between morphine effects on EBS and activity level, we examined shuttle-box behavior for EBS in the mouse.

Swiss Webster(ICR) mice were implanted with 36 gauge nicrome electrodes using standard stereotaxic procedures. Electrodes were aimed at the perifornical lateral hypothalamus. Following recovery, animals were tested for shuttling to obtain EBS. Only animals which attained stable shuttling behavior with on times under 5 sec. and off times under 10 sec., with less than 50uA. stimulation were retained. Each animal then received control, 10 and 20 mg/kg I.P. injections of morphine in counterbalanced order, ½ hour prior to daily 15 min. testing sessions. Each drug day was separated by one day of non drugged testing. Mean on and off times were recorded for each condition. On times averaged 2.8 sec. for control days, 2.2 sec. for 10mg/kg and 2.6 for 20mg/kg. These times were not statistically different(P 0.10). Off time was 5.5 sec. for controls, 10.0 sec. at 10mg/kg and 12.1 at 20mg/kg. Both drug tests differed from controls (P 0.01) but did not differ from each other (P 0.10).

Mice respond to morphine by increasing the time between stimuli while rats respond by increasing the duration of the stimulus. The fact that mice and rats differ in the effect of morphine on their shuttling behavior for EBS suggests that the effect of morphine on EBS is more closely linked to its effect on activity level(where rats and mice also differ) than to its analgesic effect (where mice and rats respond similarly). The selective effect on off times in the present study rules out nonspecific toxic effects of the morphine as the reason for the increased off times.

110.2 PHARMACOGENETICS OF INITIAL TOLERANCE TO ETHANOL. STUDY OF PHARMACOKINETIC AND PHARMACODYNAMIC TOLERANCE USING DROSOPHILA AS ANIMAL MODEL. F. Garcin[1], S. Chawla[1]*, J. M. Perron[2]* and C. Radouco-Thomas[1]. Unit for Research on Drug and Alcohol Abuse, Hospital St.François d'Assise, Dept. of Pharmacol., Fac. of Med.[1], and Dept. of Biology, Fac. of Sciences[2], Laval Univ., Quebec, Canada.

It is well known that the two Drosophila sibling species, D. melanogaster and D. simulans, differ in their initial tolerance to ethanol (ETOH). D. melanogaster possess a much higher tolerance level to ETOH than D. simulans. Initial tolerance is known to be the resultant of two components, the metabolic or pharmacokinetic tolerance related to disposition of ethanol and the functional or pharmacodynamic tolerance related to the sensitivity of the main target tissue, the central nervous system.

Biochemical studies on alcohol dehydrogenase (ADH) activity have shown that differences in initial tolerance to ethanol in the two species are, at least partially, due to metabolic factors. As a matter of fact, ADH activity in D. melanogaster is twofold higher than in D. simulans (Garcin et al. 1979, 1980). No study has been devoted to the functional tolerance to ethanol. This is due to the lack of valid biochemical studies.

In our laboratory we have developed a specific behavioral test which allows, on the one hand, to differentiate the two components of the initial tolerance and on the other hand, to assess them quantitatively. Individual flies are introduced into a air tight tube of 155 ml containing ethanol vapors at a concentration of 245 mg/l. The "knock down" is recorded for each individual fly. Time elapsing from introduction until knock down is referred to as "knock down induction time" (Ki) and that elapsing from the beginning to the end of knock down as "knock down duration" (Kd). Ki which is related to the immediate response of the fly is proposed as a measure of functional tolerance, whereas Kd would be an indicator of the rate of ethanol metabolism.

Our results show that Ki is shorter in D. simulans (4,62 min) than in D. melanogaster (7,5 min). On the contrary, Kd is higher in D. simulans (15,5 min) than in D. melanogaster (7,4 min). These data suggest that the higher initial tolerance found in D. melanogaster would be related to both pharmacokinetic and pharmacodynamic factors.

110.3 INTRACRANIAL SELF-ADMINISTRATION OF MORPHINE INTO VARIOUS BRAIN REGIONS IN RATS. M. A. Bozarth and R. A. Wise. Center for Research on Drug Dependence, Department of Psychology, Concordia University, Montreal, Quebec, H3G 1M8.

In an attempt to specify the opiate receptor population at which morphine acts as a reward, we have begun studies of intracranial drug self-administration (ICSA). To minimize the problem of poorly controlled drug delivery, infusions were given by a method that did not require flexible tubing or a fluid swivel to maintain unrestricted movement of the animals during testing (M. A. Bozarth & R. A. Wise, J. Neurosci. Methods, in press).

Experimentally naive rats quickly learned a lever-pressing response which produced 100 ng infusions of morphine sulfate (in 100 nl of Ringer's solution) into the ventral tegmental area (VTA). Mean response rates were relatively stable across 4 hours of testing and they markedly exceeded lever-pressing rates of rats passively receiving the same number and pattern of infusions (yoked control condition) or of rats working for Ringer's solution alone. ICSA was blocked by naloxone (10 mg/kg, i.p.) indicating that ICSA was due to an action at opiate receptors and not due to nonspecific changes in local pH, osmolarity, or calcium flux. Additional behavioral controls and manipulations of unit dose and volume are in progress.

These results indicate that truly rewarding (not merely behaviorally activating) effects of morphine can be demonstrated with central injections. Although injections of morphine into the VTA produced increased general activity, this effect did not result in increased accidental lever contacts as evidenced by the nearly identical response rates of the yoked and Ringer's control groups. The use of experimentally naive animals eliminated the possibility, inherent in other paradigms, that responding was due to reinstatement of habits previously learned for other rewards.

Preliminary results suggest that rats may learn to self-administer drug into the lateral hypothalamic area (LHA), caudate nucleus (CAUD), and central gray, but ICSA into the LHA and CAUD has been much more variable than ICSA into the VTA. In addition, morphine injections into the LHA has thus far been accompanied by increased lever-press counts in yoked control rats who receive their drug passively. Additional testing is necessary before ICSA at these sites can be meaningfully compared to that from the VTA. Confirmation of an anatomically restricted target for the rewarding effects of opiates will require demonstration that responding is contingent on drug delivery and that the drug is not acting by diffusion to other sites.

110.4 REPEATED NIALAMIDE TREATMENT BLOCKS THE BEHAVIORAL SYNDROME PRODUCED BY 5-METHOXY-N, N-DIMETHYLTRYPTAMINE I. Lucki and A. Frazer. Depts. of Psychiat. and Pharmacol., Univ. of Penna. and Vet. Adm. Hospital, Phila., Penna. 19104.

We have shown (J. Pharmacol. Exp. Therap. 212:259, 1980) that repeated, but not acute, administration of monoamine oxidase inhibitors (MAOIs) to rats reduces binding sites for ^{3}H-serotonin in brain. It was of interest to determine whether the decrease in brain serotonin receptors induced by repeated administration of MAOIs had any behavioral effects. To do this, the behavioral syndrome produced in rats given intraperitoneal injections of the serotonin agonist 5-methoxy-N, N-dimethyltryptamine (5-MDMT) was studied. This behavioral syndrome is characterized by repetitive forepaw treading, hindlimb abduction, tremor, lateral head weaving, and Straub tail (J. Pharmacol. Exp. Therap. 206:339, 1978). Rats were given either a single intraperitoneal injection of nialamide (40 mg/kg) or 13 injections of the drug over a period of seven days. Control rats received injections of 0.9% NaCl. Twenty-four hours after the final saline or nialamide injection, rats were administered 5-MDMT, at a dose of either 3 mg/kg or 9 mg/kg. In saline-treated rats, both doses of 5-MDMT produced the behavioral syndrome (in seven of eight rats). In rats given a single injection of nialamide, 5-MDMT produced the same behavioral syndrome that it did in control rats. By contrast, 5-MDMT failed to produce the behavioral changes described above in all ten rats given nialamide repeatedly. This difference between the effect produced by 5-MDMT in control rats and in animals treated repeatedly with nialamide is significant ($\chi^2 = 10.9$; $p < 0.005$). Thus, the decrease in ^{3}H-serotonin binding sites produced by repeated administration of MAOIs may be correlated with a reduced behavioral response elicited by activation of serotonin receptors in brain. (Supported by Research Funds from the Vet. Adm., USPHS Grants MH 29094 and MH 14654).

110.5 MODIFICATION OF AMYGDALOID-KINDLED SEIZURES IN RATS BY OPIATES. William S. Stone*, Cynthia E. Eggleton*, and Robert F. Berman (SPON: David Asdourian). Dept. of Psychology, Wayne State University, Detroit, MI 48202.

A variety of experimental data indicate that endorphins may be involved in the development of amygdaloid kindling. Morphine and the enkephalins have both analgesic and epileptic properties when injected intraventricularly in the rat (Urca, Frenk, & Liebeskind, Science, 197: 83, 1977). Furthermore, kindling develops most rapidly following electrical stimulation of the amygdala; a region extremely high in opiate receptors (Kuhar, Pert, & Snyder, Nature, 245: 447, 1973) and enkephalinergic terminals (Uhl, Kuhar, & Snyder, Brain Res., 149: 223, 1978). Previous attempts to alter amygdaloid-kindled seizures with the opiate agonist morphine or the antagonist naloxone have either failed or have reported only slight effects (Post, Davenport, Pert, & Squillace, Comm. Psychopharm., 3: 185, 1979; Corcoran & Wade, Life Sci., 24: 791, 1979), while results of the present studies, however, indicate that these agents can significantly alter amygdaloid kindled seizures. Male Long-Evans rats (300 g) were stereotaxically implanted bilaterally with bipolar electrodes in the medial amygdala. After recovery from surgery, the after-discharge (AD) threshold was determined for each rat by stimulating through one of the implanted electrodes (1 sec, 1.0 msec pulse duration, 100 Hz, biphasic, symmetrical, square waves) with increasing current intensities until an AD was recorded. Rats were then kindled once daily for 1 sec at the AD threshold. Kindling was continued until Stage V seizures (Racine, EEG & Clin. Neurophysiol., 32: 281, 1972) were elicited on two consecutive days. On the following day, animals were injected (ip) with either saline, naloxone (10 mg/kg), naltrexone (10 mg/kg) or morphine sulfate (10 mg/kg) and were stimulated at the AD threshold 20 minutes later. Saline injected animals showed long bilateral AD's (27.5± 3.5 sec ipsilateral, 21.0± 4.0 sec contralateral) and behavior typical of Stage V kindled animals. In contrast, rats injected with 10 mg/kg naloxone showed significantly reduced AD activity (11.5± 1.9 sec ipsi., 6.6± 2.1 sec contra.) with almost complete absence of behavioral seizure activity. Naltrexone (10 mg/kg) similarly reduced AD's and behavioral seizures. In contrast, rats injected with morphine sulfate (10 mg/kg) showed increased AD's and more severe behavioral seizures than controls. Morphine potentiation of kindling was more pronounced when given during an intermediate stage of kindling (Stage III) suggesting that previous failures to observe potentiation by morphine may have been due to a relative ceiling effect present at Stage V.

110.6 Generality of Selective Breeding for Sensitivity to Alcohol in Mice. Michael E. Abbott* and Bruce C. Dudek. Dept. of Psychology SUNY at Albany, Albany, NY 12222

The selective breeding program of McClearn and Kakihana (Behav. Genet. 3: 490-410, 1973) produced lines of mice which differ markedly in sensitivity to the hypnotic effects of ethanol. The Long Sleep (LS) mice lose the righting reflex for about four hours and the Short Sleep (SS) mice for less than 30 min after a 4.2 g/kg, i.p., dose. This has been shown to reflect differential neural sensitivity to ethanol. These lines thus are a tool for investigation of genetic effects on the nervous system and behavior. For example, LS mice are more sensitive to the actions of gamma-butyrolactone on brain dopamine levels.

Behaviorally, the LS and SS mice also show differential response to low doses of ethanol. SS mice are highly activated while LS mice are depressed and severely uncoordinated. There exists controversy as to whether these low dose phenotypes are genetically independent of the original selection phenotype (sleep-time) or whether they are also a direct result of the selective breeding. The present studies addressed this question with a genetic analysis. Reciprocal F_1 hybrids were tested for loss of righting reflex at 3.8 or 4.2 g/kg of ethanol. Their loss of righting reflex durations were intermediate of the two parental lines at both doses. No differences between the reciprocal hybrids were found, suggesting that maternal effects were not important for the selection. Small but reliable sex differences showed male mice to have longer loss of righting reflex times. A second experiment investigated coordination with the grid test. Locomotor activity was concurrently measured by photocell beam interuption for 20 min following treatment. Mice were treated with ethanol at 0.0, 1.5, 2.0 or 2.5 g/kg, i.p. SS mice were more active at all doses of ethanol than controls. LS mice showed depressed locomotor activity at all doses. These effects were dose dependent in both lines. Hybrid mice were activated relative to controls when treated with 1.5 g/kg, but were depressed at the other two doses. The two reciprocal hybrids did not differ from each other. Ethanol had marked disruptive effects on coordination (normalized to activity) in all genotypes, but LS mice were most severely affected and SS mice were least affected. Clear dose response effects were apparent in all groups. Reciprocal hybrids did not differ from each other, but were again intermediate of the two parental lines. In sum these studies suggest a shift of the ethanol dose response curve to the left for LS mice and to the right for SS mice. The intermediacy of F_1 mice is consistent with a common polygenic interpretation of the genetic influence on both low and high dose responses.

110.7 EFFECTS OF COCAINE ON THE DETECTION OF FOCAL BRAIN STIMULATION. Henry Lesse and Jeremiah P. Collins. Department of Psychiatry and Brain Research Institute, School of Medicine, University of California, Los Angeles, Calif. 90024

It has been found that cocaine reduces the electrical current necessary to evoke epileptiform afterdischarges (AD) in the amygdala and hippocampus (Lesse, Collins & Denea 1977; Lesse & Collins 1980). However moderately high doses are required to alter these thresholds. Repeated evocation of AD results in progressive electrophysiological changes, and this method is limited to brain structures in which AD are readily induced. The present study provides a more sensitive indicator of regional excitability changes. The method is applicable to most cerebral structures, and tests can be repeated over prolonged periods of drug administration without inducing AD or kindled seizures.

Cats prepared with arrays of indwelling electrodes were trained to use low intensity electrical stimulation (3Hz, 200-350 ma, 0.5 msec. pulses) of selected subcortical sites as a discriminative stimulus (cue) for a milk-reinforced bar pressing response. Stimulus detection thresholds (the minimal current required to elicit the discriminative response) were determined using a modified method of limits. After stable threshold values were obtained, the effects of alternate administrations of saline and cocaine were examined. Repeated testing over periods extending to 9 months resulted in neither electroencephalographic abnormalities nor evidence of seizure development. Results indicate that low doses of cocaine (0.1-0.4 mg/kg, i.m.) reduce detection thresholds for both amygdalar and hippocampal stimulation. These dose levels, an order of magnitude lower than those required to change AD thresholds, result in few, if any, observable aberrations in behavior. The stimulus detection threshold reductions were not correlated with non-specific changes in discriminative behavior (e.g. changes in responses rates, response latencies or error responses). These results suggest that cocaine alters the sensitivity of limbic structures functionally important in the regulation of emotion. The excitatory effects following administration of low doses are manifest in the absence of induced afterdischarges and appear independent of the convulsant properties of cocaine.

110.8 THE ESCALATING EFFECT OF COCAINE ON AGGRESSION IN ISOLATED FIGHTING MICE. M.G. Hadfield, D.E.W. Mott* and E.A. Nugent*, Med. Coll. Va., Va. Commonwealth U., Richmond, VA 23298 Neuropathology Laboratory

Illicit cocaine use is currently increasing at a rapid rate, partly because it has been promoted as a relatively "safe" drug. Yet Jaffe warns us that violence may accompany cocaine use because the stimulant properties may drive the toxic abuser to act out on his persecutory delusions (in Goodman and Gilman, 1965). The results of the present study in isolated fighting mice also indicate that cocaine enhances aggression. Thus cocaine may not indeed be a "safe" drug.

ICR male mice, isolated for six weeks, were separated into 12 groups of four. Each group was tested twice under each of four different conditions: no injection, physiological saline medium injection (1cc/100 gm. body weight), 10 mg/kg cocaine hydrochloride and 35 mg/kg cocaine hydrochloride. Injections were given, i.p., approximately 10 minutes before the animals were placed together. The no-injection controls were not handled at all during the ten minute interval. The order of treatments was different for each group, except that drug conditions alternated with no-drug conditions. The mice were tested on four consecutive weekdays, two weeks in succession. Minute-by-minute fight durations as well as behavioral observations were recorded for fifteen minute sessions, after which the animals were returned to their home cages. A total of 24 fights were observed under each condition. The fighting arena had a floor approximately 13 x 13 cm.

Cocaine produced a dose dependent increase in fight duration. The total fight duration was approximately 110 seconds in the saline injected animals, 175 seconds in animals receiving 10 mg/kg. cocaine and 240 seconds in animals receiving 35 mg/kg. cocaine. The fight duration in the non-injected resting controls was approximately 140 seconds. By graphical methods, the ED_{50} for cocaine on the fighting response (over a saline baseline) was determined to be about 15 mg/kg. assuring a logarithmic dose-response characteristic. As regards fighting over the time course, cocaine produced its greatest effect in the last five minute time block. Again, this effect appears to be strongly dose dependent. Without cocaine, there was no significant difference in fight duration between the 2nd and 3rd 5 minute time block. The first 5 minute time block displayed shorter fight durations than later time blocks for all conditions, but again cocaine elevated fighting in this block. The cocaine treated animals also showed qualitative differences. They were more agitated and initially tried to jump over the steep walls of the fighting arena. The initial response was one of irritative--avoidance but this soon gave way to intense fighting.

110.9 EFFECTS OF ATROPINE ON PHENCYCLIDINE (PCP)-INDUCED RESPIRATORY TOXICITY AND LETHALITY IN RATS. M. P. Holsapple*, D. J. Ritter*, W. R. Pfister*, and G. K. W. Yim (SPON: R. Babington). Dept. of Pharmacology and Toxicology, Purdue University., W. Lafayette, IN 47906.

To further evaluate the potential role of the anticholinesterase actions of PCP (Kloog et al., Eur. J. Pharmacol. 45: 221, 1977), the effects of atropine were determined. In rats anesthetized with urethane (1.2 g/kg ip), PCP infusion (0.25 mg/min into the jugular vein) induced apneusis and gasping, followed by progressive depression of respiratory rate and diaphragmatic contractions, and eventual respiratory arrest (within 40-60 min). After stopping the PCP infusion at the apneustic stage (2mg/kg), approximately 30 min was required for recovery to pre-drug respiratory rates and phrenic discharge patterns. Intravenous atropine (0.8 mg/kg) immediately converted the irregular apneustic-gasping respiration to a more regular pattern (rate and amplitude). Atropine pretreatment also prevented the development of the apneustic PCP pattern. However, apneusis could not be induced by infusion of the centrally active anticholinesterase agent, physostigmine. In addition, atropine had an erratic effect on lethality. Possible protection, suggested in initial experiments, could not be consistently duplicated in subsequent experiments. Moreover, pretreatment with atropine (1 mg/kg ip) failed to protect unanesthetized rats (and mice) from convulsions and lethality induced by 100 mg/kg PCP ip.

These results thus indicate that atropine is not an effective antagonist of PCP-induced respiratory toxicity and lethality, and that PCP-induced apneusis is not solely due to the anticholinesterase actions of PCP. (Supported, in part, by a Purdue Research Foundation Fellowship to M.P.H., N.S.F. Grant #SPL-7826649 and U.S.P.H.S. Grant DA/DA-02327-01).

110.10 COCAINE-INDUCED SPINDLES ARE GENERATED IN THE PREPYRIFORM CORTEX IN THE RAT. Jeffrey S. Stripling. Department of Psychology, University of Arkansas, Fayetteville, AR 72701.

In large doses, cocaine produces a characteristic form of extracellular field potential in the olfactory forebrain (cocaine spindles) which consists of bursts of high-amplitude sinusoidal electrical activity in the range of 20 - 50 Hz. This phenomenon was first reported by Eidelberg, Lesse, and Gault (1963), who recorded it from electrodes implanted in the amygdala of the cat. Subsequent experiments indicated that other local anesthetics such as lidocaine produce a similar effect. Because this form of drug-induced electrical activity can be recorded by electrodes in the amygdala, it has sometimes been assumed that it is generated by neuronal activity within that structure. However, cocaine spindles closely resemble naturally occurring activity generated in the olfactory bulb and prepyriform cortex in the presence of olfactory input (olfactory spindles). The purpose of the present experiment was to determine if the drug-induced spindle activity which can be recorded in the amygdala is in fact generated in the adjacent portion of the prepyriform cortex by the same circuits which generate naturally occurring olfactory spindles. Rats with chronically implanted electrodes in the prepyriform cortex were injected with doses of cocaine or lidocaine sufficient to produce spindle activity (5 mg/kg i.v. or 40 mg/kg i.p.). Both drug-induced and naturally-occurring spindles showed the same amplitude profile, with the lowest amplitude in the posterior prepyriform cortex (nearest the amygdala). Multipolar recordings indicated that the amplitude of naturally-occurring or drug-induced spindles was highest within the prepyriform cortex and lower at sites 1 - 2 mm dorsal to the prepyriform cortex (e.g., in the amygdala). Furthermore, both naturally-occurring and drug-induced spindles exhibited a polarity reversal near the superficial pyramidal cell layer of the prepyriform cortex. Finally, neither form of spindle occurred when nasal air flow was blocked (absence of olfactory input). These observations support the conclusion that cocaine and lidocaine-induced spindle activity which can be recorded in the amygdala is generated by circuits in the adjacent prepyriform cortex which also produce naturally occurring olfactory spindles.

110.11 EFFECTS OF DOPAMINERGIC AND CHOLINERGIC AGENTS ON PHENCYCLIDINE-INDUCED BEHAVIORS IN RATS. S. Castellani and P.M. Adams. Department of Psychiatry and Behavioral Sciences, University of Texas Medical Branch, Galveston, Texas 77550.

Previous studies have shown that many biochemical and behavioral effects of phencyclidine (PCP) are affected by dopaminergic and cholinergic neurotransmission. Thus, PCP-induced dopaminergic effects include reuptake blockage and potentiation of presynaptic dopamine action in the corpus striatum, and dopamine mediation of stereotyped behaviors. Also, cholinergic effects of PCP indicate competitive inhibition of CNS and peripheral acetylcholinesterase activity in vitro, and anticholinergic potentiation of locomotor activity. This study was undertaken to examine the effects of dopaminergic and cholinergic agents on concurrent PCP-induced locomotor activity, stereotypy and ataxia in rats.

Fischer 344 male rats were rated for PCP-stereotypy and ataxia in 1 minute observation periods at 10, 20, 30 and 40 minutes post-injection (0.0,2.0,4.0, and 6.0mg/kg) and assessed for locomotor activity by means of automated counters in three 10 minute post injection intervals through 70 minutes. The rating scales used in this experiment were developed by the authors for quantification of PCP-induced stereotypy and ataxia, and were validated in previous dose-response studies. Dopaminergic drugs used were haloperidol (.5mg/kg) and apomorphine (.2mg/kg); and the cholinergic drugs used were atropine (1.0mg/kg) and physostigmine (.2mg/kg).

Both stereotypy ratings and locomotor activity counts were decreased by haloperidol and increased by apomorphine, and also showed decreases and increases following injection of physostigmine, and atropine, respectively. However, these effects were PCP dose dependent for dopaminergic and cholinergic agents. In contrast to higher PCP dosages, apomorphine decreased PCP locomotor activity at the 2mg/kg dose level, which is in agreement with a recent study of Garey et.al. (Life Sci. 26:277-287, 1980) who reported an inhibition of PCP motor behaviors with low doses of apomorphine. Ataxia ratings were increased following injections of haloperidol at 2 and 6mg/kg dosage levels. These data indicate that dopaminergic and cholinergic mechanisms are important in the mediation of PCP-induced stereotypy and locomotor activity across a wide range of PCP dosage levels. The inhibitory effects of apomorphine on locomotor activity may be due to presynaptic effects of this drug, as suggested by Garey et.al. (1980). In addition, the enhancing actions of haloperidol on PCP-induced ataxia could be the result of extrapyramidal effects (akinesia) of the drug.

110.12 ALCOHOL EFFECTS ON NEUROELECTRICAL ACTIVITY AND BEHAVIOR OF MONKEYS IN A COGNITIVE TASK. J. M. Fuster, T. J. Willey, D. M. Riley* and J. W. Ashford*. Dept. Psychiatry and Brain Res. Inst., Sch. of Med., Univ. California, Los Angeles, CA 90024.

This study is designed to elucidate effects of ethyl alcohol on electrophysiology of brain structures involved in visual perception and short-term memory. Monkeys were trained in a delayed color-matching task. A trial consists of the following sequence: (1) a white (strobe) flash as an alerting signal; (2) a colored light--the sample, red or green--in a translucid button (which the animal turns off by pressing); (3) a delay of 10 sec; (4) simultaneous appearance of both colors, red and green, in two separate buttons; (5) animal's choice of one color. If the chosen color matches the sample, juice reward is given. The color of the sample and its position in the choice buttons are changed randomly. Thus the animal must perceive and retain through the delay the sample-color. Measures of performance are: (a) number of correct choices; (b) sample reaction time; (c) choice reaction time. Electrodes were implanted for recording EEG from lateral geniculate body, visual cortex, inferotemporal cortex, amygdala, and reticular formation; Ag/AgCl electrodes for recording eye-position. Control saline or ethanol solution (0.25, 0.5, 1.0, and 2.0 g/Kg) was injected intravenously to performing animals with remote Sage pump. Blood alcohol levels were determined. All records were analyzed by PDP-12 computer.

Alcohol induced a performance deficit: increase of matching errors and generally longer and more variable reaction times. Following alcohol injection, a transient lowering of spectral intensity was observed in EEG (Fourier analysis). It was followed by long-lasting increase of spectral intensity to higher levels than before injection. This increase was dose-dependent and affected most markedly frequencies in 0.5-3.5 and 13-24 cps ranges. It was accompanied, especially at highest dose, by cyclical fluctuations of intensity in the four canonical frequency bands. Visual evoked responses (VER's) to the alerting flash were scarcely modified by alcohol, even at high doses. In some locations, notably reticular formation, the amplitude of these responses was increased. By contrast, VER's to sample were diminished in dose-related manner everywhere, in correlation with effects on performance. However, the effect on sample VER's could be seen even at alcohol levels insufficient for performance deficit. In conclusion, alcohol has a general effect on electrical excitability of the neural substrate of vision. Remarkably susceptible to alcohol are central reactions to discrete stimuli that contain critical information for short-term memory.

110.13 EFFECTS OF PRENATAL EXPOSURE TO METHADONE ON REACTION TO METHADONE AND ENVIRONMENTAL STIMULI. L.D. Middaugh, L.W. Simpson*, T.N. Thomas and J.W. Zemp. Depts. of Biochem. and of Psychiat., Med. Univ. So. Car., Chas., S.C. 29402.

Methadone injected into pregnant rats alters behavior of both developing and mature offspring. The behavioral changes suggest that the offspring are more reactive to environmental stimuli. Other studies have demonstrated that prenatal exposure to narcotics alters the analgesic properties of the drugs after maturity. The present experiments were completed to test the hypothesis that prenatal exposure to methadone alters reactivity to stimulus presentation and to acute injections of the drug.

C57BL/6J mice were injected for the last third of pregnancy, with saline or methadone hydrochloride in doses of 2.5 mg, 5.0 mg or 10 mg/kg. Control dams received equivalent volumes of saline (.01/ml/g). At birth litters were reduced to 6 and reared by their biological mothers until weaning at 24 days of age. The 10 mg/kg dose reduced weight gains during pregnancy by 28% and delayed parturition by 12-24 hours. The two lower doses did not influence these parameters. Litter size and body weight of 21-day-old offspring were unaffected by maternal drug exposure.

Reaction to environmental stimuli was assessed by recording activity prior to, during, and following presentation of a one minute pulsating tone-light complex stimulus. One male and female animal per dam injected with either saline or methadone at 5 mg/kg was tested. Male offspring of both treatment groups had similar patterns of activity with an initial reduction following stimulus presentation and a gradual return to pre-stimulus levels. Female offspring of the two groups, however, differed extensively. Activity of saline offspring changed very little across the entire test having only a slight reduction immediately following termination of the stimulus. Female offspring of methadone dams, however, reduced their activity during the entire period of stimulus presentation and for a short period of time following termination of the stimulus.

Behavioral reaction to methadone (.75 mg or 1.5 mg/kg) of male and female offspring of dams injected with saline or methadone (5 mg or 10 mg/kg) was assessed by determining drug effect on 120 day-old mice lever pressing for food delivered according to a fixed-ratio 20 schedule of reinforcement. Methadone, as previously reported for offspring of untreated dams, disrupted the lever response. Prenatal exposure to methadone, however, did not influence the degree of disruption for either male or female offspring. In summary, maternal injections of methadone at high doses decreased weight gains of pregnant mice and delayed parturition. The treatment did not alter the behavioral response to the drug in mature offspring, however, did increase the reactivity of female offspring to environmental stimuli. (Supported by Grant #01750).

110.14 SPECIFIC INHIBITION OF D-AMPHETAMINE BUT NOT APOMORPHINE-INDUCED STEREOTYPY BY MORPHINE. T.F. Seeger* and K.R. Carlson. Department of Pharmacology, University of Massachusetts Medical School, Worcester, MA 01605.

It is a long-standing hypothesis that morphine can act as a post-synaptic dopamine receptor blocking agent in the striatum, and thereby inhibits the stereotyped behaviors elicited by dopamine (DA) agonists (Puri and Lal, 1973).

However, recent evidence suggests that there are opiate receptors located on the pre-synaptic dopamine axon terminals, suggesting that antagonism of dopamine-mediated behaviors may come about via inhibition of transmitter release (Pollard et. al., 1977).

We have tested the relative inhibitory effect of morphine on the actions of an agonist which releases DA (D-amphetamine), as opposed to a direct DA receptor agonist (apomorphine). In addition, we have tested the effect of the opiate antagonist naloxone on DA agonist-elicited behaviors, in order to determine whether the pre-synaptic opiate system may exert a tonic modulatory influence on dopaminergic activity.

Experimental subjects were male, Sprague-Dawley rats, weighing between 400 and 500 grams at the time of testing. Groups of twelve were given i.p. injections of apomorphine (0.25, 0.50 or 2.0 gm/kg) or D-amphetamine (2.0 or 5.0 mg/kg). Beginning 5 min. after apomorphine injection and 15 min. after D-amphetamine injection, the durations of stereotypic chewing and sniffing behaviors were individually quantified and recorded, during three 2-min. rating periods spaced 10 min. apart. Three days later, the testing was repeated 45 min. after pretreatment with morphine (5 mg/kg i.p.). Three days after this test, the procedure was repeated 15 min. after pretreatment with naloxone (2 mg/kg i.p.)

The most prominent stereotypy at 2 mg/kg D-amphetamine, sniffing, was 45% inhibited by morphine ($p < .001$). At 5 mg/kg, a considerable amount of chewing behavior was seen, which was 72% inhibited by morphine ($p < .002$). In contrast, morphine did not inhibit apomorphine-induced chewing or sniffing at any dose tested. Naloxone had no effect on the stereotypic behaviors induced by either drug.

The results thus provide behavioral evidence for a pre-synaptic interaction of morphine with dopamine neurons in the striatum. In addition, the lack of effect of naloxone argues against a tonic modulatory action by the endogenous opiate peptide system.

110.15 KETAMINE: CONVULSANT OR ANTI-CONVULSANT? Michael S. Myslobodsky, Vladimir Golovchinsky * and Matti Mintz *, Psychobiology Research Unit, Dept. of Psychology, Tel-Aviv University and Dept. of Anaesthesiology, UCLA School of Medicine, Los Angeles, LA 90024

Ketamine hydrochloride has fallen from favor due to seizure phenomena reportedly time-related to its action. However, the ability of ketamine to inhibit the high affinity transport system responsible for the uptake of norepinephrine (Pharmacol. 16:325, 1974) and to accelerate dopamine turnover (Acta Anesth. Scand. 20:216, 1976) may suggest that is has antiepileptic properties.

In experiments with Wistar and Sprague-Dawley rats ketamine alone (doses from 5 to 100 mg kg^{-1}, I.P.) never produced electrographic or clinical epileptiform manifestations.

In doses producing narcotic-cataleptic effects in rats (50-100 mg kg^{-1} I.P.), ketamine reduced the intensity of picrotoxin-induced convulsions and eliminated seizures caused by metrazol (40 mg kg^{-1}) administration. Subcataleptic doses (5-20 mg kg^{-1}) increased the duration of mitigated convulsive symptoms (abortive grand mal fits, jerks) especially those evoked by picrotoxin (4 mg kg^{-1}). Narcotic-cataleptic doses of ketamine considerably increased the duration of the period of single and multiple jerks produced by picrotoxin administration. Animals pretreated with GABA-transaminase inhibitor, γ-acetylenic GABA (100 mg kg^{-1} I.P.) and given ketamine 4-5 hr later, responded to challenging doses of metrazol with lethal status epilepticus. In a dose of 50 mg kg^{-1} ketamine completely antagonized grand mal seizures while myoclonic phenomena were not controlled by this dose of ketamine.

Both convulsants transformed 1-2 Hz "Ketamine complexes" into 2-4 Hz Wave-spike discharges which appeared in a quasi-periodic fashion alternating with periods of relatively suppressed electrocortical activity. Electroencephalographic grand mal patterns were typically dissociated from behavioral manifestations under 50-100 mg kg^{-1} of ketamine, followed by a short period of postictal depression and a rapid recovery of preseizure electrographic patterns. The findings are interpreted as suggesting that mechanisms involved in seizure alleviation may be responsible for sustaining mitigated convulsive phenomena.

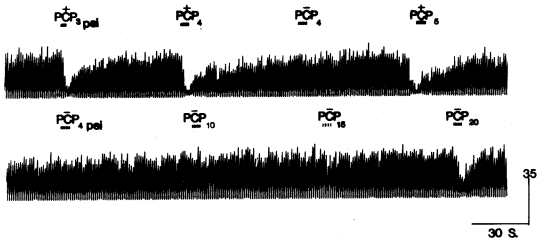
110.16 THE INTERACTIONS OF PHENCYCLIDINE WITH CENTRAL NORADRENERGIC SYNAPSES. M.R. Palmer, J. Marwaha, K. Rice†*, S. Paul†*, P. Skolnick†*, B.J. Hoffer* and R. Freedman*. Dept. of Pharmacology, Univ. of Colorado Health Sciences Center, Denver, CO 80262, and †NIAMDD, Bethesda, MD 20205.

The interactions of locally administered phencyclidine (PCP) with noradrenergic (NE) synapses was studied. The PCP-induced depression of noradrenoceptive cerebellar rat Purkinje (P) cells is reversibly antagonized by agents which block NE input, such as phenothiazine and butyrophenone antipsychotics, and lithium. PCP is ineffective when administered to animals in which central NE fibers were destroyed by 6-hydroxydopamine or in which transmitter release was reduced by local application of Mg^{++}. The dextrorotatory isomer of 3-methyl PCP is 5-10 fold more potent than the levorotatory enantiomer in slowing P cell discharge.



A similar difference in potency is found behaviorally using the rotorod test. After parenteral administration of (+)-3-methyl PCP, the time course of slowing of P cell discharge is similar to the disruption of rotorod behavior. Taken together, these results suggest that the behavioral effects of PCP are, in part, mediated by presynaptic noradrenergic mechanisms. 110.17 AMPHETAMINE-INDUCED GROWTH IMPAIRMENT IN THE RAT. Wm. J. Pizzi and June E. Barnhart*. Dept. of Psychology, Northeastern Illinois Univ., Chicago, IL 60625.

In recent years a scientific controversy has developed around the use of stimulant drugs in the treatment of hyperactive children. The primary cause for concern is that stimulant drugs have been implicated in the production of growth deficits in these patients. The original studies based on clinical populations have been severely criticized for their methodological inadequacies, especially those concerning sampling. Recent studies on clinical populations have failed to demonstrate growth impairments in children treated with stimulants.

This study was carried out to determine if amphetamine administered to young animals is capable of producing growth impairment. Subjects were 51 Long Evans hooded male rats born in the laboratory and randomly assigned to a control group or one of four drug groups. The drug groups included 0.75, 1.5, 7.5, or 15 mg/kg b.w. amphetamine. These doses were calculated to range from a moderate therapeutic dose in humans to an extremely toxic dose in the rodent. The drug was administered s.c. daily from day 20 to 40 after birth. All animals were autopsied between days 41 and 43, and femur lengths were determined to the nearest .025 inch. An ANOVA of femur lengths resulted in a significant F ($p < 0.01$). A post hoc analysis showed all amphetamine treated groups to have shorter femurs than controls ($p < 0.006$). An analysis of body weights at day 40 failed to show any significant differences when amphetamine-treated animals were compared to their respective control groups. The lack of a significant change in the body weights of amphetamine-treated animals indicates that the growth impairment seen in this study resulted independently of the anorexic effects of the stimulants which might have led to a nutritional deficit. Our tentative working hypothesis is that amphetamine interferes with the normal release of growth hormone in these animals.

The results of this study suggest an immediate need for further study of the growth impairing ability of various stimulant drugs. If future studies verify the results of this research it will also be important to determine if any other neurobehavioral toxicological effects occur following the administration of stimulant drugs to immature organisms.

110.18 EFFECTS OF HIPPOCAMPAL LESIONS ON ALCOHOL DISCRIMINATION IN RATS. H. E. Modrow*, F. A. Holloway and L. D. Devenport (SPON: J. A. Holloway) Dept. Psych. Behav. Sci., Oklahoma University Health Sciences Center, Oklahoma City, OK 73190.

Hippocampal lesions have been shown to produce a wide variety of behavioral impairments (Kimble, J. COMP. PHYSIOL. PSYHCOL. 56:277, 1963). One of us (Devenport, SCIENCE 2-5:712, 1979) has suggested that hippocampal lesions produce a state of behavioral invariance in which the animal has a diminished capacity to change or shift its response rate or topography. Unlike shams, hippocampals do not display response shifts with the introduction of a novel stimulus (Wickelgren and Isaacson, NATURE 200:48, 1963). In our lab, hippocampals have been shown not to exhibit alcohol-induced state-dependency in a runway task (Devenport, Devenport & Holloway, SWPA, 1980). Perhaps the hippocampals were either unable to detect the cue properties of alcohol or were unable to exhibit a behavioral shift in response to the novel state change. To decide between these possibilities, we attempted to train hippocampals to discriminate alcohol from a saline state utilizing a standard operant discrimination paradigm.

Twelve male food-deprived rats (6 shams, 6 hippocampals) were shaped to bar-press on one lever in a two-lever operant chamber, while in the saline state. Operant training in the saline state continued until a stable performance was obtained under a terminal FR30 schedule of food reinforcement. Animals then were placed in the alcohol drug state (1.5 g/kg, 10% w/v, i.p.) for two days and given further training with food reinforcement on the opposite lever. Alcohol-drug discrimination training continued (2 days alcohol, 2 days saline, etc.) until an alcohol discrimination criterion was met. The animals then were given generalization tests with various doses of alcohol every third day in order to obtain an alcohol generalization curve.

The results of this study indicate that although the hippocampal animals learned to bar press slightly more rapidly than the shams in the saline state, they required significantly more sessions to meet the alcohol discrimination criterion. The alcohol generalization curves indicated that hippocampals required a higher dose of alcohol (i.e., nearer the training dose) before they responded to the drug lever. The hippocampals may have been less sensitive to the discriminative properties of alcohol. However, they eventually were able to meet the alcohol discrimination criterion. Thus, the hippocampals' difficulty in learning the discrimination as well as the differences in their alcohol generalization curve also might reflect an inability to shift responding with a change in state.

113.1 RELATIONSHIP BETWEEN DISCHARGE FREQUENCY AND GLUCOSE UTILIZATION IN VISUAL CORTEX OF CAT AND KITTEN. A. Schoppmann* and M. P. Stryker. Department of Physiology, University of California, San Francisco, CA 94143.

It has been clear for several years that, at least in a general way, increased neuronal firing frequency is associated with increased cerebral glucose utilization as determined by the 2-deoxyglucose autoradiographic technique (Sokoloff et al., J. Neurochem. 28: 897-916, 1977). We have attempted to measure this relationship for cells in several layers of the visual cortex and for animals of several ages.

Cats were prepared for visual physiology in the conventional manner, and were then flaxedilized and artificially ventilated using a mixture of 75% nitrous oxide and 25% oxygen. Horizontal microelectrode penetrations were made through the medial bank of the visual cortex in order to sample the activity of a long sequence of cells within a single cortical layer. Fine electrodes (maximum OD 50 μm) were used in order to minimize disruption of the brain. We isolated single units at intervals of approximately 100 μm and measured both the spontaneous discharge frequency and that evoked by a moving pattern of vertical stripes. Under the conditions of this experiment, these discharge frequencies were fairly stable. Six to eight electrode positions along the course of the 6-8 mm penetration were marked with microlesions. On completing the electrode penetration, we injected 100 μCi/kg 14-C-2-deoxyglucose in order to measure the rates of glucose utilization evoked by the same pattern used for measurement of impulse discharge frequency. Brains were sectioned in the plane of the microelectrode penetration, and the sections, along with radioactive standards, were used to expose X-ray films. Densitometric scans of the course of the microelectrode penetrations on the autoradiographs allowed us to relate discharge frequency to local glucose utilization. The relation is quite steep in adult cats and less so in 5-week kittens.

We have also attempted to measure the loss of resolution that results from our histological and autoradiographic procedures. Brains were labelled using different doses of 14-C-2-deoxyglucose and cryostat sections of known thickness cut from each of these brains. Alternate high- and low-dose sections, still frozen, were assembled into sandwiches. These sandwiches were then cut in a plane perpendicular to the plane of their component sections, picked up on cover glasses, dried conventionally on a 70 degree hot plate, and used to expose X-ray films. Periodic variations in density visible in autoradiographs of sandwiches composed of 20 μm sections suggests that the loss of resolution is no worse than 20 μm. [Supported by NIH and DFG.]

113.2 RETINOTOPIC ORGANIZATION OF THE MACAQUE VISUAL SYSTEM AS DEMONSTRATED BY THE ^{14}C-DEOXYGLUCOSE TECHNIQUE. S.J.Herdman, S.Juliano P.Hand and L.A.Palmer. Depts. of Anat. and Animal Biol., Schools of Med. and Vet. Med. and Inst. of Neurol. Sciences, Univ. of Pa. Phila., Pa. 19104.

The ^{14}C-deoxyglucose technique has an advantage over electrophysiological mapping in that multiple cortical and subcortical visual areas can be studied simultaneously. Four Macaques were used in this study - two blindfolded control animals and two experimental animals; all animals were prepared according to the protocal established by Sokoloff et al ('77). The experimental animals were studied in room light with both eyes open. A moving stimulus of high contrast black and white lines of all orientations was used to activate a specific portion of the visual field.

In the blindfolded control animals, area 17 was faintly labeled only in layers IVc and IVb. By contrast, the portion of the striate cortex which was activated by the background lighting of the room was labeled more heavily in layers IVc, IVb and VI; the other layers were less densely labeled. These findings correspond well with those of Kennedy et al ('76). As one moves into the portion of area 17 driven by the moving stimulus, the labeling becomes markedly denser and, in addition, layer IVa is noticeable labeled. The boundaries of this densely labeled area correspond to the extent of the stimulus and to the electrophysiologically defined organization of area 17 as defined by Gattass et al ('79).

Area 18 in the blindfolded animals is essentially unlabeled except for a faint line in layer IV; in the visually stimulated animal distinct patches of labeling appear, often with a regular configuration which suggests columns. In the portion of area 18 not driven by the moving stimulus, at the 17/18 border there is a decrease in the density of the labeling extending into area 18 as well as into area 17. As one moves into the portion of the area activated by the moving stimulus, the labeling again becomes more dense. The portion of area 18 which is more densely labeled corresponds to the portion of the visual field occupied by the moving stimulus and to the electrophysiological maps of Gattass et al.

The LGNd also shows a difference in the density of the labeling which corresponds to the portion of the visual field stimulated by the moving stimulus and which corresponds to the electrophysiological map of the LGNd by Malpeli et al ('75). We are in the process of analyzing other areas, such as OA, caudal STS, and TE, which appear to be labeled.

113.3 A COMPARISON BETWEEN SLEEPING AND WAKING OF SPONTANEOUS AND VISUALLY EVOKED ACTIVITY IN CAT STRIATE CORTEX, EXAMINED BY SINGLE CELL RECORDING AND 2-DEOXYGLUCOSE AUTORADIOGRAPHY. David H. Hubel and Margaret S. Livingstone*. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

We began this study by examining electrophysiologically the influence of waking state on single cells in cat striate cortex. Under halothane anesthesia sleep-deprived cats were implanted with EEG electrodes and a pedestal to hold a microelectrode advancer. All skin incisions were infiltrated with local anesthetic. The trachea was intubated, the animal was paralyzed with intravenous succinylcholine and artificially respirated, and then the anesthetic was discontinued. Single cells were recorded two at a time with tungsten microelectrodes independently positioned by a multiple advancer. Waking state fluctuated spontaneously, or cats could be lulled to sleep or aroused by noise or tactile stimulation. The effects of arousal from slow wave sleep to waking varied from cell to cell but each cell showed a consistent type of change through several sleep/wake cycles. Most often (69/109 cells) an irregular bursty firing during slow wave sleep gave way to a smoother regular firing upon arousal, while the overall rate was unchanged, diminished (sometimes markedly) or occasionally elevated. This confirms previous findings. Visually evoked responses were unchanged (80/109) or enhanced (26/109), only rarely decreased. Usually evoked responses became more obvious against the more regular spontaneous firing. Receptive field properties were generally unchanged. During REM sleep most cells showed very irregular spontaneous activity with high frequency bursts during PGO waves. The spontaneous activity during REM sleep was often so erratic that it obscured any visually evoked response. There were hints that an increase in responsiveness on waking from slow wave sleep was more common in deeper-layer cells. To pursue this further we used the ^{14}C-2-deoxyglucose method in three cats, one awake, one in slow wave sleep, and one in REM sleep, stimulating the left half visual field with vertical stripes. Each brain showed orientation columns on the right. In the awake cat these were densely labeled above and below layer IV, whereas in slow wave sleep the columns were much fainter in the deeper layers than in the superficial layers. The columns in the cat in REM sleep extended through all cortical layers but were less distinct than the columns in the waking animal. (Supported by NIH Grant EY00605).

113.4 DIFFERENCES BETWEEN SLEEPING AND WAKING IN VISUALLY EVOKED CORTICAL ACTIVITY IN THE CAT, MEASURED BY A DOUBLE-LABEL 2-DEOXYGLUCOSE TECHNIQUE. Margaret S. Livingstone* and David H. Hubel (SPON: S. W. Kuffler). Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

We have developed a double-label 2-deoxyglucose technique to compare in a single animal the effects of two different stimuli, or a single stimulus under two different conditions. Our immediate objective was to compare visually evoked cortical activity in the cat, awake and in slow wave sleep. Under halothane anesthesia a sleep-deprived cat was implanted with EEG electrodes, intubated, paralyzed with intravenous succinylcholine and artificially respirated. The anesthetic was then discontinued. We waited until the EEG showed normal slow wave sleep, from which the cat could be aroused, then injected a pulse of ^{14}C-deoxyglucose intravenously, and stimulated the left visual field for 45 min. with moving vertical stripes. Then a second pulse, of ^{3}H-deoxyglucose, was followed by 45 min. of right visual-field stimulation during which the cat was kept awake by noise and tactile stimulation as needed. The cat was injected with thiopental, perfused with formalin, and the brain frozen. The heat-dried cryostat sections were exposed first on X-ray film (whose protective coating partially blocks ^{3}H radiation) and then on LKB Ultrafilm ^{3}H, which lacks a protective coating. We determined optimum doses of ^{14}C and ^{3}H to be injected into the cat by exposing the two films to spots of filter paper soaked in graded dilutions of the two labels; such spots were also exposed along with the brain sections to serve as standards for subsequent optical subtraction. On X-ray film the right (^{14}C, asleep) cortex showed much denser orientation columns than the left (^{3}H, awake) while on the unprotected film columns were denser on the left. The two autoradiographs from a given section were subtracted optically by making a negative of one and superimposing its projected image on the original (positive) of the other: the relative intensities of the two images were determined from the autoradiographed filter-paper standards--for example, enough of the LKB negative image was added to the X-ray positive image to make several successive ^{14}C spots in the intermediate density range equal in brightness. At these intensities columns were then seen only in the left hemisphere. Similarly when the process was repeated so as to equalize the ^{3}H spots, columns were seen only on the right. The results confirm our previous findings: columns in the waking state were about equally distinct above and below layer IV, whereas in slow wave sleep they were well labeled in the upper layers but much fainter in V and VI. Slow wave sleep would thus seem to produce a selective decline in activity in layers V and VI of area 17. (Supported by NIH Grant EY00605).

113.5 CYTOCHROME OXIDASE STAIN PREFERENTIALLY LABELS INTERSECTION OF OCULAR DOMINANCE AND VERTICAL ORIENTATION COLUMNS IN MACAQUE STRIATE CORTEX. Jonathan C. Horton* and David H. Hubel (SPON: Edwin J. Furshpan). Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Cytochrome oxidase histochemistry has been introduced as a method for mapping oxidative metabolism in the central nervous system (Wong-Riley, 1979). We have examined the pattern of cytochrome oxidase staining in the macaque striate cortex. In coronal section heavier staining was visible in those layers receiving geniculate input: VI, IVC, and an upper tier in IVA. In layers II, III there was a distinct periodic fluctuation in density of reaction product which appeared in tangential section as a network of dark oval patches, roughly 200 × 150 µm. These patches were aligned in rows spaced about 550 µm apart, intersected by rows 350 µm apart. The second, more closely spaced rows resembled ocular dominance columns in spacing, regularity, and by running orthogonal to the 17-18 border. To test this impression we examined cytochrome oxidase staining in a monkey 10 days after damaging one eye. Tangential reconstruction of layer IVC showed dark and light bands arrayed in the characteristic ocular dominance pattern; in layers II, III alternating rows of light and dark patches were in register with the light and dark bands in IVC. Another monkey was stimulated with moving vertical stripes following a ^{14}C-2-deoxyglucose injection. Alternate tangential sections, processed for autoradiography and cytochrome oxidase histochemistry, showed that the rows of patches spaced 550 µm apart matched the pattern formed by the vertical orientation columns. It thus appears that in normal macaque striate cortex, regions of higher oxidative metabolic activity are located at the intersection of the ocular dominance and vertical orientation columns.

Cytochrome oxidase staining of human striate cortex obtained from autopsy material revealed a similar although less regular network of patches in layers II, III. The rows approaching perpendicular to the 17-18 border were spaced about 900 µm apart, corresponding to the width of human ocular dominance columns (Hitchcock & Hickey, 1980). (Supported by NIH Grant EY00605).

113.6 RADIAL ZONES OF HIGH METABOLIC ACTIVITY IN SQUIRREL MONKEY STRIATE CORTEX. A. L. Humphrey & A. E. Hendrickson, Department of Ophthalmology, University of Washington, Seattle, WA 98195.

Hendrickson and Wilson (Brain Res., 170, '79) recently showed that squirrel monkeys had radial zones of increased(^{14}C)-2-deoxyglucose (2DG) uptake in their striate cortices after monocularly viewing a visual scene having many orientations. The radial zones were most distinct in layers II & III; in tangential sections the zones formed separate spots roughly 500µm apart. Layers IVa & IVc were continuously and densely labeled, raising a question as to whether the radial zones above layer IV represented ocular dominance columns or another functional system. We addressed this question in further (14C)-2DG experiments using alert, restrained squirrel monkeys, and we also examined a second metabolic label, cytochrome oxidase (Wong-Riley, Brain Res., 171, '79), in the same animals' cortices.

Radial zones of increased 2DG uptake, roughly 500µm apart, were present in autoradiographs from animals that binocularly viewed black and white stripes (4' to 2^{o} vis. arc) at all orientations. The radial zones still were present, though less distinct, in an animal binocularly stimulated by diffuse light in a ganzfeld, but they were not present in a binocularly occluded animal. In all conditions in which the radial zones were elicited, they were the same in shape, laminar location and spacing.

A laminar and radial pattern of cytochrome oxidase activity virtually identical to the 2DG pattern was present throughout the binocular and monocular regions of normal squirrel monkey striate cortex. Single sections of striate cortex sequentially processed for 2DG and cytochrome oxidase showed that the two labels mark the same spots in cortex. The two labels are dissociable, however, since in the binocularly occluded animal that showed no radial zones of high 2DG uptake radial zones of high cytochrome oxidase activity were present. Preliminary EM indicates that the cytochrome oxidase reaction is labeling mitochondria primarily in postsynaptic, presumably dendritic, processes. These results show that in squirrel monkey striate cortex there are regularly spaced radial zones of high metabolic activity which can be triggered by diffuse light activation of the visual system and which are not dependent on eye dominance, stimulus orientation or spatial frequency for their demonstration.

Supported by grants EY07013, EY01208 & EY01730.

113.7 ORGANIZATION OF OCULAR DOMINANCE COLUMNS IN GALAGO DEMONSTRATED BY AUTORADIOGRAPHIC AND DEOXYGLUCOSE METHODS. V. A. Casagrande and L. C. Skeen. Depts. Anat. & Psych., Vanderbilt U., Nashville, TN 37232 and Dept. Psych., Univ. Delaware, Newark, DE 19711

Previous investigators have demonstrated the presence of ocular dominance columns in the striate cortex of the galago using both anterograde degeneration and transneuronal autoradiographic methods (Glendenning et al., '75; Casagrande et al., '77; Hubel and Wiesel, '77). However, while degeneration techniques suggest that input from the two eyes is almost completely segregated in cortex, transneuronal autoradiographic evidence shows a partial segregation of geniculo-cortical terminals which is more pronounced for the ipsilateral cortex. In this experiment, we used two additional methods to determine the degree of segregation of ocular input within the cortex. In the first study, we injected ^{3}H-proline into laminae of the lateral geniculate nucleus (LGN) in galagos under electrophysiological guidance. These animals were sacrificed 24-48 hours later and the brains processed according to standard autoradiographic techniques. In the second study, galagos were given I.V. injections of ^{14}C-2-deoxy-D-glucose (2-DG) and monocularly exposed for 45 minutes to moving stripes at all orientations. Immediately thereafter, the animals were sacrificed, the brains cut, and sections were exposed to X-ray film (Kennedy et al., '76). Laminar injections of ^{3}H-proline produced one or more 300 µ wide labelled patches in layer IV of striate cortex. No differences in patterns of label were observed following injections of ipsilaterally versus contralaterlly innervated LGN layers. Consistent with previous evidence we found that the parvocellular LGN layers (3 and 6) projected to the ventral tier of cortical layer IV, the magnocellular layers (1 and 2) projected to the dorsal tier of layer IV and the small celled layers (4 and 5) projected to layer I (Glendenning et al., '76; Carey et al., '79). Large LGN injections involving all layers produced additional labelled patches in cortical layer III where label was continuous in layer IV indicating that some periodicity of LGN afferents may not reflect ocular segregation. The 2-DG experiments revealed the following results: In layer IV, sharp, alternating 300 µ wide bands of high and low activity were apparent in layer VI. Consistent with the results of the LGN laminar injections, no differences in periodicity were observed between ipsilateral and contralateral retinal pathways. Taken together, our main results suggest that ocular segregation in galago visual cortex may be more complete and more balanced with respect to the two eyes than originally reported.

113.8 INTERLEAVING PROJECTION BANDS IN CORTICO-CORTICAL CONNECTIONS. Gilbert, C.D. and Wiesel, T.N. Dept. of Neurobiology, Harvard Medical School, Boston, Mass.

Cortico-cortical connections are made between topographically corresponding sites. On a smaller scale, the cells in the superficial layers of a given cortical area that project to a restricted location in another cortical area are distributed in cell-dense patches which are separated by cell-sparse intervening zones (Gilbert and Kelly, 1975). In the present study we have examined the cortical projection patches in greater detail.

Area 17 of the cat's visual cortex projects to area 19, which in turn sends a recurrent projection to area 17. Injecting a small (.05 ul) volume of a 15% solution of horseradish peroxidase (HRP) in area 19 resulted in labeling a large number of cells in area 17 by retrograde transport. These cells were grouped into distinct patches, located approximately 600 micrometers apart. The patches tended to line up, from one coronal section to the next, and when reconstructed from serial sections formed parallel bands running in an anteroposterior direction. The intervening bands also projected to area 19, but to a site adjacent to the site to which the labeled bands projected. This was demonstrated by making large (0.5 ul) injections of HRP in area 19, which resulted in a continuous band of labeled cells in area 17. The recurrent projection from 19 to 17 gave a complementary picture, with patches in 19 resulting from localized HRP injections in 17.

A similar phenomenon was observed in the anterograde direction, between areas 17 and 19. A small patch of one area projected to bands within the receiving area. This was shown by anterograde transport of HRP or of 3H-proline. Thus there was a combination of divergent and convergent connections between bands in areas 17 and 19. Our results suggest that in the projection from 17 to 19 convergence predominates, with a larger number of bands in 17 projecting to a smaller number of bands in 19. Conversely, in the projection from 19 to 17 divergence is predominant. This was not unexpected, since area 17 covers a larger area, has a larger magnification factor, and consequently has many more bands than area 19.

It appeared, furthermore, that the anterograde and retrograde systems of bands were in register, as shown by combining HRP and 3H-proline in a single injection: a given site in one area received input from the bands to which it projected.

This banding pattern of interconnections is a general phenomenon which we observed in several visual cortical areas of the cat and monkey. Thus the columnar system, which is initiated in the cortex by the thalamocortical projection, is repeated in subsequent stages of processing. 114.3 SACCADIC EYE MOVEMENTS IN PATIENTS WITH DISCRETE UNILATERAL FRONTAL-LOBE REMOVALS. H.A. Buchtel* and D. Guitton (SPON: B. Milner). Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada H3A 2B4

In primates, visually-guided saccades can apparently be controlled either by a visual cortex-superior colliculus-brainstem system, or by a frontal cortex-brainstem system (Schiller, P.H. et al., Science, 206: 590, 1979). It seems probable that these two systems usually work together in producing appropriate eye movements. In an attempt to clarify the particular role of eye-movement related mechanisms located in the frontal lobes, we have studied the saccades of patients who have had discrete unilateral removals of frontal-lobe tissue for the relief of intractable epilepsy.

Two tasks were used. In the first task, the patient was asked to look toward or away (anti-saccade) from a tachistoscopically-presented target (small open circle) located at various eccentricities from central fixation. In the second task, the patient was always required to look at the target but on some trials a distractor (a filled circle of the same size) was presented in the opposite visual field. Eye movements were monitored by electro-oculography.

In both tasks, the patients showed disturbances of eye movements that were related to the direction of the required saccade. For example, in the anti-saccade task, they experienced great difficulty in suppressing a reflex-like saccade to the stimulus when it was located in the visual field contralateral to their lesion. When the stimulus was presented to their ipsilateral field, and therefore projected initially to their intact cerebral hemisphere, they were better able to initiate an eye movement in the opposite direction. The data on 6 patients to date suggest that eye-movement related mechanisms of the frontal lobes are useful in inhibiting saccades to inappropriate but visually-attractive stimuli.

114.4 DIFFERENTIAL AFFERENT INPUT TO SUBDIVISONS WITHIN THE FRONTAL EYE FIELDS (AREA 8) OF MACAQUES. H. Barbas and M-M. Mesulam. Harvard Neurol. Unit, Beth Israel Hospital, Boston, MA 02215.

The sources of ipsilateral cortical afferents to subdivisions of the frontal eye fields (Walker's area 8) were studied with horseradish peroxidase (HRP) in macaques. Labeled neurons were noted in: 1- visual association areas of peristriate and inferior temporal cortex; 2- auditory association cortex of the superior temporal gyrus; 3- the ventral bank of the intraparietal sulcus, the inferior parietal lobule, and medial parietal cortex; 4- the depths of the superior temporal sulcus; 5- prefrontal cortex; 6- paralimbic regions of cingulate and retrosplenial cortex.

There were striking differences when the distribution of cells projecting to the caudal part of area 8 was compared with the distribution of cells projecting to its more rostral part. To demonstrate these differences, the number of labeled cells within a specific area was expressed as a percentage of the total number of labeled cortical cells. In a case with HRP injections within the caudal part of area 8, most labeled cells (53%) were in visual association cortices. An additional 23% were in the caudal half of the ventral bank of the intraparietal sulcus, where neurons have predominantly visual and visuo-motor properties. Most other labeled cells were in regions which may be considered high order association areas (the banks of the superior temporal sulcus, and prefrontal cortex). In sharp contrast, when the HRP injections covered the rostral part of area 8, a much lower percentage of labeled neurons (5%) was in visual association areas, with an additional 8% in the caudal ventral bank of the intraparietal sulcus. In addition, there were labeled cells in auditory (21%) and paralimbic (13%) regions. The number of cells in high order association areas (banks of superior temporal sulcus, inferior parietal lobule, medial parietal cortex, and prefrontal cortex) was higher (55%) than in the case with a caudal injection.

The results indicate that most of the cells projecting to caudal area 8 are situated in visual association areas. In contrast, rostral parts of area 8 receive projections from cells that are mostly in high order association areas but also from those in auditory association cortex and paralimbic regions. Differences in neuronal response properties in subdivisions of area 8 may reflect these differences in the source of their cortical afferents. The caudal parts of area 8 may be involved in head and eye movements in response to visual stimuli, while its anterior subdivisions may play a role in directing the head and eyes in response to auditory stimuli. Furthermore, limbic input may also be relevant to the neural processing occurring in the anterior part of the frontal eye fields.

114.5 AN ANTEROGRADE HRP STUDY OF PREFRONTAL EFFERENTS TO BRAINSTEM OCULOMOTOR CENTERS IN THE MONKEY. G.R. Leichnetz, Department of Anatomy, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia 23298.

Using cortical horseradish peroxidase gel implants (Griffin et al 1979), TMB neurohistochemistry (Mesulam 1978) and dark-field microscopy, we have been able to achieve remarkable visualization of anterogradely-labelled corticofugal systems. In particular, the technique has led us to a new appreciation for, and description of, the projections from the monkey prefrontal cortex to several preoculomotor and oculomotor targets in the brainstem which have been directly or indirectly associated with eye movement. These projections not only reach the midbrain and pons through the classically-defined "capsular-peduncular-tegmental" route, but also through the internal medullary lamina (and paralaminar regions of VA and MD) of the thalamus. After principal sulcus and "frontal eye field" (FEF) implants, a prominent bilateral prefrontal-oculomotor bundle was observed in the medial subthalamic region (dorsomedial to the fasciculus retroflexus and ventral to the interstitial nucleus of the MLF) - an area involved in vertical eye movements (Graybiel 1977; Buttner-Ennerver 1978), the bilateral lesion of which produces downward gaze paralysis (Kompf et al 1979). This same bundle was followed caudally into the rostral oculomotor nucleus. Prefronto-tectal projections appeared to be topographically organized. A considerable portion of these, particularly from FEF, reached the midbrain through the "trans-thalamic" pathway, probably giving off fibers (perhaps collaterals) into the intralaminar complex, MDmf, medial pulvinar and pretectum, before terminating in the superior colliculus (SC) and dorsolateral central gray. The capsular-peduncular prefronto-fugal projection traversed the medialmost posterior limb of the internal capsule and medialmost crus cerebri, and thus would not have been interrupted in reported lesions of the internal capsule (Bender and Shanzer 1964) which produced "no defect in gaze." This ipsilateral bundle was followed caudally into the rostral medial pontine reticular formation (PPRF) where some of the fibers decussated. Lesions of PPRF have been reported to produce defects involving both horizontal and vertical gaze. The findings may explain the experiments of Conway and Schiller (1979), demonstrating that combined bilateral FEF and SC lesions in monkeys were required to produce a severe, non-recoverable deficit in visually-triggered saccades, by describing an independent pathway from FEF to oculomotor centers. Thus the efferents of the prefrontal cortex, including FEF, provide several pathways through which a direct cortical influence may be exerted on eye movement mechanisms. 114.7 THALAMIC NEURONS CODING EYE POSITION IN MONKEY. J. Schlag and M. Schlag-Rey. Dept. of Anatomy and BRI, UCLA, Los Angeles, CA 90024.

In the course of microelectrode descents to explore the region of the thalamic internal medullary lamina (IML) in alert monkeys, units firing in relation with eye position were found at the most dorsal aspect of the thalamus. These cells were among the first encountered after leaving the ventricle. By histological control, the majority were located in n. anterior dorsalis; yet some may have been situated in the rostral part of n. lateralis dorsalis or in the capsule formed by the IML around the anterior nuclei. These units discharged with great regularity at rates varying from 0/sec with the eyes near the center in the orbit to 150/sec for gaze deviations of 35 degrees. All had a horizontal preferred direction, 93% contraversive, 7% ipsiversive. Stable rates were maintained sometimes for several seconds at any eye position along the axis of preferred direction. The activity was the same in complete darkness as in light or in presence of discrete photic stimuli. The frequency was modulated as a function of eye position when the animals followed a sinusoidally moving target. Changes of firing levels occurred abruptly in the course of saccades, with no bursts or pauses. The exact timing of the changes seemed to depend primarily on the prior eye position. With respect to the saccades, the latency was shortest when the eyes were already deviated toward the preferred direction before moving further in this direction. In such cases, changes of firing could even precede saccades. In contrast, changes of firing were delayed after saccades starting far away from ipsilateral sites and not reaching much further than the midline. As for neurons of the cortical frontal eye field described by Bizzi, the time relations with eye movements neither support an hypothesis of motor command nor one of proprioceptive feedback.

Further down in the same tracks, other cells were found in the IML itself, which also discharged as a function of eye position. In general, their firing pattern was less regular, and bursts or pauses accompanied saccades, especially in the on- or off-direction of the cells.

These new observations add evidence on the existence of cell populations involved in gaze control in the medial thalamus. Such populations seem to expand further than the boundaries of the IML itself. (Supported by USPHS Grant EY 02305).

114.6 SACCADE-RELATED NEURONS IN PRIMATE THALAMUS. M. Schlag-Rey and J. Schlag. Dept. of Anatomy and BRI, UCLA, Los Angeles, CA 90024.

Previous research has revealed the existence of saccade-related (S-R) neurons in the internal medullary lamina (IML) of the thalamus in cats. The present experiment was undertaken to determine if such neurons exist in primates. Four Macaca Nemestrina were trained to fixate stationary and moving targets presented in dim red light or complete darkness. Between conditioned trials, single unit activity was studied in relation to spontaneous saccades, monitored by DC electro-oculography. Histologically reconstructed microelectrode tracks explored an area extending frontally from planes F 4.5 to F 8.7 (Olszewski), laterally from 2 to 6 mm from the midline and down from the floor of the third ventricle to 4 mm below.

In and above the IML region, three general types of unit firing were found specifically related to saccades in complete darkness as well as in light. 47% of S-R units discharged before and during saccades in light or dark, with or without triggering stimuli. Most of these units showed a sharp tuning in their on-direction. Vertical-oblique preferences were more frequent than purely horizontal ones in our restricted sample of IML neurons. The majority of presaccadic units were of the long lead burst variety, with lead time often exceeding 250 ms. Quantitative analyses of the discharges revealed that in many cases a position component was mixed with the velocity or amplitude component in the preferred direction. These units were found mainly in n. centralis superior lateralis and the upper part of the IML.

41% of the S-R units, typically found in n. lateralis dorsalis stopped firing during saccades. Thalamic omnipausers differed from brain stem and cerebellar omnipausers by the timing of the pause which often led and outlasted saccades and by the presence of rebound activity. Thus, there were pause-rebound and rebound-only types. While pauses were omnidirectional in all cases, rebounds sometimes were not.

The remaining 12% of the S-R units were seen active only during (not before) saccades and were scattered in the region explored. These results support the hypothesis that the medial thalamus, in particular the IML region, is involved in the control of gaze, in primates as well as in cats. (Supported by USPHS Grant EY 02305).

115.1 NALOXONE-SENSITIVE EEG AND BEHAVIORAL EFFECTS OF ECS IN RATS. F.C. Tortella, E.F. Berman*, A. Cowan, M.W. Adler, G.L. Belenky and J.W. Holaday, Dept. of Pharmacology, Temple University School of Medicine, Philadelphia, Pa. 19140 and Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, D.C. 20012.

Electroconvulsive shock (ECS) produces opiate-like effects in rats which are attenuated by naloxone (Holaday et al, Soc. Neurosci. Abstr. 4: 409, 1978). In the present study we characterized the EEG and behavioral effects of ECS and provide additional evidence for a functional role of opioid peptides in postictal events.

Male S.D. rats (250-300 g) were prepared with chronic cerebrocortical electrodes. Three to five days after surgery, the rats were placed in individual recording chambers and allowed to acclimate and move freely while control EEG recordings were taken. Rats were subjected to transauricular ECS (0.2 sec, 50 mA, 60 Hz) and the effects of electroshock studied after (a) single shock (acute ECS) and (b) following 10 consecutive once-daily shocks (chronic ECS). ECS produced a generalized convulsion marked by a polyspike EEG seizure. The seizure was followed by a period of postictal depression (PID) characterized by EEG high-voltage synchrony. During the postictal period following acute ECS, quantitation of the EEG voltage output (V.O.) revealed a significant increase in power to 27 ± 7% (S.E.) above control. The duration of the associated PID was 2675 ± 658 sec. Chronic ECS increased the EEG V.O. and duration of PID 55 ± 16% above control and 3310 ± 697 sec., respectively. This represented a statistically significant increase compared to the acute ECS response. Pretreatment with naloxone (0.3-10 mg/kg, s.c.), 10 min before acute ECS, antagonized the postictal increase in EEG V.O. and duration of depression, implicating involvement of endogenous opioid peptides. Naloxone did not markedly alter the EEG or behavioral pattern of the seizure itself, however, nor did it (3 and 10 mg/kg, s.c.) significantly antagonize the chronic ECS responses. Possible explanations for these effects are currently being investigated.

The ECS-induced EEG and behavioral changes in the rat reported here are similar to those seen after the icv administration of morphine and opioid peptides (Tortella et al, JPET 206: 636, 1978). Furthermore, the postictal events appear analogous to the EEG synchrony and depression reported in man following generalized seizures. ECS in the rat thus appears to be a potentially useful model for the study of the interrelationships of endogenous opiate peptides and seizure events.

115.2 BEHAVIORAL EFFECT OF β-ENDORPHIN (β-EP) AND NOREPINEPHRINE (NE) IN THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS (PVN). S. F. Leibowitz and L. Hor*. The Rockefeller Univ., New York, NY 10021.

Hypothalamic NE injection in the rat is known to elicit feeding through α-adrenergic receptor stimulation. The most sensitive site for observing this phenomenon is the PVN, a brain area which receives a dense innervation of noradrenergic fibers. Evidence from this laboratory suggests that NE release from these fibers mediates the increased feeding observed with local injection of tricyclic antidepressants and also possibly contributes to the increased feeding observed after glucoprivation. In line with this latter suggestion is the finding that noradrenergic feeding is abolished by hypophysectomy and adrenalectomy and is specifically related in magnitude to circulating levels of glucocorticosteroids.

The relationship of this noradrenergic system to brain endorphins was examined in the present study, in which male Sprague Dawley rats (350 g) were stereotaxically implanted with chronic brain cannulas aimed at the PVN. All drugs were injected directly into the PVN through this cannula, and the rats' eating behavior (of lab chow pellets) was measured over the next 2 hr. During this period, satiated rats, after injection of the saline vehicle, generally ate relatively little, approximately 0.6 g. Injection of NE into the PVN produced a significant feeding response of 2.7 g, with a latency of 1 to 2 min and a duration of 15-20 min. Injection of β-EP (1 nmole) also elicited a reliable feeding response (2.0 g), although the latency of this response was approximately 30 min and sometimes longer. (Also see Grandison and Guidotti, 1977.) The magnitude of the NE and β-EP feeding responses in these rats was significantly correlated (r = +.75), suggesting a possible relationship between these two phenomena.

Further support for this relationship was obtained with the α-adrenergic receptor blocker phentolamine (60 nmoles) which inhibited the β-EP feeding response as well as the NE response. This contrasts with the dopamine receptor antagonist fluphenazine (10 nmoles), which had no effect on either response. While this suggests that β-EP may ultimately act through endogenous noradrenergic neurons to alter behavior, evidence obtained with opiate antagonist naloxone (100 and 200 nmoles) indicates that β-EP's immediate action involves local opiate receptors. PVN injection of naxolone abolished the eating response of β-EP but had no effect on NE's action or on spontaneous feeding in hungry rats.

This evidence reveals a possible relationship between opiate and noradrenergic neurons within a discrete region of the hypothalamus. This relationship may broaden our understanding of the neurochemical mechanisms through which this brain area operates physiologically to maintain and achieve energy homeostasis, during normal and perhaps stressful conditions. 115.3 EFFECTS OF SYSTEMIC ADMINISTRATION OF α-ENDORPHIN (β-LIPOTROPIN 61-76) ON INTRACRANIAL SELF-STIMULATION IN THE RAT. George T. Bain*, Ralph U. Esposito and Conan Kornetsky. Laboratory of Behavioral Pharmacology, Boston University School of Medicine, 80 E. Concord St., Boston, MA 02118

This report concerns an attempt to determine if systemically administered α-endorphin (β-lipotropin 61-76) would affect intracranial self-stimulation behavior in the rat. Subjects were implanted with electrodes aimed at the ventral tegmentum and intracranial reinforcing thresholds were determined by means of a modification of the classical psychophysical method of limits (Esposito and Kornetsky, Science 195:189, 1977). Alterations of reinforcing thresholds were observed after microgram doses (25-75 µg/kg) of the peptide were administered subcutaneously. Both significant increases and decreases of threshold occurred, dependent on dose and time after administration. These threshold effects occurred within 1.5 hours after injection and were not accompanied by any gross behavior changes. The findings demonstrate that systemically administered α-endorphin induces specific alterations in central reward processes.

115.4 INDUCTION OF MATERNAL BEHAVIOR FOLLOWING INTRACEREBROVENTRICULAR ADMINISTRATION OF POSTERIOR PITUITARY HORMONES. C. A. Pedersen*, and A. J. Prange, Jr.* (SPON: G. H. Greeley, Jr.). Biol. Sci. Res. Center and the Neurobiology Program, Univ. North Carolina School of Medicine, Chapel Hill, North Carolina 27514.

Since oxytocin (OXY) is released during birth and nursing, we tested, in virgin female Sprague-Dawley rats, the possibility that this nanopeptide would induce maternal behavior.

Informal experiments revealed that OXY (0.4 µg) given through a lateral ventricular cannula often produced maternal behavior. In all subsequent experiments this route of administration was employed. Behavior was assessed by observers ignorant of treatments.

Intact rats were given 0.4 µg OXY in normal saline (n=36), or normal saline alone (10 µl) (n=12) and immediately placed in individual cages containing nest material and three pups. Quantitative criteria in all of five behavioral categories (grouping, licking, crouching, nest building, retrieval) had to be fulfilled by an animal within two h of injection for its behavior to be considered fully maternal. Fifteen (42%) of OXY injected animals showed full maternal behavior while none of the saline treated animals displayed this effect.

Estrogen dependence of the OXY effect was suggested by the observation that, with one exception, all animals that responded fully maternally to OXY injection (n=15) were in the last day of diestrus, or in proestrus or estrus, when estrogen levels are rising, elevated, or recently elevated respectively. To test the possibility that estrogen is necessary to permit OXY-induced maternal behavior, a number of cannulated virgin females were ovariectomized (OVX). Immediately after operation 27 animals were injected sc with 100 µg/kg of estradiol benzoate (EB) in corn oil (0.1 ml) or corn oil vehicle alone. Forty-eight h later all subjects received 0.4 µg of OXY icv. Eleven of 13 EB primed virgins and none of 14 nonprimed virgins displayed full maternal behavior.

Specificity of the OXY effect was investigated by administering either 0.4 µg OXY or equimolar quantities of other hormones into OVXed, EB primed virgins. OXY produced a 76% rate of full maternal behavior (22/29) while arginine vasopressin induced a 52% response rate (11/21). Lysine vasopressin as well as a large number of peptides, steroids, and prostaglandins were no more effective than saline in inducing maternal behavior.

Dose-response relationships were studied in rats given 100 µg/kg EB at OVX, followed 48 h later by doses of OXY between 0.1 and 0.4 µg. The incidence of full maternal response was linearly related to log dose OXY.

115.5 BEHAVIORAL EFFECTS OF PERIPHERAL ADMINISTRATION OF ENDORPHINS: MEMORY OR MOTIVATION? M. Le Moal, O. Gaffori*, J. Rossier, N. Ling*, G. F. Koob, and F. E. Bloom. Laboratoire de Neurobiologie des Comportements, Université de Bordeaux II, Bordeaux, FRANCE, and A. V. Davis Center for Behavioral Neurobiology, Salk Inst., San Diego, CA, 92138.

Subcutaneous injections of 1 to 10 µg per rat of alpha (β-LPH_{61-76}) and gamma(β-LPH_{61-77}) endorphin significantly altered the extinction of aversively and appetitively motivated learning. Alpha endorphin, when injected immediately after the first 10 trials of extinction of an active (pole jump) avoidance task,significantly prolonged extinction on subsequent trials. When injected 1 hour prior to the test trial of a passive avoidance task, alpha endorphin significantly inhibited extinction, but facilitated extinction when injected immediately after the training (shock) trial. In contrast gamma endorphin, when injected immediately after the first 10 trials of extinction of the active avoidance task, significantly facilitated extinction on subequent trials, and when injected 1 hour prior to the test trial of a passive avoidance task, facilitated extinction. Des-tyr^1-gamma (β-LPH_{62-77}) endorphin at doses of 1 to 10 µg per rat failed to alter the extinction of either active or passive avoidance. Both alpha and gamma endorphin, when injected after the first extinction trial of a water- motivated runway task, significantly delayed extinction on subsequent trials. These effects were not reversible by pretreatment with naloxone (5 mg/kg). Measurements of alpha endorphin in the blood and brain with radioimmunoassay following subcutaneous injection revealed measurable levels in the blood at 5 and 10 min. post- injection, but virtual dissappearance after 20 minutes. No detectable levels were found in the brain at any time post- injection. Results confirm that the peripheral administration of minute amounts of endorphins can produce significant behavioral effects, but suggest that these effects are independent of a memory substrate. In addition, the results fail to confirm a behavioral role for des- tyr^1- gamma endorphin. Thus, it appears that the endorphin analogs, alpha and gamma endorphin, act independently of metabolism via removal of the N- terminal tyrosine and act independently of traditional opiate receptors to produce subtle motivational effects.

115.6 DIFFERENTIAL EFFECTS OF MET- AND LEU-ENKEPHALIN ON BEHAVIOR: NALOXONE REVERSIBILITY AND THE DEVELOPMENT OF TOLERANCE. Henk Rigter and Joe L. Martinez, Jr. CNS Pharmacology Department, Organon, Oss, The Netherlands, and Department of Psychobiology, University of California, Irvine, CA 92717 USA.

We have previously shown that Met- and Leu-enkephalin (M-ENK and L-ENK) impair acquisition of an active avoidance response when injected i.p. before training (Rigter et al., Life Sciences, 1980, 26, 337-345). The purpose of the present study was to further characterize the nature of the opiate receptor mediating this response by studying: 1) several opioid agonists, 2) naloxone reversibility of the enkephalin effect and 3) the development of behavioral tolerance by repeated administration of enkephalins.

Male Wistar rats were trained to avoid electric shock by stepping on a platform in the middle of a conditioning box. Shock (0.3 mA) was turned on 10 sec after the rat was placed in the apparatus unless the rat made an avoidance response by stepping on the platform. Rats were trained in a single 10-trial session and drug treatments were given i.p., 5 min before training.

In the first series of studies we found that µ agonists, such as etorphine and morphine, did not affect acquisition of the avoidance response. Also, long-chain endorphins, such as α-, β-, and γ-endorphin, were inactive. Thus, the behavioral effect of enkephalins is probably not due to an interaction with µ opiate receptors. We feel that enkephalin effects on avoidance conditioning are related to δ opiate receptor activity since D-Ala-D-L-ENK was active at a dose level 10-100x lower than the lowest effective dose of L-ENK (Rigter et al., 1980).

In order to further investigate this question we attempted to block the enkephalin effects with naloxone. $ACTH_{4-10}$ was included in this study because pilot work had shown it impaired acquisition at equivalent doses to the enkephalins. It was found that 10 µg/ kg of L-ENK, M-ENK and $ACTH_{4-10}$ given i.p., 5 min before training significantly impaired acquisition. Naloxone (10 mg/kg), given as a cocktail with the peptides, reversed the effect of M-ENK, but failed to antagonize the effect of L-ENK. Surprisingly, naloxone potentiated the behavioral effect of $ACTH_{4-10}$. Thus, it is possible to differentiate between the behavioral effects of different classes of peptides by examining naloxone reversibility.

Tolerance studies also differentiated between M-ENK and L-ENK. While no tolerance developed to the effect of M-ENK during 7 treatments with the peptide, tolerance to L-ENK did develop. The results point to the existence of complex physiological differences between related peptides.

115.7 ENKEPHALIN AND $ACTH_{4-10}$ EFFECTS ON ACTIVE AVOIDANCE CONDITIONING ARE ATTENUATED BY ADRENAL DEMEDULLATION. Joe L. Martinez, Jr. and Henk Rigter. Department of Psychobiology, University of California, Irvine, CA 92717 USA, and CNS Pharmacology Department, Oss, The Netherlands.

Previous research has shown that small amounts of systemically administered Leu-enkephalin (Rigter et al., Life Sciences, 1980, 26, 337-345) and $ACTH_{4-10}$ (Rigter and Martinez, this meeting) impair acquisition of an active avoidance response. Other findings showing both Leu- and Met-enkephalin immunoreactive material in chromaffin granules of adrenal cells suggested that the adrenal medulla may be important for enkephalin effects on avoidance conditioning (Schultzberg et al., Neuroscience, 1978, 3, 1169-1186; Viveros et al., Molecular Pharmacology, 1979, 16, 1101-1108). Thus, we investigated whether Met- or Leu-enkephalin impaired acquisition of an avoidance response in adrenal demedullated (ADXM) rats. Also, we included $ACTH_{4-10}$ in this study because its behavioral actions in this task are similar to the enkephalins.

Male Wistar rats, either ADXM or sham operated (SHAM), were trained to avoid footshock (0.3 mA) in a step-up active avoidance task. Ten µg/kg of either Leu- or Met-enkephalin, or $ACTH_{4-10}$ given i.p. 5 min before training significantly reduced the number of avoidance responses made by the SHAM groups in comparison to saline-injected animals. Peptide-treated ADXM rats did not differ from saline-treated controls. Thus, adrenal demedullation abolished the effects of the peptides.

In a further experiment, we examined whether in ADXM rats increasing the dose of either Leu- or Met-enkephalin would restore their behavioral actions. ADXM or SHAM rats were administered either 100 or 1000 µg/kg Leu- or Met-enkephalin i.p. and trained as described previously. Both the 100 and 1000 µg/kg dose of Leu-enkephalin impaired acquisition of the avoidance response in ADXM rats, whereas neither dose of Met-enkephalin affected the response in ADXM animals.

These results suggest that the behavioral effects of enkephalins and $ACTH_{4-10}$ in this task may be related to peripheral mechanisms. The fact that adrenal medullectomy shifts the dose response function for Leu- but not Met- enkephalin suggests that their behavioral actions are related to distinct physiological processes.

This research was conducted while JLM was a Postdoctoral Fellow at Organon International, B.V.

116.1 NON-ENDORPHIN PATHWAYS SUPPRESS PAIN IN HUMANS. J.B. WALKER* AND R.L. KATZ, DEPARTMENT OF ANESTHESIOLOGY, UCLA SCHOOL OF MEDICINE, LOS ANGELES, CALIFORNIA 90024.

Subcutaneous electrical stimulation (20 HZ) of median, radial, and saphenous nerves produces prolonged analgesia. This effect of subcutaneous nerve stimulation (SCNS) is not mediated by opiate receptors: (1) there is no cross-tolerance with opiates, and SCNS suppresses pain in patients who have received chronic administration and meperidine every two hours for months (2) patients unresponsive to morphine benefit from SCNS (3) there is no tolerance to SCNS, and (4) SCNS, can be administered with oral analgesics (both opiate and non-opiate) to increase patient comfort. These observations suggest that non-endorphin pathways produce powerful analgesia.

A follow-up of patients treated for surgically documented gynecological pain (endometriosis) shows them to be pain free 5 years after cessation of treatment, as measured by verbal report, attendance at work, and analgesic abstinence. To our knowledge, this represents the first such long term follow-up on the clinical pain literature.

Although the mode of action of SCNS is unknown, it decreases the excitability of spinal reflexes. In a double blind study, SCNS suppresses clonus in spastic patients for three hours. The effect is contralateral so that each patient can serve as his own control. Suppression is not mediated by opiate receptors because it is not mimicked by opiates nor is it naloxone-reversible. After multiple treatments, clonus suppression occurs for months. We are currently investigating the neurochemical basis for the long duration of SCNS-induced alterations in neural excitability.

116.2 CORTICAL PROJECTIONS TO THE PERIAQUEDUCTAL GRAY IN MONKEYS: A POTENTIAL ROUTE FOR INFLUENCING NOCICEPTION. S.G.P. Hardy* and G.R. Leichnetz (SPON: J.A. Astruc). Dept. of Anatomy, Med. Col. of Va., Richmond, VA. 23298.

Numerous behavioral manifestations have been associated with the periaqueductal gray (PAG). In recent years the PAG has been shown to participate in analgesic mechanisms. In order to assess the potential influence that the cortex may exert upon this structure a study was made of the cortical efferents to the PAG in the monkey using the horseradish peroxidase (HRP) technique. In a series of Old and New World monkeys, including Macaca fascicularis and Cebus albifrons, stereotaxic HRP fluid injections (0.01-0.05 µl 25% HRP in sterile saline) were made into the PAG. HRP gel implants were subsequently made in various regions of the cerebral cortex. Fluid injection cases were studied with regard to retrograde transport and gel implant cases were used to study orthograde transport. After survival periods of 24-48 hrs. the monkeys were processed according to the tetramethylbenzidine protocol (Mesulam 1978) and sections were studied under bright and dark field microscopy. Results from this study indicate that the prefrontal cortex projects significantly to the PAG, whereas few cortical areas outside the frontal region are involved. The prefrontal-PAG projection arises primarily from small lamina V pyramids (8-15 µ) in the rostral medial prefrontal and dorsal convexity cortices. Other areas of the prefrontal cortex also contributed projections to the PAG, with the exception of the medial orbitofrontal cortex. Prefrontal-PAG fibers were found to terminate primarily in the dorsolateral aspect of the PAG, an area which has been shown to receive nociceptive input via the spinothalamic tract (Mehler 1969). In view of the heavy termination in this precise PAG region we are led to speculate that prefrontal-PAG projections may influence nociception by acting either directly or indirectly upon the spinothalamic system.

116.3 DISRUPTION OF STIMULATION-PRODUCED ANALGESIA BY LESIONS OF THE NUCLEUS RAPHE MAGNUS. J. Timothy Cannon, Guadalupe J. Prieto*, and John C. Liebeskind. Dept. Psychol., UCLA, Los Angeles, CA 90024.

The n. raphe magnus (NRM) has been proposed as a relay carrying pain inhibitory messages from the periaqueductal gray matter (PAG) to the spinal cord. Supporting this view, it was shown, for example, that NRM lesions disrupt analgesia caused by glutamate injections in PAG (Behbehani and Fields, 1979). However, we found that NRM lesions between the inferior olive and the trapezoid body fail to alter analgesia from PAG electrical stimulation (Prieto et al., 1979). In subsequent work, we have extended our efforts in two ways: 1. We find that distinct loci exist within and near PAG, stimulation of which causes analgesia that is differentially sensitive to naloxone blockade. Thus, analgesia from stimulating in or just below the dorsal raphe n. is reliably blocked by naloxone, but that deriving from more dorsal PAG sites is not (Cannon et al., 1980; Prieto et al., 1979). In the present work, we have studied the naloxone-sensitive ventral sites. 2. Recent anatomical studies (Basbaum et al., 1978; Watkins et al., 1980) show a cluster of NRM cells extending over the decussation of the trapezoid body that went undamaged in our previous work. Consequently, lesions were modified in the present study to include these cells.

Rats were implanted with bipolar stimulating electrodes in or just below dorsal raphe n. One week later, current thresholds were established for inhibition of the tail-flick response to radiant heat (7 sec cutoff) by use of a modified ascending method of limits. Brain stimulation consisted of constant current, biphasic pulse pairs (20/sec). Each pulse was 50 µsec in length with a 100 µsec interpulse interval. Stimulation was delivered for 10 sec prior to and during each tail-flick trial. Following threshold determinations, animals received one of the following NRM lesions: 1. On midline between trapezoid body and inferior olive; 2. As (1) but bilateral and displaced .5 mm off midline; 3. As (1) but with a second lesion involving NRM cells above trapezoid body. One week later, analgesic thresholds were determined as before.

All animals sustaining NRM damage from the level of the inferior olive through the region of the trapezoid body exhibited large elevations in analgesia thresholds ($n = 6$, mean = 97%, $p < .05$). No other lesion produced comparable effects in any animal ($n = 25$). Preliminary evidence indicates that these same NRM lesions do not disrupt analgesia from more dorsal PAG placements, those yielding analgesia insensitive to naloxone blockade. (Supported by NIH grant NSO7628 and CONACYT-Mexico)

116.4 ANALGESIA PRODUCED BY MICROSTIMULATION IN THE MEDULLA OF THE RAT. G. Zorman*, I.D. Hentall, J.E. Adams* and H.L. Fields. Depts. of Neurosurgery, Neurology and Physiology, Univ. of California San Francisco, CA 94143.

Extensive evidence implicates the ventromedial medulla in opiate and stimulation produced analgesia (SPA). In the rat, the nucleus raphe magnus (NRM) and adjacent reticular formation ventral to reticularis gigantocellularis (Rgc) are rich in enkephalin fibers and perikarya, and contribute to medullospinal pathways. This ventral region includes the reticularis magnocellularis and pars α, collectively referred to as the nucleus reticularis paragigantocellularis (NRPG). Inhibition of nociceptive reflexes results from opiate microinjection and electrical stimulation of these sites; however, there is disagreement about whether NRM or NRPG is the more effective site. To resolve this issue, we systematically mapped the rat medulla using low-intensity monopolar microstimulation. No marked difference between NRM and NRPG was observed. Male Sprague-Dawley rats (290-340g) were anesthetized initially with 70 mg/kg pentobarbital i.p.. 1µ tip stainless steel stimulating electrodes were stereotaxically placed. Tail-flick latency to noxious heat was used as the measure of analgesia. After stable baseline latencies ($\leq$4sec) were obtained, conditioning medullary stimulation (50Hz, 400µ sec continuous pulse trains) was applied for 5 sec before and during application of noxious heat. Stimulation was considered effective if the tail remained motionless for 10 sec (cut-off). Threshold current for SPA was determined in each animal at 9 sites in a 3x3, transverse grid. In each experiment iron was deposited at three sites, allowing reconstruction of the grid from Nissl-stained sections. The lowest threshold (5-10µA) sites for SPA were found only in NRM and NRPG. Current intensities $\geq$20µA were necessary for tail-flick suppression from other regions including Rgc. Low threshold SPA from NRM and NRPG was naloxone reversible (5 mg/kg i.p.), an effect which usually had a 5 min onset and 20 min duration. Raising stimulus intensity to 20µA at these sites could reestablish SPA. The threshold current values make it unlikely that SPA from microelectrode placements in NRPG is due to current spread to NRM, and the converse is also true. Thus both NRM and NRPG can elicit SPA. Since naloxone reversibility was demonstrated in NRM and NRPG, both nuclei may produce effects mediated by endogenous opioids. Tail-flick suppression from Rgc was obtained only at stimulation intensities $\geq$20µA and was not blocked by naloxone. This suggests that Rgc suppresses tail-flick by a non-opioid mechanism. These results support the concept that NRM and NRPG but not Rgc contribute to an opioid-mediated descending system controlling spinal pain transmission neurons.

116.5 ANALGESIC RESPONSES TO STRESS AND OPIATES FOLLOWING SELECTIVE DESTRUCTION OF EITHER CATHECHOLAMINERGIC, SEROTONERGIC OR SUBSTANCE P PATHWAYS. R.J. Bodnar, M.M. Wallace, J.H. Kordower*, A. Kirschgessner*, D. Simone*, K. Merrigan*, J. Scalisi* and M. Lattner*. Dept. of Psychology, Queens College, C.U.N.Y., Flushing, NY 11367, U.S.A.

Extensive evidence suggest that the analgesic responses to opiates and electrical stimulation of the periaqueductal gray are mediated by an interaction of endorphinergic and serotonergic descending systems which inhibit nociceptive afferents in the dorsal horn. Moreover, acute exposure to a number of stressful events results in a transient analgesia. While certain stressors, such as 2-deoxy-D-glucose (2-DG)-induced glucoprivation share common analgesic characteristics with opiates, other stressors, such as cold-water swims (CWS), appear to act independently of this system, and rather rely in part upon the hypothalamo-hypophyseal axis for their effects. To determine further the properties of each of these analgesic manipulations, separate experiments investigated whether morphine, CWS and 2-DG analgesia were affected by a) systemic administration of parachlorophenylalanine (PCPA - 350 mg/kg), b) bilateral lateral hypothalamic (LH) lesions, c) bilateral locus coeruleus (LC) lesions, and d) intraventricular capsaicin injections. PCPA lowered basal pain thresholds, attenuated morphine analgesia, but did not alter CWS or 2-DG analgesia 48 hours after injection. LH lesions, which produced aphagia for two post-operative weeks, failed to alter any of the analgesic responses following recovery of normal eating patterns. By contrast, LC lesions diminished the analgesic responses to morphine and both stressors. Finally, intraventricular capsaicin, which produces hyperalgesic responses when applied intrathecally, did not affect basal pain thresholds or morphine analgesia, but lowered substantially CWS and 2-DG antinociception. Data will be discussed in terms of heterogeneous mechanisms modulating pain-inhibition. (Supported by NIH Grant NS 14449, NYSHRC Grant 1518 and NIH GRSG 5-S05-PR-07064.)

116.6 ENHANCEMENT OF STRESS-INDUCED ANALGESIA BY ADRENALECTOMY IN THE RAT. M. Glusman, R. J. Bodnar, A. Mansour* and D. D. Kelly. Dept. of Psychiatry, Columbia Univ., and N.Y. State Psychiatric Institute, New York, NY 10032.

We previously reported that stress-induced analgesia (SIA) was greatly attenuated by hypophysectomy (1); and further, that it was dependent on the anterior pituitary (2). The possibility, however, was not excluded that the reduction of SIA was not a primary effect due to loss of anterior pituitary function, but a secondary effect of hypophysectomy in impairing adrenal function.

To test this possibility we investigated the effect of adrenalectomy on SIA in 18 adrenalectomized (ADX) rats and 16 sham operated (SADX) controls. Basal pain thresholds, measured by flinch-jump and tail-flick were not significantly different between the ADX and SADX groups. Cold water swims at 2°C for 3.5 min (CWS) significantly elevated flinch-jump thresholds for both groups; but the elevations for the ADX animals were significantly greater than for the SADX controls. Naloxone 10 mgm/kilo 5 min pre-stress did not significantly alter the responses of either the ADX or SADX animals. CWS similarly increased thresholds for tail-flick; again,the increase was greater for the ADX than for the SADX animals although not statistically significant. The ADX animals also responded with greater SIA than the SADX animals to a second stressor, foot-shock. At 1.0 mA for either 20 sec or 5 sec, foot-shock produced significantly greater analgesia, measured by tail-flick, in the ADX animals than in the SADX controls. Naloxone 10 mgm/kilo did not significantly decrease SIA in the ADX animals, although it reversed the analgesia produced by 3 mg morphine in both the ADX and SADX animals.

Our study demonstrated that SIA following cold water swims or foot-shock is greater in adrenalectomized rats than normals (3). Further SIA in both groups was not mediated by endogenous opioid mechanisms because it was not significantly decreased by Naloxone. Taken with our earlier findings (1,2) this study supports the conclusion that SIA is mediated by endocrine mechanisms involving the anterior pituitary not the adrenals. The enhancement of SIA in the adrenalectomized animals probably reflects compensatory responsivity of the anterior pituitary following adrenalectomy.

Neurosci. Abstr. 5: #2069, 609, 1979. (3) A. Pert noted similarly that adrenalectomy enhanced cold water swim analgesia (unpublished observations). Supported by NIH Grants MH 15174 and NS 14449.

116.7 CROSS-TOLERANCE BETWEEN MORPHINE AND ONLY THAT FORM OF STRESS ANALGESIA ANTAGONIZED BY NALOXONE. J. W. Lewis, J. E. Sherman* J. C. Liebeskind. Dept. Psychol., UCLA, Los Angeles, CA 90024.

Exposure to a variety of stressful manipulations has been shown to induce analgesia. It has been suggested that opioid peptides mediate this phenomenon, although evidence on this point has been contradictory. We have shown (Lewis et al., Science, in press) that by varying only the temporal parameters of inescapable footshock stress, profound analgesia is elicited that is either opioid or nonopioid in nature: prolonged intermittent footshock causes analgesia that is powerfully antagonized by naloxone, whereas brief continuous footshock provides comparable analgesia that is not. These data suggest the existence of separate analgesia systems selectively activated by different stress parameters. To characterize further these systems, we have examined the effect of prior exposure to morphine on the analgesic response to both types of stress.

Male, Sprague-Dawley rats were assigned to 4 groups (n = 6) each receiving 5 daily injections of either morphine (5 mg/kg) or isotonic saline followed 3 days later by either brief (2.5 ma, 3 min) or prolonged (2.5 ma, 1 sec pulse/5 sec for 20 min) stress. Two measures of pain responsiveness were used, the tail-flick and hot-plate tests. Prior to stress, baseline latencies indicated no differences among groups. Immediately after footshock, each rat received a single hot-plate test followed by 12 tail-flick trials, then another hot-plate test.

In saline treated animals, both types of stress induced potent analgesia in hot-plate and tail-flick tests. Prior exposure to morphine, however, differentially affected tail-flick latency in brief versus prolonged stress groups. Thus, in morphine treated animals, analgesia induced by prolonged stress was severely abbreviated compared to saline controls ($p < .05$) whereas that induced by brief stress was unaffected. This differential effect was not observed on the hot-plate, possibly due to the time of testing. Both groups showed hot-plate analgesia on the first test; neither group did on the second. That morphine treated rats were tolerant to the drug's analgesic effect was indicated by their being significantly less analgesic than saline treated animals to a test dose of morphine (5 mg/kg) given 24 h after stress.

Cross-tolerance between morphine analgesia and only that form of stress analgesia antagonized by naloxone provides additional evidence for the existence of an endorphinergic pain-inhibitory system. Similarly, the lack of effect of morphine tolerance on the naloxone-insensitive stress analgesia emphasizes the importance of nonopioid mechanisms in antinociception.

116.8 THE ANALGESIA OF DEFEAT IS BLOCKED BY NALOXONE AND BY MORPHINE TOLERANCE. Klaus A. Miczek, Michael L. Thompson* and Louis Shuster. Depts. Psychology, Biochemistry and Pharmacology, Tufts University, Boston, MA 02111.

The role of endogenous opioids in stress-induced behavioral analgesia is still unclear. We have produced analgesia in mice by exposing them to a social stress, that is, defeat of an intruder by a resident attacker. The intruder is introduced into 5 different home cages for successive one minute periods. In each cage he is subjected to repeated attacks by the resident male mouse. Male mice subjected to extensive defeat (a total of 70 attacks in 5 minutes) showed a significant prolongation of latency to tail-flick in response to radiant heat (5.95 ± 0.7 vs. $1.23 \pm .02$ seconds). Analgesia was most pronounced immediately after the first experience of defeat in mice that had previously not been subjected to attack.

When naloxone, between 1 and 10 mg per kg i.p., was administered before fighting, there was no change in the frequency of defensive upright postures, escape leaps, audible vocalizations and non-agonistic locomotor activity. However the analgesia produced by defeat was effectively blocked by naloxone in a dose-dependent manner.

In additional experiments, mice were implanted with pellets containing 75 mg morphine base or placebo pellets. They were subjected to defeat on the 7th day after pellet implantation. The morphine-treated mice exhibited an intact pattern of defensive and flight behavior when attacked, but did not show any analgesia after defeat. We are presently examining whether mice that have been subjected repeatedly to defeat may show decreased analgesia and/or cross tolerance to morphine.

Our results suggest that social stress, in the form of repeated attacks, can produce marked analgesia in mice. In contrast to most other types of analgesia induced by behavioral stress, the analgesia produced by defeat is effectively antagonized by naloxone, and is not observed in morphine-tolerant animals. These results suggest that endogenous opioids may play a role in the analgesia of defeat.

116.9 EFFECTS OF NALOXONE ON THRESHOLDS FOR ESCAPE BEHAVIOR MAINTAINED BY INTRACRANIAL STIMULATION. Stephen Sasson* and Conan Kornetsky (SPON: N.K. Mello). Laboratory of Behavioral Pharmacology, Boston University School of Medicine, 80 E. Concord St., Boston, MA 02118.

Natural ligands of the opiate receptor have received attention relative to their role in the modulation of painful stimuli. Recent evidence has indicated a critical role for the reticular formation (RF) in the central processing of nociceptive input. Electrical stimulation to the RF is a reliable stimulus for maintaining escape behavior in rats. We have previously demonstrated that the threshold for escape from RF stimulation increases after morphine (Marcus and Kornetsky, Psychopharm. 38: 1, 1974) and recently reported tolerance to this effect with repeated injections (Sasson, Wheeling and Kornetsky, Soc. Neurosci. Abst. Vol. 5, p. 2254, 1979). Considering the putative involvement of the endogenous opioids in pain perception, we conducted this experiment to determine if drug naive animals would show a decrease in escape thresholds when challenged with naloxone.

Male albino rats were implanted with bipolar electrodes aimed at the RF and subsequently trained to turn a wheel manipulandum to escape RF stimulation. Threshold determination involved varying the current intensity by means of a modification of the psychophysical method of limits. Results indicated that naloxone (2-16 mg/kg, s.c.) produced dose-dependent decreases in escape thresholds. These findings suggest that naloxone may enhance the aversiveness of RF stimulation by blockade of a central opiate receptor.

116.10 NEUROCHEMICAL SUBSTRATES OF KETAMINE AND MORPHINE ANALGESIA. G.M. Pekoe* & D.J. Smith, WVU Medical Ctr., Morgantown, WV 26506

Two potential mechanisms for ketamine hydrochloride (KH) analgesia are its interaction with opiate receptors (Smith et al, Life Sci. 26:489, 1980) and inhibition of biogenic amine (norepinephrine, NE & serotonin, 5HT) neuronal reuptake (Azzaro & Smith, Neuropharm. 16:349, 1977). Morphine sulfate (MS) analgesia is also mediated by opiate and 5HT systems (Yaksh & Rudy, Pain 4:299, 1978). MS analgesia uses central gray (PAG) opiate receptors which activate the nucleus raphe magnus (NRM) to inhibit pain transmission in the dorsal horn, and spinal opiate receptors (Basbaum & Fields, Ann. Neurol. 4:451, 1978). MS-PAG interaction also causes release of spinal NE which inhibits pain transmission (Yaksh, Brain Res. 160:180, 1979). KH may also use the PAG-NRM-dorsal horn pathway, spinal opiate receptors, and NE to produce its analgesia. KH and MS analgesia were compared in the rat using the tail-flick test after biogenic amine depletion, spinal transection (T4-6) and receptor antagonism. A 70% analgesic dose of KH (160 mg/kg) or MS (4 mg/kg) was administered i.p. Antagonists were given 10 min prior to KH or 5 min after MS.

KH analgesia was antagonized by 4 fold less methysergide (ID50 0.41 mg/kg), 47 times less phentolamine (ID50 0.18) and 20 times more naloxone (ID50 0.46) than that needed to inhibit MS analgesia. Depletion of 5HT by p-chlorophenylalanine (300 mg/kg, 48h prior) attenuated KH and MS analgesia. Depletion of NE by FLA-63 (25 mg/kg, 6h prior) enhanced KH analgesia while not affecting MS. The increase with KH was reduced by naloxone (1 mg/kg) or methysergide (1 mg/kg) suggesting KH interacts with opiate and 5HT processes independent of NE. NE involvement is important but paradoxical in KH analgesia, perhaps due to opposing central and spinal NE action.

Spinal transection increased the sensitivity of rats to KH's analgesic effect 8 fold but reduced 2 fold their response to MS. In these animals KH was antagonized only by methysergide suggesting a local 5HT influence and indicating that KH may not utilize spinal opiate receptors for its analgesia. MS was antagonized by naloxone, with only the higher dose of MS affected by methysergide. These data suggest that the opiate component of KH analgesia is centrally located, as naloxone is effective in intact but not transected rats. Transection revealed a spinal 5HTergic component of KH and MS analgesia which does not appear dominant in intact rats and requires further study. It is likely that the central KH-opiate interaction in intact rats modulates the KH-5HT interaction, probably by activating the spinofugal NRM-dorsal horn pathway. KH may activate this system via PAG opiate stimulation and simultaneously enhance spinally-released 5HT action by neuronal reuptake blockade. A contribution may also be made by a spinofugal NE influence. (USPHS #5 T32 GM07039 & Anes. Res. Fund)

117.1 PHARMACOLOGICAL EVIDENCE FOR A STIMULATORY EFFECT OF SEROTONIN ON RENIN SECRETION IN RATS. L.D. Van de Kar*, C.W. Wilkinson*, and W.F. Ganong. Department of Physiology, University of California, School of Medicine, San Francisco, CA 94143.

There is evidence that central release of serotonin in dogs stimulates renin secretion via a neural pathway (Zimmermann and Ganong, Neuroendocrinology 30:101, 1980). In rats, administration of the serotonin synthesis inhibitor parachlorophenylalanine (pCPA; 300 mg/Kg i.p. 64 and 40 hours before sacrifice) caused a significant decrease in plasma renin activity and hypothalamic serotonin content. Subsequent administration of 5-hydroxytryptophan (L-5HTP; 30 mg/Kg i.p. 2 hours before sacrifice) restored the serotonin content of the hypothalamus, and plasma renin activity was increased above control level. 14 days after injection of the serotonin neurotoxin 5,7-dihydroxytryptamine (5,7-DHT; 150 µg/20 µl) into the lateral cerebral ventricle of rats pretreated with desmethylimipramine (25 mg/Kg i.p.), there was a significant decrease in plasma renin activity and the serotonin content of the hypothalamus and midbrain. The norepinephrine and dopamine content of the hypothalamus remained unchanged. In rats treated with the serotonin agonist quipazine (10 mg/kg i.p.), plasma renin activity was elevated at 30 and 45 min compared to saline controls at 45 min, with a return to control values at 60-120 min. Administration of the serotonin releaser parachloroamphetamine (PCA; 10 mg/Kg i.p.) caused a significant, but slower increase in plasma renin activity, which reached a peak 2 hours after administration. Pretreatment of the rats with pCPA (300 mg/Kg i.p. 72 hours before sacrifice) abolished the effect of PCA on plasma renin activity. These results show that serotonin stimulates renin secretion in rats as well as dogs, and that the effect is probably due to release of this amine from serotonergic neurons in the central nervous system. (Supported by USPHS Grant AM06704 and a fellowship from the Sloan Foundation.)

117.2 THE EFFECT OF HYPOTHALAMIC KNIFE CUTS IN THE REGION OF THE ANTEROVENTRAL THIRD VENTRICLE (AV3V) ON THE PRESSOR RESPONSES TO CENTRAL ANGIOTENSIN II. Steven L. Bealer, Dept. Physiology and Biophysics, University of Tennesee Center for the Health Sciences, Memphis, TN 38163

Electrolyte lesions of the tissue surrounding the anteroventral third ventricle (AV3V) region have been shown to have profound effects on fluid-electrolyte balance, including adipsia, hypernatremia, and attenuated pressor responses to intraventricularly (IVT) administered angiotensin II (AII) (Bealer et al., Am. J. Physiol., 236: E610, 1979; Johnson et al., Brain Res., 157: 61, 1978.). The present experiment tested whether discrete knife cuts surrounding the AV3V region would also effect pressor responses to central AII. An encephalatome was used to produce knife cuts in the coronal plane just posterior to the organum vasculosum of the lamina terminalis (OVLT), extending ventrally from the level of the anterior commissure to the optic chiasm,and bilaterally 2.0 mm from the midline. Cuts in this region did not damage either the OVLT or the supraoptic nucleus. Each animal was subsequently implanted with a cannula in the lateral cerebral ventricle, and allowed to fully recover from surgery. On the day before testing, a catheter was placed in the femoral artery to record blood pressure. During testing, 100 ng and 500 ng AII were administered IVT in awake, unrestrained animals. Control pressures were 118 ± 6 mmHg in animals which had received cuts, and 116 ± 4 mmHg in animals which had undergone control surgical procedures. Following IVT administration of 100 ng AII, pressure in control animals rose to 133 ± 6 mmHg, while rats with cuts showed only a slight pressor response, with peak pressures of 120 ± 5 mmHg. A similar pattern was seen following stimulation with 500 ng AII, with mean blood pressure in control animals reaching 138 ± 8 mmHg, while rats with cuts increased to 125 ± 6 mmHg. Rats which had received coronal knife cuts posterior to the OVLT showed significantly attenuated pressor responses to IVT AII when compared to animals which had undergone control surgical procedures. These data indicate that the neural substrates which mediate the pressor response to IVT AII pass through this portion of the hypothalamus. (This research was supported in part by an award from the UTCHS New Faculty Research Grant Program and a grant from the American Heart Association-Tennessee Affiliate.)

117.3 DRINKING, VASOPRESSIN, AND BLOOD PRESSURE DURING CHRONIC CENTRAL INFUSION OF ANGIOTENSIN II IN THE RAT. Tommy A. Brock* and M. Ian Phillips (SPON: R. K. Wong) Dept. of Physiology, Louisiana State University Medical Center, Shreveport, LA 71130 and Dept. of Physiology, University of Iowa, Iowa City, IA 52242.

Acute injections of the peptide angiotensin II (A-II) into the central nervous system of the rat indicate that A-II can act as a stimulus to increase drinking, vasopressin release, and blood pressure in conscious animals. Since the components of a complete renin-angiotensin system endogenous to the brain have been characterized, theseobservations suggest that A-II formed locally in the brain may be involved in the regulation of these phenomena. In the present study, we have examined the effects of prolonged one to two week infusions of A-II into the lateral ventricle of the rat in order to determine whether or not A-II is effective in producing sustained elevations in drinking, vasopressin and blood pressure.

Male Sprague-Dawley rats, 300-400g, were implanted with chronic ICV cannulas which were attached to an Alzet osmotic minipump, filled with either saline or A-II (6µg/µl). Infusion of A-II (6 µg/hr) lasted for either 6 or 12 days. Daily water intake, food consumption and systolic pressure (BP) were measured. At the end of the test period, rats were decapitated and trunk blood was collected for measurements of arginine vasopressin (AVP) plasma renin activity (PRA) and angiotensin II.

Drinking in the A-II rats was increased following the first 24 hr of infusion and remained significantly elevated throughout the 6 or 12 day test period ($p<.001$). Food consumption and body weight of the A-II rats were decreased during the first few days of infusion, but A-II rats exhibited a slightly increased weight gain as soon as the appetite returned to normal. BP was increased in the A-II group after the third day of infusion and continued to increase throughout both test periods ($p<0.001$). Plasma AVP levels were increased in both 6 day ($p<0.02$) and 12 day ($p<0.05$) A-II infused rats when compared to control animals. Plasma AVP and BP exhibited a high positive degree of correlation. Plasma Na^+ concentration and osmolality were significantly decreased. PRA was less than 10% of control after 6 days of A-II infusion, while plasma A-II levels in the A-II infused group were increased 10 fold above that seen in control animals.

These results indicate that chronic central infusion of A-II can result in sustained increases in drinking, plasma AVP, and blood pressure. The increase in drinking and plasma AVP is most probably due to activation of specific receptors located in the subfornical organ or the OVLT, while the increase in blood pressure was due both to high plasma AVP and A-II levels. The data suggest that the increase in plasma A-II was not due to increased PRA, but may be due to spillover of A-II from the CNS.

117.4 A DISCONTINUOUS PATTERN OF NUCLEAR ESTRADIOL BINDING IN BRAIN IS SUFFICIENT TO ACTIVATE THE LORDOSIS REFLEX AND INCREASE PROGESTIN RECEPTORS IN THE RAT. B. Parsons*, D.W. Pfaff and B.S. McEwen. The Rockefeller University, New York NY 10021.

We have defined a minimum period of estradiol (E_2) treatment which is sufficient to induce sexual receptivity in the female rat and used this paradigm to measure associated changes in nuclear E_2 and cytosol progestin receptors (PRs) in the mediobasal hypothalamus-preoptic (MBH-POA) and pituitary (PIT).

Female rats ovariectomized for 5-7 days were implanted with 5mm Silastic capsules of E_2. For behavior, females were tested with males 24h after initiation of E_2 treatment. Four h prior to testing, each animal received 500µg progesterone. PRs in the MBH-POA and PIT were measured in vitro using ^{3}H-R5020 as a radioligand, 24h after initiation of E_2 treatment. Animals received no exogenous progesterone. Nuclear E_2 receptors (NRs) were measured in the MBH-POA and PIT using an in vitro exchange assay. NRs were measured 1/2h and 1h after implantation of capsules, as well as 3 and 6h after their removal.

Findings: 1) Lordosis quotient (LQ) scores of animals given E_2 for 6h or 24h are equivalent at 24h; 2) PRs in MBH-POA and PIT in animals given E_2 for 6h or 24h are equivalent at 24h; 3) Receptivity comparable to 6 or 24h of continuous E_2 treatment is seen if animals receive only two 1h periods of E_2 treatment, provided that the second treatment period is not fewer than 4 or not greater than 13h after the first period (Sufficient Treatment). If animals receive two 1/2h periods of E_2 during these times, receptivity is not observed (Insufficient Treatment ; 4) Sufficient treatment is associated with ≃30% increase in PRs in MBH-POA and PIT. Insufficient treatment does not significantly increase PRs in these tissues; 5) One h of E_2 treatment produces twice the levels of NRs (≃60% saturation capacity) as does 1/2h of E_2 (≃30%) in MBH-POA and PIT. After capsule removal, levels of NRs sharply decreased, although the ratio of the differences in NRs produced by these two stimuli is maintained at 3 and 6h post E_2. 6) Anisomycin (100mg/kg), which inhibits protein synthesis in the brain for 6h, blocks lordosis when administered 15min. prior to either of the 1h periods of E_2 exposure, and, at any point in the 4-13h interval between the 1h periods of E_2.

We conclude that 2 pulses of E_2 treatment with total exposure time of 2h during 24h is sufficient to activate the lordosis reflex. The discontinuous presence of nuclear E_2 receptor occupation is sufficient to effect more continuous changes in macromolecular synthesis in the MBH-POA, which are necessary for the activation of the lordosis response.

Supported by USPHS grant NS07080 and Institutional Grant RF70095 from the Rockefeller Foundation.

117.5 AN INTERACTION BETWEEN THE PINEAL GLAND, PHOTOPERIOD AND NUTRITIONAL STATUS IN THE NEUROENDOCRINE REGULATION OF MAMMARY TUMORIGENESIS AND PROLACTIN IN THE RAT. David E. Blask* (SPON: D. Stuart). Dept. of Anatomy, Univ. of Arizona, Coll. of Med., Tucson, AZ 85724.

In female rats, mammary tumorigenesis induced by 7,12-dimethylbenz(a)anthracene (DMBA) is dependent upon prolactin (Prl). Environmental factors such as nutritional intake influence tumor growth presumably by altering neuroendocrine mechanisms controlling Prl secretion. The pineal gland, whose activity is markedly potentiated in undernourished rats deprived of photic input, represents a potentially important extrahypothalamic regulator of Prl release. Inasmuch as the pineal has been implicated as having anti-tumor effects, it was of interest to examine a possible interaction between the pineal gland, photoperiod and dietary intake with respect to mammary tumorigenesis. At 50 days of age female rats received an i.v. injection of a lipid emulsion containing 5 mg of DMBA. Three weeks later the animals were either pinealectomized (Px), sham-pinealectomized (S-Px), blinded (B) + S-Px, B + Px or left intact (I). Four days later all operated rats began receiving 50% of the intake of a stock diet consumed daily by the I controls for a 6 week period. From the end of this period until the termination of the experiment rats received 75% of the dietary intake of the controls. All rats were palpated weekly for the presence of mammary tumors (MT) until the end of the experimental period 18 weeks after DMBA treatment. Upon termination of the study half the rats in each group were killed during the day (D) (1300-1400 h) while the other half was killed during the night (N) (2400-0100 h). All animals were maintained on 14L:10D (lights on 0600-2000 h) for the duration of the experiment. Serum Prl levels were measured via a double antibody radioimmunoassay. For the entire experimental period the prevalence of palpable tumors was 44.4% in the I group. Underfeeding reduced the prevalence of tumors to 20.0% in the S-Px group while in the Px rats the prevalence remained at about the same level (22.2%). In the B + S-Px group no tumors developed whereas in the B + Px animals the prevalence of tumors was 41.6%. The B + S-Px rats exhibited a 66% ($p < 0.001$) depression in N levels of Prl versus D levels not seen in the B + Px rats with tumors. Also the combined D + N Prl levels in B + S-Px rats were 43% ($p < 0.02$) lower than in sighted + S-Px rats exhibiting significantly ($p < 0.02$) higher N levels of Prl as compared with D levels. These data show that the reduced development of MT in underfed rats is completely obviated in rats which are also deprived of light. This is a pineal-mediated effect since pinealectomy reversed the effects of blinding and underfeeding. The absence of MT in B + S-Px rats may be related to an overall reduction in serum Prl titers. (Supported by ACS Institutional Grant #IN-110C).

117.6 ENDOGENOUS CEREBROSPINAL FLUID PEPTIDES MONITORED IN THE CONSCIOUS ANIMAL. R. Roger Barnard* and Mariana Morris* (SPON: James G. McCormick). Dept. Physiol. Pharmacol., Bowman Gray Sch. Med., Winston-Salem, NC 27103.

A push-pull technique was used to sample third ventricular cerebrospinal fluid (CSF) in the conscious, unrestrained male rat (250 gms). Cannulae were placed in the anterior (above the optic chiasm, A3V) or middle third ventricle (medial basal hypothalamic region, MBH-3V) and the animals were perfused with artificial CSF at a rate of 10 µl/min. The perfusate was acidified to .1 N HCl, boiled for 10 min, and vasopressin (VP) and oxytocin determined by radioimmunoassay (RIA).

Measureable amounts of VP and oxytocin were consistently found when the cannula tip was located in the mid-hypothalamic region. Levels were 282.7 ± 48.5 pg VP/ml perfusate (n=13) and 285.9 ± 80.5 pg oxytocin/ml perfusate (n=7) (mean ± SEM). Evidence of specificity includes a lack of assay crossreactivity with extracted artificial CSF or a perfusate from the cerebral cortex. Furthermore, dilutions of the MBH perfusate produced a dose-response parallel to the RIA standard curves. Significantly lower amounts of VP were measured when the cannula was located in the anterior 3rd ventricle (39.7 ± 10.4 pg/ml, n=12). Many of the samples collected from this region were below the sensitivity of the RIA. Measurement of timed perfusate samples (15 min periods) illustrates the consistency of the vasopressin levels when using this approach:

Cannula Location	Perfusion Period 1	2	3	4
Anterior 3rd Ventricle	29*	36	43	38
MBH 3rd Ventricle	461	438	390	209

*pg VP/ml

In addition to the presence of VP and oxytocin in the CSF, significant amounts of angiotensin II were also detectable. Extraction of control solutions and perfusion of other brain areas support the conclusion that this was angiotensin itself and not due to artifactual interactions with the RIA.

These results demonstrate that using a push-pull technique vasopressin, oxytocin and angiotensin II can be reliably measured in third ventricular CSF. Secondly, they suggest that this approach may be useful in evaluating dynamic changes in central peptides in response to various physiological manipulations. (Supported by NIH grant HL-22411)

117.7 VASOPRESSIN INVOLVEMENT IN FEBRILE CONVULSIONS. W.L. Veale, N.W. Kasting, K.E. Cooper, K. Lederis*. Div. Medical Physiology and Div. Pharmacology and Therapeutics, University of Calgary, Calgary, Alberta.

There is evidence that the neuropeptide, arginine vasopressin (AVP), is intimately involved in the brain in the negative control or modulation of fever. It has also been observed that AVP can cause convulsions when administered into the lateral cerebral ventricles of rats. This study sought to determine if AVP may be involved in the mediation of febrile convulsions by using a hyperthermia-induced convulsion model.

Long Evans (LE) and homozygous Brattleboro (DI) rats of 250-300 g body weight were used for these experiments. Some LE rats were stereotaxically implanted with guide cannulae directed towards the lateral cerebral ventricles. Body temperature (Tb) was recorded by a rectal thermistor probe. Hyperthermia was induced by placing the rats in an environmental chamber at 50°C. Blood samples were assayed for AVP by a specific and sensitive RIA. Four groups of rats were observed. Group 1 consisted of LE rats whose Tb increased until 42.7°C and they were then removed from the heat and guillotined for blood collection. Group 2 consisted of LE rats whose Tb increased until convulsions began and then they were guillotined for blood samples. Group 3 was DI rats whose Tb increased until either convulsions began or death occurred and then they were guillotined for blood collection. Group 4 was LE rats given anti-AVP antiserum icv and put into the heat. Their Tb increased until convulsions began or death occurred.

Group 2 LE rats all convulsed and these convulsions occurred at a mean Tb of 43.19 ± 0.12°C. Group 3 DI rats did not all convulse and the mean Tb of convulsions or death was 44.40 ± 0.18°C which was statistically higher than Group 2. Group 4 LE rats given anti-AVP antiserum icv did not all convulse and the mean Tb of convulsions or death was 44.00 ± 0.20°C which was also statistically higher than Group 2 LE rats. Mean serum levels of AVP in Group 1 LE rats which were hyperthermic but did not convulse was 56.1 ± 24.1 pg/ml whereas Group 2 LE rats which had convulsed had levels of 325.5 ± 124.6 pg/ml. DI rats which convulsed or died had AVP levels not statistically different from the limit of the assay.

These data suggest that AVP may play a role in the brain to mediate or contribute to the convulsions of hyperthermic animals.

117.8 THE TRH TEST IN THE DIFFERENTIAL DIAGNOSIS OF DEPRESSION. A.L.C. Pottash, I. Extein, and M.S. Gold. Fair Oaks Hospital and Psychiatric Diagnostic Laboratories of America, Summit, NJ 07901, and Yale Univ. School of Medicine, New Haven, CT 06510

Prange et al. (Lancet 2:999,1972) were the first of many groups to report that depression may be associated with a decreased release of thyroid-stimulating hormone (TSH) by the pituitary after infusion of thyrotropin-releasing hormone (TRH). We studied the TRH-induced TSH response in subtypes of depression because of the data of Prange, studies suggesting antidepressant efficacy for T-3 and TRH. The discovery of stereospecific TRH receptors in the brain, the extrahypothalamic distribution of TRH, the data suggesting a role for TRH as a neurotransmitter, and Hofelt's hypothesis that TRH is an "arousal" peptide. We performed the TRH test on 134 consecutive inpatients who met Research Diagnostic Criteria for a depressive disorder: 99 major depression (81 unipolar, 18 bipolar) and 35 minor or intermittent depressions. Patients with thyroid disease, drug or alcohol addiction, OBS, or recent lithium use were excluded. All patients were free of all medications except flurazepam for at least one week prior to the TRH test. 500 ug of synthetic TRH was administered via an indwelling venous catheter to patients at bed rest after an overnight fast. Blood samples were taken before and 15,30,60, and 90 minutes after TRH infusion for determination of serum TSH in duplicate by radioimmunoassay. Maximum TSH response (ΔTSH) was determined for each patient by subtraction of the baseline TSH from the peak TSH after TRH infusion. Mean ΔTSH (uIU/ml ± SEM) of 7.5 ± 0.6 for unipolars was significantly lower than that of 11.7 ± 1.2 for bipolars ($p < .01$ by t-test) was demonstrated. All patients with a ΔTSH $\leq$ 7 uIU/ml were considered to have a decreased TSH response to TRH. 62 patients had a decreased TSH response to TRH, including 57 patients with unipolar depression, 3 with bipolar depression, and 2 with minor depression. These data suggesting group differences for similarly appearing depressed patients supports the biochemical concept of heterogeneity. In addition, these TRH test data suggest that this test may help confirm the clinical diagnosis of major unipolar depression, and distinguish it from bipolar and minor depressions. If a decreased TSH response to TRH is used to test for a major unipolar depression in patients with depressive disorder, the false-positive rate in our series is 5 in 62 (8%), and the false-negative rate is 24 in 81 (30%). Norepinephrine and dopamine stimulate and serotonin inhibits the release of the hypothalamic tripeptide TRH. Hence, the decreased TSH response to TRH in unipolar depression may reflect changes in brain monoaminergic neurons or release of endogenous TRH in this disorder. The TRH test may identify biologically homogeneous subgroups of depressed patients for research purposes and help in treatment decisions.

118.1 MEMBRANE STRUCTURE IN DEVELOPING, MATURE, AND CULTURED ASTROCYTES
D.M.D. Landis, T.S. Reese, K.J. Sweadner and L.A. Weinstein*
Dept. Neurology, Harvard Medical School, Boston, MA. 02114

Certain regions of the membranes of astrocytic processes in mammalian central nervous system are found, when freeze-fractured, to contain "assemblies", aggregates of uniform intramembranous particles packed in orthogonal array with a center-to-center spacing of 4-6nM. The function of these aggregates is unknown, but they are concentrated in astrocytic membranes facing blood vessels and the subarachnoid space, and so are nicely situated to transport substances into or out of the blood and CSF compartments. We have found the structure of assemblies to be the same in tissue prepared for freeze-fracture by standard aldehyde fixation and glycerol cryoprotection as in tissue rapidly frozen against copper cooled by liquid helium. Preliminary studies of rapidly-frozen, deep-etched tissue indicate some representation of the particle array on the true outer surface of the membrane. Assemblies are unusually labile, and begin to clump and disappear from tissue slices excised and rapidly frozen 35 to 45 seconds after decapitation. Loss of assemblies is progressively more complete with increasing interval between decapitation and excision for rapid freezing, but there is no change in the morphology of particles constituting tight junctions, gap junctions, and postsynaptic aggregates. The loss of assemblies can be prevented by incubating the slices *in vitro* in the presence of bubbling oxygen for 30 minutes, but incubation in bubbling nitrogen or with dinitrophenol (100μM) results in loss of virtually all assemblies. This membrane specialization is characteristic of mature, differentiated cells. In developing postnatal cerebellar cortex, processes of Bergmann astrocytes span the molecular layer, penetrate the proliferating external granular layer, and over 14 days acquire increasing numbers of assemblies as they spread out over the surface of the cerebellum. The vertical portion of these processes appears to guide migrating granule cells from external to internal granular layers, but there is no change in the concentration of assemblies or other specialization of membranes at the juxtaposition of astrocytic and neuronal processes. Assemblies appear in the astrocytic processes of cerebellar explant cultures from neonatal mice. Primary astrocyte cultures derived from newborn rats contain scattered assemblies only under restricted conditions, while rodent C-6 glioma and human astrocytoma cell lines appear not to express the membrane specialization at all. We anticipate that the formation of assemblies in primary cultures may permit the studies necessary to define the nature and function of this membrane specialization.

118.2 GAMMA-GLUTAMYL TRANSPEPTIDASE IN GLIA: IMMUNOCYTOCHEMICAL LOCALIZATION. H. D. SHINE, J. D. COULTER, AND B. HABER. Depts. of Physiol. and Biophys., Pysch. and Behavioral Sciences, Biochem. and Human Genetics, Neurology, and Marine Biomedical Inst., Univ. of Texas Medical Branch, Galveston, TX.

Gamma-glutamyl transpeptidase (E.C. 2.3.2.2., γ-GTP) may participate in the transport of amino acids and peptides across cell membranes, in mechanisms of detoxification, or in the metabolism of neuropeptides. Precise determinations of the cellular localization of γ-GTP activity in the brain have been hampered by the lack of sensitivity and specificity of histochemical methods used to identify the enzyme in nervous tissue. We have employed the peroxidase anti-peroxidase (PAP) technique of Sternberger and the fluorescent technique of Coons to identify sites of γ-GTP within the rat CNS. The antibody was made to γ-GTP isolated from the rat kidney. The isolation procedure included deoxycholate extraction, ammonium sulfate precipitation, papian digestion, ion exchange chromatography, gel filtration, and concanavallin A affinity chromatography. The isolated γ-GTP used for immunization was homogeneous as shown by PAG electrophoresis which produced one band that stained for protein and γ-GTP activity. The antibody (IgG fraction only) raised in rabbits to γ-GTP cross-reacted with rat tissues only and upon immunoelectrophoresis produced one arc without spurs that stained both for protein and γ-GTP activity. Enzymatic activity of solubilized rat γ-GTP was inhibited by the addition of the anti-γ-GTP in a dose dependent manner. Immunocytochemical techniques using this antibody demostrated the presence of γ-GTP in microcapillaries (isolated and in situ), choroid plexus, and ependymal cells of the rat brain. In sections of rat CNS, immunoreactive cells were found both in gray and white matter, which were identified as glia. The immunocytochemical localization of γ-GTP in glial cells supports our previous suggestion of the preferential localization of γ-GTP in glial cells

118.3 PRELIMINARY CHARACTERIZATION OF MÜLLER CELLS ISOLATED FROM RABBIT RETINA. M.C. Trachtenberg and D.J. Packey. Div. of Neurosurgery and Dept. of Physiology & Biophysics, University of Texas Medical Branch, Galveston, TX., 77550.

Studies of the regulation of the extracellular ionic milieu in the mammalian CNS require an examination of the cellular contributions to ion and water homeostasis. The complex morphology of the cellular interactions in the brain make in vivo determination of relative glial and neuronal contributions of other than single cells so difficult as to be beyond currently available technology. Therefore, in order to investigate the glial contribution to ion regulation in nervous tissue, we have developed a procedure for the bulk isolation of Müller cells (glia) from the retina of the rabbit.

We have modified the retinal dissociation procedure of Sarthy and Lam (Brain Res. 176:208, 1979) to give a rapid yield of about 4 million Müller cells per rabbit. Purification of the crude dissociate by centrifugation on continuous density gradients of either BSA or percoll provides approximately 3 million cells. These yields correspond to a final wet weight of 34 mg of Müller cells per 100 mg of retina with about 2 mg of protein present in each preparation. At the completion of the purification the cells appear to be intact as judged by exclusion of vital dye. Light microscopy reveals the cell morphology to be strikingly similar to that demonstrated in fixed tissue by Ramon y Cajal. Fine lamellar and filamentous processes are clearly visible. Electron micrographs show the cell membranes to be intact and numerous microprojections are evident. The cells contain both 8-9 nm filaments and glycogen, both characteristic of glia. Two enzymes taken to be glial specific markers (carbonic anhydrase and glutamine synthetase) have been assayed in these cells and show significant enrichment over the values for intact retina. Carbonic anhydrase activity is measured to be 1068 U/μg protein in isolated Müller cells (49% of which is membrane bound) as compared to 546 U/μg protein in the whole retina (39% membrane bound). Glutamine synthetase activity also is relatively enriched in the isolated Müller cells as compared with the whole retina - 1000 U/μg protein are present in Müller cells while only 783 U/μg protein are found in retina.

Glial cells respond to elevations of extracellular $[K^+]$ with an increase in metabolic activity, as evidenced by K-stimulated 0_2 consumption (Hertz, J. Neurochem. 13:1373, 1966). We find that isolated Müller cells show an increase in glucose uptake in 53 mM $[K^+]$ to a rate double that seen in 3 mM $[K^+]$.

118.4 MYELIN BASIC PROTEIN (MBP) IN DEVELOPING ALBINO RAT OPTIC NERVE: AN IMMUNOPEROXIDASE STUDY OF PARAFFIN EMBEDDED MATERIAL.
Richard G Dixon* and L. F. Eng. Dept. of Path., V. A. Med. Ctr. & Stanford U. Sch. of Med., Stanford, CA 94305.

The distribution of MBP in the optic nerve of the developing albino rat was studied by the peroxidase-anti-peroxidase method of Sternberger using paraffin embedded material from animals ranging in age from 0 to 14 days of age. The eyes with attached optic nerves were removed immediately after decapitation and fixed with Perfix for 30 min. at room temperature and were then embedded in paraffin using a 30 min. processing schedule. With this method MBP activity could be demonstrated in perikarya of immature oligodendrocytes without the use of $HgCl_2$/formaldehyde fixation. It was found that cytoplasmic MBP antigenicity was somewhat less sensitive to the deleterious effects of formaldehyde fixation than is the case for glial fibrillary acidic protein, and that the antigenicity of MBP within the myelin sheath is quite stable with respect to formaldehyde fixation.

As in other regions of the central nervous system, MBP activity could be detected in immature oligodencrocytes prior to the formation of myelin as judged by the appearance of periaxonal sheaths in electronmicrographs (Sternberger et al, J. Cell. Neurocytol., 7:251, 1978; Proc. Natl. Acad. Sci., 75:2521, 1978). A correlation was found between the distribution of MBP containing cells and the early deposition of myelin reported by previous investigators (Skoff et al, Neurosci. Letters, 7:191, 1978). They first appeared as small islands of MBP containing cells which then expanded until assuming the distribution found in the mature optic nerve.

118.5 GLIAL MEMBRANE POTENTIALS AND THEIR RELATIONSHIP TO $(K^+)_o$ IN GUINEA PIG AND MAN: A COMPARATIVE STUDY OF INTRACELLULARLY MARKED NORMAL, REACTIVE AND NEOPLASTIC GLIA. S. Picker*, C.F. Pieper* and S. Goldring. Dept. of Neurol.& Neurol. Surg., Wash. Univ. Sch. Med., St. Louis, Mo. 63110

Cells were studied in-virto using physiologically viable brain slices (Gibson, I.M. and McIlwain, H., J. Physiol., 176:261-283, 1965). After recording the resting membrane potential (RMP) or the relationship of RMP to changes in $(K^+)_o$ in the cells with very stable RMPs, the cell was injected iontophoretically with HRP for later visualization and correlation with the physiologic data.

Normal glial cells were studied in cortical tissue obtained from the occipital pole of guinea pig (GP), and in man from cortex overlying tumor tissue or from an epileptogenic focus where the tissue was microscopically normal but electrically abnormal. Reactive glial cells were studied in cortical slices from human epileptogenic foci which showed neuronal drop-out and astrocytosis. Neoplastic cells were studied in tissue obtained from one human glioblastoma multiforme (53 cells) and one mixed glioma (7 astroglia and 5 oligodendroglia).

The average RMP of 335 GP glia was -70 ± 7mV and -69 ± 8mV in 68 cells from histologically normal human cortex. The cells in both GP and man were protoplasmic astrocytes, appearing either as densely labeled cells with short processes, or cells with small somas and delicate veil-like processes. The average RMP of 59 reactive glia was -63 ± 9mV. The cell population consisted of fibrous astrocytes with long tortuous processes exhibiting varying degrees of swelling, glia with short thickened processes containing rounded nodules, and some normal protoplasmic astrocytes.

In the glioblastoma multiforme the average RMP from 53 cells was 32 ± 7mV. These cells were large, varied in size, resembled more the fibrous astrocyte and had numerous radiating processes covered with irregular nodules. The labeled cells from the mixed glial tumor showed oligodendroglia, and astroglia resembling some of the glioblastoma cells. The average RMPs of the astrocytic and oligodendroglial cells were -50 ± 11mV and -53 ± 3mV respectively.

In 13 GP protoplasmic astrocytes RMP was recorded while the perfusate (4mM K^+) was exchanged for solutions having (K^+) of 7, 12 and 20 mM. The slope of the RMP vs. log $(K^+)_o$ was 58 ± 2mV/dec approximately the value predicted by the Nernst equation if glia are permeable only to K^+. In 8 human protoplasmic astrocytes from histologically normal cortex a slope of 56 ± 5mV/dec was obtained when a (K^+) was changed from 4-12 mM. In 11 human reactive glia a similar change in (K^+) yielded a slope of 32 ± 8mV/dec.

118.6 ANALYSIS OF GLYCOPROTEINS SYNTHESIZED AND RELEASED BY C6 GLIOMA CELLS. N. Shitara*, P. E. McKeever*, B. H. Smith, R. E. Pleasants*, M. A. Banks*, and P. L. Kornblith*. Surgical Neurology Branch, NINCDS, NIH, Bethesda, MD 20205.

As part of a study of glycoproteins characterizing malignant glial cells, the synthesis and extracellular release of ^3H-fucose labeled glycoproteins by the C6 glioma cell line was analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and autoradiography.

Cultured C6 glioma cells (10^6 cells at passage 64) in Ham's F-10 medium plus 1% fetal calf serum in a 95% air:5% CO_2 atmosphere at 37°C show significant glycoprotein synthesis within three hours after addition of 10μC/ml ^3H-fucose. There is a linear increase in synthesized protein from the initiation of labeling to 120 hours. Five major glycoprotein groups can be detected in NP-40 detergent lysates of (washed) cells. Molecular weights were calculated from plots of logs of the known m.w. of protein standards versus the linear migration distances of these proteins. Estimated molecular weights are 82,000; 110,000; 120,000; 140,000 and 160,000 daltons.

Six hours after initiation of fucose labeling, the C6 cells begin to release six major glycoproteins into the extracellular medium. These released glycoproteins accumulate linearly from 12 to 120 hours. The most prominent band (GP85) comprises 80% of the total released glycoprotein and occurs at 85,000 daltons. The other five bands occur at 55,000; 115,000; 130,000; 150,000; and 170,000 daltons in 7.5% SDS-PAGE. The ratio of TCA-precipitable released glycoprotein to total synthesized glycoprotein at 24-120 hours is 52.5% which is greater than the 39.1% ratio of 3-24 hours. Cycloheximide (100μg/ml) resulted in 98% reduction in both intracellular and released glycoprotein.

Little or no fucosylated GP85 was synthesized or released by a syngeneic normal fibroblast line or by a cell culture derived from normal rat cortex, suggesting that GP85 may be specific to malignant C6 glioma cells. Further characterization of GP85 with respect to its possible functions and/or antigenicity is now underway.

118.7 INDUCTION AND PREVENTION OF ASTROGLIAL SWELLING IN CEREBRAL CORTEX. K.D.Barron, R.S. Bourke*, J.B. Waldman* and S. Easton*. Department of Neurology and Division of Neurosurgery, Albany Medical College, Albany, NY 12208

After placement of plastic perfusion domes (Bourke et al,1970), edema was induced in feline temporoparietal gray matter by superfusion for 60 minutes with artificial CSF (Bourke and Nelson, 1972) containing K+ (54 mM) or adenosine (0.125 to 2.5 mM) or norepinephrine (0.2 mM). Two control cats were superfused with unmodified artificial CSF solution. Vital signs, arterial pH and blood gases, microhematocrits, serum and urine osmolalities and Na+, K+ and Cl- concentrations were monitored at the inception of superfusion and 30 and 60 mins. afterward. At conclusion of superfusion animals were killed by intracardiac formaldehyde-glutaraldehyde perfusion. Samples of cortical ribbon at 3 graded depths beneath the pia (named pial, subpial and deep) were post-fixed and prepared for electron microscopy. Anatomical findings were correlated with estimates of total solids and Na+, K+ and Cl- contents of gray matter of cats treated identically but used for biochemical assays.

Cortex of control cats showed no changes. Both K+ (2 cats) and adenosine (6 cats) induced massive astroglial swelling at pial and subpial levels. Adenosine was about equally effective at 0.125 and 2.5 mM concentrations. Astrocytic enlargement involved perikarya and processes throughout the parenchyma but was greatest perivascularly. In areas of astroglial swelling degeneration of neuronal somas and dendrites was manifested by increased electron-density of hyaloplasm, disintegration of ER etc. Expanded electron-lucent dendrites were rare. Axoplasm and boutons were seemingly little affected but adaxonal, oligoglial invaginations were common. Norepinephrine-induced swelling (3 cats) was practically limited to tissue within 300 um of the pia and was mild.

Acylaryloxyacetic acid derivatives included in the adenosine superfusates greatly reduced astrocytic swelling.

We conclude the following: (1) astroglial edema is induced in superfused cortex by K+ concentrations equivalent to those encountered in traumatic, hypoxic and ischemic insults; (2) increases in extracellular K+ may act indirectly to produce glial swelling by release of putative neurotransmitters; (3) acylaryloxyacetic acid derivatives effectively reduce astrocytic edema; (4)expansion of astroglial cytoplasm, by increasing intercapillary distances (Auen et al, 1979), may critically prolong diffusion pathlengths for O_2 and other vital metabolites and thereby cause neuronal necrosis.

Supported by NS Grant 13042.

118.8 PRESERVATION OF PULSATORY AND MIGRATORY ACTIVITIES OF RAT SCHWANN CELLS BEFORE AND AFTER MITOTIC STIMULATION. B. Rentier*, M. Dubois-Dalcq*, A. Baron* (SPON: T.S. Reese). NINCDS, National Institutes of Health, Bethesda, Maryland 20205.

Rat primary (I) and secondary (II) Schwann cells (SC) have been cultured following Brockes et al.(Brain Res. 165:105, 1979). These SC have no basement membrane but contain numerous bundles of intermediate and actin filaments. All motility is reversibly suppressed by cytochalasin B. The motility pattern of I SC was compared to that of II SC after intense mitotic stimulation by choleratoxin and a pituitary extract (Raff et al., Cell 15:813, 1978). Continuous recording by time-lapse video intensification microscopy (VIM) allowed analysis of various SC movements. In I SC, slow rhythmic undulation episodes were observed as described (Pomerat, Science 130:1759, 1959; Forman et al., Soc. Neurosci. Abstr. 5, 1955, 1979) and lasted 2.3 ± 0.2 min. In spite of the extreme variability of the interval between these episodes, the total number of episodes per day remained rigorously identical for different cells (166.3 ± 0.2). Short and long intervals occurred at random. Cycles, consisting of an undulation episode followed by a resting interval, had mean durations of 8.6 ± 4.1 min. and a sharp peak of occurrence at 6 min., with exponential distribution of the longer periods, indicating a non-random event. Migratory events often alternate with undulatory episodes. Migration speed was 135 ± 50 μ per hour and the path of migration was often oriented along a constant axis for every cell, in contrast with the random migratory path of occasional fibroblasts observed in I cultures.

During mitotic stimulation, subcultured SC acquired a "fried egg" shape and both their undulatory and migratory activities were dramatically reduced. Undulation was replaced by a pulsation of approximately the same periodicity, but occurring only in 2% of the cells. Migration was reduced to 24 ± 2 μ per hour. Six to 12 hours after removal of mitogenic factors, 80% of the SC started pulsating twice as fast for 2 to 3 days. When mitosis ceased, SC quickly recovered their spindle shape and rhythmic undulation while their migration speed increased to 92 ± 20 μ per hour. When II SC were seeded over dissociated neuron cultures, they rapidly attached to neurites and showed migratory and undulating movements along these neurites.

In conclusion, VIM revealed that 1) frequency of undulation episodes show a remarkable uniformity, perhaps demonstrating a genotypic basis; 2) in spite of dramatic modification of shape and behavior during mitotic stimulation, SC subsequently recover their unique motility pattern which might be essential for their myelinating function.

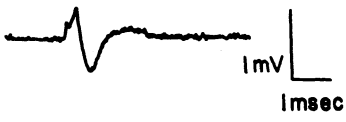
119.1 DEVELOPMENT OF CEREBRAL CORTEX IN VITRO: FUNCTIONAL INFLUENCE OF SUBCORTICAL INPUTS. Arnold L. Leiman & Frederick J. Seil (SPON: Irving Zucker) Department of Psychology, University of California, Berkeley and Department of Neurology, University of Oregon Health Sciences Center and Veterans Administration Hospital Portland, Oregon.

Our previous studies described the functional and structural development of organotypic tissue cultures of fetal mouse cerebral neocortex. Such completely isolated cerebral neocortex shows cellular differentiation and the establishment of cortical networks. Extracellular microelectrode observations reveal similarities and differences with in vivo functional development. This present study examined the possible role of subcortical tissue in the guidance and control of cerebral neocortical functional development in vitro.

Parasagittally oriented explants were obtained from newborn Swiss-Webster mice. They were placed on collagen coated coverslips with nutrient medium and sealed in a Maximow assembly. Some explants were prepared so that they consisted of cortex and attached subcortical tissue which probably included caudate-putamen. Extracellular electrophysiological comparisons were made between completely isolated cerebral neocortical explants and those grown with connected subcortical tissue. At different post explant intervals, responses were recorded to dorsal surface and deep cortical electrical stimulation. Explants that included subcortical inputs/outputs showed the development of larger amplitude extracellular slow wave responses. These responses also displayed a better columnar organization than was evident in explants that were completely isolated cultures where horizontal spread of activity is quite evident. At all stages of post explant development a greater responsiveness to repetitive stimulation was also evident. The basic progression of electrophysiological development was not different in the two explant states nor were there major distinctions in the timetable of functional development. The data suggest that subcortical inputs/outputs may influence the progressive functional development of cerebral neocortical circuitry.

119.2 ELECTROPHYSIOLOGICAL CHARACTERISTICS OF SUBSTANTIA NIGRA BRAIN GRAFTS IN THE LATERAL VENTRICLE. S.M. Wuerthele, L. Olson*, W.J. Freed*, J. Morihisa*, L. Spoor*, R.J. Wyatt, B.J. Hoffer*. Dept. of Pharmacology, University of Colorado, Denver, CO 80262.

Pieces of fetal rat mesencephalon containing the substantia nigra were homologously transplanted into the lateral ventricle of rats pretreated with 6-OHDA injections into the ipsilateral substantia nigra. Dopamine-containing cells from such grafts innervate the adjacent caudate. Apomorphine-induced rotation is significantly reduced in the host animals (Perlow et al., Sci. 204: 643-647, 1979), suggesting that the grafts provide functional input to the denervated striatum as well. Extracellular recordings from nigral grafts, using NaCl-filled micropipettes, revealed spontaneously active neurons with action potential waveforms (1.5-2.5 msec duration; distinct break between initial segment and somatodendritic component) and firing rates (0.5-8.0 Hz) similar to that previously reported for dopaminergic nigral neurons in situ:



Furthermore, local application of dopamine agonists inhibited the activity of such neurons in a dose-dependent manner. These data support the hypothesis that neurons in substantia nigra grafts are functionally active. The data also suggest that some of the mechanisms regulating nigrostriatal neuronal activity present in situ are also present in this preparation. Supported by USPHS Grants DA-07043, NS-09199, and Swedish MRC Grant 04X03185.

119.3 LONG-TERM POTENTIATION OF THE HIPPOCAMPAL SLICE RESULTS IN A STIMULATED SECRETION OF NEWLY SYNTHESIZED PROTEINS. C. Duffy*, T. J. Teyler and V. E. Shashoua (SPON: Timothy J.Teyler). Mailman Research Center, McLean Hospital, Harvard Medical School, Belmont, MA 2178.

Long-term potentiation (LTP) of synaptic responses in the rat hippocampus has been extensively used as a model system for the neurophysiological study of plasticity. Recent studies have demonstrated that LTP can change the pattern of phosphorylation of specific proteins in the hippocampal slice (Browning, M., et al., Science, 203:60, 1979). There have, however, been no reported findings which show a relationship between LTP and the pattern of protein synthesis. We have, therefore, explored this question using the techniques developed in our laboratory in studies of the pattern of protein synthesis in goldfish brain after training. In the goldfish, we found that two specific proteins (Ependymins β and γ) are rapidly labeled and secreted into the extracellular fluid (ECF) after the animals acquire a new pattern of behavior. If LTP in the hippocampal slice is also an indicator of neuronal plasticity, then by analogy to the goldfish data (Shashoua, V. E., Brain Res., 166:349, 1979) some changes in the pattern of synthesis and secretion of proteins might be expected in the rat hippocampal slice after LTP.

Using the double-labeling procedure, in which the pattern of protein synthesis in a single potentiated slice (^{3}H-valine) of rat brain hippocampus is compared with that of an unpotentiated control slice (^{14}C-valine), we found that a 150% increase in the secretion of labeled proteins into the ECF occurs after LTP. An examination of the remaining, unsecreted cytoplasmic proteins showed that the biochemical changes were limited to the area potentiated. Thus potentiation of the CA1 region, by stimulation of Schaffer collaterals, resulted in local protein secretion within the hippocampal region, as compared with the unstimulated dentate area of the same slice. Conversely, when the dentate area was potentiated via the perforant path, enhanced secretion occurred, as compared to the unstimulated CA1 region of the same slice. Control experiments in which nonpotentiated slices received the same number of stimuli as did tetanized slices, but spaced 20 seconds apart, did not show changes in protein synthesis. Also, some slices which received the tetanus but did not develop LTP showed no protein changes. These results suggest that there is a link between the LTP and the metabolic processes that lead to the class of protein synthesis destined for secretion into ECF.

119.4 DEVELOPMENTAL DECREASE IN NEURITE EXTENSION IN CULTURED CHICK EMBRYO RETINA AND SPINAL CORD NEURONS. Jeffrey M. Thompson. Laboratory of Neurosciences, National Institute on Aging, National Institutes of Health, Baltimore, Maryland 21224

Both retina neurons and spinal cord neurons from chick embryos attach to collagen-coated tissue culture dishes and extend neurites. The ability to form neurites in culture as a function of developmental age of the donor was studied. The neurons were dissected from chick embryos of different ages, trypsinized and 1 X 10^{6} cells cultured on collagen-coated 35 mm tissue culture dishes in MEM plus 10% fetal calf serum. After 24 hr, photomicrographs were taken of each culture with phase-contrast optics. The photographic negatives were enlarged and the neurites from each cell were traced. The total number of cells and number of cells with neurites were counted. The length of each neurite was measured with a Graf/Pen-6 Sonic Digitizer. Length measurements made at 24 hr of culture reflect rates of extension rather than the maximum extent which may be achieved. It is not possible, however, to show in this mixed culture which neuronal cell type extends processes and undergoes changes in the number and length of neurites. The percent of chick embryo retina neurons which formed neurites was 12.3% in cultures from 8-day embryos and decreased to 2.4% with 16-day embryos. The average length of retina neurites was 36.2 μm in cultures from 6-day embryos, whereas, 16-day embryo retina neurons only extended neurites an average of 11.8 μm. Thirty-eight percent of spinal cord neurons from 6-day embryos formed neurites, whereas, 31% formed neurites with 16-day embryos. The average length of spinal cord neurites declined from 50 μm with 4-day neurons to 27.8 μm with 14-day neurons. There is a statistically significant age-related decrease in both the percent and average length of neurites formed in cultures of chick embryo retina and spinal cord neurons. The decrease in neurite extension during development may be important in synaptogenesis as it would restrict synapse formation to a discrete period of development. This is consistent with developmental decreases in synapse formation in culture between rat muscle cells and either chick embryo retina neurons (Ruffolo et al., Proc. Nat'l. Acad. Sci., U.S.A. 75:2281-2285, 1978) or chick embryo spinal cord neurons (Thompson et al., manuscript in preparation).

119.5 SYNAPTIC RESPONSE IN A SIMPLE CORTICAL SYSTEM TO THALAMIC REMOVAL: TYPE OF SYNAPSE AND POSTSYNAPTIC TARGETS OF TWO DIFFERENT SPROUTING FIBER SYSTEMS. L.M. Smith and F.F. Ebner. Neurosci. Sect., Div. of Biol. and Med., Brown Univ., Prov., R.I. 02912

Two types of axons increase in numbers in cerebral cortex following thalamic removal in Pseudemys turtles. Quantitative EM analysis at known depths through the molecular layer shows that those axons containing small flattened or pleomorphic vesicles (FVCPs) increase in number in the outer 100um of cortex before the electron dense phase of degeneration and are 3X normal by 14 days postoperative (DPO). Their numbers stay elevated by 180% above normal levels for longer than 90 DPO (from 6.6±1.7/200um^2 to 19.3±1.6/200um^2 at 90 DPO). Substantial increases in FVCPs also occur in the contralateral cortex, and although the increase takes a longer time course, it is ultimately as great. The number of FVCPs that make a symmetrical synapse (FS contacts) in the plane of section increases significantly by 90 DPO, and throughout the molecular layer, that is, on the entire extent of the dendritic tree. These new contacts are mostly on dendrites. Round VCPs contain spherical 50nm lucent vesicles, usually make asymmetrical (RA) contacts, and are depleted by 50% in the subpial zone after thalamectomy. RVCPs return to almost normal levels by 40 DPO (55.0/200um^2 to 25.2 at 14 DPO to 53.5 at 40 DPO), and RVCPs remain at normal levels below the zone of thalamic fiber terminations. RVCPs and RVCP synapses of spines decrease slightly throughout cortex by 90 days. At 90 DPO there is a concomitant increase of RA contacts on dendrites.

Shrinkage of the whole cortex or of the deafferented area does not occur in this system at any of the survival times reported (14, 40, and 90 DPO). Rather cortical thickness increases slightly, but significantly over time. Areas and diameters of RVCPs and FVCPs do not change from unoperated values.

These results support the hypothesis that there are two types of collateral sprouting in turtle cortex following partial deafferentation; one is the RVCPs that replace synapses lost by degeneration and removal of RVCP thalamic fibers and the other is the FVCP response that is triggered by, but partially independent of, the loss of thalamic fiber inputs.

119.6 DEVELOPMENT OF APPARENT PRESYNAPTIC ELEMENTS. Richard W. Burry, Department of Anatomy, The Ohio State University, College of Medicine, Columbus, Ohio, 43210.

In cell cultures of the rat cerebellum axons have been shown to grow out onto polylysine coated beads and form apparent presynaptic elements with the beads positioned like postsynaptic elements (Burry, Brain Res., 184: 85-98, 1980). These observations were made on cultures at 7 days in vitro (DIV) when neurons have begun to form synaptic contacts between themselves. Sepharose beads coated via cyanogen bromide with poly-L-lysine were then added and the cultures were fixed 24 hrs. later for transmission electron microscopy (TEM). Neuronal elements in contact with the beads displayed both numerous synaptic vesicles and a slight electron density at the site of contact with a bead.

In this report, results show the morphology of the early development of these elements using both the TEM and the scanning electron microscope (SEM).

With cultures, 7 DIV, beads were added for time periods from 1 to 24 hrs. For TEM, sapharose coated beads were used; with SEM, polyacrylamide coated beads were used. Axons appeared to grow up on to beads following the growth of non-neuronal cells. The non-neuronal cells were identified both by their broad, flat processes and by their very fine filopodia (0.1-0.5μm). The cytoplasm of the non-neuronal cells contained small clusters of polysomes. The axons were both large (1-2μm) and round, and, in addition, contained both microtubules and dense core vesicles.

As the axons grew over the non-neuronal cells, they made contact with the beads forming their first apparent presynaptic elements by 3 hrs. In addition to the apparent presynaptic elements seen at 3 hrs., several 1-2μm neurites with only amorphous cytoplasm were seen in contact with the bead. These processes, resembling growing neurites, were seen only rarely after 3 hrs. The apparent presynaptic elements at 3 hrs. had few synaptic vesicles and were smaller in diameter than those seen later. By 9 to 12 hrs. the appearance of the apparent presynaptic elements resembled that of cultures incubated for 24 hrs. with beads. With SEM at 24 hrs. axons were seen to form dense nests of processes and swellings on areas of the bead not covered by non-neuronal cells.

These results show that apparent presynaptic elements have begun to form by 3 hrs. after contact. By 9-12 hrs. apparent presynaptic elements had a stable appearance. In addition, the results suggest that neurons may be able to form a morphologically identifiable contact within 3 hrs. (Supported by a NINCDS Grant No. NS-15894.)

120.1 DUAL EXPRESSION OF TRANSMITTER SYNTHESIS IN CULTURED AUTONOMIC NEURONS. L.I. Iacovitti, T.H. Joh, D.H. Park and R.P. Bunge. Dept. of Anatomy & Neurobiology, Washington University School of Med., St. Louis, MO; Laboratory of Neurobiology, Cornell University, Medical College, New York, NY.

Previous studies have demonstrated that when the predominantly adrenergic neurons of the neonatal rat superior cervical ganglion (SCG) are grown under certain culture conditions, they will express a number of cholinergic functions, including: the development of hexamethonium-sensitive synaptic contents, the accrual of choline acetyltransferase (CAT) activity and the accumulation of clear vesicles in their synaptic endings. In the present study we sought to determine whether, as cultured SCG neurons accumulate these cholinergic characteristics, they simultaneously relinquish or retain certain of their adrenergic properties. To address this issue, we cultured SCG neurons under conditions which foster the accrual of cholinergic properties and measured: a) the activities and amounts of the specific norepinephrine-synthesizing enzymes tyrosine hydroxylase (TH) and dopamine-β-hydroxylase (DBH) and the acetylcholine-synthesizing enzyme, CAT and b) the number and distribution of neurons which stain with the antibody to TH.

Dissociated neurons from SCG of perinatal rats were established in culture in the virtual absence of supporting cells for up to 7 weeks. Cultures were maintained in 5% CO_2 using medium containing serum, embryo extract, and NGF. After 1,3,5 or 7 weeks in vitro, the activities of TH, DBH and CAT were measured in cultures of predetermined neuronal number. The results of these studies demonstrate that the activities of TH, DBH and CAT increase in a synchronous and linear fashion: enzyme activities were barely detectable at 1 week in vitro but increased rapidly thereafter with a 3-4 fold increment between weeks 3 and 7. Immunotitration studies using specific antibodies to TH and CAT indicate that the increase in the activities of these enzymes was entirely due to increased amounts of enzyme protein. Furthermore, immunocytochemical staining of sister cultures with the antibody to TH demonstrated that 95-99% of all neurons contained this adrenergic enzyme througout their in vitro development.

We conclude, that under these culture conditions, virtually all SCG neurons retain the enzymatic machinery required for the synthesis of norepinephrine. The simultaneous occurrence in these neurons of high CAT activity strongly suggests that SCG neurons are capable of dual transmitter production. This capability is not restricted to a transient phase, but increases throughout in vitro development.

120.2 MEMBRANE COMPONENTS OF SATELLITE CELLS WHICH MEDIATE AXON GLIA INTERACTION. H. M. Liu and D. Sackett*. Division of Biomedical Sciences. Brown University, Providence, Rhode Island 02906.

There has been a recent serge of interest toward the production of Nerve Growth Factor (NGF) by many lines of non-neural cells, both normal and neoplastic. In particular, the macromolecular NGF elaborated by neurolemma cells and by glial cells is considered to be of physiological significance as this substance appears to provide the chemical basis for the neurotropism postulated by Ramón y Cajal and confirmed by many recent experimental studies (Windle, W.F., Exp. Neurol., 67:251, 1980). The question of how the NGF molecule fits in with the membrane components of the satellite cells in providing a chemical environment which recognized and attracts the neuraxon has been our main interest in recent studies (Liu, H.M., Exp. Neurol., 66: 123, 1979).

The present report is a preliminary study of the chemical properties of the membrane components of the satellite cells which may have intimate interaction with the NGF molecules produced by the same cells. Two types of cells were used in this study: one a rat glioma cell, C_6 (Am. type culture collection), and the other neurolemma cells from sciatic nerve of 16 day-old chick embryos. The cells were grown on cover-slips placed in Falcon dish; after various period of growth the cells were fixed in formaline and used in a two-step immunocytological study. The cells were first incubated in rabbit anti-NGF serum (Collaborative Research Laboratory) followed by incubation in fluoresein-conjugated horse anti-rabbit immunoglobulin G serum (Sigma). The degree of fluorecence varied considerably among cells of various cultural ages; it was more intense in young cells. A comparable degree of NGF molecules appeared on C_6 and chick embryonic neurolemma cells.

Initial chemical study was performed on conditioned media and membrane extract from both cell lines. The cells were grown to near confluency in culture medium enriched with 10% fetal bovine serum. The cultures were then rinsed thoroughly in saline and maintained in serum-free medium for 3 days, after which the medium was collected, dialyzed against 0.01 M ammonium acetate and lyophilized. Membrane extract of these cells were obtained by incubating the culture in 0.2 M urea for 2 hours; the solution was likewise dialyzed and lyophilized. S.D.S acrylamide gel electrophoresis of samoles from both cell lines showed identical major protein bands, one with molecular weight of approximately 68,000 daltons and a minor band in the range of 55,000 daltons. These protein fractions appear to be membrane in origin and shed into the microenvironment as they appear in both conditioned media and in membrane extract.

120.3 TISSUE INTERACTIONS BETWEEN CO-CULTURED TRIGEMINAL GANGLIA AND CORNEA IN THE CHICK EMBRYO. Betty F. Sisken and Roger W. Beuerman. Wenner-Gren Research Laboratory, University of Kentucky, Lexington, KY 40506 and Div. of Opthalmology, Stanford Medical Center, Stanford, CA 94305.

This study was undertaken to determine if a system could be developed to investigate neuro-epithelial cell relations in the cornea in vitro. Recent work has shown that the trigeminal nerve can exert a trophic effect on the maintenance of the corneal epithelium in vivo (Beuerman and Schimmelpfennig, Exp. Ner., in press). We decided therefore to test the developmental significance of this nerve by co-culturing the trigeminal ganglia with the cornea. These tissues were removed from chick embryos from 6-12 days of incubation and placed 0.5 - 3.0 mm apart in plasma clots. They were grown for periods of 2-10 days and fed with Dulbecco MEM-10% dialyzed fetal bovine serum plus added glucose, glutamine and antibiotics. Neurite outgrowth was promoted by the addition of nerve growth factor (10^{-8}M) or direct current stimulation (10nAmp/dish). Similar cultures were also placed in Rose chambers for time-lapse cinematographic observation. At the conclusion of these experiments, the cultures were fixed and processed for scanning and transmission electron microscopy.

Analyses of movie film demonstrated that within 24 hours the corneal epithelium migrated as a sheet differentially toward the ganglia; the rate approached .02 mm/hour finally overgrowing the ganglia by 72 hours. In contrast, neurite outgrowth did not appear to have a preferred orientation and actually seemed to contain fewer neurites directed toward the cornea. Microcinematography revealed that the limited neurite extension disappeared as the advancing epithelial cells reached them. Electron microscopy verified the absence of neuronal profiles between the explants which contained a bilayered epithelium. At the ganglion, a multilayered, unstratified epithelium was found. The desmosomal junctions of these epithelial cells were developmentally more mature than those found in the bilayered epithelium and in addition contained mats of tonofilaments. Although the underlying ganglion had many degenerating structures, numerous axons containing neurotubules and neurofilaments were found in various stages of Schwann cell developments; this was particularly the situation in NGF-treated cultures. These tissue interactions and the absence of neurites at the cornea are under further investigation.

120.4 GLIAL GROWTH FACTOR: A NEW COMPONENT OF THE BRAIN AND PITUITARY. G.E.Lemke, D.R.Balzer,Jr*, K.A. Stygall*,and J.P.Brockes*. Div. of Biology 216-76, Calif. Inst. of Technology, Pasadena, CA 91125

In a normal tissue culture medium containing 10% fetal calf serum, purified rat Schwann cells divide very slowly. We have previously reported that the cells are stimulated to divide by an activity present in extracts of the brain and pituitary (Brockes, J.P., Fields,K.L., and Raff,M.C. (1979) Brain Res. 165,105-118) and that this activity appears to be both novel and restricted in its distribution (Raff,M.C., Abney,E.R., Brockes,J.P.,and Hornby-Smith, A., (1978) Cell 15, 813-822). The pituitary activity, assayed by the incorporation of ^{125}I-UdR into the DNA of Schwann cells growing in microwells, has been purified over 4000-fold from a pool of 10kg of frozen glands and 4000 lyophilized anterior lobes. It has an apparent molecular weight of 6 x 10^4 on gel filtration and adheres strongly to the cation-exchange resins CM-cellulose and phosphocellulose. The most purified (phosphocellulose) fraction was analyzed by native gel electrophoresis at pH 4.5, followed by a second dimension of SDS gel electrophoresis and the activity was consistently associated with a component of molecular weight 3 x 10^4, suggesting that the native species is a dimer. The effect of phosphocellulose fraction on proliferation of central glial cells in dissociated cultures of the rat corpus callosum was also investigated. The oligodendrocytes and 'macrophage-like' microglia were not significantly stimulated, but the astrocytes, as well as fibroblasts prepared from neonatal rat muscle, were stimulated over the same range of concentration as the Schwann cells. The activity against astrocytes, fibroblasts, and Schwann cells co-migrated on native gel electrophoresis at pH 4.5, providing strong evidence that the same molecule acts on all three cell types. The activity isolated from bovine brain, as analyzed by phosphocellulose chromatography and native gel electrophoresis at pH 4.5, is closely related, if not identical, to the activity isolated from the pituitary. The brain exhibits a distinct regional variation in growth factor activity, with the caudate nucleus (the most active region assayed) yielding crude extracts of an even higher specific activity than those of pituitary. The question as to whether or not this activity is present in serum is currently under investigation. In view of its derivation and effect on Schwann cells and astrocytes, the activity has been named glial growth factor (GGF).

120.5 MODULATION OF EPIDERMAL GROWTH FACTOR RECEPTORS BY NERVE GROWTH FACTOR IN RAT PHEOCHROMOCYTOMA (PC12) CELLS IN CULTURE. D. End*, K Huff*, and G. Guroff. Laboratory of Developmental Neurobiology, NICHD, NIH, Bethesda, MD 20205.

Previous reports from this laboratory have described the attenuation of biological responses to, and the reduction in binding of, the mitogenic peptide, epidermal growth factor (EGF), following treatment of PC12 cells with nerve growth factor (NGF) (Biochem. Biophys. Res. Comm. 89, 175, 1979). While NGF and EGF share several common effects in PC12 cells including an induction of ornithine decarboxylase and rapid increases in 2-deoxyglucose transport and cellular adhesion, the enhanced cellular proliferation observed with EGF contrasts with the decreased cell division and the morphological differentiation induced by NGF. This report presents a further characterization of both the EGF receptor and its modulation in PC12 cells. Kinetic analysis of the binding of iodinated (^{125}I) EGF to PC12 cell monolayers revealed a single class of binding sites with an apparent dissociation constant (K_d) of 1.75 x 10^{-9} M. A single cell possessed approximately 7200 binding sites. The binding of (^{125}I)-EGF was independent of cell density. (^{125}I)-EGF was specifically displaced by native EGF, but not by NGF, insulin, cytochrome c, or growth hormone. Treatment of PC12 cells with NGF produced a morphological differentiation into sympathetic neuron-like cells with a concomitant decrease in EGF binding. The reduction in EGF binding reached a maximal 90% decrease after 72 hours treatment with NGF with a lag of nine hours preceding the disappearance of binding. Scatchard analysis of (^{125}I)-EGF binding to NGF-treated cells demonstrated that this decreased binding represented a loss of binding sites rather than an alteration of receptor affinity. The loss of EGF binding sites was dependent upon the concentration of NGF with 20 ng/ml producing a maximal effect. When PC12 cells were cultured under conditions which prevented attachment and neurite outgrowth, NGF treatment still induced a loss of EGF binding suggesting that this receptor modulation represented a direct response to NGF rather than an indirect consequence of surface changes accompanying morphological differentiation.

120.6 COMPONENTS IN CHICK EYE EXTRACT THAT STIMULATE GROWTH AND DEVELOPMENT OF CHICK CILIARY GANGLION NEURONS IN DISSOCIATED CELL CULTURE R. Nishi and D. K. Berg, Dept. of Biol., UCSD, La Jolla, CA. 92093

We have previously shown that chick ciliary ganglion (CG) neurons (including those normally destined to die in vivo) can survive and develop for long periods of time in dissociated cell culture when supplied with culture medium supplemented with embryo extract or conditioned by heart or skeletal muscle cells. We have now found conditions permitting neuronal survival in the absence of tissue extracts or conditioning, but growth under such conditions is slow. We have used these observations to construct a bioassay for factors that stimulate development of CG neurons. Extracts prepared from chick eye tissue, the normal target of CG neurons, contain at least two such activities. One activity appears to selectively stimulate cholinergic development, while the other activity stimulates overall growth of the neurons.

Complete survival of the CG neuronal population was achieved for periods of at least 3 weeks in dissociated cell culture using only basic culture medium (MEM + 10% horse serum) supplemented with 20 mM KCl, if the substratum was first prepared with fibroblasts. The fibroblasts were grown to confluency, lysed and removed with distilled water; the neurons were then plated. It is not clear whether the fibroblast treatment contributed a specific component necessary for neuronal survival, or whether it simply promoted neuronal adhesion and subsequent survival in a relatively non-specific way. Cholinergic development as assayed by choline acetyltransferase (CAT) activity and overall growth of the neurons as assayed by lactic dehydrogenase (LDH) activity, a general cytoplasmic marker enzyme, lagged considerably behind that obtained for neurons grown with muscle or conditioned medium.

Inclusion of eye extract in the basic medium resulted in a substantial increase in CAT and LDH levels associated with the neurons (e.g. 3-fold at 9 days). Fractionation of the eye extract by gel filtration resolved two separate activities. One activity, with an apparent mol. wt. of ca. 5x10^4, stimulated CAT levels while having no effect on LDH levels. The other activity, with an apparent mol. wt. of ca. 2x10^4, stimulated overall growth as indicated by LDH levels and relative rates of protein synthesis, but had no effect on CAT levels. The increased growth did not reflect contaminating nonneuronal cells since (1) few nonneuronal cells were present at 9 days, and (2) the increase in LDH levels correlated well with an increase in the mean neuronal soma.

The activities described here may represent factors normally produced by the target tissue to help direct the growth and development of neurons in vivo. It will be of interest to determine the range of cell types responsive to the activities, and to characterize their modes of action on CG neurons. (Supported by USPHS Grant #12601 & The Muscular Dystrophy Assoc.)

120.7 NEUROTROPHIC FACTOR: CHARACTERIZATION AND PARTIAL PURIFICATION. Heinz Popiela and Stanley Ellis*. Biomedical Research Division, NASA-Ames Research Center, Moffett Field, CA 94035.

Recently published in vivo (Popiela, Exp. Neurol. 55:160, 1977) and in vitro evidence (Bonner, Dev. Biol. 66:207, 1978; Popiela, Exp. Neurol. 62:405, 1978) suggests that neurotrophic activity is required for normal proliferation and development of muscle cells. In the present work two independent and quantitative in vitro assay methods are used to monitor partial purification of neurotrophic activity from adult chicken ischiatic-peroneal nerves. The greatest amount of neurotrophic activity is extracted at pH 8. With either increasing or decreasing pH progressively less activity is extracted. Aqueous suspensions of neurotrophic activity are labile to changes in pH but not to longterm storage at room temperature or to storage for more than a week at 37°C. Specific activity is doubled upon precipitation of extract with ammonium sulfate at 50-75% saturation or after gel filtration on Sephadex G-100 columns. Salt gradient elution from DEAE-cellulose columns yields a single active peak with specific activity increased 4-5 fold. The active fraction obtained after gel filtration and rechromatography on DEAE-cellulose yields a single active peak with a 7-10 fold increase in specific activity. Purification of neurotrophic activity, as indicated by an increase in specific activity, is revealed in the lower concentration range of 20-60 µg/ml. At greater concentrations, the more highly purified material shows a plateau in activity which is much lower than in the presence of unfractionated extract. It seems that maximum activity is progressively reduced with increasing purity of active fractions. These observations lead us to postulate the existence of a co-factor necessary for the expression of maximum activity. Purification of inhibitory activity seems unlikely because the partially purified material does not seem to show inhibitory properties.

Heinz Popiela is a National Research Council Resident Research Associate.

120.8 BASAL LAMINA FRACTION FROM THE ELECTRIC ORGAN OF TORPEDO ORGANIZES ACETYLCHOLINE RECEPTORS ON CULTURED MYOTUBES. Lee L. Rubin, Adrienne S. Gordon and U.J. McMahan, Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305 and Dept. of Neurology, UCSF Sch. of Med., San Francisco, CA 94143.

Each skeletal muscle fiber is ensheathed by a basal lamina (BL) which extends through the synaptic cleft at the neuromuscular junction. Associated with the synaptic portion of the BL are factors that direct the formation of active zones in regenerating motor nerve terminals and of dense subsynaptic accumulations of acetylcholine receptors (AChRs) in regenerating myofibers. To examine these factors in detail it would be helpful to have an in vitro preparation where BL, nerve terminals, and muscle cells can be easily manipulated. A particularly rich source of cholinergic synapses and one that may provide large amounts of synaptic BL for in vitro studies is the Torpedo electric organ. The aim of the experiment described here was to determine whether BL fractions from the electric organ induce dense accumulations of AChRs on cultured myotubes.

To obtain electric organ BL we used procedures similar to those of others (Carlson et al, J. Ultrastruct. Res. 62:26-53, 1978) who isolated BL from kidney and blood vessels. The BL fraction consisted of insoluble particles that ranged from less than one micron to 30 microns in their greatest dimension. They contained acetylcholinesterase, an enzyme thought to be associated with the BL. When BL particles were added to cultures of chick myotubes whose surface AChRs had been labelled with ^{125}-α-bungarotoxin, autoradiograms showed that there was an increase in the number of AChR clusters per myotube within 2 hr. By 8 hr the BL particles had induced a 3-5 fold increase in clusters. Thus, the BL fraction had a marked effect on the organization of AChRs. Since the AChRs were labelled prior to addition of particles to the culture, clusters induced by BL particles must have been formed by lateral migration of the receptor molecules. Boiled BL fractions produced only a small increase (<2 fold at 8 hr) in AChR clusters; thus most clusters were induced by a temperature-sensitive component of the BL particles. BL fractions from rat muscle, which contains little synaptic BL, produced a small effect similar to that of the boiled fraction from the Torpedo electric organ. We conclude that the BL fraction from the Torpedo electric organ is rich in factors that organize AChRs on myotubes in vitro, mimicking the influence of the synaptic BL on AChRs of regenerating muscle cells in vivo.

120.9 PARTIAL PURIFICATION OF A NERVE TROPHIC FACTOR REGULATING MUSCLE ACETYLCHOLINESTERASE ACTIVITY. Thomas L. Lentz and Janice Chester*. Section of Cell Biology, Yale University School of Medicine, New Haven, CT 06510.

A fraction influencing acetylcholinesterase (AChE) activity of newt triceps muscle in organ culture has been isolated from rat brain homogenates. Fractions were assayed for effects on AChE by comparing the AChE activity as measured with a photometric method of muscles cultured for one week in the presence of a fraction with the activity of paired muscles cultured without treatment. Rat brains were homogenized in Tris (0.05 M, pH 7.2) buffered saline (0.9%). Ultrafiltration of crude brain extract revealed that a fraction passing through a filter retaining species >100,000 in MW and retained by a filter retaining species >10,000 in MW had an effect on AChE. After gel filtration chromatography on Ultrogel AcA 44, a fraction containing proteins 21,000 to 60,000 in MW maintained AChE activity of cultured muscle. Ion exchange chromatography of the fraction obtained by gel filtration showed that the active material did not bind to DEAE Sephadex A-50 in buffer at 0.1 M ionic strength, pH 8, and bound to CM Sephadex C-50 at 0.1 M and 0.75 M ionic strength and was eluted by 1.5 M buffer, pH 5. The gel filtration fraction was bound to CM-Sephadex C-50 in 0.1 M buffer at pH 6.5 and eluted stepwise at increasing pH. The fraction affecting AChE bound to CM-Sephadex at pH 8 and was eluted at pH 9, indicating the active factor is basic with a pI between 8 and 9. SDS polyacrylamide gel electrophoresis of the pH 9 eluate revealed one major and a few minor bands. The major protein has a MW of 28,000. Muscles treated with the pH 9 fraction had up to 17% higher total AChE activity than paired untreated muscles after one week in organ culture. The fraction was active at a concentration of 5-15 µg protein/ml culture medium. Analysis of the molecular forms of AChE by sucrose gradient centrifugation revealed four major molecular forms of newt triceps muscle AChE with sedimentation coefficients of 16.5 S, 12.6 S, 9.7 S, and 5.2 S and a small amount of a 19.4 S form. The isolated fraction had the greatest effect on the 16.5 S AChE, increasing it more than 100% over untreated controls, and a smaller effect on the 12.6 S form. The fraction prevented the decrease in the 16.5 S form of AChE occurring as a result of denervation and in addition increased the amount of this form relative to normal muscle. This study shows that a protein, termed neurotropin, which mediates neuronal trophic effects on skeletal muscle AChE has been identified and partially purified from nerve tissue. (Supported by NSF Grant BNS 79-12898).

120.10 NEUROTROPHIC CONTROL OF 16S ACETYLCHOLINESTERASE FROM MAMMALIAN SKELETAL MUSCLE IN ORGAN CULTURE. Hugo L. Fernandez and Myron J. Duell. Neuroscience Research Lab., V.A. Medical Center, Kansas City, MO 64128 and Dept. Physiology, Univ. of Kansas Med. Ctr.

The effects of rat obturator nerve extracts on total and 16S acetylcholinesterase (AChE) activity were studied in endplate regions of denervated anterior gracilis muscles maintained in organ culture for 48 hr. The decrease of total AChE activity in cultured muscles was similar to that observed in denervated muscles *in vivo*. This decrease in activity was partly prevented by addition of either 100 µl or 200 µl nerve extract (2.7 mg/ml protein) to the nutrient medium. Nerve extract-treatment also decreased the release of AChE activity from the muscle into the bathing medium. Conversely, rat serum (20 µl; 90 mg/ml protein) had no effect on total AChE activity in muscle endplates, nor on release of the enzyme by the muscle. The 16S form of AChE was confined to motor endplate muscle regions and its activity was drastically decreased by denervation in both organ culture and *in vivo* preparations in a comparable manner. Nerve-extract supplemented cultures contained a significantly ($p << 0.001$) larger amount of endplate 16S AChE activity (140-145%) than the corresponding controls (100%). Our results suggest that some nerve soluble substance, other than serum contaminants or 16S AChE itself, affects the maintenance of 16S AChE at the neuromuscular junction. Whether the nerve extract affected the formation and/or prevented the degradation of 16S AChE is being currently studied.

121.1 AFFERENT AND EFFERENT CONNECTIONS OF THE TORUS SEMICIRCULARIS IN THE ELECTRIC FISH, Eigenmannia virescens. S. O. E. Ebbesson and H. Scheich, Institut für Zoologie, Technische Hochschule, Darmstadt, West Germany.

Teleost fish with an electroceptive sense have highly differentiated cell aggregates related to this system. In order to determine the interconnections of these cell groups, horseradish peroxidase (Miles, 40-50% solution) was injected into the torus semicircularis in 40 animals. Survival times ranged from 1-15 days, and after removal the entire brains were cut on a cryostat and processed according to a modification of the De Olmos procedure (De Olmos, J., Exp. Brain Res. 29:541-551,1977).

A preliminary analysis of our data reveals that the torus receives a topographic input from 1) the stratum griseum centrale of the ipsilateral optic tectum, 2) some of the layers of the contralateral torus, and 3) the ipsi and contralateral posterior lateral line lobe. The torus projects in a topographic manner to 1) three ipsilateral, hitherto unnamed, thalamic cell groups, 2) the stratum centrale and stratum griseum et fibrosum superficiale of the ipsilateral optic tectum, 3) the contralateral cerebellar cortex, 4) the ipsi and contra lateral posterior lateral line lobe, 5) the pacemaker, 6) the anterior nuclei bilaterally, 7) the ipsilateral nucleus praeeminentalis,and 8) several hitherto unidentified cell groups in the rhombencephalon.

These results suggest that the torus serves an important role in the intergration of electrical information from both sides of the body and in the correlation with visual input in relation to orientation. A direct influence on the pacemaker by the torus is also indicated by the findings.

121.2 ORIGINS OF OLIVOCOCHLEAR NEURONS IN THE RAT. J.S. White and W.B. Warr. Human Communications Laboratories, The Boys Town Institute for Communication Disorders in Children, Omaha, NE 68131.

Recent studies of the origins and terminations of olivocochlear neurons in the cat provide evidence that dual efferent systems differentially innervate inner and outer hair cells in the organ of Corti. In order (to begin) to test the generality of the dual nature of the olivocochlear system in other mammals, the cells of origin of the (vestibular and) olivocochlear bundle were labeled in the rat by the method of retrograde axonal transport of horseradish peroxidase (HRP). HRP (20% in saline + 2% DMSO) was injected into the labyrinths of adult rats and after allowing 18-30 hours for transport of the tracer, its presence in neurons of the brain stem was demonstrated histochemically using tetramethyl benzidine as the chromogen. The locations and counts of labeled cells were made on the basis of 2 cases with the greatest number of labeled cells so far obtained. Two groups of labeled cells were found in nuclei of the superior olivary complex, but their numbers and locations differed from that reported in the cat. Approximately 150 small ($15\mu \times 20\mu$) cells were located within the lateral superior olivary nucleus, entirely on the ipsilateral side. Approximately 240 large ($18\mu \times 25\mu$) cells were found bilaterally in the medial periolivary nucleus, the majority of which (approximately two-thirds) were situated on the contralateral side. Another group of labeled neurons (presumably vestibular efferents) was found in the region between the medial vestibular nucleus and the abducens nucleus. These findings show that, as in the cat, two morphologically distinct groups of neurons project to the cochlea in the rat. In contrast to the cat, however, 1) there are more large than small olivocochlear neurons, 2) the large cells are localized in a single nucleus, and 3) the small cells are incorporated directly within the lateral superior olivary nucleus and only on the side ipsilateral to the injection site. These findings suggest that there may be significant species differences in the extent of efferent innervation of inner as compared to outer hair cells.

121.3 KAINIC ACID: ITS USE AS A LESIONING TECHNIQUE FOR DETERMINING THE ORIGINS OF AUDITORY BRAINSTEM RESPONSES. J.N. Gardi and S.C. Bledsoe, Jr. Coleman Laboratory, University of California, San Francisco, Ca. and Kresge Hearing Research Laboratory, New Orleans, La.

Previous attempts to clarify the origins of the auditory brainstem response (ABR) have produced only general conclusions, with one group's results often contradicting those published by others. In feline and rodent populations, the response waveform consists of four to five waves. Each wave is thought to arise from a progressively higher order relay station in the auditory pathway; such that wave I reflects VIII nerve activity, while wave II cochlear nuclear complex activity, wave III activity from the superior olivary complex, wave IV activity from the nuclei and tracts of the lateral lemnisci, and wave V activity from the inferior colliculi. However, traditional sectioning, aspiration, cooling, or thermal coagulation techniques have not been suited to precise definition of ABR generators because such techniques indescriminately destroy both soma and axons of passage. A more precise technique, which affects cell bodies without significantly disrupting axons of passage, is the micro-infusion or iontophoretic deposition of kainic acid. In the present study, the feasibility of this new procedure was explored in hopes of developing a more punctaform and precise lesioning technique by micro-infusing kainic acid into one of the nuclei of the superior olivary complex - the medial nucleus of the trapezoid body (MNTB).

The scalp, posterior skull, and overlying cerebellum were removed in seventeen guinea pigs. Kainic acid (0.25 - 10.0 nmoles dosage, and 0.1 - 10.0 microliters volume) was infused into the MNTB contralateral to the stimulated ear. Click-evoked, scalp-recorded ABRs were collected before, during and up to two hours after infusion. All brains were fixed in formol-saline, sectioned at 40 microns, and stained with cresyl-violet.

Among the results were the following: 1. Infusion of small doses (0.1-0.2 microliters) of kainic acid in the MNTB produced relatively restricted lesions, approximately 300 microns in diameter. 2. Such restricted lesions produced decrements in the amplitude of waves III (60-80%) and IV (20-30%) without affecting the amplitude of waves I and II. 3. Infusion of larger dosages in larger volumes (1.0 - 10.0 microliters) produced more extensive lesions extending into adjacent portions of the medial superior olive and in some cases portions of the lateral superior olive without producing significantly different ABR amplitude changes other than those observed in the more restricted lesion cases.

These results suggest that: 1. The MNTB is the primary if not exclusive locus of activity that contributes to the generation of the third wave of the guinea pig ABR. 2. Discrete kainic lesions placed all along the auditory pathway should yield valuable information about the contributions that such structures make to the various waves comprising the ABR. 121.4 ELECTROPHYSIOLOGICAL PROPERTIES OF INFERIOR COLLICULAR NEURONES IN THE BIG BROWN BAT, EPTESICUS FUSCUS. P. H.-S. Jen (Div. of Biological Sciences, Univ. of Missouri, Columbia, MO 65211) and P. A. Schlegel* (Fachbereich Biologie, Goethe Univ., Frankfurt/Main, Federal Republic of Germany).

With 3M KCl micropipette electrodes, 230 single unit activity in the inferior colliculus of Eptesicus fuscus were isolated between the depth of 44 and 2092 µm of the brain surface. During acoustic stimulus, 59 (26%) units discharged tonically, 155 (67%) fired phasically, and the remaining 16 (7%) units either showed phasic off response (10 units) or phasic on-off response (3 units) or discharged impulses upon the cessation of the stimulus (3 units). The latency of those tonic and phasic responders ranged from 5 to 35.5 msec, but the majority were below 12 msec. Individual neurons had either broad or sharp or upper threshold tuning curves with Q_{10} dB values ranging from 1.3 to 39.5. Their best frequencies (BF) were between 11.1 and 92.5 kHz with most of them below 70 kHz. A tonotopical organization of units according to their BFs was demonstrated when an electrode was orthogonally penetrated into the brain surface. As the electrode advanced, BF of the encountered units systematically changed from low to high. The lowest minimum threshold (MT) obtained from those units was 4 dB SPL. Those units with higher BFs do not necessarily have higher MT. Properties of these single units are apparently suitable for encoding signals used by the bat. (Work supported by NSF of USA and DFG of FRG.)

121.5 DIFFFERENTIAL ENCODING OF COMMUNICATION AND ECHOLOCATION CRIES IN THE INFERIOR COLLICULUS OF THE BAT. George J. Carman*, George Pollak, Robert Bodenhamer*, and David Marsh*. Department of Zoology, University of Texas, Austin, Texas.

Recent investigations in our laboratory have revealed intriguing differences in the encoding of constant frequency (CF) and frequency modulated (FM) pulses by neurons of the inferior colliculus (IC) of the Mexican free-tailed bat, Tadarida brasiliensis mexicana. Based on their observed characteristic frequencies and response properties, neurons of the medial IC appear to subserve echolocation, whereas those of the lateral IC seem poorly suited for such a function (Marsh, D., Pollak, G., and Bodenhamer, R., in preparation). This finding raised the interesting possibility that lateral neurons may encode communication calls emitted by members of this species in social settings.

In order to investigate this hypothesis, we decided to examine the response of neurons in the IC to recorded communication and echolocation cries. Various calls of this species, recorded from roosts and in the field, as well as in the lab, were selected for use as stimuli. After preparation under anaesthesia, single unit recordings were made from the IC of awake bats using conventional techniques. The responses of neurons to free-field stimuli were determined, using synthesized CF and FM pulses as well as communication and echolocation cries presented iteratively via a Lockheed Store 4D tape recorder under microprocessor control. Data were collected with a Declab 11/03 laboratory computer in the form of post-stimulus histograms having a minimum resolution of one millisecond per bin. At the end of each experiment, animals were sacrificed and prepared for histology.

The results of these experiments clearly indicate that neurons of the lateral IC respond vigorously to one or another of our recorded communication calls. Furthermore, those neurons which responded to synthesized FM pulses were generally found to respond to recorded echolocation calls as well. As yet, no neurons have been found in the lateral IC which respond to our synthesized or recorded echolocation cries to the exclusion of recorded communication signals; however, a more systematic sampling of the IC may yet reveal such units.

These and other results tentatively support the hypothesis of differential encoding of communication and echolocation cries by neurons of the IC. Our findings do not, however, suggest that the lateral IC is so highly specialized as to preclude a role in echolocation. We are pursuing further systematic neurophysiological and neuroanatomical studies which we hope will reveal the mechanisms of this differential encoding.

121.6 THE RESPONSE PROPERTIES OF CELLS IN THE MEDIAL GENICULATE BODY (MGB) OF THE AWAKE SQUIRREL MONKEY TO SPECIES SPECIFIC VOCALIZATION. N.Allon* and Z. Wollberg. Dept. of Zoology, The George S. Wise Faculty of Life Sciences, Tel-Aviv University, Tel-Aviv (Israel). (Spon: E.E. Decima).

The possible mechanism underlying the response properties of cells in the MGB of the squirrel monkey to species specific vocalization was studied. The approach used in this work was to record the responses of single cells in the MGB of awaked squirrel monkey to simple acoustic stimuli as pure tones and to compare them to the responses of the same cells to complex acoustic stimuli. The spectral and temporal composition of the complex stimuli, including the species specific vocalizations, were analyzed for correlation with the response patterns of the cells.

The response band widths of cells in the MGB to pure tones presented at 80dB SPL ranged between 1-6 octaves. Forty percent of the cells responded to all the six octaves which were presented (0.5 - 32 KHz).

The best frequencies (BFS) of 28% of cells in the MGB were in the range of the first two octaves (0.5 - 2KHz). Eighteen percent of the cells had their BFS in the range of the two middle octaves (2 - 8KHz), and 54% of the cells in the range of the last two octaves (8 - 32KHz).

Most of the cells responded to most of the vocalizations presented, however, with different response patterns. The response patterns' characteristics were qualitatively and quantitatively dependent upon the stimulus intensity. When the vocalizations were presented at low intensity (near threshold), the cells' response patterns were dominated by the intensity modulations in the vocalizations around the best frequency of the cell.

At high dB levels (80dB) one could find a number of cells which responded with the same response pattern to a given vocalization ("typical pattern"). These cells had similar BFS and response patterns to pure tones. The BFS of these cells did not fall in the range of frequencies of the vocalization which contained the most energy.

Of the 7 vocalizations that were tested the "typical" responses were found most frequently to presentation of "long peep."

It was suggested that the "typical" responses may represent a coding of those features of a vocalization which serves to distinguish the individual monkey's vocalization in a group. It was further suggested that the "long peep" can be a very efficient carrier for this information..

121.7 FUNCTIONAL CLASSES OF AUDITORY CORTICAL NEURONS DISTINGUISHED BY SENSITIVITY TO SOUND LOCATION. J.C. Middlebrooks and J.D. Pettigrew. Beckman Labs, Caltech, Pasadena, CA 91125.

We have explored the possible role of the primary auditory cortex (AI) of the cat in the representation of sound location. We determined the direction (location) sensitivity of cortical neurons and compared these properties with the passive acoustics of the cat's head and pinna.

Tonal stimuli were generated by a loudspeaker that could be positioned in any direction a constant distance from the animal; the animal and loudspeaker were enclosed in an anechoic chamber (see Knudsen et al., Science 198:1278). The activity of single units was recorded from AI of cats lightly anesthetized with Ketamine. The spatial receptive fields (rf's) of neurons were plotted by noting the area of the sound field in which a tone of characteristic frequency elicited a reliable response. Units were grouped into three classes on the basis of spatial location sensitivity. Omnidirectional units (O units) responded to sounds presented anywhere in the sound field. Hemifield units (H) responded only to sounds presented in the contralateral sound hemifield. Axial units (A) had circular or eliptical rf's (as small as 30°) located on the acoustical axis of the contralateral pinna (approx. 30° lateral to the midline and 10-20° above horizontal). In radial electrode penetrations, all units tended to show the same class of rf. Along tangential penetrations, sequences of O, H, and A units were segregated from each other in a manner consistant with the pattern of binaural interaction bands demonstrated with diotic stimulation (Middlebrooks et al., Br.Res. 181:31).

In correlative acoustical experiments, a probe microphone was introduced from behind the pinna into the acoustic meatus. Sound levels were recorded while varying the location of the loudspeaker. Iso-intensity contour plots were derived and compared with the rf's determined physiologically. Many of the characteristics of the measured rf's could be inferred from such contour plots, but neither the H nor the A rf's can be explained entirely by the passive acoustics of the head and pinna.

There was no indication of an orderly map of sound space in AI of the cat. All well-circumscribed rf's lay on the acoustical axis of the pinna. The results suggest the presence of at least three independent processing systems in AI. One system, the O units, does not appear to play a role in sound localization. The H units may be involved in the approximate localization of sounds, while the A units are suited for active scrutiny of relevant sound stimuli.

121.8 NEURONAL MECHANISMS OF ECHO DELAY PROCESSING IN BAT ECHOLOCATION. W.E. Sullivan*. (SPON: N. Suga). Dept. of Biology, Washington Univ., St. Louis, MO. 63130.

Many neurons in the auditory cortex of the FM bat Myotis lucifugus respond poorly or not at all to synthesized orientation sounds or echoes, but respond vigorously to echoes which follow loud sounds after some preferred time delay. Such neurons are presumably involved in target range analysis since behavioral studies have shown that echo delay is the primary cue used by bats for the determination of target distance. However, it is conceivable that delay sensitive neurons may also participate in other forms of information analysis, because other parameters such as echo intensity will be affected by target distance. In fact, two kinds of delay dependent facilitation have been found, one in which the best delay is insensitive to changes in echo amplitude, and another in which echo amplitude has a marked effect on the best delay.

In studying the response latency of cortical units to single FM sounds, it was found that some units responded at shorter latencies for weaker sounds than for loud sounds. This latency difference appeared as an abrupt change rather than a gradual decline as amplitude was decreased. Often, there was an intermediate amplitude at which no response could be observed. The response latencies to loud sounds were also found to be related to anatomical position, such that there was a progressive increase in latency as the electrode was moved to more posterior locations. The latency for weak sounds remained relatively constant.

Several lines of evidence indicate that these two phenomena are functionally linked. First, for units which demonstrated both a paradoxical latency shift and delay dependent facilitation, the best delay was correlated with the size of the latency shift. Secondly, both the best delay and the response latency for loud sounds increased as the electrode was moved from anterior to posterior. This data supports a model in which facilitation is achieved by the synchronization of synaptic inputs from the loud outgoing sound and the returning echo. Because the orientation cry occurs at an earlier time, it's input must be delayed relative to the input from the weak echo. The length of this input delay, which is mapped on the cortical surface, will then be related to the echo delay which produces maximal facilitation. This suggests that the processing of delay information is related to the existence of a spatial-temporal excitation pattern in the bat's auditory cortex. The latency and best delay maps represent a unique situation in which the cortical representation is produced by neuronal processing rather than by orderly projections from the periphery. (Supported by NSF grant BNS78-12987, PHS BRSG grant 50324C and PHS training grant 1-T32-NS07057-01).

121.9 UNILATERAL REMOVAL OF SUPERIOR TEMPORAL CORTEX IN MACAQUE MONKEYS AFFECTS DELAYED MATCHING PERFORMANCE. J.A. COSTALUPES AND J.H. DEWSON, III. Auditory Neurobiology Laboratories, Hearing and Speech Sciences, Stanford University School of Medicine, Stanford, CA 94305.

In our previous report (Costalupes, et. al., Soc. Neurosci. Abstr., 5, 1979, 360) we suggested that unilateral removal of superior temporal cortex -- the so-called auditory association area -- in macaque monkeys effects a performance decrement on a visual delayed conditional matching task while leaving visual delayed match-to-sample performance unaffected. Earlier work had indicated a comparable deficit on an auditory-to-visual delayed matching task. The present report will compare pre- and post-operative performance on these visual and cross-modal delayed matching tasks following serial removal of right-sided and subsequently of left-sided superior temporal cortex in a single monkey. Previous delayed visual and delayed auditory-to-visual matching performance and confirmation of the locus and extent of the lesions will be considered in view of recent anatomical and physiological evidence of polysensory function in superior temporal cortex.

121.10 AUDITORY FATIGUE: BEHAVIORAL AND NEURAL OBSERVATIONS IN MONKEYS. B.L. Lonsbury-Martin and G.K. Martin*. Dept. Otolaryngology, Univ. Washington Sch. Med., Seattle, WA 98195.

Using a simple auditory reaction-time task, the fatiguing effects of pure tones (100 dB SPL, 3 mins) were quantified in terms of magnitude of threshold shift and duration of recovery time. These psychophysical experiments formed a framework for later physiological observations in the awake monkey investigating changes in level-dependent properties of single neurons in cochlear nucleus (CN) and inferior colliculus (IC) following stimulation with similar pure tones. The behavioral observations indicated that: a) both the magnitude and time course of recovery of the hearing loss were a function of the frequency of the fatiguing stimulus with higher-frequency stimuli producing greater threshold shifts and longer recovery times; b) although the peak hearing loss was located either at or above the frequency of the fatiguing stimulus depending upon the portion of the hearing range stimulated, threshold shifts were always asymmetrically distributed towards frequencies higher than that of the fatiguer; c) alterations in functions relating response latency to stimulus intensity were demonstratable; and, d) recovery-time courses were monotonic and approximately exponential. Similarly, neuronal measures revealed that: a) the magnitude of threshold elevation for CN units did not significantly differ from those measured for IC neurons; b) a decrement in driven discharge rate at all tested intensities was noted for most units, but approximately one-third of our sample demonstrated a decrement in poststimulatory activity for threshold-related test stimuli, while for high-level tone bursts, discharge rate increased above control levels; c) spontaneous activity levels for units with moderate to high discharge rates either increased or decreased, while those for low-spontaneous rate neurons (<2 spikes/s) were generally unchanged; d) short-lasting alterations were also observed in stimulus-level dependent properties as reflected in rate-intensity curves and in functions relating latency of the first evoked spike to signal intensity; and, finally, e) recovery from fatigue was generally more rapid for spontaneous than for driven activity and for IC than for CN units. Although these results indicate that stimulation with fatiguing stimuli reduced the sensitivity and altered the driven and spontaneous neural activity of neurons in brainstem auditory structures in a manner that was consistent with the behavioral symptoms of auditory fatigue, the magnitude and duration of these changes were frequently much greater and longer lasting than those indicated by the pure-tone behavioral threshold measures.

122.1 STUDY OF MECHANISM(S) OF PEPTIDE MODULATION OF CATECHOLAMINE RELEASE IN BOVINE ADRENAL PARANEURONS. Deanne M. Dean* and Bruce G. Livett. (SPON: M. Rasminsky). Division of Neurology, The Montreal General Hospital and McGill University, Montreal, Canada.

Adrenal chromaffin cells in culture provide a model system for examining the development and function of cells of neural crest origin. Bovine adrenal medullary cells were isolated and purified as previously described, and maintained in a nutrient medium based on Eagle's minimum essential medium, human placental serum and chick embryo extract. Studies were carried out on cells 3-20 days old, during which they attach to a collagen-coated surface and extend processes. For pharmacological studies, the cells were loaded with ^{3}H-norepinephrine (^{3}H-NE) as previously described[1]. These studies have demonstrated that ^{3}H-NE release is mediated by stimulation of nicotinic cholinergic receptors, and that various peptides including substance P (SP), somatostatin, and enkephalins, as well as other opiates (e.g. morphine) inhibit the release of ^{3}H-NE induced by nicotine, but not that induced by K^+[1,2].

We have now examined whether depolarization of the voltage sensitive Na^+ channel is involved in the modulation of catecholamine release by peptides. Tetrodotoxin (10^{-9}-10^{-5}M) inhibited the release of ^{3}H-NE induced by veratridine ($5x10^{-5}$M), but not that induced by nicotine ($5x10^{-6}$M). At a concentration of SP ($1x10^{-5}$M) that abolished the nicotine-induced release of ^{3}H-NE, the veratridine-induced release of ^{3}H-NE was not depressed. Thus, SP modulation of catecholamine release does not involve depolarization of voltage-sensitive Na^+ channels.

Blockade of neuromuscular transmission by agents such as quinacrine, amantadine and procaine is mediated by binding to the ionophore of the receptor-ionophore complex. We have found that these agents also depress the nicotine-induced release of ^{3}H-NE from adrenal chromaffin cells in culture. The depression of ^{3}H-NE release produced by quinacrine and SP is similar. In addition, SP does not add to the depression produced by quinacrine. These studies suggest that SP acts to modulate catecholamine release by regulating the ionophore of the receptor-ionophore complex.

122.2 REGULATION OF TYROSINE HYDROXYLASE IN ISOLATED CHROMAFFIN CELLS: EFFECTS OF 8Br-cAMP AND ACh ON DEAE-SEPHACEL ELUTION PATTERNS. *John Haycock, Robert George and Jack Waymire*. Dept. Neurobiology & Anatomy, Univ. Texas Medical School, Houston, TX 77025.

Treatment of intact, isolated chromaffin cells with either ACh or cAMP (or analogues) increases catecholamine synthesis rates.[1] 8Br-cAMP, e.g., not only increases catecholamine synthesis but activates tyrosine hydroxylase activity *in vitro* as well.[2] And, such increases in tyrosine hydroxylase (TH) activity have been attributed to increases in ^{32}P incorporation.[3] Thus, the acceleration of catecholamine biosynthesis by cAMP and its analogues seems closely related to phosphorylation processes. On the other hand, the nature of ACh-induced increases in catecholamine biosynthesis in chromaffin cells remains speculative.

A recent report by Sze et al.[4] suggested that DEAE-cellulose chromatography might separate activated and nonactivated TH. Sze and coworkers reported that TH activity from rat striatal supernatants, passed over a DEAE-cellulose column, was eluted as two peaks (corresponding to 0.1M and 0.2M NaCl). Prior phosphorylation shifted TH activity to the 0.2M peak whereas phosphatase or prolonged incubation (0°C) shifted TH activity into the 0.1M peak. Sze and coworkers conclude that the 0.1 and 0.2M peaks correspond to unphosphorylated and phosphorylated TH, respectively.

In the present study, we investigated the effects of ACh and 8Br-cAMP on intact, isolated chromaffin cells on the basis of the TH elution pattern from DEAE-Sephacel columns. Isolated chromaffin cells were incubated in MES-buffered saline (pH 6.2,15',37°C) with or without ACh (100µM) or 8Br-cAMP (1mM). *In vitro* TH activity (100,000g supernatant) was increased by 8Br-cAMP, and the ratio of activity shifted toward the 0.2M peak. On the other hand, although both 8Br-cAMP and ACh increased catecholamine synthesis rates, ACh had no discernible effect upon *in vitro* TH activity.

The present data are consistent, then, with the notion that exogenous 8Br-cAMP alters catecholamine synthesis by increasing the phosphorylation (hence catalytic activity) of tyrosine hydroxylase. To the extent that the elution patterns on DEAE cellulose may reflect the relative phosphorylative state of TH, these data do not support a role for phosphorylation in the increase in catecholamine synthesis produced by exogenous ACh.

122.3 SUGGESTIONS FOR A NEW CLASS OF OPIATE RECEPTORS IN BOVINE CHROMAFFIN CELLS. L. Saiani* and A. Guidotti (SPON: D. L. Cheney). Lab. Preclin. Pharmacol., NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

P-2 membranes prepared from primary culture of bovine adrenal chromaffin cells and from adrenal medulla homogenates contain opiate receptors. This binding was characterized with ^{3}H-dihydromorphine, ^{3}H-D-Ala^2-leu-enkephalin, ^{3}H-etylketazocine and ^{3}H-SKF10047 to label the µ, δ, κ and σ receptors, respectively. ^{3}H-etorphine, which labels both µ and δ receptors, was also studied, as well as the two antagonists, ^{3}H-naloxone and ^{3}H-diprenorphine. The K_D was similar for all the compounds, approximately 2 nM.

A similar K_D was obtained studying the same ^{3}H-ligands in P-2 membranes prepared from bovine frontal cortex. In brain the Bmax for all the compounds ranged from 50 to 80 fmol/mg protein, whereas in adrenal medulla the Bmax of the various compounds ranged from 20 to 200 fmol/mg protein. ^{3}H-etorphine, ^{3}H-naloxone, ^{3}H-diprenorphine and SKF10047 bind with a Bmax of 200, 150, 100 and 90 fmol/mg protein respectively; ^{3}H-dihydromorphine, ^{3}H-D-Ala^2-leu-enkephalin and ^{3}H-etylketazocine bind with a Bmax smaller than 20 fmol/mg protein.

In membrane of adrenal medulla, morphine, D-Ala^2-leu-enkephalin, β-endorphin, naloxone, etylketazocine and pentazocine displaced ^{3}H-etorphine (K_I = 100-400 nM), while diprenorphine, phenazocine and SKF10047 displaced ^{3}H-etorphine with a K_I of 4, 12 and 45 nM, respectively. The potency of morphine and D-Ala^2-leu-enkephalin for displacing ^{3}H-etorphine was greater in membranes prepared from adrenal medulla than in those prepared from frontal cortex.

Kinetic studies revealed that the frontal cortex possesses two populations of receptors, while the adrenal medulla has only one labelled by ^{3}H-etorphine. The ^{3}H-etorphine binding was not displaced by the non-opioid peptides, substance P, bradykinin, oxytocin, neurotensin and cosyntropin; it was decreased by NaCl (100 mM) and GMP-P(NH)P (50 µM). These results suggest that etorphine receptors in the bovine chromaffin cells are different from the ones in the frontal cortex, and that they are not µ, δ or κ type.

The correlation between the potency of different opiate agonists in displacing ^{3}H-etorphine from receptors and in inhibiting nicotine-induced catecholamine release, shown to exist in primary cultured chromaffin cells, indicates a functional role for these receptors.

122.4 UPTAKE OF NUCLEOTIDES INTO CHROMAFFIN GRANULES OF VARIOUS SPECIES. Stephen W. Carmichael* Andreas Weber* and Hans Winkler*. (SPON: C. R. Craig)., Department of Anatomy, West Virginia University, Morgantown, WV 26506 and Department of Pharmacology, University of Innsbruck, Innsbruck, Austria.

ATP is known to be the most abundant nucleotide within the chromaffin granule of the adrenomedullary cell. It is thought to play an important role in the uptake, storage, and secretion of catecholamines. Uptake of ^{3}H-ATP has been demonstrated in isolated bovine chromaffin granules (Kostron et al., Neuroscience 2:159-166,1977). The present study also identifies a similar uptake of ATP in other species and an uptake of other nucleotides into bovine chromaffin granules. Uptake of ^{3}H-ATP was measured in chromaffin granules isolated from the adrenal medulla of pigs and horses. Medullas were separated from fresh adrenals and homogenized. A large granule fraction was isolated and washed by centrifugation. The granules were incubated at 37°C for 5 minutes with tritiated ATP in concentrations of 6, 4, 2, 1, and 0.5mM. Granules were washed and purified by centrifugation over 1.5M sucrose. After measuring the radioactivity taken up into the granules, the apparent Km was 1.34mM for pig and 0.89mM for horse. This is similar to the Km (1.4mM) reported for bovine chromaffin granules (Arberer et al., Biochem. J. 172:353-360,1978). By thin layer chromatography, 66% and 54% of the radioactivity taken up into the granules was identified as ATP for pig and horse, respectively. The uptake of nucleotide was inhibited by atractyloside and uncouplers of oxidative phosphorylation. Reserpine, a specific inhibitor of the carrier for catecholamine uptake, did inhibit ^{14}C-norepinephrine uptake but not ^{3}H-ATP uptake. Bovine chromaffin granule were incubated with labeled UTP and GTP and the uptake was found to be similar to that for ATP. The same nucleotide carrier of the chromaffin granule transports all three nucleotides which contrasts with the mitochondrial ATP/ADP carrier which is specific for adenine nucleotides. $Mg^{++}$and Ca^{++}reduced the affinity of ATP for the carrier by apparently inducing a less favorable configuration of the molecule.

This investigation was supported in part by Biomedical-Research Support Grant 507 RR0543317 by the WVU Medical Corporation, by the Dr. Legerlotz-Stiftung and by the Fonds zur Förderung der wissenschaftlichen Forschung (Austria).

122.5 ACTIVATION OF TYROSINE 3-MONOOXYGENASE IN PHEOCHROMOCYTOMA CELLS BY ADENOSINE. Raymond Erny*, Michael Berezo*, and Robert L. Perlman* (SPON: Richard E. Zigmond). Committee on Cell and Developmental Biology and Department of Physiology, Harvard Medical School, Boston, MA 02115.

We have been studying the regulation of tyrosine 3-monooxygenase (TH) activity in cell suspensions prepared from a transplantable rat pheochromocytoma. When pheochromocytoma cells are incubated with tyrosine and brocresine (an inhibitor of DOPA decarboxylase), they produce DOPA and release it into the incubation medium. We have used high pressure liquid chromatography with electrochemical detection to measure the rate of DOPA production, and thereby the activity of TH in these cells. The activity of TH in pheochromocytoma cells can be increased acutely by two distinct mechanisms. Incubation of the cells in medium containing depolarizing concentrations of K^+ results in an activation of TH that is dependent upon extracellular Ca^{2+}, that is accompanied by an increase in catecholamine secretion, and that is not associated with a change in cellular adenylate cyclase activity. In contrast, incubation of the cells with cholera toxin causes an activation of TH that is accompanied by a large increase in the cyclic AMP content of the cells, but that is independent of extracellular Ca^{2+}. We now report that adenosine (Ado) also increases the activity of TH in pheochromocytoma cells. Incubation of the cells with 100μM Ado rapidly results in a 40-70% increase in TH activity. The variability of the response to exogenous Ado is due in part to the presence of variable amounts of endogenously produced Ado, since addition of adenosine deaminase to cell suspensions decreases basal TH activity by 10-30%. The effect of added Ado is virtually abolished under these conditions. In contrast, the Ado analog 2-chloroadenosine (2-Cl-Ado) causes a greater than two-fold increase in TH activity in the presence of adenosine deaminase. Half-maximal activation of TH is produced by 100nM 2-Cl-Ado, and maximal activation at approximately 10μM. Activation of TH by Ado and by 2-Cl-Ado is not dependent upon extracellular Ca^{2+}, and is not accompanied by a significant increase in the secretion of catecholamine from the cells. Moreover, the maximal effects of Ado and of 2-Cl-Ado on TH activity are additive with the activation produced by K^+-induced depolarization. Finally, 2-Cl-Ado causes a 6-fold increase in the accumulation of [^{3}H]-cyclic AMP in cells preincubated with [^{3}H]-adenine. We propose that pheochromocytoma cells contain Ado receptors coupled to adenylate cyclase, and that the stimulation of these receptors by Ado or by 2-Cl-Ado causes an increase in intracellular cyclic AMP and thereby activation of TH. Adenosine may be a physiological regulator of adenylate cyclase activity and of TH activity in normal chromaffin cells.

122.6 ACETYLCHOLINE INHIBITS CATECHOLAMINE UPTAKE INTO CHROMAFFIN CELLS Lorna W. Role* and Robert L. Perlman* (SPON:K. Rockland), Department of Physiology, Harvard Medical School, Boston, MA 02115.

We have been studying catecholamine (CA) uptake into isolated chromaffin cells. Chromaffin cells are prepared by collagenase digestion of guinea pig adrenal glands, and purified by isopycnic centrifugation. The cells are pre-incubated with pargyline, to inhibit monoamine oxidase, and are then incubated with l-[^{3}H] norepinephrine (NE) or l-[^{3}H]epinephrine (EPI). We now report that freshly dissociated chromaffin cells have a high affinity uptake system for CA, similar to that described for sympathetic neurons, and that acetylcholine (ACh), the physiological agonist for CA secretion from chromaffin cells, inhibits this CA uptake system.

CA uptake is linear for at least 20 min., is concentration-dependent, and is saturable. CA uptake is energy, temperature, and Na^+-dependent, and is inhibited by imipramine. In the presence of 130 mM Na^+, the apparent K_ms for the uptake of NE and EPI are ∿1 μM and ∿4 μM respectively. The apparent V_{max} for both NE and EPI uptake is in the range of 100-200 pmol/min/mg protein. Half-maximal uptake of 6 μM NE is observed at 34 mM Na^+.

ACh, veratridine and pilocarpine, which cause CA secretion from chromaffin cells, inhibit CA uptake into these cells. ACh (100 μM) and veratridine (25 μM) cause the release of 10-20% of the CA content of the cells, but block uptake by more than 90%. Atropine (50 μM) inhibits the effects of ACh on CA secretion and on CA uptake; tetrodotoxin (1 μM) inhibits the effects of veratridine on these processes. Somatostatin and substance P are present in guinea pig adrenal glands. At a concentration of 10 μM, these peptides partially reverse both ACh-induced CA secretion and the inhibition of CA uptake produced by ACh. Replacement of extracellular Ca^{2+} by Co^{2+} prevents ACh and veratridine-induced CA secretion, but does not block the inhibition of CA uptake caused by these agents. Therefore, the inhibition of CA uptake can not be accounted for by the stimulation of CA secretion. ACh and veratridine may depolarize chromaffin cells, and thereby decrease the electrochemical gradient for the entry of Na^+ into the cells; this decrease in the electrochemical gradient for Na^+ may then cause a decrease in CA uptake.

The Na^+-dependent CA transport system may be important in maintaining a low basal release of CA from the adrenal medulla in vivo. The inhibition of CA uptake by ACh may prevent the reuptake of CA during physiological stimulation of CA secretion.

122.7 SIMULTANEOUS USE OF THE RETROGRADE TRACER 'TRUE BLUE' AND IMMUNOHISTOCHEMISTRY: INNERVATION OF THE RAT ADRENAL MEDULLA. V.R. Holets, T.J. Mullett*, and R.P. Elde. Department of Anatomy, University of Minnesota Medical School, Minneapolis, MN. 55455

The adrenal medulla is innervated by preganglionic sympathetic neurons in the intermediolateral cell column (IML) of the thoracic and upper lumbar spinal cord. This innervation is interesting in that: i) these presumed cholinergic neurons innervate adrenal medullary cells which contain and release enkephalin-like material concomitant with catecholamines; and ii) we have an incomplete understanding of neurotransmitter-specific circuitry impinging upon IML which in turn project to the adrenal medulla. Retrograde axonal transport of the fluorescent dye 'True Blue' was utilized to identify the neurons in IML which project to the adrenal medulla, and by combining this with indirect immunofluorescence, it was possible to visualize met-enkephalin (M-ENK), serotonin (SER), somatostatin (SOM), and substance P (SP) immunoreactive fibers in IML in the same section.

Five days following an injection of 'True Blue' (5 ul 1% 'True Blue') into the left adrenal medulla of rats, the animals were perfused with buffered 4% paraformaldehyde. Serial horizontal or transverse 10 and 30um cryostat sections were taken through IML in the thoracic and upper lumbar spinal cord. Adjacent sections at each level of the spinal cord were processed for immunofluorescence with primary antisera directed against M-ENK, 5-HT, SOM, and SP, with additional sections serving as absorption controls.

The largest number of retrogradely-labeled neurons were observed at T7 and T8, but neurons were observed in a long, continuous column between T1 and L2. Cell clusters could be seen at each spinal cord level. Fusiform (8 x 22 um) to round (12 um) neurons as described by Schramm et al. (Exptl. Neurol. 49:548, 1975) were observed in IML, as well as a small population of large round neurons in the lateral horn-lateral funiculus border. Occasionally, neurons medial to IML were retrogradely-labeled. Axons and dendrites could be seen arising from most perikarya, the latter branched close to the soma and extended either laterally into the white matter, or medially for short distances.

5-HT and SP immunoreactive fibers were prominent in IML, whereas M-ENK and SOM immunoreactive fibers were sparse. These fibers could be seen surrounding the retrogradely-labeled neurons and traveling parallel to the long axis of IML.

The occurrence of several putative neurotransmitters in nerve fibers and terminals suggests diverse control of IML neurons projecting to the adrenal medulla.

122.8 SPONTANEOUS AND NERVE GROWTH FACTOR INDUCED AXON OUTGROWTH FROM RAT AND BOVINE ADRENAL CHROMAFFIN CELLS IN CULTURE. K. Unsicker and W. Ziegler*. Dept. of Anatomy and Cell Biology, Philipps University, D-3550 Marburg, West Germany.

Adrenal chromaffin cells from young rats have been shown to extend axon-like processes, when grown in low density primary cultures with 2.5 S nerve growth factor (NGF). We have recently observed that processes may also develop spontaneously without exogenous NGF in the presence of large amounts of adrenal non-neuronal (Schwann, fibroblast-like) cells. Spontaneous axon outgrowth could not be blocked by administration of an antiserum to NGF, but was abolished, when non-neuronal cell growth was suppressed by γ-irradiation. Irradiation did not affect the vitality and capacity of chromaffin cells to respond to NGF. The addition of both separately grown intact adrenal non-neuronal cells and diluted high speed supernatants of homogenized cells, but not of conditioned medium, re-established fibre outgrowth from irradiated chromaffin cells.

Chromaffin cells isolated from adult bovine adrenal glands and kept in long-term cultures also exhibited spontaneous axon outgrowth, which was neither blocked by an antiserum to NGF nor enhanced by administration of NGF. The role of non-neuronal adrenal cells in promoting fibre outgrowth from bovine chromaffin cells is under investigation.

We conclude that adrenal non-neuronal cells may be involved in fibre outgrowth from chromaffin cells. Moreover, our results suggest that the response of chromaffin cells to NGF in terms of fibre outgrowth is age- and/or species-dependent.

122.9 PROLONGED SURVIVAL OF BOVINE ADRENAL CHROMAFFIN CELLS IN RAT CEREBRAL VENTRICLES. M. J. Perlow, K. Kumakura* and A. Guidotti. Lab. of Clinical Psychopharmacology and Lab. of Preclinical Pharmacology, NIMH, St. Eliz. Hosp., Wash. D.C. 20032

Dispersed, cultured bovine adrenal chromaffin cells transplanted into the cerebral ventricles of neonatal and adult rats survive at least two months without evidence of immunological rejection. The cells can be identified for their strong yellow fluorescent reaction using glyoxylic acid, thus suggesting that they maintain intact the capability of synthesizing and storing catecholamines. The cells did not show sprouting or process formation and appear free in the ventricle or aggregated in clusters. This is the first report showing that cells from different animal species and from different tissue origin can be transplanted and survive in the cerebral ventricles.

123.1 STERNBERGER'S UNLABELED ANTIBODY METHOD USED TO STAIN NEURON SPECIFIC ENOLASE AND LYMPHOCYTIC CHORIOMENINGITIS VIRUS ANTIGENS IN TISSUES CONVENTIONALLY PREPARED FOR ELECTRON MICROSCOPY. Manuel del Cerro[1,2], Paul J. Marangos*[3], Robert L. Stoughton[1], Andrew A. Monjan*[4], and Coca del Cerro*[1]. 1)Center for Brain Research, Univ. of Rochester Med. Ctr., Rochester, NY 14642. 2)Center for Visual Science, Univ. of Rochester, Rochester, NY 14627. 3)Clinical Psychobiology Branch, NIMH, Bethesda, MD 20205. 4)Dept. of Epidemiology, School of Hygiene and Public Health, The Johns Hopkins Univ., Baltimore, MD 21205.

The extreme sensitivity of Sternberger's unlabeled antibody method permits detection of antigens in paraffin sections from tissues originally processed by routine histological techniques (retrospective cytochemistry). We thought it of interest to test this technique on one µm thick plastic sections of tissues conventionally prepared for electron microscopy, i.e., fixed with glutaraldehyde-containing mixtures, post-fixed with OsO_4, and stained with uranyl acetate. Antibodies (Ab) against neuron specific enolase (NSE) and lymphocytic choriomeningitis virus (LCMV) were obtained from rabbits by standard immunological procedures. These Ab were used on one µm sections of rat retina and cerebellum from both normal animals and animals infected with LCMV. The tissues had been prepared as described above and embedded in epoxy resin. The plastic was removed from the sections; the tissues were incubated with the Ab in dilutions ranging from 1:100 to 1:2000, and then with anti-immunoglobulin and peroxidase-antiperoxidase, and reacted with diaminobenzidene-hydrogen peroxide. NSE was detected in the somas of bipolar and ganglion cell neurons, and in the neuropil of the inner plexiform layer. LCMV antigens stain most prominently over the internal granular layer and in the white matter. The results suggest that other antigens may be demonstrable retrospectively in tissues conventionally prepared for electron microscopy. The strength of the reaction depends on the fixative used. For example, the LCMV antigens stain more strongly after fixation with 3%paraformaldehyde - 1% glutaraldehyde than with 1% acrolein - 2% paraformaldehyde - 1% glutaraldehyde; nonetheless, positive results are obtained with either fixative. The possibility may exist of performing retrospective ultrastructural studies, even on glutaraldehyde fixed material, using this approach.

123.2 STUDIES ON THE SUBCELLULAR DISTRIBUTION OF THE MAJOR POSTSYNAPTIC DENSITY PROTEIN: A SYNAPSE SPECIFIC PROTEIN? Paul T. Kelly. Division of Biol., Kansas State Univ., Manhattan, KS 66506.

The subcellular distribution of the major PSD protein (M_r=52K) in both bovine and rat brain was examined in subcellular fractions enriched in myelin, mitochondria, microsomes, synaptic membranes, synaptic junctions (SJ)/postsynaptic membrane specializations (PSMS) and soluble brain proteins (cytosol). The unambiguous identification of the major PSD protein among all other subcellular fraction proteins in the 49,000-55,000 M_r range was accomplished by the following biochemical and morphological analyses: (1) estimates of M_r by gel electrophoresis, (2) 2-dimensional peptide fingerprints of individual proteins, (3) interprotein cross-linking resulting from disulfide bond formation, (4) insolubility in SDS of protein-protein complexes produced in (3) above, and (5) examination of subcellular fractions by EM. In addition to the fractions listed above, purified mitochondria, microsomes, cytosolic proteins and a light plasma membrane fraction (0.8-1.0M sucrose interface) were individually treated with sulphydryl cross-linking reagents, extracted with Triton X-100 (0.4%, v/v) and their respective detergent insoluble counterparts were examined for major PSD protein content. Additional experiments, employing similar strategies, were carried out on a plasma membrane/gap junction fraction isolated from chick lens as well as plasma membranes purified from rat liver.

With the exception of synaptic membranes and synaptic junctions, the only fraction that contained significant amounts of the major PSD protein were microsomes (P_3B fraction) prepared by the method of de Blas and Mahler (J. Neurochem., 30:563, 1978); and then, only after these microsomes were treated with INT (p-iodonitrotetrazolium violet) and extracted with Triton X-100. In addition to containing large amounts of the major PSD protein, the resulting Triton-insoluble P_3B material displayed endless numbers of structures that resembled isolated PSDs when examined by EM. Interestingly, the P_3B fraction has been shown to be enriched in transmitter receptors of presumptive post-synaptic origin (de Blas & Mahler, J. Neurochem., 30:563, 1978).

These results suggest that the major PSD protein in brain is confined to structures of postsynaptic origin in either synaptic membrane (SPM) or P_3B (microsomal) fractions. Previous studies of synaptic junctional polypeptides during brain maturation have shown that the appearance and accumulation of the major PSD protein parallels the later periods of synaptogenesis (postnatal days 17 through 30) (Kelly, P. & C. Cotman, Neurosci. Abstr., 4:117, 1978). Together, these results support the notion that the major PSD protein is a molecular marker specific to asymmetric synapses (Gray Type II) in the CNS. This work was supported by NIH grant NS 15554.

123.3 INDIVIDUAL NERVE CELLS ARE IMMUNOLOGICALLY DISTINGUISHABLE IN THE LEECH. Birgit Zipser, Ron McKay*, John Farrar*. Cold Spring Harbor Laboratory, N.Y. 11724, Uniformed Services University of Health Sciences, Bethesda, Maryland 20014.

Immunological techniques showed that leech neurons are characterized by macromolecular specificity labels. Both conventional antisera raised against purified antigens and monoclonal antibodies raised against the entire leech nerve cord distinguish individual neurons in the stereotypic 400 neuron leech ganglion. The possibility exists that such antigens constitute cell markers for specific cell to cell interaction. Extensive data will be presented showing immunocytochemical staining of identified and identifiable neurons by monoclonal antibodies and conventional antisera against peptides. Our preliminary results strongly suggest that every leech neuron has one or more immunologically recognizable unique macromolecules.

Supported by NSF grant 78-13064.

123.4 THE MORPHOLOGY OF NOCICEPTIVE NEURONS IN THE SKIN OF THE LEECH. Susanna Blackshaw* (SPON: J. G. Nicholls). Dept. Neurobiol., Stanford Med. Sch., Stanford, CA 94305.

The cell bodies of nociceptive or "N" cells in the leech lie within the central nervous system. They respond to noxious or painful stimulation of the skin. A great deal is known about the electrical properties of N cells, the morphology and physiology of their synapses, and the way in which they regenerate connections after injury. The receptive fields of individual N cells have been mapped physiologically and each of the 4 neurons within a ganglion innervates a specific quadrant of the body wall. There is however little information on the way in which individual axons branch and terminate within their receptive fields. N cells have now been visualised directly in the skin of the leech by injecting horseradish peroxidase into their cell bodies within the ganglion. Branches of the axon run within the network of peripheral nerves at deep levels of the body wall. The N cell terminals consist of fine axon branches that form continuous loops and spirals in close association with the hillock region of large neuron cell bodies that lie within the sheath of a peripheral nerve. Previous experiments have shown that N cells respond to noxious stimulation of the skin, and are not activated by temperature, pH, osmotic pressure or stretching the body wall (Nicholls, J. G. and Baylor, D. A., J. Neurophysiol., 31: 740-756, 1968). The finding that the N cell terminates on peripheral neurons raises the question of the role of the peripheral cells, and also the possibility that the N cells repond to some other form of stimulation in addition to noxious stimulation of the skin.

A striking feature of the N cell morphology was that the axon terminals were found at specific locations within the receptive field in animal after animal. This emphasizes the high degree of specificity of the connections of these neurons with their peripheral targets.

123.5 LECTINS AS MARKERS FOR STUDIES OF NEURONAL CONNECTIVITY. J.D. Coulter, M.C. Sullivan* and M.A. Ruda. Marine Biomedical Inst., and Depts. of Physiol. and Psychiat., Univ. of Texas Med. Branch, Galveston, TX. 77550 and Nat'l Inst. Dental Res., NIH, Bethesda, MD. 20014.

Lectins, a class of proteins with selective affinities for carbohydrates, were investigated as axoplasmic transport markers for light and electron microscopy. Two lectins, wheat germ agglutinin and concanavalin A, were found to be transported in both anterograde and retrograde directions, as well as, transneuronally. In rats, 0.1-2.0% solutions of lectin were injected (0.1-50 µl) into various well-defined neuronal pathways. These included subcutaneous injections in the vibrissal region for retrograde labeling of facial motoneurons and for anterograde labeling in trigeminal pathways, and intraocular injections for anterograde labeling in retino-geniculo-tectal pathways. Immunohistochemical (Sternberger, PAP method) localization of transported lectin was found to be superior to localization by histochemical methods for lectin-peroxidase conjugate. In facial motoneurons the subcellular localization of retrogradely transported lectin was examined in the electron microscope. Punctate reaction product occurred in proximal dendrites and the cell body cytoplasm, exclusive of the nucleus, and could be identified in lysosomes, multivesicular bodies, and discrete, circular foci over saccule-like profiles. In the spinal trigeminal nucleus anterogradely transported lectin was localized to the superficial laminae. Cell somata in this same region also contained reaction product suggesting transneuronal labeling. Intraocular injections of lectin anterogradely labeled retinal projections to the lateral geniculate and tectum. In the superior colliculus, reaction product was most dense in the stratum griseum superficiale, but also occurred, presumably by transneuronal transport, in cell bodies of the superficial layers and the stratum griseum intermediale. Suppression of anterograde/transneuronal labeling, while preserving substantial retrograde labeling, can be achieved by decreasing the sensitivity of the histochemical reactions. Neurons projecting to the spinal cord were retrogradely labeled with lectin in this way using $CoCl_2$ to yield a black, punctate reaction product in labeled cells. Sections were then stained with an antiserum to serotonin to give a brown reaction product (Bowker et al., this volume). In the raphe nuclei, spinally projecting neurons containing serotonin were identified by the presence of both the brown and black labels in the same cell. These results indicate that lectins are sensitive markers and show considerable promise for studies of neuronal connectivity in the light and electron microscope.

(Supported by NIH Grants NS12481 and NS11255).

123.6 WHY ARE NERVE CELL DENDRITES ARRANGED IN TREE SHAPES? J. D. Daniels. Division of Engineering and Center for Neuroscience, Brown University, Providence, RI 02912.

Notions that dendrites support surface area increase or enable algebraic summation of inputs are dismissed as inadequate to provide a necessary condition for the bifurcating structure of dendritic trees. We offer instead the idea that bifurcations are involved in a nonlinear, possibly binary logic, action upon the two distal dendritic branch signals which enter the bifurcation. Considering activity within the dendrites to be represented by positive logic only, we classify bifurcations as OR or AND. We then suggest that the bifurcation may be an important site for external influence of dendritic signals, and we offer a truth table definition for competitive inhibition, assuming inhibitory synapses make contact at the bifurcation.

We show an example which demonstrates the power of dendritic logic to solve problems of pattern recognition. Such solutions require the hierarchical tree structure which dendrites provide.

Dendo-dendritic synapses have a ready explanation from our point of view. Information partially processed by one section of a dendritic tree can be made available to a neighboring dendrite before the information is combined with other signals in the main part of the tree.

We review physiological data which demonstrate nonlinear dendritic "spikes". Such behavior could be a consequence of regenerative logic processing at bifurcations. We searched electron microscopic data and found that dendritic bifurcations are structurally different from other regions of dendrites. Bifurcations contain less microtubule material and often harbor Nissl bodies and endoplasmic reticulum.

A model is set forth which shows the neuron to be a biological digital-to-analog-to-frequency converter, with digital processes in the dendrites, analog conversion at the cell body, and voltage-controlled oscillation at the axon hillock.

We surveyed Golgi material from Cajal's studies of cortical neurons to compute an average of 4.4 separate dendrite trunks per cell body. The relative influences of these trunks on the cell body determine the digital-to-analog transfer function. We conjecture that changes in these relative influences can be an important basis for modification of a cell's response. For example, a binocular neuron may have separate trunks for left and right eye inputs; monocular deprivation may affect the relative strengths of the two trunk-to-cell body contacts without any necessary modification of the distal synaptic contacts.

123.7 ANALYSIS OF THE GEOMETRIC PARAMETERS WHICH GOVERN THE SHAPE OF DENTATE GRANULE CELLS IN THE MOUSE. R. S. Williams*& S. B. Matthysse, Harvard Medical School, Boston.

The mammalian central nervous system is composed of literally billions of neurons which are so complex in their branching structure that essentially no two are alike. Nevertheless, most share similarities in the size and shape of their somas and the tree-like structure of their neurites which permit a parcellation into morphologic subclasses. The geometric parameters of neuronal trees are governed to some extent by the genome, but in large part their characteristic shape is governed by the environmental mileu in which growth and differentiation occurs. Most quantitative studies of dendritic branching have concentrated on analysis of geometric parameters which govern size but are independent of shape. To date, no information is available as to which parameters govern the characteristic shapes of neurons regardless of their size.

In this pilot study granule cells of the mouse dentate gyrus were examined in Golgi impregnations using a computer-assisted microscope. One or more primary dendrites exit from the superior pole of each cell to enter the molecular layer. Multipolar neurons are confined to the outer 1/3 of the cellular layer. Over 50% of all branch points are found in the inner 20% of the molecular layer, the zone of convergence of association and commissural afferents. In general, the dendritic arbor inscribes a cone with its apex at the superior pole of the cell, and its base at the pial surface. The base of the cone is compressed into an ellipse the long axis of which bears no systematic relationship to the septo-temporal axis. Dendritic segments in the walls of the conical ellipse are highly axial. This characteristic shape derives from the narrow range of the angle of inclination made by the planes of the daughter branches with the ideal axis, and of the angle formed by the bisector of that triangular plane and a projection of the axis. Values for the angle between the daughter branches vary widely but cluster about a mean of 90^{o}. The range of values for these three angles coupled with the more widely varing values for numbers of segments and segment lengths can be used to synthesize tree-like structures of similar characteristic shape by computer simulation. Future studies will analyze how these shape parameters vary in response to genetic and environmental manipulation.

123.8 DENDRITIC VARICOSITIES AND MICROTUBULE DISARRAY IN HUMAN CORTICAL NEURONS IN DEVELOPMENTAL FAILURE. D.P. Purpura, K. Suzuki, I. Rapin* and S. Wurzelmann*. Dept. of Neuroscience, Rose F. Kennedy Center, Albert Einstein College of Medicine, Bronx, NY 10461.

Although more than 200 causes of neurobehavioral deterioration in infancy have been catalogued there are few clues to common mechanisms whereby these diverse factors influence brain maturation. That dendrites of cortical neurons are particularly vulnerable to developmental perturbations has long been appreciated, but why this is so remains unknown. Studies of cerebral biopsy tissue from 5 infants with developmental failure suggest that mechanisms regulating microtubule orientation may be especially sensitive links in the chain of developmental events underlying dendritic growth and maintenance. Golgi studies of cortical tissue obtained at the time of diagnostic biopsy revealed variable dendritic abnormalities including reduced branching, decreased and abnormal spines, and short segment lengths in all subjects (ages 5-21 months). The most striking changes in dendrites occurred in neurons with otherwise robust dendritic arbors such as layers II and III pyramidal cells. In these neurons distal dendritic branches exhibited 'string-of-beads' varicosities, each 'bead' ranging from 1-3µm with intervening 'string' segments less than 1µm. Both the varicosities and intervening thin dendritic segments bristled with hairlike spines. Electron microscopy confirmed the presence of long thin spines, many with ribosomes present in the spine necks. Bundles of microtubules exhibited S- and U-shaped orientation patterns beginning at somadendritic junctions. In distal dendrites microtubule bundles criss-crossed in jumbled arrays in normal-appearing dendritic shafts and particularly in varicosities. Intervening 'string' segments were devoid of microtubules. Organelles usually confined to the perikaryon or proximal dendrites were frequently encountered in distal dendrites. While it is unlikely that the neurobehavioral deterioration in these infants is due to similar causes, nonspecific precipitating factors appear to induce a specific cytological lesion, microtubule disarray. Hence, disorganization of cytoskeletal elements may be a primary pathogenetic event underlying dendritic morphological abnormalities in developmental failure and profound mental retardation.

(Supported by NIH HD-1799 and NIH NS-03356.)

123.9 THE NUCLEUS RAPHE DORSALIS: A MORPHOMETRIC GOLGI STUDY IN RATS OF THREE AGE GROUPS. S. Díaz-Cintra*, L. Cintra*, T. Kemper*, O. Resnick* and P.J. Morgane. Worcester Foundation for Experimental Biology, Shrewsbury, Mass. 01545.

Using Rapid Golgi and Nissl techniques, three major cell types: fusiform, multipolar and ovoid were identified in the nucleus raphe dorsalis (NRD) of male rats at 30, 90 and 220 days of age. One hundred neurons per age group encompassing all three cell types were selected for quantitative study. The major and minor axes of the cell body were measured at their maximal extent and the number of spines on the somal surface was counted. Dendritic number, extent, thickness and the number of spines along a 50 μ segment near the midpoint of the dendritic length in primary and secondary dendrites were quantified in each age group. The origin of the axon was characteristic for each cell type. All cell types showed an increase in the linear extent of their primary dendrites and spine density on primary and secondary dendrites between 30 and 90 days. The most striking age related changes were in the multipolar and ovoid cells involving the dendritic number, length, thickness and spine number and in the number of perisomatic spines. Between 90 and 220 days we found a significant decrease in the linear extent of primary dendrites in ovoid cells. Between 90 and 220 days there is an increase in the number of primary dendrites on the ovoid cells and in the number of secondary dendrites on multipolar cells. Between 30 and 90 days multipolar and ovoid cells show an increase in perisomatic spines. Between 90 and 220 days both multipolar and ovoid cells show a dendrite and somal spine loss, particularly in the multipolar cells. In the present study we found special relationships between the raphe cell dendrites and blood vessels throughout the NRD. In the ovoid and multipolar cells this relationship was established by dendrites at 30 days. At 90 and 220 days of age some cell bodies of ovoid cells were found to be closely applied to raphe blood vessels. During the period 30-220 days there is progressive increase in rostro-caudal length of NRD which is proportional to the increase in growth of the brain stem. The cells of the NRD mostly have characteristic reticular features, i.e., few, long, straight and poorly ramified dendrites. The fusiform cells have a special tangential orientation with respect to the medial longitudinal fasciculus (MLF) and were the most frequently encountered cell in the entire NRD. Some of the dendrites of these cells extend into and through the MLF. The dendrites of the multipolar cells of the NRD overlap with dendrites of the nucleus raphe medianus and with dendrites of both the dorsal and ventral nuclei of Gudden. (Supported by grants BNS 77-16512 (NSF), HD-06364 (NICHHD) and PHS International Fellowship 5 F05 TWO 2693-02).

123.10 STIMULATION OF NEURONAL GLUCOSE UTILIZATION BY ANTIDROMIC ELECTRICAL STIMULATION IN THE SUPERIOR CERVICAL GANGLION OF THE RAT. P. Yarowsky, A.M. Crane*, and L. Sokoloff. Laboratory of Cerebral Metabolism, NIMH, Bethesda, MD 20205.

Previous studies with the 2-deoxyglucose method demonstrated a linear relationship between frequency of electrical stimulation of the cervical sympathetic trunk and rate of glucose utilization (LCGU) in the superior cervical ganglion (SCG) of the rat (Yarowsky et al., Soc. Neurosci. Abstr. 5:421, 1979). The linear relationship was confined to the physiological range of impulse frequency of the SCG. The orthodromic stimulation resulted in functional activation of presynaptic and postsynaptic elements, as manifested by physiological responses in the distribution of the efferent nerves of the SCG; it was, therefore, uncertain whether the metabolic activation occurred in presynaptic or postsynaptic elements or both. Earlier studies have provided evidence that functional activation stimulates LCGU in presynaptic terminals (Schwartz et al., Science 205:723-725, 1979), but it has been uncertain whether cell bodies are similarly metabolically activated. The SCG appeared to offer an appropriate model system to resolve this question. The horseradish peroxidase technique has shown that the cell bodies of origin of the axons of the efferent internal and external carotid nerves are located in different regions of the SCG. (Bowers and Zigmond, J. Comp. Neurol. 288: 227, 1979). The 2-[^{14}C]deoxyglucose method was, therefore, applied to measure LCGU in the SCG of the rat during antidromic stimulation of the external carotid nerve (ECN). The experiments were carried out under combined urethane (700mg/kg) and α-chloralose (40mg/kg) anesthesia. The SCG was acutely deafferented bilaterally by section of the cervical sympathetic trunks. An intact branch of the ECN of the experimental side was placed on platinum electrodes and electrically stimulated for 45 minutes via a stimulus isolation unit. The control SCG was left unstimulated. Stimulation was initiated 5 minutes prior to the 45 minute period of measurement of LCGU. Effectiveness of stimulation was ascertained by recording of the compound action potential on the surface of the ganglion and by impedance plethysmographic monitoring of blood volume in the extracerebral tissues. Electrical stimulation resulted in increased LCGU above the control level only in the region of the SCG containing the cell bodies of origin of the ECN. The activation of LCGU was frequency-dependent; LCGU was linearly correlated with frequency of stimulation in the range of 0-15 hz ($r = 0.80$, $p < 0.001$). These results indicate that the energy metabolism of the perikaryon and/or dendrites is coupled to functional activity and that the 2-deoxyglucose method, when combined with antidromic stimulation, can be used to identify sites of origin of neurons of antidromically stimulated fiber tracts.

124.1 ULTRASTRUCTURE OF ENKEPHALIN NEURONS IN THE MONKEY NEOSTRIATUM AND GLOBUS PALLIDUS. M. DiFiglia, N. Aronin*, A. Liotta* and J.B. Martin. Dept. of Neurology, Mass. General Hosp. Boston, MA and the Endocrine Div., Mount Sinai Sch. of Med., N.Y.C., N.Y.

The immunoperoxidase method was used to localize leu-enkephalin (leu-enk) in the monkey basal ganglia. The leu-enk antiserum cross-reacts less than 0.1% with met enkephalin in radioimmunoassay. We studied affinity of the antiserum to extracts of monkey neostriatum by immunoprecipitation with excess leu-enk antiserum, followed by various separation methods. Preliminary results show that at the high concentrations (1:500) used in the immunoperoxidase method, leu-enk antiserum can bind with relatively high affinity to intact leu-enk and several larger, related species (4620 and 31,000 Dal) and with lower affinity to a peptide (1900 Dal) with separation characteristics of leu-enk-arg6.

Following colchicine pretreatment the neostriatum exhibits an intense immunostaining within numerous medium-size neurons (10-20 μm) and fine beaded axonal processes. The globus pallidus shows a dense plexus of fibers primarily in the outer segment. At the electron microscope level, caudate leu-enk somata have relatively large nuclei with little surrounding cytoplasm. They receive many synaptic contacts which are also present on proximal dendrites. Distal dendrites have many spines and both are contacted by various types of axon terminals. Such features are characteristic of neurons identified as spiny type I using the Golgi-EM method (DiFiglia et al, J. Neurocytol., in press). Immunoreactive axon terminals (1 μm) are abundant and contain many ovoid (50 nm) and some dense core (100 nm) vesicles. They form synapses with unlabeled cell bodies and primary dendrites. Less frequently they contact the distal shafts of unstained spiny dendrites and dendritic spines. Finally some leu-enk boutons synapse with axon initial segments of medium size cells. Most of the above contacts appear to be symmetric and at the synaptic site some of the postsynaptic elements contain subsurface cisterns or form slight swellings which invaginate the enkephalin profile. Peroxidase reaction product is also present in myelinated axons (0.5 μm) which are present throughout the neostriatal neuropil and collected into bundles. In the globus pallidus similarly labeled fibers are present, and in addition fine, unmyelinated immunostained axons (0.15 μm) are found. Leu-enk axon terminals ensheath and synapse with the shafts of long pallidal dendrites and occasionally with their emerging spines. The present results suggest that in the monkey neostriatum enkephalin-like peptides are contained within long axon spiny type I neurons. Moreover, it is likely that intrinsic leu-enk terminals belong to axon collaterals known to arise from these output cells which may also contribute enkephalin fibers to the globus pallidus. Supported by grants # 1-RO1-AM-26252-01 and # 1-F32-AM06143-01.

124.2 APOMORPHINE AND AMPHETAMINE INDUCE ASYMMETRIC CHANGES IN CEREBRAL GLUCOSE UTILIZATION IN RATS WITH UNILATERAL SUBSTANTIA NIGRA LESIONS. G.F. Wooten and R.C. Collins; Depts. of Neurology and Pharmacology; Wash. Univ. Sch. of Med. St. Louis, Mo. 63110

We have studied cerebral glucose utilization with the ^{14}C-2 deoxyglucose autoradiographic method in rats 21 days after unilateral 6-hydroxydopamine-induced lesions of the substantia nigra (SN) following treatment with apomorphine (Apo) or amphetamine (Amph). In "control" rats with only a unilateral SN lesion there was a 30-40% increase in glucose utilization in the ipsilateral globus pallidus (GP) and a 15-25% increase in the ipsilateral lateral habenular nucleus (LH).

Glucose Utilization after Treatment with Apo or Amph Compared to Unilateral 6-hydroxydopamine Lesioned Controls

	Relative to Lesion	Apo (0.5mg/kgSC)	Amph (2.5mg/kgSC)
Substantia Nigra	Ipsi	↑ 313%	↑ 53%
Pars Reticulata	Contra	↑ 50%	↑ 109%
Corpus Striatum	Ipsi	↑ 20%	NC
	Contra	NC	↑ 43%
Globus Pallidus	Ipsi	NC	↑ 18%
	Contra	↑ 13%	↑ 45%
Entopeduncularis	Ipsi	↑ 168%	↑ 27%
	Contra	↑ 33%	66%
Subthalamic Nucleus	Ipsi	↑ 47%	↑ 42%
	Contra	↑ 69%	↑ 89%
Lateral Habenular Nucleus	Ipsi	↓ 43%	↑ 33%
	Contra	↓ 24%	↓ 10%
Turning		Contraversive	Ipsiversive

No asymmetrical changes were noted elsewhere including neocortex, thalamus, or hippocampus.

Apo, a direct dopamine agonist, is thought to produce contraversive turning in rats with unilateral nigral lesions by stimulating supersensitive dopamine receptors in the ipsilateral CS. Amph, in contrast, presumably produces ipsiversive turning by releasing endogenous dopamine from nigrostriatal neuron terminals in the contralateral CS. It follows that the most striking changes produced by Apo were ipsilateral, and by Amph, contralateral to the nigral lesion. Elucidation of the exact significance of these alterations in glucose utilization in the local neuronal circuits of the basal ganglia awaits a precise determination of the neural elements in which these dramatic changes are occurring.

124.3 INTRACAUDATE DOPAMINE INJECTION BLOCKS APOMORPHINE-INDUCED GNAWING. R. E. Davis, J. N. Joyce, C. J. Rogers*, L. Kuhn*, and C. Van Hartesveldt. Psychology Dept., University of Florida, Gainesville, FLA. 32611.

High doses of apomorphine (APO) are known to induce stereotyped, repetitive behavior, characterized in the rat by continuous gnawing, licking, or sniffing over restricted regions of the environment. At least some components of these stereotypes may be influenced by dopaminergic mechanisms in the neostriatum. Large intrastriatal injections of dopamine (DA) produce intense gnawing behavior in rats pretreated with MAO inhibitors. Since the pretreatment may alter other neurotransmitters in various brain regions, we decided to investigate the effects of discrete intracaudate DA injections on both spontaneous and APO-induced behavior in the normal rat.

Male Long-Evans hooded rats were implanted bilaterally with 27 ga stainless steel cannulae stereotaxically directed at the dorsal or ventral anterior caudate nucleus (CN). Through these cannulae rats were administered either DA (100 μg/ .5 μl) or isotonic saline (.5 μl) followed 20 min later by a subcutaneous (SC) injection of either APO or saline. All rats received all drug combinations in a counterbalanced order. Immediately after intracaudate injection rats were observed for 20 min in a rectangular environment; they were then removed, given the SC injection, and returned to the same test chamber where they were observed continuously for 60 min. During these intervals the durations and frequencies of 10 different behaviors were recorded.

Intracaudate DA injections elicited frequent shifts from immobile, "trance-like" states to bursts of sniffing directed toward the floor and walls during rapid movements about the cage. Gnawing and licking behavior were never seen.

Intracaudate DA injections also influenced APO-induced stereotyped behavior. The appearance of stereotyped gnawing was blocked and the duration of stereotyped sniffing was increased after DA injection into the dorsal but not the ventral anterior CN. This shift in APO-induced stereotypes by intracaudate DA is similar to that seen after large 6-OHDA lesions of the CN. This evidence suggests that small, discrete injections of DA into the dorsal anterior CN may increase local recurrent inhibition in areas outside the sphere of our injections.

124.4 SYSTEMIC APOMORPHINE REVERSES INTRACAUDATE DOPAMINE-INDUCED CONTRALATERAL DEVIATION. J. N. Joyce, R. E. Davis, C. J. Rogers*, P. Craig*, C. Rodrigues*, and C. Van Hartesveldt. Psychology Dept., University of Florida, Gainesville, FLA 32611.

In previous work we have shown that dopamine (DA) injected unilaterally into the dorsal anterior caudate nucleus (CN) induces contralateral asymmetry in spontaneous ongoing behaviors. In order to further explore this phenomenon we administered apomorphine (APO) systemically to rats with unilateral intracaudate DA injections to determine whether the stereotyped behaviors elicited would be expressed contralaterally.

Male Long-Evans hooded rats were implanted bilaterally with 27 ga cannulae directed either at the dorsal or ventral anterior CN. Through these cannulae either DA (100 ug/ .5 μl) or isotonic saline (.5 μl) was injected unilaterally, and time spent in ipsilateral or contralateral postural deviation was recorded. Twenty min later 1 mg/kg APO was administered subcutaneously, and postural asymmetry recorded for 60 min.

Consistent with previous research, unilateral DA injection into the dorsal anterior CN induced significant durations of contralateral deviation; unilateral DA injection into the ventral anterior CN was less effective. Neither DA injection outside the CN nor vehicle injection inside or outside the CN induced contralateral asymmetry of behavior.

Subcutaneous injection of APO unexpectedly reversed the contralateral deviation induced by unilateral intracaudate DA injection. Stereotyped sniffing ipsilateral to the side of intracaudate DA injection was recorded. The ipsilateral asymmetry was of greater duration when DA was injected into the dorsal rather than ventral anterior CN. The reversal of postural deviation induced by systemic APO is consistent with the hypothesis that small injections of DA into the dorsal anterior CN may increase local recurrent inhibition of regions outside the sphere of our injections.

124.5 NON-DOPAMINERGIC NIGRO-STRIATAL NEURONS IN THE RAT. P.G. Guyenet, J.K. Crane* (SPON = P.E. Gold), University of Virginia, Department of Pharmacology, Charlottesville, VA 22908.

A double fluorescence technique was used to simultaneously examine in the same substantia nigra (SN) sections the cellular localization of a retrogradely transported fluorescent label (Evans Blue, EB) introduced in the striatum and the topography of the dopamine-containing cell bodies (DA). The animals were perfused according to the Faglu method of Blessing et al. (Neurosci. lett (1978) 9, 311) for DA histofluorescence and 25 µ frontal sections were cut on a vibratome, mounted and coverslipped in mineral oil.

Each fluorochrome could be visualized independently of the other by an appropriate selection of excitation wavelengths and filters. The location of single (EB+) and double (EB+DA+) labelled neurons was recorded throughout the SN on charts drawn from Nissl and Woelcke stained sections.

The unilateral injection of 0.2 µl of EB in various striatal locations (10 rats; the globus pallidus and overlying cortex but not the thalamus nor limbic areas were occasionally involved) resulted in 30 to 50% of the SN DA+ cells being EB+ ipsilaterally (60-100 cells/section). An average of 3 to 9 cells per section were EB+ but DA-; these were predominantly located in the upper half of the pars reticulata from its medial to its lateral edge depending on the injection site and were occasionally found in the pars compacta (PC).

In two animals 6-hydroxy-dopamine (6OH-DA, 1.2 µl, 4.8 µg in saline) was pressure injected 0.5 mm above the PC 10 days before introducing the 0.2 µl of EB in the striatum. The 6-OHDA resulted in the total (98%) disappearance of DA+ cells in all but the medial border of the SN and the adjoining A10 area. In the area of the SN essentially devoid of DA+ cells, 3 to 10 cells per section were EB+ and over 90% of these were DA-. Their general location was identical to that of the EB+ DA- cells found in control rats.

In 2 additional rats, 6 OHDA (1.2 µl, 4.8 µg) was injected 0.5 mm above the median forebrain bundle (level of subthal. nuc.) 6 days before injecting EB (0.2 µl, 10%) in the striatum. This procedure did not decrease significantly the number of DA+ cells ipsilaterally but decreased the total number of EB+ cells to 20-40 per section. The number and location of EB+ DA- neurons was the same as in non-6-OHDA treated animals (4-9 cells per section) but they accounted for 10 to 20% of all EB positive cells instead of 3 to 5% in non 6-OHDA treated rats.

In conclusion, the present study establishes the existence of a non-DA nigrostriatal pathway. The actual number of SN cells belonging to this pathway is still uncertain. Supported by a BRS award #5 S07 RR 05431-18.

124.6 OPIOID PEPTIDES, SUBSTANCE P AND SOMATOSTATIN IN THE STRIATUM: AN IMMUNOHISTOCHEMICAL STUDY IN THE CAT AND KITTEN. A.M. Graybiel, C.W. Ragsdale*, E.S. Yoneoka* & R.P. Elde. Dept. Psych.,MIT, Cambridge, MA 02139 & Dept. Anat., U. Minn., Minneapolis, MN 55455.

Immunohistochemical localization of met- and leu-enkephalin (ENK), substance P(SP), and somatostatin(SS) in the striatum was attempted in 5 cats and 2 kittens. Frozen 30-50µm sections were processed by the peroxidase-anti-peroxidase(PAP) technique and,in selected sections,by immunohistofluorescence with FITC-IgG. Control procedures included serial dilutions, substrate blocks, and omission of the primary antisera.

In the caudate nucleus of both cat and kitten distinct macroscopically visible inhomogeneities appeared in the distribution of enkephalin-like and SP-like immunoreactivity. In PAP cross sections ENK-immunoreactivity was organized into variably shaped patches and bands, 100-400µm wide and up to 1mm long, in which reaction product was more dense than in the surrounding matrix. The patches were darkest ventrally and many, especially dorsally, were bounded by thin (ca. 50µm) very pale septa. These were prominent in the kittens. In the adults, stain in the caudate nucleus was present both in cell bodies (8 to 26µm) and in fine granular material; the stained neuropil appeared to account for the darkness of the patches. Reaction product in the n. accumbens was darker than in the caudate nucleus and interrupted by 200-300µm bands of light staining. ENK-positive patches rarely appeared in the putamen. In two cats, sets of serial sections were stained alternately for acetylcholinesterase and enkephalin. There was a striking correspondence between the AchE-poor zones in the caudate nucleus ("striosomes") and the patches of dense opioid immunoreactivity in every pair of sections studied; matches also occurred in the n. accumbens.

Patches of SP-reaction product (50-200µm, up to 30 per section, some surrounded by pale septa) marked the caudate nucleus in the kittens. In the adults circumscript SP-positive 200-400µm wide zones were prominent dorsally in the caudate nucleus, while ventrally (and in n. accumbens) pale zones of low SP-like immunoreactivity were present. The SP-positive patches contained dark granular material in one case while SP-positive perikarya accounted for the darkness of the patches in a second case. SP-inhomogeneities could in many instances be lined up with AchE-poor zones visible in serially adjoining sections.

SS-like immunoreactivity was mainly confined to perikarya (cat: 8-20µm; kitten: 7-16µm) scattered throughout the striatum. Although some clustering of SS-positive cells was present, striosomal organization was not obvious in the material so far prepared.

We thank Drs. H. Karten and N. Brecha for advise on technique and acknowledge NSF grant BNS78-10549 and NIH5S07-RR07047.

124.7 AXON COLLATERALS OF SUBSTANTIA NIGRA PARS RETICULATA NEURONS. A.B. Karabelas* and D.P. Purpura. (SPON. S.U. Walkley). Dept. of Neuroscience, Rose F. Kennedy Center for Research in Mental Retardation, Albert Einstein College of Medicine, Bronx, NY 10461.

Intracellular recording and intracellular HRP staining was employed to study the axonal branching of substantia nigra pars reticulata (SNR) neurons in barbiturate anesthetized cats. SNR neurons were antidromically activated following stimulation of the VM-VL thalamic nuclei and the intermediate layer of the superior colliculus with latencies of 0.6-2.8msec and 0.5-2.5msec, respectively. For up to 60% of the physiologically tested SNR neurons, axonal branching was demonstrated with antidromic activation from both sites. Caudate stimulation elicited IPSPs with latencies of 4-14msec in SNR neurons.

Axons of HRP-stained SNR neurons emerge from the soma or a primary dendrite. They run caudally and eventually turn dorsally. During their initial trajectory within the substantia nigra all the SNR axons emit 1-8 collaterals originating at distances of 90µm to 1850µm from the axon hillock. The majority of SNR axons has 4-8 collaterals of varying diameter. After branching, most SNR axons pursue a dorsal course towards the collicular intermediate layer, while some axons follow indirect routes. The collaterals of a single SNR neuron can be classified as local, ascending and descending. Local collaterals exhibit extensive branching and emit numerous terminals within the vicinity of the parent cell. Light microscopy, strongly suggests that en passage and terminal boutons of a local collateral contact dendrites of the parent cell. The ascending collaterals may bifurcate once or twice within the SNR and/or at long distances from the SNR. One such collateral has been observed to arborize and give off terminals within the dorsal pole of the subthalamic nucleus. At the thalamic level most ascending collaterals turn dorsally towards the ventral thalamic complex, while some continue more rostrally. Most of the SNR axons emit one long descending collateral which travels through the substantia nigra pars compacta where it may branch and give off terminals. These data indicate that a single SNR neuron 1) can send axonal branches to at least three separate locations and 2) can provide an extensive local plexus of terminals for intrinsic synaptic operations. (Supported by NIH NS-07512 and NIH HD-01799)

124.8 RECOVERY FOLLOWING DAMAGE TO THE ASCENDING DA SYSTEM: REVERSAL OF LESION-INDUCED CHANGES IN CEREBRAL ^{14}C-2DG UPTAKE. Michael R. Kozlowski*, Kim A. Neve*, John F. Marshall. Dept of Psychobiology, Univ. of California, Irvine, CA 92717.

Damage to the ascending dopamine (DA) system of the rat brain produces impaired orientation to sensory stimulation. Remarkably, almost complete behavioral recovery can occur postoperatively. Such damage also alters the ^{14}C-2-deoxy-D-glucose (2DG) uptake into the basal ganglia and associated brain regions (Kozlowski and Marshall, Brain Res., in press). We now report that many of these metabolic changes are reversed in animals which show behavioral recovery.

Male rats were given unilateral tegmental injections of 6-hydroxydopamine (6-OH-DA, 4.5 µg) into the ascending DA system. One group showed a profound deficit in orienting to contralateral somatosensory stimulation that persisted for the next six weeks (Unrecovered group). Other animals gradually recovered orientation over the next two weeks (Recovered group). The time course of the recovery is similar to the development of behavioral supersensitivity to i.p. apomorphine, measured using rotational behavior. ^{14}C-2DG (15 µCi/100 g, i.v.) was given either 3 d or 6 weeks after the 6-OH-DA injection. The animals were sacrificed 45 m later and their brains processed for autoradiography.

Three days after the 6-OH-DA injection, all animals which exhibited a loss of somatosensory orientation showed a characteristic pattern of altered cerebral ^{14}C-2DG incorporation. An ipsilateral decrease of ^{14}C-2DG uptake was found in several forebrain structures normally innervated by the ascending DA system (neostriatum, olfactory tubercle (OT), nucleus accumbens septi (NAS), and central amygdaloid nucleus). An increased labeling was observed in structures which receive striatal efferents (globus pallidus (GP), entopedunclear nucleus (EN), and substantia nigra, pars reticulata (SNr)). In addition, there was a decrease of ^{14}C-2DG uptake in the ventral tip of the internal capsule, an area through which striatal efferent fibers course. These changes in 2DG uptake persisted for at least six weeks in animals of the Unrecovered group.

In contrast, many of these asymmetries in ^{14}C-2DG uptake were reversed by six weeks in animals of the Recovered group. The asymmetries of labeling in the striatum, internal capsule, and several structures which receive striatal efferents (GP, SNr) were abolished. The asymmetries of labeling remained in the OT, NAS and EN.

These findings suggest that after damage to the ascending DA system, cellular changes can occur in the striatum and its output pathways (i.e., strionigral and striopallidal systems) which compensate for the decreased DAergic innervation and therefore may underly behavioral recovery.

124.9 DEVELOPMENT OF SUPERSENSITIVE GABA RECEPTORS IN SUBSTANTIA NIGRA AFTER EITHER CHRONIC BLOCKADE OF DOPAMINE RECEPTORS OR DESTRUCTION OF NIGROSTRIATAL DOPAMINE NEURONS. Karen Gale and Holli Bernstein*, Dept. of Pharmacology, Georgetown Univ., Schools of Medicine and Dentistry, Washington, D.C. 20007.

After 8 weeks of daily treatment with chlorpromazine or haloperidol, the density of binding sites for GABA in substantia nigra (SN) was increased by 35%, as previously reported (Gale, Nature 283: 569, 1980). This increase in nigral GABA receptors probably occurs in response to a loss of striatonigral GABAergic tone which is normally maintained by nigrostriatal dopaminergic activity. In order to determine whether the increased GABA binding could have a functional impact, the behavioral effects of intranigral muscimol were examined in rats which had been treated with chlorpromazine (20mg/kg) daily for 8 weeks. When infused into the SN bilaterally, muscimol, a potent GABA receptor agonist, is known to cause stereotyped sniffing and gnawing behavior. Rats which had been chronically treated with chlorpromazine showed a significant increase in sensitivity to the intranigral muscimol treatment; in these animals, a dose of 2.0ng produced marked stereotyped behavior, equivalent to that observed in control rats which had received 5.0ng. Similarly, supersensitivity of nigral GABA receptors was observed following virtually total destruction (>85%) of nigrostriatal dopaminergic neurons after 6-hydroxydopamine injections into either caudate-putamen or medial forebrain bundle. The data suggest that GABA receptors, located on non-dopaminergic neurons in SN, become supersensitive in response to the sustained loss of nigrostriatal dopaminergic function; these receptors may participate in the behavioral supersensitivity to dopamine agonists that develops after chronic interference with dopamine transmission.

125.1 ONE EYE CAN INCREASE THE SENSITIVITY OF ANOTHER IN LIMULUS. R. B. Barlow, Jr., S. C. Chamberlain,* S. J. Bolanowski, Jr., L. A. Galway, Jr.,* and D. P. Joseph.* Institute for Sensory Research, Syracuse University, Syracuse, NY 13210.

Illumination of the median eyes (ocelli) can increase lateral-eye sensitivity by increasing efferent optic nerve activity. At night a circadian clock in the brain generates the efferent activity (Barlow et al., Science 197:86, 1977) which can be enhanced by illumination of the ocelli. During the day when no efferent activity is generated by the clock, ocellar illumination is ineffective. Since the efferent input to the lateral eyes increases their sensitivity, ocellar illumination causes an additional increase in sensitivity.

No reciprocal effect has been detected, that is, lateral-eye illumination does not increase the sensitivity of the median ocelli. On the other hand, lateral-eye illumination can shift the phase of the circadian clock, but ocellar illumination cannot. As a result of endogenous clock activity, both sets of eyes exhibit circadian rhythms in response to visible stimuli (400-700 nm). The median ocelli are also sensitive to ultraviolet radiation (λ_{max} = 370 nm), but the UV responses do not exhibit a prominent circadian rhythm.

The ability of the circadian clock to gate the ocellar influence on lateral-eye sensitivity requires a brain circuitry involving the neuronal processes of all three structures. Cobalt impregnation of the major afferent pathways shows that both sets of eyes innervate neighboring loci in the brain, but thus far tracing the neural pathways has not revealed the location of the circadian clock.

The Limulus visual system is not simple. Neural interactions among widely separated visual structures and a centrally located circadian clock point to a complex system. Although the functional organization of the system is not yet understood, one consequence of the neural interactions is that at night maximal lateral-eye sensitivity cannot be achieved in complete darkness. Maximal visual sensitivity appears to require ambient illumination--a case of negative dark adaptation.

125.2 SPECTRAL SENSITIVITY AND PHYSIOLOGICALLY ADAPTIVE ASPECTS OF THE LATERAL AND PARIETAL EYES OF A WESTERN FENCE LIZARD SCELOPORUS OCCIDENTALIS. T.G. Hedberg, and D.J. Kimeldorf*. Dept. of Physiol. Biophys., Univ. of Illinois, Urbana, Illinois 61801 and Radiation Center, Oregon State University, Corvallis, Oregon 97331.

To clarify and compare functional and adaptive aspects of the lateral and parietal eyes of a lizard in which the parietal was well developed, electroretinograms were obtained from both eyes of Sceloporus occidentalis. The animals were collected in the field, dark adapted and anesthetized by oral administration of sodium pentobarbital. Under varying conditions of exposure to white light and monochromatic radiation the lateral eye exhibited extremely rapid dark adaptation, a linear stimulus-response correspondance and showed peak photosensitivity at 575 nm. Responses to monochromatic radiation were seen only between 425 and 700 nm. Responses in all tests were measured at an irradiance of 0.69 mW/cm^2 and as the amplitude of the b-wave component. Maximum amplitude at this irradiance was 40 μV, obtained from the lateral eye under white light. The parietal eye, situated dorsally on the cranium, after removal of the interparietal scale, showed an ERG in which b-wave amplitude was reduced to 20% of the lateral eye response under white light of identical irradiance. Relative to the lateral eye, the parietal displayed a greater spectral sensitivity (350-770 nm), a peak response at 570 nm and a secondary sensitivity peak at 375 nm. The isolated interparietal scale transmitted monochromatic radiation with a 90% attenuation of middle and longer wavelengths but a 40% attenuation of wavelengths between 360-385 nm. While the spectral sensitivity peaks of both eyes compare favorably with the colors of the surrounding environment and thus may be useful to contrast colors of potential prey or predators, the secondary sensitivity peak in the parietal eye at 375 nm. may indicate a greater biological involvement of UV in parietal function than previously suspected. Heightened UV sensitivity coupled with the bright sunlight and open, unshaded environment in which this species commonly occurs supports speculation that the parietal utilizes a ratio of variable UV intensity to more stable mid-range wavelengths in the zenith sky as a zeitgeber, to aid in its established function as a circadian rhythm synchronizer and thermoregulation mechanism.

125.3 NEURONAL AND PHOTORECEPTOR CELL TYPES IN THE FRONTAL ORGAN OF RANA PIPIENS: A GOLGI STUDY. W. D. Eldred, Dept. of Neurobiology and Behavior, State University of New York at Stony Brook, Stony Brook, N.Y. 11794.

The frontal organ, part of the anuran pineal complex, is a photoreceptive system capable of distinguishing different wavelengths and intensities of illumination. Little is known concerning the cellular elements underlying these physiological responses. The present Golgi study was undertaken to determine the detailed morphology of the cells present, and on the basis of their morphology several types of photoreceptors and neurons in the frontal organ were identified. Frontal organs from adult Rana pipiens were impregnated using procedures similar to those of Stell and Lightfoot (J. Comp. Neur. 159:473-502, 1975).

It is possible to divide the photoreceptors into two classes based on differences in their size and morphology. One class has a small, rounded cell body, averaging 13μm long by 9μm wide. The second class is larger, with a more elongated cell body averaging 24μm in length and 10μm in width. Both photoreceptor classes can send long (up to 50μm), branching processes from the bottom or side of their cell body to adjacent regions of neuropil.

In addition to these two classes of photoreceptors, impregnated neurons can be found with three types of dendritic arrays. The first type has a multipolar arrangement with long dendritic processes (up to 80μm) radiating uniformly from the cell body. These dendrites can exhibit small spines and varicosities along their length. The second neuronal type has a large elongated cell body with dendrites projecting primarily from the narrow ends of the cell body; thus producing a bipolar dendritic array. The third neuronal type has long dendrites projecting primarily from one side of its cell body which creates a unipolar dendritic pattern.

In some preparations, cutaneous nerve fibers in the region of the frontal organ were also impregnated. These small cutaneous sensory axons ramified primarily in the dermis and epidermis, but in several cases, they also sent numerous processes with varicosities into the frontal organ as well.

The existence of different morphological classes of photoreceptors and neurons suggests that the frontal organ is capable of complex neural processing of light stimulus information.

125.4 MELATONIN EFFECTS ON CIRCADIAN ROD OUTER SEGMENT SHEDDING. M. P. White and L. J. Fisher. Departments of Psychology and Anatomy, Univ. of Mich., Ann Arbor, MI 48109.

The hypothesis that melatonin regulates circadian rod outer segment (ROS) shedding was tested by determining the effect of exogenous melatonin on ROS disposal.

Albino rats were adapted to a 14hr:10hr light-dark cycle for 2 weeks (light onset at 4 am). At 4:30 pm melatonin was administered as a subcutaneous implant or a single 100 ug injection. Injected rats and paired controls were sacrificed throughout the night and during the time of expected ROS shedding the next morning (5 - 8 am). Implanted rats were sacrificed at the time of shedding on the following 2 days, or 7 weeks later. To measure ROS shedding, phagosomes were counted and phagosome diameters were measured in electron micrographs of retinal pigment epithelium. Tissue samples from 130 eyes were analyzed. These counts were converted to size-frequency distributions, corrected for the sampling biases due to section thickness and eccentric sectioning of phagosomes.

The daily morning peak in large phagosomes (those with diameters greater than .375 um) was not abolished by melatonin treatment, nor did injected melatonin induce abnormal shedding. However, implanted melatonin increased the frequency of large phagosomes seen during the shedding peak to .233/um^2 retinal planimetric area, compared to .176/um^2 in controls ($p < .01$). Long-term melatonin implants resulted in higher frequencies of small phagosomes as well.

These data support the hypothesis that melatonin is involved in the control of ROS shedding. The failure of injected melatonin to affect shedding suggests that duration of melatonin exposure was an important factor.

In control eyes, the volume of phagosome material present during the shedding peak was .215 um^3/um^2 retinal planimetric area, 55% of which was due to large phagosomes. As this does not appear to account for the total daily volume of ROS disposal, small phagosomes may constitute a significant amount of the daily shedding. Alternatively, very many large phagosomes may be shed during the daily burst, but become reduced in volume so quickly that only a few are observed histologically.

This work was supported, in part, by Vision Research Training Grant NIH 5 T32 EY07022 and NEI research grant 01281.

125.5 THE EFFECT OF A GLIOTOXIN, L-ALPHA-AMINOADIPIC ACID, ON THE FROG ELECTRORETINOGRAM. Roger P. Zimmerman. Departments of Neurological Sciences and Physiology, Rush University, Chicago, IL 60612.

The vertebrate electroretinogram (ERG) is the extracellularly recorded mass electrical response of the retina to light. Two major components of the ERG, the b-wave and the slow PIII component, are believed to be generated by the retinal glial cells (Mueller cells) in response to changes in extracellular potassium ion concentration caused by electrical activity of postsynaptic neurons and photoreceptors, respectively. L-alpha-aminoadipic acid (a structural analog of L-aspartate, a putative photoreceptor synaptic transmitter) abolishes the b-wave and slow PIII components while leaving that produced by the photoreceptors, the fast PIII, relatively unchanged. Histological examination of retinas treated with L-alpha-aminoadipic acid reveals that the retinal glial cells show signs of necrosis: dense cytoplasm and extensive vacuolization. These effects are reversible and are found after either in vivo or in vitro treatment with L-alpha-aminoadipic acid.

L-alpha-aminoadipic acid is a relatively ineffective blocker at the aspartate synaptic receptor when compared to D-alpha-aminoadipic acid. This point, and the reduction of the slow PIII component, argues for a direct effect on the Mueller glial cells. One possible hypothesis is that L-alpha-aminoadipic acid interacts with the high affinity glutamate uptake system, a glial mechanism for inactivation of amino acid neurotransmitters. Toxic but reversible consequences produce observable cytological changes and an inability to respond to changes in extracellular potassium ion concentration.

125.6 USE OF KAINIC ACID AND AMINOADIPIC ACID AS TOOLS FOR THE LOCALIZATION OF NEURONAL AND GLIAL NEUROTRANSMITTER RECEPTORS IN THE RETINA. P.F. Spano, M. Memo and M. Trabucchi (SPON: L. Beani) Dept.s of Pharmacology, Universities of Milan and Cagliari, Italy.

The search and the use of specific neurotoxins have become of particular significance in the last few years. The finding, in fact, that chemical compounds, such as kainic acid or aminoadipic acid, are capable to selectively affect neuronal or glial components, respectively, has provided the bases for new tools in neurochemical pharmacology. In the present report we show that the above mentioned compounds, injected intravitreally in adult rats, differentially affect retinal radioreceptor binding of various neurotransmitters and some enzymes considered specific markers of neuronal population or glial cells.

Adult Sprague-Dawley rats wheighing about 150 g, were administred intravitreally through the sclera either kainic acid (50 nmoles in 5 µl) or aminoadipic acid (100 µl in 10 µl) and then killed at various times. Radioreceptor binding and enzyme activities were measured in retina homogenates. Intravitreal injection of kainic acid elicited a rapid reduction in the activities of the enzymes in the biosynthetic pathways for ACh and GABA (CAT and GAD) suggesting, as previously described for chick retina, the ablation of retinal cholinergic and gabaergic neurons. In contrast, the administration of aminoadipic did not elicit any change in the activities of CAT and GAD, as previously found. However we observed that aminoadipic acid, contrary to kainic acid, elicited a remarkable reduction of glutamine-synthetase activity, which is considered to be selectively localized in the glial compartment of the retina. In addition the retinas of aminoadipic acid treated rats exhibited severe alterations of ^{3}H-GABA and ^{3}H-spiroperidol binding. Kinetic analysis of the results indicated that the observed alterations are due to a decrease in the number of binding sites (Bmax) with no change in the affinity constant. The entity of Bmax reduction for ^{3}H-GABA and ^{3}H-spiroperidol binding closely paralleled the reduction of retinal glial Muller cells (as observed by light microscopy) elicited by aminoadipic intravitreal administration. On the other hand the kinetics of other neurotransmitter receptors are not affected by aminoadipic acid. These results may overall indicate that glial cells, at least in rat retina, possess specific binding sites for GABA and dopamine.

125.7 THE EFFECT OF INTRAOCULAR KAINIC ACID ON CHICKEN RETINA. I.G. Morgan, C. Ingham*, F. Guldner* and D. Ehrlich* Department of Behavioural Biology, Research School of Biological Sciences, Australian National University, Canberra, 2600, Australia.

Intraocular kainic acid has been reported to destroy the amacrine cells of chicken retina (Schwarcz and Coyle, *Invest.Opthalmol.vis.Sci.* 16 (1977) 141-148). Using similar doses (60 nmol in 10µl adjusted to pH 7) we have found that other cell types are destroyed. One week after the injection, a population of small neurons in the ganglion cell layer was destroyed. They probably correspond to the displaced amacrine cells, since they were resistant to section of the optic nerve.

The horizontal cell layers were also eliminated. One day after injection, necrotic cells could be seen along the border between the outer plexiform and the inner synaptic layer. One week after injection the outer plexiform layer could no longer be seen by light microscopy. Under the electron microscope no trace of the complex synaptic arrangements characteristic of the outer synaptic layer, including the cone and rod terminals and their synaptic ribbons, could be seen. Nor could the complex array of horizontal cell and bipolar cell processes be detected. Instead the photoreceptor cell bodies appeared to sit directly upon layers of bipolar cell bodies. Although there were only slight changes in the numbers of photoreceptors, bipolar cells and ganglion cells there were changes in their morphology which suggested that their functioning had been severely disturbed.

Biochemical estimations confirmed that there had been extensive loss of cells, since one week after injection there was a marked decrease in the amount of DNA per retina. Other general parameters, including glutamine synthetase, a marker of the Muller glial cells, were less severely disturbed.

In contrast, neuronal transmitter systems were extensively lesioned. Taurine levels were normal despite the loss of the photoreceptor terminals, which suggests that taurine is not a photoreceptor transmitter, and that it is concentrated in non-terminal parts of the photoreceptor. The levels of aspartic acid were slightly decreased, consistent with a role for the amino acid as a transmitter in the photoreceptors. In addition, the activities of components of the GABA, glycine and acetylcholine neurotransmitter systems associated with horizontal and amacrine cells were markedly decreased.

The pattern of cell death, coupled with the biochemical changes, can be interpreted by assuming that the horizontal and amacrine cells are innervated by photoreceptor and bipolar cell terminals which use aspartic and/or gluatmic acid as transmitters. However, this assumption raises the question of why the bipolar and ganglion cells, which are innervated by photoreceptor and bipolar respectively, are not killed.

125.8 DEPLETION OF RETINAL TAURINE CONTENT BY GUANIDINOETHYL SULFONATE. Norma Lake. Department of Research in Anaesthesia, McGill Univ., Montreal, Canada.

Taurine is the most abundant free amino acid of the vertebrate retina, and over half is located in the photoreceptor cell layer where its concentration has been estimated to be 30-50 mM (Voaden, Lake, Marshall & Nathwani, Exp. Eye Res. (1977) 25, 249-257). There is evidence that one source of retinal taurine is the blood, via a blood-retinal transport system located in part in the pigment epithelium (frog: Lake, Marshall & Voaden, Brain Res. (1977) 128, 497-503; mouse: Voaden, Oreadu, Marshall & Lake, in press).

The source of blood taurine is either directly from the diet or from biosynthesis by peripheral organs such as the liver. As yet the functions of retinal taurine are unknown, however the importance of taurine for normal retinal function is indicated by the finding of specific photoreceptor degeneration and ERG abnormalities associated with reduced plasma and retinal taurine in cats placed on taurine-free diets (Schmidt, Berson & Hayes, Invest. Ophthal. (1976) 15, 47-51). The peripheral biosynthesis of taurine is virtually non-existent in cats, however taurine-free diets are ineffective in reducing retinal taurine levels in other species such as guinea pig, rat or rabbit probably because liver biosynthesis provides sufficient taurine to maintain retinal levels (Lake, Voaden & Morjaria, unpublished).

Recently Huxtable and colleagues have shown that treatment of rats with guanidinoethyl sulfonate (GES), a competitor with taurine for transport into the heart, leads to a rapid depletion of the taurine content of peripheral organs and some CNS sites (Huxtable, Laird & Lippincott, J. Pharmacol. Exp. Ther. (1979) 211, 465-471). The present study used a protocol similar to Huxtable et al. Male Sprague-Dawley rats were treated by adding 1% GES to their drinking water, while control rats consumed water with no additives. After 11 or 21 days their eyes were enucleated, the retina dissected and its free amino acids extracted into ethanol. Dual label microdansylation was used to estimate the levels of taurine, γ-aminobutyric acid, glycine, glutamate, aspartate and glutamine in the retinal extracts. Treatment with GES led to a reduction of retinal taurine to 73% of control after 11 days ($n = 6$; $p < .02$) and to 27% of control levels after 21 days ($n = 3$; $p < .001$). There were no significant changes in any of the other free amino acid levels.

These findings indicate that transport of taurine across the blood-retinal barrier is required to maintain retinal taurine levels in the rat, and that GES may be a useful tool to study the involvement of taurine in retinal function and degenerations.

125.9 IDENTIFICATION OF SYNAPSES FOR Y-AMINOBUTYRIC ACID IN CHICK RETINA USING ^{3}H-MUSCIMOL. S. Yazulla and N. Brecha. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Long Island, NY 11794.

In the vertebrate retina several classes of neurons transport the neurotransmitter ^{3}H-Y aminobutyric acid (^{3}H-GABA). However, the identity of neurons which actually use GABA as their neurotransmitter and the distribution of their synaptic contacts are unknown. We attempted to answer these questions by localizing the binding sites for ^{3}H-muscimol, a GABA analogue, in the synaptic layers of the chicken retina by light microscopic (LM) and electron microscopic autoradiography (EM-ARG).

LM-ARGs of cryostat sections incubated in ^{3}H-muscimol or ^{3}H-GABA displayed identical binding patterns: a band over the outer plexiform layer (OPL) and a uniform band over the inner plexiform layer (IPL). This binding pattern differs from the transport pattern for ^{3}H-GABA which shows labeling over horizontal, amacrine and ganglion cell bodies as well as very intense labeling over lamina 5 in the proximal IPL. For further analysis, isolated retina were incubated in ^{3}H-muscimol and processed through EPON for EM-ARG. In the IPL, statistical analysis indicates that only amacrine synapses bind ^{3}H-muscimol (i.e. make GABAergic synapses). Processes of amacrine, bipolar or ganglion cells can be post synaptic to these amacrine synapses. The highest concentration of synapses binding ^{3}H-muscimol occurred in laminae 2 and 4 of the IPL and not in lamina 5 as might be expected from the density of ^{3}H-GABA transport. In the OPL, ^{3}H-muscimol binding occurs over specialized junctions proximal to photoreceptor terminals. The identity of these junctions is unknown, but they behave as integrated point sources of radioactivity. In cone receptor terminals ^{3}H-muscimol binding is suspected near horizontal cell dendrite/receptor terminal membranes lateral to the synaptic ribbon. This supports the hypothesis that horizontal cells are involved in a GABAergic feedback loop with cone terminals.

We conclude that the synaptic binding pattern provides a more accurate conception of GABAergic synaptic interaction than the transport pattern for ^{3}H-GABA because, in the IPL, the two patterns are unrelated. ^{3}H-muscimol can be an effective probe for GABA synapses when cautions are taken to account for neuronal transport of ^{3}H-muscimol. (Supported by NIH grant EY01682 and EYO 2146.)

125.10 LOCALIZATION OF NEUROPEPTIDES, INCLUDING VASOACTIVE INTESTINAL POLYPEPTIDE AND GLUCAGON, WITHIN THE ADULT AND DEVELOPING RETINA. N. Brecha, H. J. Karten and B. Davis*. Dept. of Neurobiology, State University of New York at Stony Brook, Stony Brook, N.Y., 11794.

The localization of several different neuropeptides within the pigeon and chicken retina was studied using immunohistochemistry. Pigeon and chicken retinas were fixed in 4% paraformaldehyde, 0.1M D,L lysine-HCl and 0.01M Na periodate in 0.1M phosphate buffer, cryoprotected in 30% sucrose buffer and sectioned at 10µM perpendicular to the vertical axis of the eyecup. Retinal sections were incubated in either enkephalin, neurotensin, somatostatin, vasoactive intestinal polypeptide or glucagon antiserum and processed according to standard immunohistochemical techniques Specificity to the antiserum was established by preabsorption of the antiserum with 10µM synthetic peptide prior to incubation of the retinal sections.

Previously, we reported the localization of specific enkephalin-like, substance P-like, neurotensin-like and somatostatin-like immunoreactivity to amacrine cells in the pigeon retina (Brecha, Karten and Laverack, '79; Karten and Brecha, '80; Brecha, Karten and Schenker, '80). This localization pattern was also observed in the chicken retina; enkephalin-like, neurotensin-like and somatostatin-like immunoreactive amacrine cells were characterized by multistratified processes which ramify within the distal (lamina 1) and proximal (laminae 3 and 4) laminae of the inner plexiform layer (IPL). In pigeon retina, specific vasoactive intestinal polypeptide-like containing amacrine cells are characterized by medium sized somata located at the border of the inner nuclear layer (INL) and IPL and bistratified processes which ramify within laminae 3 and 5 of the IPL. In pigeon and chicken retina, glucagon-like containing amacrine cells are also characterized by medium sized somata located at the border of the INL and IPL and bistratified processes which ramify within laminae 1 and 3 of the IPL.

The appearance of specific enkephalin-like immunoreactivity within the developing chicken retina was also studied using immuno histochemistry. Retinas from staged chick embryos and 1, 2 and 3 day posthatched chicks were processed for immunohistochemistry as described above. Within the embryonic chick retina, very sparse enkephalin-like immunoreactivity was detected within somata located in the proximal INL at stage 39. At later stages, (st.42-44), sparse enkephalin-like immunoreactivity was observed within both somata in the proximal INL and processes in the IPL. 24-48 hours after hatching the intensity of enkephalin-like immunoreactive staining within amacrine cells was similar to that observed in the adult retina. These studies have demonstrated a variety of peptidergic amacrine cell populations within the bird retina.

125.11 CHANGES IN RETINAL MORPHOLOGY AND LOCAL GLUCOSE UTILIZATION (LGU) IN 1 TO 34 MONTH OLD FISCHER-344 RATS. N.L. Shinowara*, S.I. Rapoport, M.J. Hoover* and E.D. London. Lab. of Neurosciences, Nat'l. Inst. on Aging, Gerontol. Res. Ctr, Balto. City Hospitals, Baltimore, MD 21224.

Local glucose utilization (LGU) and morphological changes were characterized and compared in retinas of 1-, 3-, 12-, 24- and 34-mo old albino male Fischer-344 rats reared in a 12 hr light/dark cycle. LGU was measured by the method of Sokoloff et al. (1977, J. Neurochem. 28:897) in light adapted retinas, optic nerves and superior colliculi from rats injected with ^{14}C-2-deoxy-D-glucose (2DG). Timed arterial samples were taken to measure radioactivity and free glucose and rats were killed after 45 min. Single retinas, dissected under saline, optic nerves and superior colliculi were assayed for total radioactivity by liquid scintillation spectroscopy. Morphological observations were made by light microscopy on plastic embedded 1 µ sections of retina strips. Measurements were made at peripheral, medial and central regions of the retinal strip and included the thickness of different retinal layers and the number of photoreceptor and inner layer nuclei. Whole retinal LGU significantly decreased between 3 and 12 mo from 59±8 to 37±3 µmoles/100g/min, plateaued at 24 mo with 34±5 µmoles/100g/min and further decreased by 34 mo to 15±3 µmoles/100g/min. Compared to the measured changes in retinal morphology from 3 and 34 mo, total decrease of 76% in LGU most closely paralled the continuous 86% decrease in mean photoreceptor nuclei for the 3 measured regions. During the developmental period from 1 to 3 mo there was a negative association between a significant increase in LGU and a 32% loss in mean photoreceptor nuclei which decreased in all 3 regions. Total retinal thickness decreased peripherally, remained unchanged medially and increased slightly centrally. Progressive retinal degeneration with photoreceptor cell loss occurred throughout the retina, but was most severe in the periphery, in agreement with Lai et al. (1978, Invest. Ophthalmol. 17:634). From 1 to 34 mo, 91% of the mean photoreceptor nuclei degenerated, while the mean inner layer nuclei decreased by only 39% with the greatest cell loss of 23% from 1 and 3 mo and a plateau from 12 to 34 mo. LGU in the superior colliculus, which receives retinal ganglion cell input, significantly increased by 29% from 1 to 3 mo, decreased by 23% from 3 to 12 mo and then plateaued with a slight decrease from 24 and 34 mo. Optic nerves showed an insignificant decrease in LGU from 3 to 34 mo. The results suggest that in the immature rats (1 to 3 mo) LGU does not decrease as a function of cell loss in the retina, but does increase in the superior colliculus. As retinal degeneration progresses in the aging adult, light-exposed eye, photoreceptor cell loss appears correlated with a decline in whole retinal LGU.

125.12 DISSOCIATED TISSUE CULTURE OF CAT RETINAL NEURONS. John K. Stevens, J. Martin Wojtowicz, John F. MacDonald, Playfair Neuroscience Unit, University of Toronto, and Toronto Western Hospital, 399 Bathurst Street, Toronto, Ontario, Canada, M5T 2S8.

Retinas from four week fetal cats were removed, and processed using conventional neural tissue culture methods. Connective tissue was enzymatically digested, remaining cells were mechanically dissociated and plated on collagen coated petrie dishes in a medium of MEM and 10% fetal calf serum. After three days the mitotic division of fibroblast cells was blocked and the medium was changed to a maintenance mixture of 10% horse serum and 90% MEM.

The cultures in early stages consisted of many nondistinctive spherical cells on a fibroblast base. At the end of one week, dendrites appeared, forming populations of monopolar, bipolar, and multipolar cells. A small number of cells also appeared to have axons. At the end of the second week the cultures were further differentiated and could be placed into four basic groups: 1) spherical small somas (SSS), approximately 10 microns in diameter with monopolar branching dendrites 2) SSS bipolar non-branching dendrites 3) SSS bipolar branching dendrites 4) irregular (square, triangular) shaped somas 10 to 50 microns in diameter with multipolar branching dendrites. Many of the class 4 cells appeared to have axons. At the end of the two week period individual cells migrated into tightly packed groups containing all four cell types. It appeared at the light level that dendrites were interconnecting within these groups to form a neural network. No photoreceptor-like cells were found in these cultures.

Intracellular recordings demonstrated that many of the cells in group 4 had synaptic potentials and clear action potentials (80 mv). Other class 4 cells displayed a small active all or non potential (2-5 mv) in response to depolarization. All other cell types had either no action potential at all, or a small potential similar to that described above. Resting potentials in all cell types ranged from -20 to -55 mv. Comparisons with our cell types and those found in the normal intact retina must await additional physiological and electron microscopic studies. (Supported by MRC grants MA-7345 and MA-7216).

125.13 VELOCITY TUNING OF RETINAL GANGLION CELLS IN TURTLE (PSEUDEMYS). J.E. Fulbrook, A.M. Granda, and J.H. Maxwell. Inst. for Neuroscience, Univ. of Delaware, Newark, DE 19711.

Receptive field (RF) properties of retinal ganglion cells (RGC) were investigated with flashing and moving light spots. We examined some of the spatial, temporal, chromatic and movement-sensitive properties of these cells. Here, we report on the velocity-tuning properties of a few specific RGC types.

Single units were isolated from optic nerves with tungsten microelectrodes. Spot stimuli were swept across RF centers at velocities ranging from 0.2 - 200°sec^{-1}. Velocity-tuning plots were made as a function of spike count or response frequency.

Most cells were sensitive to moving stimuli and were on the average twice as sensitive and more responsive to moving than to stationary, flashed stimuli. They responded as classic, transient on, off and on-off units, on-off being most common. About 5% of the cells gave sustained responses. 40% of the units were directionally selective (DS).

Some cells showed very broad velocity-tuning curves, responding over the entire velocity range. Other units showed narrower curves giving peak responses to either slow (4.5°sec^{-1}), moderate, or fast (45°sec^{-1}) stimulus velocities.

Units with preferences for slow stimulus velocities responded differentially within this range. Non-directional, center-surround, opponent-color cells failed to respond to stimuli moving faster than 4.5°sec^{-1}. Some DS units did not respond to stationary stimuli, but responded to velocities below 9° sec^{-1}, preferentially at 0.2° sec^{-1}. Most DS units, however, showed response peaks at higher velocities, had broader tuning curves, and responded to stationary stimuli.

One cell type responded optimally to fast-moving targets. These units gave on-off responses to stationary flashes but usually demonstrated only a single component response to moving stimuli. Peak responses were obtained between 90 - 160° sec^{-1}. These cells were non-directional with circular RF centers, 6-9° in diameter. The same velocity-tuning curve was obtained with both spike-count and spike-frequency criteria. Velocity preferences were essentially the same for different stimulus intensities, spot sizes and adaptation conditions for most of the units tested.

These results support the notion that a high degree of visual information is processed at the retinal level in turtle.

Supported by Grant 01540, from the National Eye Institute.

125.14 BETA GANGLION CELLS RECEIVE CONVERGENT INPUT FROM 2 TYPES OF CONE BIPOLARS. Barbara A. McGuire*, John K. Stevens, Peter Sterling (SPON.: P. Sterling). Anatomy Dept., Sch. of Med., Univ. of Penn., Phila., PA 19174.

The inner plexiform layer of cat retina is stratified into sublamina a, which contains the dendrites of off-center ganglion cells, and sublamina b, which contains the dendrites of on-center ganglion cells. We have identified two types of cone bipolars in each sublamina by reconstructing adjacent cells from electron micrographs of 188 serial sections taken near the area centralis. Both members of a bipolar pair converged onto the same ganglion cell.

In sublamina a, the first type of cone bipolar had pale processes with smooth contours and made many reciprocal connections with the lobular appendages of AII amacrines. The second type had dark processes with scalloped contours and made only rare contacts with AII cells. This type has been determined by electron microscope autoradiography to accumulate ^{3}H-glycine.

In sublamina b, the first type of cone bipolar had pale processes which branched and made synapses (ribbon contacts and gap junctions with AII cells) throughout the sublamina. The second type had darker cytoplasm, branched only in the outer half of the sublamina, and made fewer gap junctions with AII cells. This cell type also accumulated ^{3}H-glycine.

Both members of a pair of cone bipolars converged strongly onto the dendrites of the same medium-sized (β) ganglion cell. For example, a β cell arborizing in sublamina a received 23 ribbon contacts from a single pale bipolar and 14 contacts from a dark bipolar. Similarly, a β cell arborizing in sublamina b received 49 ribbon contacts from a single pale bipolar and 33 contacts from a darker bipolar.

The convergence onto β cells (presumed X-cells) of two types of cone bipolars might suggest that one cone bipolar in each sublamina is excitatory, and the other, possibly the cell that accumulates ^{3}H-glycine, is inhibitory. An on-center X-cell's excitation might then result from the excitatory input of a depolarizing cone bipolar, and its inhibition might result from the inhibitory input of a hyperpolarizing cone bipolar. X-off cells would have the complementary arrangement. Convergence of excitatory and inhibitory cone bipolars may therefore underlie the anatagonistic properties of X-cells' receptive fields.

125.15 GLUCOSE USE CHANGES IN THE SUPERIOR COLLICULUS AFTER CHOLINERGIC ACTIVATION AND INHIBITION OF RAT RETINA. S.R. Nelson, T.L. Pazdernik,* R.S. Cross* and F.E. Samson. Dept. Pharm. and R.L. Smith Research Center, Univ. of Kansas Med. Ctr., Kansas City, Ks. 66103.

The 2-deoxyglucose functional mapping procedure developed by Sokoloff et al. was used to measure changes in glucose regional metabolism induced by the acetylcholine esterase inhibitor, diisopropyl fluorophosphate (DFP). Thirty minutes after DFP injection (i.m., 2.2 mg/kg) glucose use in many gray and white areas is depressed. One exception is a striking increase in the stratum griseum superficial (SGS) of the superior colliculus. The rate of glucose use of the SGS was 61 μmoles/100g/min in 8 control rats, whereas after the DFP injection, the rate of glucose use in the SGS rose 36% to an average of 83 μmole/100g/min (3 rats). Pretreatment with the nicotinic cholinergic blocker, mecamylamine (i.m., 75 mg/kg) prevented the increase from DFP and decreased the rate in the SGS to 36 μmole/100g/min. The muscarinic blockers atropine or benactazine did not prevent the DFP activation of the SGS.

Since the retina sends fibers to the SGS, the question was raised that the increased metabolism in SGS with DFP might be a result of increased activity coming in from the retina. DFP (0.26 μg) injected into one eye of anesthetized rats induced an increased rate of glucose use in the contralateral SGS (3 rats). However, when mecamylamine (7.5 μg) was injected into the eye 30 min. before DFP (2 rats), the response of the SGS was prevented. These results support the view that cholinergic fibers are involved in the activation of retinal ganglion cells and that these fibers are largely nicotinic.

Supported in part by U.S. Army Med. Res. Command, DAMD 17-78-C-8039.

125.16 GANGLION CELL PROJECTIONS TO THE SUPERIOR COLLICULUS, LATERAL GENICULATE, PRETECTUM AND VENTRAL LATERAL GENICULATE IN THE CAT. K. Itoh*, M. Conley* and I.T. Diamond. Dept. of Psychology, Duke University, Durham, NC 27706.

The goal of this study was to identify retinal ganglion cells after restricting HRP to single layers of the lateral geniculate, to single layers of the superior colliculus or to other known targets of the optic nerve. After each injection we tried to identify the labeled cells in terms of the morphological classification proposed by Boycott and Wässle (1974), α, β, and γ cells. Electrophysiological evidence has led many researchers to believe that these morphological classes correspond to physiological classes usually designated as Y, X, and W. Since electrophysiological studies of the lateral geniculate and other targets of the optic tract also reveal the same physiological distinctions, one could predict that the α or β cell might project to some, but not to other, layers of the lateral geniculate nucleus. The present results support the idea of a close correspondence between the cytoarchitectonic features of the various visual centers and the types of ganglion cells that project to them. For example, when HRP is injected into those layers of the lateral geniculate which contain the largest neurons, in particular, A, AI, C, and MIN, then a large proportion of the labeled cells in the retina appear to be of the α class. Similarly, a large number of α class cells were labeled after injections of lower SGS of the superior colliculus and the nucleus of the optic tract in the pretectum. On the other hand, very small ganglion cells, presumably of the γ class, were labeled after injections in the upper SGS of the superior colliculus, the olivary pretectum, the nucleus of the optic tract, the parvocellular C layers of the lateral geniculate, and the ventral lateral geniculate body. Cells of the β class are not so easy to distinguish with the HRP method, but the evidence suggests that the cells of this type project to layers A and AI of the lateral geniculate body.

The long run goal of this research is to shed light on the functional significance of parallel visual pathways. It is now possible to identify separate pathways in terms of cell size and fiber size from the retina to the cortex. For example, the smallest cells of the retina project to the small celled C layers of the lateral geniculate as well as upper SGS. The small celled C layers also receive fibers from upper SGS and project to the entire visual field from the middle suprasylvian sulcus to the caudal extremity of the striate cortex. Where these pathways overlap, e.g. in the striate area, they terminate in separate layers. Thus, the small celled small-fiber pathway terminates in layer I, while the large celled, large-fiber pathways terminate in the deeper layers, primarily III and IV.

125.17 MORPHOLOGICAL DIFFERENCES IN NASAL AND TEMPORAL RETINA OF THE CAT. V. L. Wise*, E. J. DeBruyn* and V. A. Casagrande, Depts. of Anatomy and Psychology, Vanderbilt Univ., Nashville, TN 37232

Previous investigations of the cat visual system suggest that nasal and temporal retina may be differentially specialized. For example, isodensity maps of the cat retina show that for a given eccentricity, the temporal retina exhibits a lower cell density than nasal retina (Stone, '78). Furthermore, studies of lateral geniculate laminae receiving from the two retinal divisions suggest that contralaterally innervated layer A contains proportionally smaller cells and fewer Y cells than its ipsilaterally innervated counterpart (Hickey et al., '77; Sireteanu and Hoffman, '79). To determine if morphological differences exist for the two retinal divisions, we have compared cell sizes along the horizontal meridian in the nasal and temporal retina of normal cats using samples matched for either density or eccentricity. Density matched samples were obtained from the area centralis (AC) and areas of 4000, 3000, 2000, and 1000 cells/mm^2. Eccentricity matched samples were taken at 1.0, 1.5, 4.0, 5.0, 5.5, and 6.0 mm from the center of AC. At each sample point, every cell in 1-6 0.01 mm^2 fields was drawn at 1000X. Two sets of comparisons were made. The first set included all cells within a sample while the second group included only geniculate relay cells as determined by retrograde horseradish peroxidase (HRP) labelling. For these experiments, each cat received 2-20 injections of .2-.5 µl of 30% HRP in layers A and A_1 of the lateral geniculate nucleus (LGN). Retinal whole mounts were reacted with Hanker-Yates reagent and counterstained with cresyl violet. Results indicate two major differences between the nasal and temporal divisions. First, although no differences exist for eccentricity matched samples in the AC, the mean cell size of temporal ganglion cells is as much as 46% larger at greater eccentricities. Second, no significant size differences exist for density matched samples; however, the size-frequency histograms indicate that temporal retina contains a greater percentage of alpha (Wässle et al., '75) and large beta cells. A separate analysis fo the HRP cases indicates similar trends for cells of the retino-geniculate pathway. These results support the hypothesis that nasal and temporal retina are morphologically and therefore possibly functionally distinct.

125.18 TREE SHREW RETINAL GANGLION CELLS: DIFFERENCES IN NASAL AND TEMPORAL RETINA. E. J. DeBruyn* and V. A. Casagrande (SPON: A. M. Burt). Depts. of Anatomy and Psychology, Vanderbilt Univ., Nashville, TN 37232

Recent investigations of the organization of the retina have suggested that information processing in the nasal and temporal retinae may differ. Our own work and that of others has demonstrated nasal-temporal differences in the topography and sizes of ganglion cells (Wässle et al., '75; DeBruyn and Casagrande, '78; Provis, '79; Wise et al., '80). For example our ganglion cell isodensity maps of tree shrew retina show that at comparable eccentricities the temporal retina exhibits lower cell densities than does nasal retina, suggesting that mean cell area of temporal ganglion cells may be increasing more rapidly with eccentricity. In order to examine the parameters of this difference in the tree shrew, we used cresyl violet-stained whole mounts to compare three specific aspects of the ganglion cell size-density relationship. First, we examined cell density at points of equal eccentricity from the area centralis; second, we compared cell size distributions at these points; and third, we compared cell sizes at points of equal cell density. Samples were taken along the horizontal meridian and at selected points in the upper and lower retina such that matched samples were taken on the same azimuth. At each sample point, every cell in 1-3 0.01 mm^2 fields was drawn under oil immersion at 1000X.

Frequency histograms of cell sizes suggest several differences between nasal and temporal retina. First, the mean cell size is significantly smaller ($p<.001$) in the nasal retina for points of equal eccentricity. Second, although the mean size of temporal cells is larger than that of nasal cells at points of equal density, the difference is not statistically significant and can be attributed to a greater proportion of large (>100 μ^2) ganglion cells in the temporal retina. Third, at points of equal density, the mean size of cells in the superior retina does not differ from that in the inferior retina.

These results demonstrate that 1) at comparable eccentricities temporal ganglion cells are larger than their nasal counterparts, and 2) that at comparable densities, the difference in mean sizes of nasal and temporal cells is not statistically significant, but the percentage of large cells is increased. Taken together these morphological differences support the hypothesis that nasal and temporal retina may process information differently.

125.19 RETINAL GANGLION CELLS IN THE NORTH AMERICAN OPOSSUM (DIDELPHIS VIRGINIANA): DECUSSATION AND CENTRAL PROJECTIONS OF CELLS OF DIFFERENT SOMA SIZE CLASSES. P. D. Wilson and D. H. Rapaport. Psychol. Dept., Univ. of California, Riverside, CA 92521.

A previous investigation (Rapaport, D. H. et al., Anat. Rec. 190: 158, 1978) indicated that the retinal ganglion cells in the opossum can be divided into four groups on the basis of soma size, and that the size groups differ in their retinal distribution, in that small and small-medium cells are relatively more common in nasal and inferior retina, large-medium cells are more prominent in superior temporal retina, and large cells are fairly evenly distributed. In order to study the central projections of these size groups, horseradish peroxidase (HRP) was injected into the optic tract (OT) and superior colliculus (SC) by pressure injection and into the lateral geniculate nucleus (LGN) by iontophoresis. After 3-4 days survival, the animal was perfused with 1.25% gluteraldehyde: 1% paraformaldehyde, and the retinae were reacted with Hanker-Yates reagent, whole-mounted on slides, and counter-stained with cresyl violet.

Following HRP injection into one OT, nasal retina was labelled only contralaterally and the distribution of labelled cells closely matched the size distribution of the total population of ganglion cells in nasal retina. Temporal retina was labelled both contra- and ipsilaterally, showing that a significant proportion of ganglion cells in temporal retina project contralaterally. Labelled cells in contralateral temporal retina included small (8-13 µm), small-medium (14-18 µm), and large (25 µm dia.) ganglion cells, while those in ipsilateral temporal retina were predominantly large-medium (19-24 µm) and large cells, though some small-medium cells were labelled.

HRP injected into the SC labelled cells in all size classes with a predominance of small-medium cells labelled in a contralateral retina and large cells in ipsilateral temporal retina. HRP injected into the dorsal LGN labelled small-medium and large-medium cells in both contra- and ipsilateral retinae, and large cells in only the ipsilateral retina. The differences in the central projections of ganglion cells of different size groups suggest that these groups may differ in function. (Supported by Biomedical Support Grant UCR and Predoctoral Fellowship MH07204 to D.H.R.)

125.20 COMPARISON OF PRIMARY RETINAL PROJECTIONS AND RETINAL GANGLION CELL SIZE BETWEEN PIGMENTED AND ALBINO RABBITS. Ellen S. Takahashi and Clyde W. Oyster. School of Optometry/The Medical Center, University of Alabama in Birmingham, Birmingham, AL 35294.

Albino animals have abnormal primary retinal projections characterized by reduced ipsilateral input. These projections have been previously described in the rabbit and the patterns of abnormal projection in the retinogeniculate pathways have been compared in some detail in rabbits of the albino allelomorphic series.

In the present study, an autoradiographic technique used to compare the primary projections between pigmented and albino rabbits confirmed and extended the results of previous studies, but also revealed some differences. In the pigmented rabbit, the retina projects bilaterally to the dorsal and ventral lateral geniculate nuclei and an intergeniculate leaflet, the olivary and posterior pretectal nuclei, the superior colliculus, and the medial terminal nucleus of the accessory optic septem (AOS). The anterior pretectal nucleus and the nucleus of the optic tract, and the dorsal and lateral terminal nuclei of the AOS receive contralateral inputs only. In the albino rabbit, all of the ipsilateral inputs were substantially reduced and/or their patterns of projection were different from those of pigmented rabbit. The ipsilateral projection to the intergeniculate leaflet, the posterior pretectal nucleus and medial terminal nucleus were not observed in the albino rabbit.

In certain respects, the retinas of pigmented and albino rabbits were similar when studied as flat mounted cresyl violet stained preparations. Both had a visual streak in which the peak ganglion cell density was about 5000 cells/mm^2, and the decline in cell density away from the visual streak was comparable. The retinas differed, however, in the size (cross-sectional area) of the ganglion cell somata. On average, ganglion cells were larger in the albino retina, and this difference was more pronounced in the nasal hemiretina in and near the visual streak. The superior retina in pigmented rabbit had more large cells than the inferior retina and was not distinguishable from the albino superior retina.

These results may be related to a different representation of functional ganglion cell classes (and therefore different soma sizes) in the albino retina and may also be reflected in the specific projections to central nuclei. (Supported in part by NIH Grant #EY02207.)

125.21 CONDUCTION VELOCITY GROUPS AND CENTRAL PROJECTIONS OF RABBITS' OPTIC TRACT. I. Lessard* and S. Molotchnikoff. (SPON: F. Leporé). Dépt. Sciences biologiques, Université de Montréal, Qué. Canada.

Axons of retinal ganglion cells can be classified in three groups in most mammals studied to date. The common criteria for this tripartite division are the conduction velocity and central projections. Since these classes of ganglion cells have not yet been detected in rabbits, this study was undertaken. In anesthetized and paralyzed rabbits, action potentials were elicited antidromically following electrical stimulation of optic tract terminals at the geniculate level (LGN). Peak latencies were converted to conduction velocities in order to account for distance variations from animal to animal. Over 150 axons were studied. The conduction velocity spectrum extended from 7 m.s. $^{-1}$ to 34 m.s $^{-1}$. The distribution of conduction velocities indicated 4 major modes at 10, 18, 22 and 26 m.s $^{-1}$. Antidromic compound action potentials exhibited a good correlation between the conduction latency (measured at the peak of 4 negative waves) and the major modes of the distribution histogram. These results suggest that the rabbit's optic tract contains four classes according to their conduction velocity.

The central projections of retinofugal axons were studied with electrical stimulations of the Superior Colliculus (CS) and the LGN while recording from the same optic tract fiber. Antidromic spikes could be elicited from all conduction velocity groups and 74% (N = 31) of axons responded to both sites of stimulation. This indicates that most retinofugal fibers branch off and innervate the CS and the LGN. In at least one fiber the response latency to a geniculate pulse was about equal to the response latency to a collicular stimulation (< .1 msec) in spite of the longer distance (5 mm) travelled by the spike originating at the collicular terminal. This result suggests that some retino-collicular collaterals have a larger diameter than the retino-geniculate branch. Further, there is a definite tendancy for fast conducting axons to have their receptive field located eccentrically relative to the optic axis of the eye.

Supp. DGES and CRSNG to SM.

125.22 RETINAL INPUTS TO LIMBIC, AUDITORY, AND MOTOR AREAS IN THE RAT. S.K. Itaya, Dept. of Anatomy, Univ. of Iowa, Iowa City, IA 52242.

Visual pathways in mammals are characterized by a constancy found throughout this class of vertebrates. With minor variations, retinal input is known to seven areas: (1) dorsal lateral geniculate nucleus (LGN), (2) ventral LGN, (3) suprachiasmatic nucleus, (4) pretectum, (5) pulvinar/lateral posterior complex, (6) superior colliculus, and (7) accessory optic system. Following intraocular injections of HRP and using the TMB incubation (Mesulam, 1978), we have followed anterogradely transported HRP from the eye to apparent terminals in limbic, auditory, and motor areas of the rat CNS.

A small number of retinal fibers leave the dorsal LGN and brachium of the superior colliculus to travel rostrally. Some fibers travel with the stria terminalis along its dorsomedial aspect, and other fibers can be followed over the dorsal surface of the lateral-posterior, lateral, and anterior-dorsal thalamic nuclei. The terminals appear to be located mainly in the bed nucleus of the stria terminalis. A somewhat similar pathway has been reported to the anterior-dorsal nucleus in the tree shrew (Conrad and Stumpf, 1975).

A small bundle of retinal ganglion cell axons can be traced caudally from the superior colliculus into the inferior colliculus. They travel mainly just beneath the surface of the inferior colliculus along its superior to caudal extent. Occasionally, fibers alter their course and travel toward the center of the inferior colliculus where they appear to terminate. In addition, in longitudinal sections containing the caudal-most portion of the optic tract as it enters the dorsal LGN, fibers of the optic tract deviate around the medial geniculate nucleus, and scattered fibers can be followed throughout the medial geniculate nucleus.

The medial terminal nucleus (MTN) (or nucleus tractus optici basalis) of the accessory optic system receives a very heavy projection from the retina in the rat. The MTN is a compact nucleus situated just medial to the cerebral peduncle and the substantia nigra. With dark field optics, scattered fibers can be observed which appear to leave the MTN and travel into adjacent substantia nigra. These fibers may terminate within the substantia nigra since they do not appear to continue as axons of passage. Several reports in the literature, all employing degeneration techniques, disagree as to the existence of a retino-nigral pathway.

Retinal information conveyed to several areas of the brain not involved in vision suggests that visual stimuli directly influence other sensory and motor systems.

125.23 THE LATERAL VISUAL PATHWAY OF THE GIANT BARNACLE. K.A.French, J.H.Hayashi*, L.A.Oland*, and A.E.Stuart. Depts. of Physiology & Ophthalmology, Univ. of North Carolina, Chapel Hill, N.C. 27514

The visual system of the giant barnacle, Balanus nubilus, comprises 10 photoreceptor (PR) cells divided among three eyes, one median and two lateral, that mediate a withdrawal reflex to shadows. The PRs, second-, and third-order cells of the median visual pathway are known (Stuart,A.E. & Oertel,D., Nature 275:287, 1978). We now describe the PRs of the lateral eyes and the effect on higher-order cells of shadowing them.

Each lateral eye consists of two large and one small PR whose axons are 15-30mm long. Cobalt backfills of the lateral ocellar nerve show that these axons enter the supraesophageal ganglion (SEG) and end near the median PR terminals. The light responses of the lateral PRs resemble those of median PRs. Dim illumination depolarizes the cells and increases the amplitude of their voltage fluctuations above that measured in the dark. Brighter light elicits a transient peak that decays to a steady plateau. A hyperpolarization follows the offset of light.

Simultaneous impalements of two lateral PRs show that these cells are not electrically coupled, unlike their equivalents in B. eburneus and B. amphitrite. First, neither depolarizing nor hyperpolarizing current pulses passed into one cell were detected in the other. If the cells are coupled, the coupling ratio must be less than 1:150. Second, Ca-dependent action potentials generated in one PR by bathing the preparation in tetraethylammonium ion caused no voltage change in the other cell. Third, there was no correlation between the voltage fluctuations seen in the two cells in dim lights.

Shadowing a lateral eye produces a burst of spikes in both ipsi- and contralateral circumesophageal connectives from the SEG, as does shadowing the median eye. While bursts mediated by the median eye are similar in the two connectives, the lateral eye produces a stronger burst in its ipsilateral connective. Both eyes drive some, but not all, of the same units in a connective. The system is sensitive to the direction of shadow movement across the eyes. Shadowing first the lateral eye and then the median elicits a burst in each connective as each eye is darkened; however, moving the shadow in the opposite direction elicits a burst only when the median eye is darkened. The lateral eye output is silenced unless more than 500msec separate the shadows.

The spatial separation of the eyes in the animal, and our observations of the interaction of their signals in the ganglion, indicate that the three eyes confer upon the barnacle a spatial sensing capability.

We thank Leslie C. Timpe for participation in initial experiments. Supported by NIH grant EY03347.

126.1 IMMUNOHISTOCHEMICAL LOCALIZATION OF CHOLINE ACETYLTRANSFERASE IN RABBIT FOREBRAIN. K.-S.K. Kan, L.-P. Chao and R.A. Giolli. Dept. Neurol. Sch. Med. UCLA, Los Angeles, CA 90024 and Dept. Anatomy, UC Irvine, CA 92717

Choline acetyltransferase (ChAc) catalyzes the synthesis of the neurotransmitter acetylcholine and is considered to be the specific enzymatic marker for cholinergic neurons. ChAc has been purified from bovine caudate nuclei and the homogeneity of the purified preparation has been demonstrated with electrophoresis, specific chemical analyses, as well as degradations, immunological criteria and direct visualization at the neuromuscular junctions (Muscle & Nerve, in press; J. Neurosci. Res. A Review, in press). Antibody to the purified bovine ChAc was produced in guinea pig and it cross-reacted with ChAc from rabbit brain. Immunohistochemical localization of ChAc in rabbit brain (Brain Res. 146: 221, 1978) was carried out with formalin-fixed, paraffin-embedded serially sectioned forebrain oriented in transverse, horizontal and sagittal planes. Some of the cholinergic structures in the forebrain from adult albino rabbits will be briefly described. The distribution of the cholinergic structure, as demonstrated by the immunohistochemical method, in the olfactory bulb is consistent with the biochemical measurements of the activity of ChAc done by others. Cholinergic axons in passage are found leaving the corpus callosum and in fasciculi of the internal capsule. Only some, not all, fibers in the fasciculi of the internal capsule are cholinergic and show the specificity of our localization. Cholinergic fibers and axons in passage are observed in the septal regions, olfactory tubercle including the islands of Calleja, neocortex, basal forebrain area, lateral hypothalamus, neostriatum, globus pallidus and other regions. The above anatomical findings correlate well with the existing biochemical determinations of ChAc activity in these areas as measured by others. This research is supported by NIH grant NS-11087.

126.2 LOCALIZATION OF CHOLINE ACETYLTRANSFERASE IN THE RAT OLFACTORY TUBERCLE. Carin R. Gordon* (SPON: G. B. Koelle)
Depts. of Pharmacology and Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA 19104

We are reporting the localization of choline acetyltransferase (CAT) in the laminae of the rat olfactory tubercle. The levels of CAT activity within this area of the cortex are amongst the highest of any region in the mammalian brain. The tubercle contains three parallel laminae within its posterior medial portion. These can be separated by cutting consecutive tangential sections from frozen tissue (Brain Res. 131: 303, 1977). Six consecutive 16μm sections were pooled, homogenized and assayed. CAT was measured according to the procedures of Schrier and Shuster (J. Neurochem. 14: 977, 1967). Every seventh section was stained to confirm the accuracy of the depth and plane of sectioning. The distribution of CAT activity as a function of depth showed a broad peak centered at 500μm from the ventral surface of the tubercle. Enzyme activity measured at this depth (85pmol acetylcholine formed/mg protein/h) was 2 1/2 times greater than that measured in the outermost plexiform layer.

Stereotaxic injections of kainic acid (1μg/1μl in artificial CSF) directly into the tubercle were used to alter the tissue composition within the laminae (Brain Res. 118: 356, 1976; 127: 235, 1977). Three days after injection, histological examination revealed the absence of cell bodies and the proliferation of glial cells. The reduction of enzyme activity, determined as a function of tubercle depth, ranges from 0-55% of non-injected controls. Within the acellular plexiform layer activity was decreased to 80% of control values. In the pyramidal layer enzyme activity was decreased to 50-70% of control values. The reduction of enzyme activity was most obvious at depths deep in the pyramidal layer and into the polymorphic layer (300-600μm); here 55% of the activity was lost. CAT activity was decreased to 70% of control values at depths greater than 600μm within the polymorphic layer.

The data are consistent with the presence of more than one cholinergic population in the olfactory tubercle. Approximately fifty percent of the CAT activity was sensitive to kainic acid injection, which suggests a neuronal derivation from cells intrinsic to the tubercle. The remaining portion of the CAT activity was insensitive to kainic acid suggesting an axonal derivation from neurons extrinsic to the tubercle.

At present we are unable to assign a specific cellular localization of CAT within the tubercle, although we have accomplished a laminar localization.

126.3 DO STRIATO-NIGRAL EFFERENTS CONTAIN ACETYLCHOLINESTERASE (AChE, EC 3.1.1.7)? Nancy J. Woolf[1], Barry Fass[2], and Larry L. Butcher[1,2]. Brain Research Institute[1] and Department of Psychology[2], University of California; Los Angeles, CA, 90024; U.S.A.

Application of the pharmaco-histochemical procedure of Butcher et al. (J. neural Transm., 1975, 37, 127-153) to the study of the rat caudate-putamen complex has revealed the existence of two major categories of AChE neurons: (1) Type A cells that stain lightly for the enzyme; have maximum cell body extents within the range 7-20 μm; are oval, fusiform, triangular, or spherical but most often oval; and comprise approximately 2.2% of the total population of striatal neurons and (2) Type B cells that stain intensely for AChE; have maximum cell body extents of 20-44 μm; possess fusiform, oval, triangular, or complex-shaped somata; and comprise roughly 1.2% of the total number of neurons in the rat caudate-putamen nucleus. The Type B AChE cells are probably the intrinsically organized cholinergic neurons whose existence has been deduced from biochemical studies (Butcher and Butcher, Brain Res., 1974, 71, 167-171; McGeer et al., Brain Res., 1971, 35, 308-314). The Type A neurons are conceivably cholinoceptive, and the enzyme could be contained within striatal efferents. Indeed, recent cytochemical evidence suggests that medium-sized, oval or triangularly-shaped striato-nigral efferents contain AChE (Kaiya et al., Neurosci. Let., 1979, 14, 7-11).

In an attempt to determine whether or not either Type A or Type B AChE neurons of the striatum contribute to the striato-nigral efferent pool, we injected Evans Blue dye into the substantia nigra and examined the caudate-putamen complex for neurons containing both the retrogradely transported, red-fluorescent dye and AChE. A total of 2950 striato-nigral neurons containing Evans Blue were studied. On the same tissue sections that contained these labelled neurons, 76 Type A and 33 Type B AChE cells were present. Of these, only one Type A and possibly one Type B neuron possessed Evans Blue label, suggesting that they might be striato-nigral efferents.

These preliminary results suggest that the vast majority of striato-nigral efferents do not contain appreciable quantities, if any, of AChE. Furthermore, our findings support the suggestions that AChE-containing striatal neurons may be intrinsically organized and the Type B cells represent the cholinergic, local-circuit neurons deduced from previous biochemical and histochemical studies (see Butcher, Ed., Cholinergic-monoaminergic Interactions in the Brain, 1978). [Support: USPHS NS 10928 to L.L.B.]

126.4 SEQUENTIAL HISTOCHEMICAL IDENTIFICATION OF ACETYLCHOLINESTERASE IN CATECHOLAMINERGIC NEURONS OF THE RAT HINDBRAIN. D. Bieger and C. Harley. Basic Sciences Division and Dept. of Psychology, Memorial University of Nfld., St. John's, Nfld. A1B 3V6.

Estimates of cholinesterasic reactivity of catecholamine (CA) neurons have been based on a comparison of histochemical maps obtained separately with the Falck-Hillarp technique for fluorescence and the Shute and Lewis technique for acetylcholinesterase (AChE). Using this approach Palkowits and Jacobowitz (J. Comp. Neurol. 157:29,1974) showed an overlap of cholinesterasic reactivity and specific CA fluorescence in cell groups A2, A5, and A6, while overlap was not seen in A1, A4, or A7. Only in A6 did they suggest perikarya contained both the enzyme and the amine.

The present investigation is based on the observation that the specific CA fluorophor produced by 30 minutes of double aldehyde perfusion (Furness et al., Histochemistry 57:285,1978) is not lost during subsequent washout in situ with phosphate buffer (50 ml) followed by vibratome-sectioning, mounting and air-drying in PO_4 buffer. Processing of specimens in PO_4 buffer subsequent to initial aldehyde fixation was critical for the demonstration of esterasic activity. Horizontal sections (30 μ), coverslipped in oil, were photographed under UV illumination then refloated in PO_4 buffer and reacted for AChE according to either Karnovsky/Roots or Shute/Lewis. Both normal and DFP-pretreated rats were used. To ensure optimal results all steps were carried out with minimal delay.

Our observations unequivocally established the presence of the enzyme and CA fluorescence in the same perikarya. Both specific fluorescence and esterasic reactivity were seen in the neurons of A6, A5, A1 and A7. The A4 group appeared to have a nonspecific ChE reaction while, as yet, we have not been able to confirm esterasic activity in A2. Inasmuch as cholinesterasic reactivity would seem to indicate the cholinoceptivity of these central CA neurons, only a minority of the pontomedullary cell population appears to lack cholinergic control.

Supported by grants from MRC and NSERC of Canada.

126.5 TOPOGRAPHICAL DISTRIBUTION OF CHOLINERGIC PARAMETERS IN THE RAT CAUDATE NUCLEUS. M.A. Rea and J.R. Simon. Institute of Psychiatric Research and Departments of Psychiatry and Pharmacology, Indiana University School of Medicine, Indianapolis, IN 46223

Several cholinergic parameters were estimated in microdissected regions of rat caudate-putamen (CP) obtained from 500 µm thick serial sections along the rostro-caudal extent of the nucleus (corresponding approximately to Konig and Klippel coordinates A9650-A4620). Except for sections A9650 and A4620, the CP from each coronal section was dissected into lateral and medial halves and, when possible (sections A8620-A6690), dissected further into dorso-lateral, dorso-medial, ventro-lateral and ventro-medial quadrants. The microregions of CP were pooled bilaterally and assayed for high affinity choline uptake (HAChU), choline acetyltransferase activity (ChAT) and muscarinic receptor binding (MRB), using [^{3}H] quinuclidinyl benzilate as a ligand. A total of 26 regions of CP (3-5 mg. wet wt.) were assayed. All three cholinergic parameters were found to be unevenly distributed within the CP and were consistently higher in the lateral aspect of the nucleus. HAChU varied approximately threefold (12 + 3 to 30 + 6 pmol/2 min/mg protein) while ChAT (0.46 + 0.07 to 1.05 + 0.07 nmol/min/mg protein) and MRB (0.9 + 0.1 to 1.6 + 0.2 pmol/mg protein) each exhibited about a twofold variation. In a given coronal section, as much as 70% of the HAChU, 65% of ChAT and 75% of MRB was localized to the lateral half of the CP. Furthermore, all three cholinergic markers were found to decrease along the rostro-caudal extent of the CP in dorso-lateral, dorso-medial and ventro-medial regions of the nucleus. In contrast, no rostro-caudal variations were apparent in the ventro-lateral region, where the highest density of cholinergic parameters was found. No statistically significant differences were noted along the dorso-ventral aspect of the CP. These data suggest that the lateral half of the rat CP may contain a relatively high density of cholinergic components, probably cholinergic interneurons. Therefore, studies of CP neurochemistry involving experimental manipulation of cholinergic parameters may require a consideration of regional effects within the CP, as opposed to treatment of the nucleus as a neurochemically homogeneous tissue. (Supported by USPHS Grant NS 15951).

126.6 THE ONTOGENY OF THE ASCENDING SEROTONERGIC SYSTEM IN THE RAT: AN IMMUNOHISTOCHEMICAL STUDY. Hart G.W. Lidov and Mark E. Molliver, Departments of Cell Biology/Anatomy and Neurology, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Recently (Neurosci. 5, 207, 1980) we have reported an extensive neocortical innervation by serotonergic brainstem neurons using an antibody direct against 5-hydroxytryptamine as an immunocytochemical marker. With this technique, which is significantly more sensitive than any previously available, we have now analyzed the development of serotonergic cell bodies and their ascending projections in fetal and perinatal rats.

Serotonin positive perikarya are present in rat embryos at 13 days of gestation. Initially they form extensive paramedian nuclei with mesencephalic and medullary subdivisions. Several features characterize their subsequent development: A) The multiplicity of serotonergic cell groups seen in the adult involves the partitioning of two embryonic serotonergic nuclei by subsequent events in brainstem ontogeny. B) At least two migratory paths may be involved in the formation of the serotonergic cell groups as seen in the adult rat brain. C) Extensive early dendritic development is in striking proximity to major early developing tracts, the pyramidal tract and medial longitudinal fasciculus.

Ascending serotonergic projections penetrate the forebrain on embryologic day 15. They appear to be subject to epiphytic guidance in that they grow along well developed non-serotonergic tracts. In the period of development of major axonal projections there is little development of terminal arborizations.

The first serotonergic axons enter the neocortex on embryonic day 19. Their mode of entry has a number of novel features. There are both medial and lateral components to the neocortical projection: the former traveling in the diagonal band, septum and supracallosal stria, and the latter crossing the ganglionic eminence and external capsule and entering the lateral neocortex. In contrast to the radial model that has been proposed for the growth of subcortical afferents into neocortex, the serotonergic axons clearly enter tangentially from the antero-medial and lateral margin of the cortex and enter the marginal and subplate zones as two independent strata. This is embryologic evidence for the existence of long tangential pathways confined to the molecular layer.

Terminal arborizations develop in the neocortex perinatally and achieve adult density by 3 weeks of age. The development lags in dorsal and parietal cortex as expected from the axonal pathways. During the development of serotonergic neocortical afferents, there is also innervation of the hippocampus and cerebellum. (Support: USPHS NS 08153; H.G.W.L. supported by GM-7309).

126.7 ULTRASTRUCTURAL CHARACTERISTICS AND RELATIONSHIPS OF SEROTONERGIC PERIKARYA IN NUCLEI RAPHE DORSALIS AND OBSCURUS OF THE RABBIT BRAIN. D.L. Felten, S.C. Rightor* and R.G. Peterson, Department of Anatomy, Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

The raphe nuclei of the brain stem contain serotonergic neurons which give rise to widespread projections. These systems have been implicated in the regulation of a wide range of motor, sensory, autonomic, and forebrain functions. Within these raphe nuclei are dendrite bundles containing both serotonergic cell bodies and dendrites. This ultrastructural study was undertaken to further examine the local relationships of the raphe cell bodies in the dendrite bundles. The nuclei raphe dorsalis and obscurus were examined with TEM as principle regions where serotonergic dendrite bundles have been previously described in this laboratory.

The raphe perikarya and proximal dendrites within these nuclei contained dense membrane-bound particles which were similar in appearance to lysosomal particles. They demonstrated a regular array of overlapping linear ultrastructural profiles within the particles at high magnification. These particles were depleted of their dense contents by pretreatment with reserpine in both the perikarya and proximal dendrites. The distribution of dense particles overlapped the distribution of yellow fluorescence with the Falck-Hillarp method. We suggest that these particles are the storage sites for serotonin in neurons of the raphe nuclei, and represent an ultrastructural marker for the qualitative identification of serotonergic neurons.

The cell bodies of the serotonergic neurons contained abundant profiles of rough endoplasmic reticulum, heavily accumulated in peripheral zones of the perikarya, and Golgi apparatus within more central regions of the perikarya. The nucleus was highly infolded and convoluted, with the infoldings sometimes cleaving a cytoplasmic channel through the nuclear region, thus expanding the surface area of the nuclear envelope. Within the dorsal raphe nucleus, more than 90% of the cell bodies had less than 5% of their surface area occupied by incoming axon terminal synapses. Most of the surface was in contact with astrocytic processes, abutted oligodendroglial cell bodies, or abutted the basement membrane of capillaries. In nucleus raphe obscurus, a similar paucity of incoming axonal synapses was noted on the somas. A much higher number of abutments with oligodendroglial cell bodies was also noted. We suggest that the glial relationships with the serotonergic cell bodies provide both an insulating and a nutritive function, and that most of the modulation of the excitability of serotonergic neurons takes place at the dendritic level.

126.8 CORTICAL MONOAMINE LEVELS FOLLOWING FRONTAL CORTEX ABLATION. A BIOCHEMICAL ANALYSIS USING HPLC. J.H. Morrison and M.E. Molliver Departments of Cell Biology/Anatomy and Neurology, Johns Hopkins University School of Medicine, Baltimore, MD 21205

In a previous report based upon histochemical analyses following cortical lesions we proposed that the noradrenergic (NA) projection from the locus coeruleus reaches most areas of neocortex primarily via tangential, longitudinal axons which run from rostral to caudal, traveling within the cortical grey matter. A large group of NA fibers enters cortex at the ventral aspect of the frontal pole, then turn dorsally and caudally passing through the frontal cortex; these same fibers continue caudally through the longitudinal extent of the dorsal and lateral cortex, supplying the cortical innervation throughout their trajectory. We have now attempted to supplement the morphologic data with the measurement of biochemical markers of monoamine neurons.

High Pressure Liquid Chromatography (HPLC) with electrochemical detection was used to measure the levels of norepinephrine (NE), serotonin (5-HT), and their principal metabolites in specific cortical areas at various survival times following cortical lesions. A mobile phase was developed that allowed for simultaneous measurement of MHPG, NE, DA, E, 5HT, HIAA and DHBA (an internal standard) in each sample injection. Dorsolateral frontal decortication resulted in a dramatic decrease in levels of NE and 5-HT throughout the remaining dorsolateral cortex of that hemisphere. The decrease in metabolites, although present, is less marked.

The present biochemical data independently confirm the proposition that the NA projection to cortex is organized tangentially and that caudal regions of neocortex are innervated by NA fibers that pass through the frontal pole. In addition, it appears that the serotonergic projection to lateral cortex has a similar organization, such that a small cortical lesion may have far reaching effects on both transmitter systems. The biochemical and morphologic data taken together suggest that the monoaminergic cortical projections from the brain stem engage the cortex in a manner fundamentally different from most other afferents, which terminate topographically and radially. The tangential, intragriseal trajectory of these non-thalamic cortical afferents (NE and 5-HT) indicates that the neocortex is organized as a three-dimensional matrix in which tangential systems are superimposed upon the columnar organization of cortical circuitry. (Supported by USPHS: MH 15330, NS 15199 and NS 08153).

126.9 THE DISTRIBUTION AND INCIDENCE OF SYNAPTIC CONTACTS OF NORADRENERGIC VARICOSITIES IN THE RAT NEOCORTEX: AN IMMUNOCYTOCHEMICAL STUDY. John A. Olschowka, Reinhard Grzanna, and Mark E. Molliver
Departments of Cell Biology/Anatomy and Neurology, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

Several laboratories have proposed that monoaminergic varicosities typically do not form synapses, but release transmitter diffusely into the extracell space. Histofluorescence and tritiated-norepinephrine autoradiographic studies have reported abundant noradrenergic (NA) varicosities in layer I of rat neocortex, with a rapid decline in numbers of varicosities in layers II-VI. In contrast immunofluorescence studies have shown that the NA projection ramifies densely through all layers of cortex and may directly influence neurons in all cortical layers. In this study a homologous antiserum directed against rat dopamine-β-hydroxylase (DBH) was visualized by an HRP-Fab conjugate to describe the distribution and ultrastructural relationships of NA axons in rat somatosensory cortex. DBH is the terminal enzyme in the synthesis of norepinephrine and is a sensitive marker for NA neurons.

Vibratome sections of rat neocortex were processed for DBH immunocytochemistry, embedded in plastic, thin sectioned, and the tissue was systematically analyzed. Every DBH-positive profile was identified, classified as either a varicosity or an intervaricose segment, and its position within the cortical laminae recorded. DBH-immunoreactive varicosities and intervaricose segments were observed in all cortical layers interspersed between unlabeled dendrites. DBH-positive profiles were not evenly distributed, but were concentrated in particular cortical layers. Over two-thirds of all DBH-positive profiles (>70% of labeled varicosities) were found in layers IV-V, followed in order of decreasing density by layers I, II-III, and VI. Overall, 64% of all DBH-positive profiles were intervaricose segments, 36% varicosities. The vast majority (80%) of labeled profiles in layer VI were intervaricose segments, suggesting that these NA fibers were axons of passage. A large proportion (>40%) of DBH-labeled varicosities, most of which are in layers IV-V, formed synaptic contacts with specialized membrane appositions. Synaptic junctions, predominantly asymmetric, were observed between DBH-positive varicosities and unlabeled dendrites and dendritic spines. No axo-axonic or axo-somatic contacts were observed. The results suggest that: NA axons may influence neurons throughout the cortex, with a major influence on neurons in layers IV and V; NA fibers in layer VI appear to be axons of passage; NA varicosities exert their influence on cortical neurons via conventional synaptic contacts. (Support: USPHS NS 06117 and NS 15199).

126.10 Visualization and Characterization of Serotonergic Perikarya and Hippocampal Terminal Fibers by Specific Reuptake and Retrograde Transport of ^{3}H-5HT. E.C.Azmitia and P.J.Gannon, Department of Anatomy, Mount Sinai Medical Center, New York, New York 10029.

Hippocampal serotonergic fibers possess a high-affinity reuptake mechanism for ^{3}H-5HT which is both specific and saturable (Azmitia and Marovitz, J.Histochem.Cytochem., 1980). We have utilized this process for the in vivo and in vitro localization and characterization of the perikarya and terminal axons of the midbrain serotonergic neurons efferent to the dorsal hippocampus in the rat. Pharmacological and biochemical in vitro studies were performed on hippocampal slices (0.3 mm) incubated (37°) in Ringer solution with pargyline (10^{-4}M) dextrose (10^{-2}M) and ascorbic acid (10^{-3}M) for 15 min. Studies with unlabeled 5-HT (10^{-5}M), NE (10^{-3}-10^{-5}M) or tryptophan (10^{-5}M) and with fluoxetine (10^{-4}-10^{-7}M), DMI (10^{-4}-10^{-7}M), metergoline (10^{-4}M), or 5,7-DHT (intracerebral injection into fornix-cingulum, 5ugm, 400nl, 6 day survival) showed a specific to non-specific reuptake ratio of 70/30 at a ^{3}H-5HT molarity of 5×10^{-8}M.

Radioautography (NTB-2, 2-5 week exposure, D-170 developer) of the hippocampus after in vitro or in vivo administration of ^{3}H-5HT revealed an extensive distribution pattern of the specific reuptake sites (dense silver grain aggregates) suggesting innervation of both pyramidal and granule neurons. Electron microscopic radioautography is currently being processed to obtain ultrastructural identification of these serotonergic axons.

Furthermore, specific retrograde transport to raphe serotonergic perikarya was seen within 6 hours after in vivo ^{3}H-5HT injection into the dorsal hippocampus (10uci, 80nl Ringer). Combination of this radioautographic method with the HRP-DAB technique was performed after ^{3}H-5HT and HRP (Sigma VI, 10%, 50nl Ringer) injections into opposing hippocampi. Sequential processing of the brains showed an equal number of ipsilateral and contralateral projecting neurons in both the MR and interfasicular part of the DR. Most important, a subpopulation of serotonergic neurons (10%) was found to have bilateral projections to this limbic center. Research supported by NSF 79-06474 and Hirschl Career Development Award.

126.11 EFFERENT ORGANIZATION OF LOCUS COERULEUS: 3-DIMENSIONAL QUANTITATIVE ANALYSIS. S.E. Loughlin, S.L. Foote, and F.E. Bloom. A.V. Davis Center for Behavioral Neurobiology, The Salk Institute, La Jolla, CA 92037.

We have previously reported a method for 3-D reconstruction of the locus coeruleus (LC) based on Nissl-stained LC's. Similar reconstructions can be created for the subsets of LC cells labelled following injection of HRP into selected terminal fields of LC. Quantitative comparisons of the distribution of cells as well as highly accurate visual representations of complete nuclei are possible. Such series of LC's ($N \geq 5$ LC's for each) have been analyzed following HRP injections into pre-frontal cortex, septal hippocampus, temporal hippocampus, hypothalamus, cerebellum, and thoracic spinal cord. Labelled cells in each section through LC were digitized, aligned and registered to a standard coordinate system. As has been reported elsewhere, cells which were labelled following injections into septal pole of hippocampus or spinal cord were distributed differently from the control distribution such that hippocampal injections labelled dorsal LC and spinal cord labelled ventral LC. Both of these differences were readily visible and have been confirmed by various statistical analyses. In addition, analysis of variance has revealed a difference in the anterior-posterior distribution of cells projecting to hippocampus which was not obvious to visual examination. The distribution of labelled cells following injection into the temporal hippocampus appears very similar to that following septal hippocampal injection, though in some cases there are differences in anterior-posterior distribution. The distributions of labelled cells following injection into prefrontal cortex, cerebellum, and hypothalamus appear very similar to each other and to the control. These three patterns of labelling, however, appear qualitatively different when carefully examined. For example, cerebellar injections tend to label large, multipolar cells especially in ventral LC, while prefrontal cortex injections label medium, round cells throughout LC. Precise analysis of these distributions by the more sensitive analysis of variance is required to confirm these qualitative differences. To attempt to answer the question of whether those populations of cells with coextensive distributions represent intersecting or distinct subsets of LC cells, we have simultaneously injected these 2 fluorescent retrograde tracers into different terminal fields. Preliminary results with the tracers true blue and nuclear yellow indicate that cells labelled with each are interdigitated within LC, but that double-labelled cells, which are evident in other brain areas, are rare in LC. The results of further experiments will be reported. Supported by Grants AA 03504 and NS 16209.

126.12 COMBINED IMMUNOCYTOCHEMICAL AND RADIOAUTOGRAPHIC STUDY OF DOPAMINERGIC TERMINALS IN THE NEOSTRIATUM. V.M. Pickel, A. Beaudet, S. Beckley, T.H. Joh, D.J. Reis, and M. Cuenod. Lab. of Neurobiol., Dept. of Neurol. Cornell Univ. Med. Coll. New York, NY and Brain Research Inst., Univ. of Zurich, Zurich, Switzerland.

The topographic relations and ultrastructure of dopaminergic terminals in the neostriatum of rat brain were studied by the immunocytochemical localization of tyrosine hydroxylase (TH) alone or in combination with radioautographic localization of ^{3}H-dopamine. Animals used only for immunocytochemistry were fixed by aortic arch perfusion with 4% paraformaldehyde and 0.2% glutaraldehyde. Animals used for the combined study were given pargyline (75 mg/kg i.p.) 1 h prior to the 2 h intraventricular infusion of ^{3}H-dopamine (100 ul of 10^{-5} M solution). In order to retain the ^{3}H-dopamine in axon terminals, the animals were perfused first with the aldehyde mixture then with 0.5% OsO_4 immediately following the intraventricular infusion (Descarries et al., Nature, in press). The neostriatum from both groups of animals were sectioned on a Vibratome, and processed for the immunocytochemical localization of TH by the peroxidase-antiperoxidase method of Sternberger. Sections used for the combined studies were subsequently processed for radioautography.

By light microscopy using only immunocytochemistry, the peroxidase reaction product was restricted to rosettes of varicose terminals which surrounded unlabeled neuronal perikarya throughout the neostriatum. In the combined study, the ventricular region which had greatest access to ^{3}H-dopamine showed rosettes of peroxidase labeled axon terminals which were superimposed with reduced silver grains. At least one other dopaminergic region, the nucleus accumbens, had a comparable dual label.

Electron microscopic examination of the sections processed only for the localization of TH allowed a more extensive sampling of the dopaminergic terminals throughout the rostrocaudal and dorsoventral extent of the neostriatum. A similar population of TH-containing axon terminals was present in all regions examined. The labeled terminals ranged in diameter from 0.2 to 1.5 μm and contained numerous small (40-60 nm) clear vesicles which were rimmed with the peroxidase reaction product. The smaller terminals, 0.2 to 0.5 mμ, showed symmetric synaptic densities with unlabeled dendrites. However, the larger axon terminals rarely showed morphologically identifiable synaptic densities in single or serial sections. The ability to combine the radioautographic localization of ^{3}H-dopamine with immunocytochemistry has considerable potential for the examination of cellular relationships between the dopaminergic terminals and other neurons having immunocytochemically detectable markers. Supported by NIH grants MH24285, HL18974, and SNF grant 3.506.79

126.13 SIMULTANEOUS DETECTION OF SEROTONIN AND TYROSINE HYDROXYLASE OR ENKEPHALIN CONTAINING NEURONS BY COMBINED RADIOAUTOGRAPHY AND IMMUNOCYTOCHEMISTRY IN THE CENTRAL NERVOUS SYSTEM OF THE RAT: A. Beaudet*, V.M. Pickel, T.H. Joh, R.J. Miller and M. Cuénod, Brain Res. Inst., Univ. of Zurich, Switzerland and Lab. of Neurobiol., Dept. of Neurol., Cornell Univ. Med. Coll., New York, N.Y.

Numerous biochemical, pharmacological and electrophysiological studies have suggested functional relationships between serotonine (5-HT), catecholamine and enkephalin (Enk) containing neurons in the CNS. In order to determine the morphological basis for such interactions, 5-HT and either catecholamine or Enk neurons were simultaneously visualized in rat brain by combining radioautography with immunocytochemistry. Adult rats were pretreated with a monoamine oxidase inhibitor and subjected to a 3h intraventricular infusion of 50 nM [^{3}H]-5-HT. The brains were fixed by intraaortic perfusion of a mixture of aldehydes (0.5-1% glutaraldehyde/1-4% paraformaldehyde) followed or not by 0.25% OsO_4. Thirty micron-thick vibratome sections from the mesencephalon and the caudal medulla were incubated with specific antisera against either tyrosine hydroxylase (TH) or leucine(Leu^5)-Enk, immunocytochemically labeled by the peroxydase-antiperoxydase method of Sternberger (Prentice Hall, 1974), and processed for light microscope radioautography.

In immuno-radioautographs of the lower brainstem, numerous [^{3}H]-5-HT labeled axonal varicosities are visible in the lateral reticular nucleus and the medial nucleus of the solitary tract, in between and often adjacent to TH immunoreactive nerve cell bodies of groups A1 and A2 respectively. Dense plexuses of 5-HT fibers are also detected in the spinal trigeminal nucleus, together with numerous terminals and occasional perikarya showing Enk-like immunoreactivity. Conversely, in the mesencephalon, scattered TH or Enk immunoreactive fibers are detected amidst the intensely labeled 5-HT nerve cell bodies of nucleus raphe dorsalis. The latter are interspersed among non-radiolabeled TH reactive perikarya, thus confirming that both belong to distinct neuronal populations.

These results demonstrate the feasibility of combining immunocytochemistry and radioautography for simultaneous light microscopic identification of different chemically specific neurons. The same approach should be applicable at the electron microscopic level and provide a powerful tool for elucidating their cellular relationships.

126.14 IMMUNOCYTOCHEMICAL AND DEGENERATIVE STUDY OF ENKEPHALIN AND SUBSTANCE P IN THE SPINAL TRIGEMINAL NUCLEUS. K.K. Sumal*, V.M. Pickel, R.J. Miller and D.J. Reis, Laboratory of Neurobiology, Dept. of Neurology, Cornell Univ. Med. Coll., New York, NY and Dept. of Pharmacol., Univ. of Chicago, Chicago, IL.

The substantia gelantinosa of the spinal trigeminal nucleus (SGV) is a site of termination of sensory afferents from the Gasserian (V) and nodose (X) ganglia. Light microscopic immunocytochemistry has shown the presence of enkephalin (E) in perikarya and processes and substance P (SP) in axon terminals in the SGV. Furthermore, the SP immunoreactivity in the SGV is reduced by lesions of the Gasserian ganglion (Cuello et al., Brain Res. 152, 1978). In this study, light and electron microscopic immunocytochemistry is combined with lesions of sensory afferents in order to determine: (1) whether any of the SP and/or E containing terminals in the SGV are derived from the nodose as well as the Gasserian ganglia and (2) the ultrastructure and synaptic relations of these peptidergic neurons in the SGV. Four days following unilateral electrolytic lesions of the Gasserian ganglion or removal of the nodose ganglion, the brains were fixed by vascular perfusion with 4% paraformaldehyde and 0.2% glutaraldehyde. Vibratome sections taken throughout the rostrocaudal extent of the SGV were processed for the immunocytochemical localization of SP and E using the peroxidase-antiperoxidase technique of Sternberger.

By light microscopy, electrolytic lesions of the Gasserian ganglia reduced the immunocytochemical reaction for SP, but not E, in the more caudal portions of the SGV. Whereas removal of the nodose ganglia reduced the immunoreactivity only for SP in the rostral portions of the nucleus. These light microscopic changes in SP immunoreactivity were accompanied by evidence of degenerating boutons in the SGV by electron microscopy.

The ultrastructural localization of SP was restricted to lightly myelinated axons and axon terminals. The SP-containing axon terminals contained numerous small (40-60 nm) clear vesicles and 1-4 large (100 nm) dense vesicles, and formed primarily axodendritic synapses. E was localized by electron microscopic immunocytochemistry to perikarya, dendrites, and myelinated and unmyelinated axons and axon terminals. The terminals showing E immunoreactivity also contained a similar vesicle population and formed primarily axodendritic synapses. We conclude that SP terminals in the SGV are derived from both the nodose and Gasserian ganglia and that SP- and E-containing terminals form primarily axodendritic synapses in the substantia gelatinosa.

(Supported by NIH grants MH24285, HL18974, and NSF grant 3.506.79)(SP antiserum generously donated by S. E. Leeman)

126.15 ULTRASTRUCTURAL FEATURES OF ENKEPHALIN NEURONS IN THE MONKEY SPINAL CORD. N. Aronin*, M. DiFiglia, A. Liotta* and J.B. Martin. Dept. of Neurology, Mass. General Hospital, Boston, MA and the Endocrine Section, Mount Sinai Sch. of Med., New York, N.Y.

Immunoreactive leu-enkephalin (leu-enk) containing neuronal elements and their synaptic relationships were identified in the monkey spinal cord with use of the immunoperoxidase technique. The leu-enk antiserum employed crossreacts less than 0.1% with met-enkephalin on a molar basis and not at all with β-endorphin or β-lipotropin in radioimmunoassay. Immunoprecipitation of spinal cord extract with excess leu-enk antiserum, followed by separation on high pressure liquid chromatography and gel filtration, reveals authentic leu-enk and 2 larger peptides (approx. M.W. 4620 and 31,000). Preliminary results show that the 4620 M.W. peptide yields intact leu-enk upon trypsinization. It is possible that any or all of these various peptides are immunostained with the titer of leu-enk antiserum used (1:500).

Light microscopy reveals positively stained cell bodies distributed throughout laminae I and outer II (IIo). Most somata are about 10 μm and have a bipolar shape. Emerging dendrites extend long distances from the cell body and are oriented in the marginal zone parallel to the plane of the lamina. A dense distribution of fibers is present in the zone of Lissauer, laminae I, II and X. Processes also appear throughout the remaining dorsal horn and laminae VII and IX. Electron microscopy shows leu-enk neurons to have relatively large indented nuclei, little surrounding cytoplasm, some small spines and few axosomatic synapses. Peroxidase reaction product is localized within proximal and distal dendrites on numerous microtubules and in large granular vesicles (LGV, 100 nm), which are occasionally present. Dendrites and emerging spines are contacted by various types of unlabeled axon terminals. Within laminae I and IIo leu-enk is found in myelinated axons having a diameter of 0.3-0.6 μm. Numerous stained axon terminals contain small round agranular vesicles (40 nm) and some LGV. Reaction product is present primarily around the membranes of small vesicles and within LGV. The boutons have a maximum size of 1.5 μm and form asymmetric synapses with unlabeled dendritic shafts and spines. Less fequently, smaller leu-enk terminals (0.5 μm) are presynaptic to cell bodies.

The present results extend to monkey previous light microscope observations of enkephalin localization in rat and cat spinal cord. Furthermore, ultrastructural data indicate that at least in laminae I and IIo numerous immunoreactive leu-enk containing axons participate in conventional axodendritic and axosomatic synapses. It is therefore possible that in the dorsal horn enkephalin has functions in addition to its proposed role in direct inhibition of primary sensory afferents. Supported by grants # 1-RO1-AM-26 252-01 and # 1-F32-AM06143-01.

126.16 LIGHT AND EM LOCALIZATION OF SUBSTANCE P, MET-ENKEPHALIN AND 5-HT IN HUMAN AND MONKEY SPINAL CORD. N.C.de Lanerolle and C. LaMotte, Sections of Neurosurgery & Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510.

Substance P (SP), met-enkephalin (ENK) and 5-hydroxytryptamine (5HT) have been localized, in recent years, in axons and terminals of the spinal cord of lower mammals. This study describes the distribution of these substances in human and monkey spinal cord as visualized by immunohistochemistry using the peroxidase anti-peroxidase technique. The following table summarizes the distribution of SP and ENK in human mid-thoracic & lumbar cord:

Area	SP	E	Area	SP	E
Lissauer's tract	+++	+	N. intermediomedialis	+	+
Marginal zone	++++	++	N. cornucommiss. post.	++	+
Substantia gelatinosa	+++	++	N. cornucommiss. ant.	-	-
N. proprius	+	+	Lateral motor nucleus	++	+
N. reticularis	+	+	Medial motor nucleus	+	-
N. dorsalis of Clarke	-	-	Central canal zone	-	-
N. intermediolateralis	++	++			

In addition, both SP and ENK positive fibers extended from the marginal zone and Lissauer's tract into the lateral white matter and into the dorsal columns. Several presumed motor neurons were heavily outlined along their soma and dendrites with SP terminal-like processes.

As part of an analysis of the relationships between SP and ENK innervation of spinal cells, serial sections of the human cord were made, and alternate sections were stained for SP and ENK. Both SP and ENK positive terminals were found in close apposition to the soma and dendrites of some neurons in the marginal zone, the reticular, intermediomedial and intermediolateral nuclei, and of motor neurons. The dual innervation of preganglionic sympathetic neurons and motor neurons in addition to neurons in laminae I & V, indicates that these peptides may be involved not only in pain modulation but also in other spinal functions.

In the monkey, the distribution of peptides was similar to that in humans. EM of laminae I to III revealed SP to be contained in fine axons and terminals which most commonly make junctions with dendrites (proximal & distal). Large dense-core vesicles are often found within the labelled terminals.

In the monkey, much of the 5HT was localized in fibers and terminals in the marginal zone, laminae III & IV, and the nucleus intermediolateralis. Less 5HT was observed in the substantia gelatinosa, nucleus intermediomedialis and nucleus dorsalis of Clarke; in the ventral horn 5HT was associated with the surface of presumed motor neurons.

(Supported by NIH grant NS 13335)

126.17 NEUROTENSIN (NT) AND SUBSTANCE P (SP) LOCALIZATION IN MONKEY AND RAT SPINAL CORD: LIGHT AND ELECTRON MICROSCOPY. S.E. Leeman, M. DiFiglia and N. Aronin*. Depts. of Physiology, Harvard Medical School and Neurology, Massachusetts General Hospital, Boston, MA.

NT and SP containing axons were identified in the monkey spinal cord. In addition, the distribution of NT in rat spinal cord was examined. Vibratome sections (20 μm thick) were incubated in NT or SP antiserum and then processed by the immunoperoxidase method. Each antiserum crossreacts with its C-terminal hexapeptide and intact peptide. Fresh spinal cord extracts from each species, when submitted to gel filtration and high pressure liquid chromatography and quantified by radioimmunoassay (RIA), show a single peak co-eluting with synthetic NT or SP and SP sulfoxide. It is likely that NT and SP are the principle immunostained peptides with high affinity to the antisera used. However, other low affinity peptides undetectable by RIA may also be immunostained at the high titer of antiserum (1:500) needed in the immunohistochemical method.

Light microscopy reveals NT fibers in the rat and monkey in the zone of Lissauer and within the dorsal horn mainly in laminae I and II. SP fibers in the monkey are present in I, II, III, IV, IX, X, and the zone of Lissauer. Electron microscopy of the monkey dorsal horn shows a similar morphology of labeled elements for both neuropeptides. Immunostained axons are unmyelinated and are about 0.3 μm for NT and 0.3-0.7 μm for SP. Terminal boutons vary in size and have maximum dimensions of 1.5x3 μm for SP and 2.0x2.5 μm for NT. The largest elements contain numerous large granular (LGV, 100nm) and small round agranular (35-40nm) vesicles both of which are scattered throughout the profiles. Peroxidase reaction product is localized primarily within the LGV and tends to be more lightly deposited on membranes of the small vesicles which are also present at presynaptic sites. NT and SP axons synapse with large and small dendrites and dendritic spines. The largest profiles can contact up to three different postsynaptic elements and frequently form more than one contact with the same dendrite. Most synapses appear to be asymmetric and are sometimes associated with subjunctional dense bodies in the postsynaptic elements. The present results show that 1) NT fibers are present in monkey and rat dorsal horn, 2) the localization and ultrastructure of SP axons in the monkey are similar to those previously reported for the rat, 3) NT and SP terminals in the monkey have a similar appearance and synaptic pattern. Moreover, some of the profiles are identical to those described as central axonal elements, a portion of which are considered to be of primary afferent origin (Ralston, H.J. and Ralston, D.D., J. Comp. Neurol. 184: 643, 1979). Supported by grants # AM-16510, 1-R01-AM-26152-01 and 1-F32-AM-06143-01 from NIH.

126.18 ONTOGENESIS OF SOMATOSTATIN (SRIF) IN THE FOREBRAIN OF THE RAT CENTRAL NERVOUS SYSTEM. R.M. Lechan*, J.L.Nestler*, R.J.Robbins*, S.Jacobson, J.Bollinger*. Endocrine Div. and Dept. of Anatomy, Tufts-New England Medical Center, Boston, MA 02111.

In order to determine the ontogenesis of somatostatinergic neurons of the rat forebrain, the time of appearance and distribution of immunoreactive somatostatin within this region was studied immunohistochemically using the indirect peroxidase-antiperoxidase technique in rats ranging from fetal day 17 to postnatal day 14. Antisera to synthetic cyclic-SRIF was raised in NZW rabbits and incubated at a final titre of 1:1000 for 48 hrs at 4°C with free floating 50 micron vibratome-sectioned tissues. Specificity of the reaction product was demonstrated by the absence of staining with preabsorbed antisera.

Immunoreactive SRIF in fetal day 17 animals was present in perikarya of the hypothalamus, subthalamus, and rhinencephalon, although beaded axons were seen only at the base of the brain coursing with the optic tracts. By postnatal day 1, rich concentrations of SRIF-reactive neurons were widely distributed throughout the forebrain, both in perikarya and neuronal processes. SRIF was present in the dorsal arcuate nucleus, lateral hypothalamic area and in a band encircling the ventromedial nucleus, but staining in these areas was no longer apparent by postnatal day 11. In addition, SRIF present at day 1 in the nucleus accumbens, zona incerta, entopeduncular nucleus and lateral habenula diminished between postnatal day 9 and 14. In contrast, SRIF immunoreactive neurons in the caudate-putamen and stratum oriens of the dorsal hippocampus, and in terminals in the median eminence, paraventricular nucleus of the thalamus and corticomedial nucleus of the amygdala present on postnatal day 1, dramatically increased by postnatal day 5. Regions of comparable immunoreactivity in all neonatal groups included cells of the hypothalamic periventricular nucleus, anterior hypothalamic area, pyriform cortex, olfactory tubercle and axons in the ventral premammillary nucleus, organum vasculosum and stria terminalis. SRIF-containing perikarya of the neocortex was present only in the deep lamina on postnatal day 1 extending into the more superficial lamina by day 14.

These results demonstrate the widespread presence of immunoreactive SRIF in immature neurons of the developing rat brain and the dynamic changes which occur in its distribution during maturation. The loss of immunoreactivity with age in some neurons suggests either a decline in cell numbers by attrition or a reduction in their content of SRIF.

126.19 DEVELOPMENT OF ENKEPHALIN-LIKE IMMUNOREACTIVITY WITHIN THE RAT HIPPOCAMPAL FORMATION. C. Gall, N. Brecha, and H.J. Karten, Dept. of Neurol. and Dept. of Neural and Behav. Bio., State Univ. of N.Y., Stony Brook, New York 11794.

Antisera to leucine-enkephalin have been used to study the developing and mature distribution of enkephalin-like immunoreactivity within the hippocampal formation of the rat. At maturity immunoreactivity was localized throughout the mossy fiber system and within a continuous zone including CA1 stratum lacunosum-moleculare and the distal third of the dentate gyrus molecular layer (the latter zone conforming to the distribution of afferent input from the lateral entorhinal cortex). Perikarya exhibiting enkephalin-like immunoreactivity were observed sparsely scattered throughout the hippocampus most notably in stratum granulosum, stratum pyramidale of field CA1, the apical dendritic field of CA1 and the subiculum.

This immunoreactive staining pattern emerges slowly rather late in the development of the hippocampus. The 'lateral entorhinal' band first appears on postnatal day 6 (p6) and fills the field by p8. Immunoreactivity within the mossy fiber system was first detectable by p11 and at this age is only present within the hilus. By p13 labeled mossy fibers are seen along the pyramidal cell layer as far as CA3b and by p14 are present throughout regio inferior. In contrast, immunoreactive axons in the fimbria and along the alveus/stratum oriens are most conspicuous at the earliest time points, prior to p8, and are seen progressively less frequently thereafter.

A few immunoreactive perikarya are present within the hilus and apical field of regio inferior by p8. Between days 11 and 13 there is an abrupt increase in somal staining such that some labeled neurons appear in all fields of the hippocampus proper; however, within the dentate gyrus labeled neurons are still seen within the hilus rather than within stratum granulosum. By p16 immunoreactive perikarya are largely absent from the hilus and are seen to lie along the base of the granule cell layer. At this age labeled neurons appear to be more intensely immunoreactive than in the adult: in some of the subgranular neurons labeling is sufficiently intense to visualize both dendritic and somal spines. Although at p16 cells are seen labeled in all areas that will include reactive somata in the adult, these neurons have clearly not established their adult morphology. By postnatal day 26 the pattern of enkephalin-like immunoreactive staining in the hippocampal formation is the same as that seen in the adult. The relationship of these patterns of peptide ontogeny will be compared to the structural and physiological development of hippocampal afferents and resident neurons.

126.20 DOUBLE IMMUNOCYTOCHEMICAL LABELING DEMONSTRATES DISTINCTIONS AMONG OPIOID PEPTIDERGIC NEURONS. Jacqueline F. McGinty and Floyd E. Bloom. A.V. Davis Ctr. for Behav. Neurobiol., The Salk Institute, La Jolla, CA 92037.

The opioid peptides, β-endorphin and enkephalin, have distinct distributions in the CNS and may arise from different precursor molecules. In contrast, β-endorphin, ACTH, and α-MSH immunoreactivity (ir) has been located in the same pituitary cells and in closely related, medial basal hypothalamic neurons. These three peptides probably arise from the same 31k precursor, proopiocortin, which also contains γ-MSH. Cell bodies containing γ_3-MSH (ir) have been observed only in the medial basal hypothalamus (Bloom et al, in preparation). To compare the cellular localization of these peptides in the brain, we have developed an immunocytochemical technique to detect two antigens on the same tissue section by modifying immunoperoxidase methods (Nakane, J. Histochem. Cytochem. 16: 557, 1968).

Primary rabbit antisera were raised against synthetic leu-enkephalin (Miller and Chang, U. Chicago), β-endorphin, ACTH, and γ_3MSH (Benoit, Shibasaki, and Guillemin, Salk Inst.). Rat brains were prepared for immunocytochemistry as described (Bloom, et al. PNAS 73: 1591, 1978). Tissue sections were incubated with one of the primary antisera, followed by HRP-labeled-IgG, and stained for HRP with diaminobenzidine as substrate. The antibody complex was eluted with 0.2M glycine-HCl (pH 2) without losing the brown reaction product or denaturing the antigen to be localized subsequently. The second primary antiserum was then applied followed by HRP-IgG. The second reaction product was visualized with o-dianisidine diHCl as HRP substrate, essentially as described (Colman and Scalia, Brain Res. 102: 156, 1976). In the medial basal hypothalamus, we observed cell bodies containing either β-endorphin (ir) or enkephalin (ir), but not both. However, potential interactions between these two neuronal populations were revealed by enkephalin (ir) fibers closely surrounding β-endorphin (ir) perikarya and vice versa, suggesting axosomatic contacts. In contrast to the separate cellular localization of enkephalin and β-endorphin, ACTH (ir) and β-endorphin (ir) were invariably found in the same cells. Although β-endorphin (ir) was always found in γ_3-MSH (ir) cells, we have not detected γ_3MSH (ir) in every β-endorphin (ir) cell. Implications for the origin and processing of these endorphin-related peptides will be examined. (Supported by DA 01785 and MH 07901.)

126.21 VARIATIONS IN AMOUNT OF TYROSINE HYDROXYLASE IN INDIVIDUAL NEURONS OF NUCLEUS LOCUS CERULEUS OF RAT DEMONSTRATED BY COMPUTER ASSISTED QUANTITATIVE IMMUNOCYTOCHEMISTRY. R.H. Benno, L.W. Tucker,* T.H. Joh, and D.J. Reis, Laboratory of Neurobiology, Dept. of Neurology, Cornell Univ. Med. College, New York, NY.

We sought to determine by computer assisted quantitative immunocytochemistry using the peroxidase-antiperoxidase (PAP) technique if there is a heterogeneity among individual neurons of the nucleus locus ceruleus (LC) with respect to the amount of tyrosine hydroxylase (TH) within each cell and, if so, whether the amount of TH is related to morphometric characteristics and/or localization of the neuron within the LC.

Rats were perfused with 4% paraformaldehyde, the brains post-fixed in picric acid paraformaldehyde and embedded in paraffin. Sagittal sections of 5 μ were immunostained for TH using reaction conditions necessary to produce linearity of staining intensity with respect to amount of immunoreactive protein (Benno et al., Neurosci. Abstr. 5., 1979). Using image analysis, 1425 cells were analyzed for amount of TH/unit cytoplasm, location within the LC, and morphometric features. Cells were assigned locations within 5 subregions: anterior, posterior, and ventral poles, central core of the LC proper, and nucleus subceruleus (Grzanna and Molliver, Neuroscience 5, 1980). Collectively, the cells of the LC varied over a three-fold range in staining intensity, a three-fold range in longest dimension (average = 33.6 $\pm$ 6.2 μ) and a seven-fold range in cytoplasmic area (100-700 μ^2). The largest and most darkly stained cells were clustered in the ventral LC and subceruleus. Overall, for each neuron there was no correlation between the amount of immunoreactive TH/unit area and total cytoplasmic area (r=.22$\pm$. 06), nuclear/ cytoplasmic ratio (r=.10$\pm$ .08), and longest dimension/breadth ratio (r=.12$\pm$.04). However, there was a significant ($p<.05$) difference between the staining intensity of neurons in the anterior, ventral, and posterior poles and the subceruleus versus those of the central core, which were lighter. Analysis of density in concentric radii from the center of the LC shows that cells farthest from the center are the most darkly stained ($P<.01$).

We conclude that neurons of LC vary with respect to amount of TH, which in turn relates to the location of the cell within the LC and not its morphometric characteristics. Since, in noradrenergic neurons, the amount of TH is directly influenced by firing rate, the results suggest that the biochemical heterogeneity of LC neurons reflects differences in their functional activities. In turn, this may relate to heterogeneity of LC with respect to projection fields.

126.22 AN IMMUNOFLUORESCENCE STUDY OF THE NUCLEUS TRACTUS SOLITARIUS IN THE CAT. B.E. Maley and R.P. Elde. University of Minnesota Medical School. Minneapolis, Minnesota 55455.

The indirect immunofluorescence method was used to map a number of putative neurotransmitters [substance P (SP), met-enkephalin (M-ENK), somatostatin (SOM), serotonin (5-HT) and neurophysin (NP)] throughout the feline nucleus tractus solitarius (NTS). Antisera were applied to consecutive ten micron sections cut in the transverse plane from normal and colchicine treated (500 μg in the cisterna magna; 48 hour survival) cats. Specificity of staining was determined using antisera pretreated with homologous and heterologous antigens. All sections were subsequently viewed in a microscope using epifluorescence. Differential amounts of immunoreactive fibers and cell bodies were observed in the various nuclei of NTS, which were named according to Loewy and Burton ('78).

In normal cats, SP and 5-HT immunoreactive fibers exhibited the greatest overall density throughout the nucleus. Both were localized to discrete areas of the NTS, with the lateral nucleus and a region just deep to the area postrema demonstrating the highest fluorescence. Fewer SP and 5-HT immunoreactive fibers were observed within the medial and commissural portions of the nucleus, while little immunoreactivity was present in the parvocellular or ventrolateral regions of NTS. A similar distribution could be found for M-ENK within the NTS, however, the amount of fluorescence was not as great as for SP and 5-HT. As before, the lateral nucleus and a region just deep to the area postrema exhibited the greatest amount of immunoreactivity, while the parvocellular and ventrolateral regions possessed the least. Immunoreactive SOM fibers present within the NTS were largely confined to the lateral and commissural regions. Other areas of the NTS exhibited minor SOM fluorescence. In a similar manner, a few immunoreactive fibers for NP were present in the NTS, however, they were restricted to the commissural region of the nucleus.

The NTS of colchicine treated cats exhibited a similar distribution of immunoreactive fibers within the nucleus, with the addition of cell bodies immunoreactive to SP and M-ENK. Most of these cell bodies were localized to discrete regions of the NTS. The differential occurrence of the previously mentioned neurotransmitters reflects not only the specific termination of afferents within the nucleus, but also its intrinsic neuronal and fiber content. Moreover, the distribution of immunoreactivity in the nucleus provides additional insight into the varied functions which have been attributed to the nucleus tractus solitarius.

127.1 β-ADRENERGIC RECEPTORS IN CILIARY PROCESS EPITHELIUM. James A. Nathanson, Dept. of Neurology, Massachusetts General Hospital, Boston, Massachusetts 02114.

Although certain studies have suggested that cyclic AMP may play a role in the control of intraocular pressure, the site of this nucleotide's synthesis and its regulation by β-adrenergic agents remains unclear. Previous studies in our laboratory (Science 204: 843) have shown that the CSF-secreting choroid plexus, a tissue with properties similar to those of the aqueous humor-secreting ciliary process, contains a very active β-adrenergic-sensitive adenylate cyclase. We now present evidence that β-adrenergic-stimulated adenylate cyclase is also present in the rabbit and human ciliary process. This enzyme is enriched in the ciliary epithelium and is more active than that found in the iris or ciliary muscle.

Adenylate cyclase activity was measured, in broken cell preparations, as the rate of synthesis of cyclic AMP from ATP under optimal cofactor and substrate conditions. Hormone stimulation was GTP-dependent and was enhanced in the absence of exogenous calcium. The enzyme was activated by low concentrations of isoproterenol (k_a=3 x 10^{-7}M) and norepinephrine (k_a=1.8 x 10^{-5}M) but was only poorly stimulated by dopamine or the α-adrenergic agonist, phenylephrine. Maximal stimulation in the rabbit ciliary process was 250-500% of control and, in the human, 500-1000% of control activity. Isoproterenol activation was inhibited by low concentrations of the β-adrenergic blockers, propranolol (k_i = 1.3 x 10^{-9}M) and timolol (k_i = 2.7 x 10^{-9}M) but only by much higher concentrations of the α-adrenergic blocker, phentolamine (k_i > 9 x 10^{-5}M) or the dopamine blocker, fluphenazine (k_i = 1.8 x 10^{-5}M). Further pharmacological studies with selective β-adrenergic agents indicated that one subtype of β-receptor predominated. Tissue dissociation and separation experiments demonstrated enrichment of hormone sensitivity in cell fractions enriched in ciliary process epithelial cells.

These findings may be relevant to physiological studies of ciliary process secretion and to the development of drugs with which to control increased intraocular pressure.

127.2 CHEMORECEPTORS FOR SEROTONIN (5-HT), ACETYLCHOLINE (ACh), BRADYKININ (BK), AND HISTAMINE (H) ARE PRESENT ON THE SOMA OF UNMYELINATED VISCERAL AFFERENTS IN THE RABBIT NODOSE GANGLION. H. Higashi* (SPON: J.P. Gallagher). Dept. of Physiology, Kurume Univ. Sch. of Med., Kurume, Japan and Dept. of Pharmacology and Toxicology, Univ. of Texas Med. Br., Galveston, TX 77550.

Rabbit nodose ganglia contain soma of both Type A, myelinated visceral afferents (conduction velocity (CV) = 6-9 m/sec), and Type C, unmyelinated fibers (CV = 0.5-1.5 m/sec). Four different algesic substances, 5-HT, ACh, BK, and H were applied to isolated rabbit nodose ganglia while recording their membrane potential and input resistance with standard intracellular reocrding techniques. Each impaled neuron was classified as to cell type, before applying an algesic. Four of 30 different neurons were Type A and 26 were Type C. None of the four algesic substances caused any significant change in membrane potential or resistance of the Type A neurons. On the other hand, 24 of the 26 Type C neurons responded with a depolarization to at least one of these four algesics. All of the algesics depolarized the soma membrane, but differed in their ionic mechanisms. 5-HT depolarized 90% of these neurons. The 5-HT depolarization was due to an increase in sodium (G_{Na}) and potassium (G_K) conductance (Nature, 267: 448, 1977). ACh depolarized these neurons by a mechanism apparently similar to 5-HT. About 30% of the Type C neurons responded to ACh. This ACh response could be blocked with d-tubocurarine (50μM) but not by atropine (50μM). About 50% of the neurons were depolarized by BK. The BK depolarization appeared to be associated with a decrease in G_K. H depolarized 25% of the Type C neurons. The mechanism for this depolarization was similar to BK, namely a decrease in G_K. Among the 26 Type C neurons 3 responded to all four algesics, 2 responded to three algesics, 11 responded to two algesics, 8 neurons were sensitive to one algesic, and 2 were insensitive to all four algesics. This preparation should prove useful for the study at the membrane level of algesics and potential analgesic substances on pain conducting fibers. (Supported by grants from the Ministry of Education, Culture and Science of Japan and USPHS Grants #NS 16228 and #NS 13727.)

127.3 MOUSE STRAIN DIFFERENCES IN STRIATAL CALMODULIN CONTENT. J.A. Severson* and C. E. Finch. Andrus Gerontology Ctr., Univ.S. Cal., Los Angeles, CA 90007

CBA/J, C57BL/6J and BALB/cJ mice differ in substantia nigra dopaminergic cells, nigral tyrosine hydroxylase (TH) activity, striatal TH activity and striatal dopamine (DA) receptors. Additionally, CBA/J mice lack the striatal DA receptor supersensitivity response to chronic haloperidol treatment. Since striatal DA receptor activation of adenyl cyclase is dependent on the interaction of the receptor-cyclase complex with calmodulin (CaM, calcium-dependent regulator protein), we examined how CaM varies with genetic differences in DA receptor number.

CaM was assayed by the activation of rat brain phosphodiesterase. Total striatal CaM was similar in all strains, however, when expressed as per mg wet wt. or per mg protein, CBA/J mice had 30% more striatal CaM than BALB/cJ mice($P< 0.001$), C57BL/6J mice had intermediate CaM levels. The distribution of CaM in soluble and particulate fractions was similar in all strains(60% soluble, 40% particulate), even though the absolute amounts of soluble and particulate CaM followed the same pattern as total CaM.

Since CBA/J mice have 50% fewer DA receptors than BALB/cJ mice, the ratio of CaM/DA receptor is about 2-fold higher in CBA/J mice. Elevated striatal CaM in CBA/J mice may represent a mechanism to compensate for depressed receptor number.

127.4 SPIPERONE BINDING SITES IN RAT BRAIN: LIGHT MICROSCOPIC AUTORADIOGRAPHIC LOCALIZATION OF DOPAMINE AND OTHER RECEPTORS. J.M. Palacios, D.L. Niehoff and M.J. Kuhar. Depts. of Pharmacology and Psychiatry, The Johns Hopkins University School of Medicine, Baltimore, Md. 21205.

Dopamine receptors have been identified in brain and other tissues by the direct binding of radiolabeled antagonists and agonists. Radiolabeled spiperone (SP: spiroperidol) has been utilized in many studies because of its high affinity for the binding sites and its relatively low level of nonspecific binding. A difficulty with SP is that it binds to more than one site; evidence suggests that it binds to a dopamine and a serotonin receptor and possibly to other sites. One must therefore use a number of pharmacological agents in displacement experiments to carefully define the various binding sites. For example, experiments in the literature indicate that, under certain conditions, ADTN can be used to selectively displace SP from dopamine receptors and cinanserin (CN) can be used to displace SP from serotonin receptors. Neuroleptics, e.g. haloperidol (HP), would displace SP from both sites.

Light microscopic autoradiographic localization of SP binding sites provides a highly sensitive measure of receptors with a correspondingly high degree of anatomical resolution. We have determined the conditions for localizing the various components of ^{3}H-SP binding in intact, mounted tissue sections. ^{3}H-SP binding to the mounted tissue sections exhibited all of the characteristics associated with receptor binding. It was saturable, of a high affinity, had the expected regional distribution and pharmacological specificity. For routine autoradiography, tissue sections were incubated with 0.4nM concentrations of ^{3}H-SP for 60 min at room temp in 0.17 Tris-HCl(pH 7.7) containing selected ions. Following two 5 min washes at 0°C, the sections were dried under a stream of cold, dry air. Autoradiograms were generated by the apposition of emulsion-coated coverslips.

Dopamine receptors, defined as ADTN displaceable SP binding, were found in the striatum, olfactory tubercle, cingulate cortex, substantia nigra and the adjacent ventral tegmentum, retina and the dorsal horn of the spinal cord. Serotonin receptors, defined as CN displaceable SP binding were found in several areas such as the cerebral cortex. In addition, there were SP sites not displaced by ADTN, CN, or haloperidol. These sites were however displaced by unlabeled SP itself. These special SP sites were found in the hippocampus, parts of the cortex, in nucleus accumbens, and in olfactory tubercles and could correspond to the "spirodecanone" site described by others.

Studies were supported by USPHS grants MH25951, DA00266, MH00053, TW02583.

127.5 IN VIVO LOCALIZATION OF 77Br-p-Br-SPIROPERIDOL. H. K. Kulmala*, R. J. Dinerstein, C. C. Huang*, and A.M. Friedman*. Dept. of Pharmacol. & Physiol. Sci., The Univ. of Chicago, Chicago, IL 60637 and Chem. Div., Argonne National Lab., Argonne, IL 60439.

The usefulness of external gamma ray imaging techniques in the localization of gamma labeled neuroleptics is dependent on the development of a labeled neuroleptic which displays a high ratio of specific to nonspecific binding. In vitro studies with Br-Spiroperidol (BrSp) showed that this ligand binds with high affinity to the dopamine receptor (Huang, C. C., et al, J. Pharm. Sci., 1980, in press).

The gamma emitter, 77Br ($t_{½}$=57hr), was produced in a cyclotron by bombarding arsenic trioxide with 37 MeV alpha particles. Following distillation, the $77Br_2$ was allowed to react with spiroperidol (Sp) to produce 77Br-p-BrSp, at a specific activity of 6.85 Ci/mmole. Twenty seven male rats were injected with 77Br-p-BrSp (7.5µg/kg,i.v.) and were sacrificed at various time points. Nine of these rats also received 0.63mg/kg of Sp, i.v. Striatum, cerebellum, frontal cortex, and pituitary were dissected out and counted in a sodium iodide well counter. The counts were corrected for wet tissue weight.

The localization of 77Br-p-BrSp was found to parallel that of 3H-Sp in levels that were highest in dopaminergically innervated areas such as striatum, pituitary, and frontal cortex (Laduron, P. M., et al, Biochem. Pharmacol., 27: (1978) 317-321). A maximal striatum:cerebellum (S:C) ratio of 6.8 was found at 8 hours after injection. Unlabeled Sp at the dose used was found to affect levels of 77Br-p-BrSp only in dopaminergically innervated areas and resulted in an S:C ratio of 1.

Three rats received $77Br^-$ (2.2mg/kg, i.v.) and were sacrificed at 2 hrs. $77Br^-$ showed a nonspecific localization with respect to dopaminergic innervation. Levels in the cerebellum were higher than those in the striatum.

The utility of 77Br-p-BrSp is being tested by administration of the gamma emitter to anesthetized cats. The animals are monitored with a seven pinhole (6mm) collimator on a gamma camera. At four hours post injection, striatum is easily distinguishable from cerebellum in the three-dimensional computerized reconstruction from the seven simultaneously obtained images. Counts detected in corresponding regions gave an S:C ratio of 2.8±0.6, in good agreement with the data obtained from rats (3.8±0.3).

(Supported by Div. Environment and Biol. Research of DOE and NIH grants GM-22220 and NS-12324 and the Schweppe Foundation.)

127.6 SELECTIVE CHANGES IN DOPAMINE RECEPTOR BINDING IN STRIATUM FOLLOWING SUBSTANTIA NIGRA LESIONS. Ira D. Hirschhorn, Maynard H. Makman* and Eliot L. Gardner. Depts. of Biochem., Mol. Pharmacol., Psychiatry and Neuroscience, Albert Einstein Coll. Med., Bronx,N.Y.10461

Following lesion of the substantia nigra, the nigro-striatal dopaminergic neurons degenerate and most of the dopamine (DA) content of the striatum is lost. Unilaterally lesioned animals develop a motor asymmetry in which DA agonists, such as apomorphine, cause the animal to turn in a circular pattern (rotational behavior). Ungerstedt (Acta Phys. Scand., Suppl. 367, 69, 1971) originally postulated that rotation was due to supersensitivity of the denervated striatum. Later, Mishra, et al. (PNAS 71, 3893, 1974) found that DA stimulated adenylate cyclase (AC) activity in denervated striatum was doubled. The present experiments examined whether there are also changes in binding of ^{3}H-spiroperidol (^{3}H-SPI), a DA antagonist, and ^{3}H-ADTN (2 amino-6,7-dihydroxy-1,2,3,4-tetrahydronaphthalene), a DA agonist, to DA receptors. Agonist and antagonist ligands label different receptors or different conformations of the same receptor. Destruction of intrinsic striatal neurons with kainic acid causes almost total loss of ^{3}H-ADTN binding with relatively little effect on ^{3}H-SPI binding. Although increases in DA receptor binding in denervated striata have been reported previously, these are considerably less than the behavioral or DA stimulated AC supersensitivity. We examined guanine nucleotide regulation of ^{3}H-ADTN binding to determine whether there is a selective change in that component of binding which is regulated by guanine nucleotides. Striata from rats that rotated at a high rate were individually homogenized in Tris HCl buffer, centrifuged twice, incubated with ^{3}H-SPI or ^{3}H-ADTN with or without 50 µM Gpp(NH)p, and filtered through glass fiber filters. ^{3}H-SPI binding was equal in denervated and control striata (con=176, les=182 fmol/mg prot). Total ^{3}H-ADTN binding was 64% increased (con=63, les=103 fmol/mg prot.), with a greater increase in the Gpp(NH)p regulated component (155%). These data provide further evidence that ^{3}H-SPI and ^{3}H-ADTN label different populations or conformations of receptors and, furthermore, that ^{3}H-ADTN, but not ^{3}H-SPI, labels receptors linked to DA stimulated AC. They are consistent with the hypothesis that it is the guanine nucleotide sensitive ^{3}H-ADTN receptors that are linked to DA stimulated AC and these receptors are selectively supersensitive following substantia nigra lesion. Rotational behavior may involve supersensitivity of the receptors labeled by ^{3}H-ADTN, particularly the guanine nucleotide sensitive component, but not the ^{3}H-SPI receptors.

127.7 RADIOAUTOGRAPHIC VISUALIZATION OF SEROTONERGIC BINDING SITES IN RAT AND CALF BRAIN. R. C. Meibach, S. Maayani and J. P. Green. Department of Pharmacology, Mount Sinai School of Medicine of the City University of New York, N.Y. 10029.

Rapid filtration methods for binding to homogenates and in vitro autoradiographic techniques (Young and Kuhar, 1979, Brain Res. 179;255) for visualizing binding sites in cryostat cut brain sections were used to characterize and visualize serotonin (5-HT) binding sites in both calf and rat brain. Specific binding was determined with cold LSD (10^{-6}M) added to ^{3}H-5-HT (29.2 Ci/mmole); in alternate sections, specificity was determined with cold 5-HT. Incubations were carried out at room temp. in 50mM Tris maleate, pH 7.4, 0.1% ascorbate and 5 x 10^{-5}M pargyline. ^{3}H-5-HT binding to both the P2 fraction and coronal brain slices were saturable with similar Kd and Bmax (Table). Binding sites were found in all layers of the cerebral cortex, olfactory tubercle and lateral septal nucleus. The thalamus was poorly labeled except for the lateral geniculate n. The superficial layer of the superior colliculus was labeled as was the midline hypothalamus substantia nigra and periaqueductal grey. No label was seen in the cerebellum. Within the hippocampal formation label was seen in the subiculum, dentate gyrus and field CA1 but not in field CA3. P2 fractions from dissected calf hippocampal subfields (Table) confirmed the absence of ^{3}H-5-HT binding to CA3. Cold LSD displaced most of the binding except in the substantia nigra and subiculum which were only displaced by cold 5-HT.

127.8 HETEROGENEITY OF [^{3}H]-D-LSD BINDING TO CALF HIPPOCAMPUS. S. Maayani, R.C. Meibach and J.P. Green. Dept. Pharmacol., Mt. Sinai Sch. Med., C.U.N.Y., New York, N.Y. 10029

Radioautographic visualization of 5-HT sensitive (1 µM) [^{3}H]-D-LSD binding sites in calf hippocampal slices (16 µm) revealed a distribution, similar to that found in rat brain hippocampus (Meibach et al., submitted). Both CA1 and dentate gyrus (DG) contain dense [^{3}H]-LSD sites while no binding could be visualized in fields CA3/CA4. Direct binding experiments on the P-2 fractions of these three hippocampal regions from calf (25°C, pH = 7.4) showed apparent homogeneous, non-interacting, 5-HT (1 µM) sensitive, [^{3}H]-LSD binding sites in both CA1 and DG but not in CA3/CA4. The binding characteristics of the 5-HT sensitive [^{3}H]-D-LSD binding in the P2 fraction of CA1 and DG were similar: K_d = 4 and 6 nM; B_{max} = 182 and 192 fmoles/mg protein, and like the binding characteristics of [^{3}H]-D-LSD in calf slices (Table). This heterogeneity of [^{3}H]-LSD binding sites, visualized by autoradiography and confirmed by direct labeling experiments, may reflect heterogeneity of in-vivo interactions of LSD in the hippocampus.

127.9 ACCUMULATION OF COATED VESICLES BEARING α BTX BINDING SITES IN BRAIN TREATED MYOTUBES. S. Bursztajn and G.D. Fischbach. Pharmacology Dept. Harvard Medical School, Boston, Mass. 02115.

Coated vesicles 80 to 120nm in diameter are present in cultured chick myotubes. We have shown that the number of coated vesicles is increased at functional nerve-muscle contacts in spinal cord-muscle co-cultures and that many of these coated vesicles contain α BTX-HRP binding sites. Coated vesicles were investigated further in myotubes treated with saline extracts of embyonic chick brain. Such extracts produce a large increase in surface receptor number and an increase in number of receptor clusters (Jessell et al., PNAS., 76:5397-5401, 1979). We measured the internal pool of ACh receptor with ^{125}I α BTX (5nM) in saponin (0.5%) permeabilized cells after blocking the surface sites with unlabeled α BTX. The number of specific ACh sites revealed by saponin was approximately 30% of the number present on the surface. There was a 3.4 fold increase in intracellular α BTX binding sites in cultures treated with brain extract daily (330μg protein/day) for 3 days as compare to controls, and a five fold increase in the number of coated vesicles as compared to non-brain treated controls. We investigated the intracellular ACh binding sites with α BTX conjugated to HRP. The conjugate blocks ^{125}I α BTX binding to the same extent as the unlabeled toxin, indicating that the conjugate has access to approximately the same number of intracellular ACh receptors. Approximately 50% of coated vesicles beneath "hot spots" in brain extract treated cells were labeled.

The following results suggests that at least some of the coated vesicles are on route to the cell surface: (1) Cultured myotubes labeled from 1 to 6 hr. with α BTX-HRP show only 17% ± 3.1% of the coated vesicles labeled. (2) Cultures whose surface receptors are blocked for 4 hr. with unlabeled toxin showed only a 6% decrease in total coated vesicles subsequently labeled following permeabilization and incubation in α BTX-HRP conjugate. (3) myotubes treated with puromycin for 6 hr. show a 50% decrease in number of coated vesicles beneath "hot spots" and only 23% of this reduced population of coated vesicles was labeled with α BTX-HRP toxin. One possible route of ACh receptor rich coated vesicle insertion into the surface membrane is via the extensive tubulo-vesicular membrane network that communicates with the cell surface. It is significant in this regard that 80% ± 3.8% of the length of the dialated sarco-tubular membrane was labeled near "hot spots" as compared to 8% ± 5.4% at "non hot spots" membrane. The cisternal membrane length that was labeled at "hot spots" decreased 4.7 fold after puromycin treatment. (Supported by NIH Grant #NS 11160 and MDA Fellowship (SB)

127.10 DEVELOPMENT OF α-BUNGAROTOXIN RECEPTORS IN CULTURED CHICK CILIARY GANGLION NEURONS. A. Messing * and S.U. Kim* (SPON: J.Q. Trojanowski). Div. of Neuropathology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104

We have maintained embryonic chick ciliary ganglion neurons in dissociated cell culture and studied the progressive appearance of surface receptors for ^{125}I-α-bungarotoxin. Cultures were established from 8-day-old embryos and fed a medium supplemented with 180 μg/ml of a soluble protein extract prepared from the eye, the target organ for the ciliary ganglion. Approximately 8100 neurons survived per ganglion and there was no evident loss of neurons through two weeks in culture. Binding of ^{125}I-α-bungarotoxin was determined at room temperature on intact cells still attached to their coverslips. Non-specific binding was less than 2% of the total. Specific binding of ^{125}I- α- bungarotoxin was saturable with respect to both time of incubation (20-30 minutes) and concentration of toxin (5-10 nM), with an apparent K_D=1.0nM. Binding sites for ^{125}I-α-bungarotoxin increased during the first week in culture from 1.8 fmoles per 10^4 neurons at 1 day in vitro (DIV) to 8.6 fmoles per 10^4 neurons at 7 DIV, after which the number of sites seemed to plateau. Light microscopic autoradiography was performed on cultures at 4 DIV and showed most of the grains associated with the surfaces of neuronal cell bodies, while scattered grains occurred over neuronal processes. When compared with the in vivo development of α-bungarotoxin receptors in chick ciliary ganglia[1], the appearance of receptors in these cultured neurons followed a time course similar to, but at lower levels than, their in vivo counterparts. Nevertheless, this culture system should prove useful for the study of questions concerning the regulation, surface distribution and intracellular pathways of neuronal α-bungarotoxin receptors.

127.11 LOCALIZATION OF NICOTINIC ACETYLCHOLINE RECEPTORS IN GOLDFISH RETINA. Charles Zucker and Stephen Yazulla. Department of Neurobiology and Behavior, SUNY at Stony Brook, Long Island, NY 11794

In goldfish retina there is evidence for nicotinic-cholinergic transmission in the inner retina. Binding of the nicotinic ligand [^{125}I] -α-bungarotoxin has been localized to three discrete bands in the inner plexiform layer (IPL). We have attempted to localize nicotinic binding sites in the IPL at the electron microscopic (EM) level using a horseradish peroxidase-α-bungarotoxin conjugate (HRP-α- BTx). An active ester method was used to crosslink HRP to α BTx (Vogel et al., J. Histochem. Cytochem. 27:846-851, 1979). Our conjugate has an apparent K_D of 6.1 x 10^{-10}M as measured by competition with native α BTx for solubilized acetylcholine receptors from Torpedo californica.

Retinal slices 150-200μ thick were incubated for 30-60 minutes in oxygenated goldfish Ringer containing either 10^{-6}M HRP-α BTx or 10^{-6}M HRP-α BTx plus 10^{-3}M d-tubocurarine chloride. The tissue was stained for HRP activity with 3,3'-diaminobenzidine and processed for EM. In the IPL, the majority of synapses containing HRP reaction product are located in two distinct bands, one in the most proximal region of sub-lamina A and the other in the proximal half of sub-lamina B. Of the identifiable synapses showing reaction product, amacrine-to-amacrine contacts are seen with the highest frequency while amacrine-to-bipolar synapses and synapses made by bipolar cells are seen less often. Synapses made by bipolar cells ordinarily have two post-synaptic processes (dyad). Reaction product at these synapses usually is restricted to one member of the post-synaptic dyad suggesting that receptors on the other post-synaptic process may be muscarinic. A significant number of small unidentified processes show discrete patches of reaction product which may indicate synaptic junctions. In control slices, prior treatment with curare abolished HRP reaction product at synaptic sites.

These results indicate that there are some classes of cholinergic bipolar and amacrine cells which make nicotinic synapses. Our findings are similar to the HRP-α BTx localization studies in chick retina but they differ from the findings in mouse retina in which HRP reaction product was never found at synapses made by bipolar cells.

127.12 MUSCARINIC RECEPTORS IN INTACT CHICK HEART CELLS IN CULTURE R.E. Siegel* and G.D. Fischbach. Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115

The muscarinic acetylcholine receptor (AChR) has been studied extensively in tissue homogenates but little is known about the receptor in intact cells. Cells dissociated from 8-day old chick embryo hearts were plated at 8x10^4 cells/6mm well. Binding assays were performed 2-3 days later with the muscarinic antagonists 1-quinuclidinyl-[phenyl 4-^{3}H]benzilate ([^{3}H]-1QNB) and [^{3}H]N-methylscopolamine ([^{3}H]-NMS). [^{3}H]-1QNB (S.A.=40 Ci/mmol) bound to a single class of sites with a K_d of 30 pM. Specific binding was defined as that which was inhibited by 10^{-6} M atropine methyl nitrate. At the K_d, nonspecific binding amounted to about 20% of the total. The number of binding sites ranged between 180-300 fmol/mg protein. Muscarinic AChRs were also assayed in separately plated atrial and ventricular cells. Atrial cells bound 200 fmol/mg protein while ventricular cells bound 150 fmol/mg protein. Since a quaternary antagonist was used to determine specific binding, it is likely that most of the specific sites represent cell surface receptors. This is supported by the fact that [^{3}H]-NMS (S.A.=53 Ci/mmol, K_d=300 pM; nonspecific binding <5%) yielded the same estimates of receptor number as [^{3}H]-1QNB.

[^{3}H]-1QNB can be used for autoradiography since it dissociates slowly ($t_{\frac{1}{2}}$>4 hr); few specific counts were lost during processing of the samples. Myocytes were distinguished from fibroblasts on the basis of cell shape and by indirect immunofluorescence using an antiserum against cardiac myosin. Grains were distributed uniformly over all myocytes. The mean receptor density on atrial myocytes was 83±5 sites/μ^2 and the density on ventricular cells was 81±4 sites/μ^2. The grain density over cells in small aggregates was greater than that over isolated myocytes. Thus, if [^{3}H]-1QNB binding is an adequate measure of functional muscarinic receptors, then reported differences in sensitivity of atrial and ventricular cells to cholinergic agonists must not be related to receptor density.

Saline extracts of embryonic spinal cord and brain produce a 4- to 5-fold increase in the number of nicotinic AChRs and a 40-fold increase in the number of receptor clusters on cultured chick skeletal muscle fibers (PNAS 76,5397-5401, 1979). The same extract produced only a 50% increase in the number of myocardial muscarinic receptors. This small increase could be accounted for by mitogenic effects of brain extract, rather than an effect on receptor densitiy. Thus muscarinic and nicotinic AChR density may be regulated in different ways.

127.14 QUINACRINE BINDING TO MOUSE BRAIN TISSUE IN VITRO: A POSSIBLE METHOD FOR LABELLING HISTAMINE RECEPTORS AND/OR HISTAMINERGIC NEURONS. E. L. Orr* and R. J. Wordinger* (SPON: I. M. Korr). Dept. of Anatomy, North Texas State University/Texas College of Osteopathic Medicine, Fort Worth, TX 76107.

Quinacrine (QC) has been shown to bind to specific cells in peripheral organs and nerves by Ålund and associates [1,2,3]. After an i.v. injection of QC hydrochloride (5 or 10mg/kg), Ålund and Olson[1] reported QC fluorescence of cell bodies in the median eminence, and the supraoptic and paraventricular nuclei of the hypothalamus. We now report the specific binding of QC to neuronal perikarya and processes (axons) after in vitro exposure of brain slices to low concentrations of QC.

Frozen sections (10 microns) of mouse brains were thaw-mounted to microscope slides and incubated for 5-30 minutes at 37°C in 50 to 100 nM QC. Phosphate-buffered saline (pH 7.4) containing 0.68 mM $CaCl_2$, and 0.49 mM $MgCl_2$ and 2.68 mM KCl (PBS) was used as diluent and incubation buffer. After incubation, the tissues were rinsed in ice-cold PBS followed by distilled water (to remove excess salts) and after air-drying approximately 30 min., covered with mineral oil and a coverslip. The fluorescence was viewed with a Zeiss Photomicroscope III equipped for catecholamine and fluorescein isothiocyanate fluorescence.

The granule cell layer of the cerebellar cortex was found to be highly fluorescent, with little or no fluorescence in the molecular layer. Purkinje cells were less fluorescent than granule cells, while the white matter was slightly fluorescent. Apparent ponto-cerebellar fibers were also fluorescent, and at 50 nM QC (30 min. incubation), these fibers were varicose in appearance. At higher concentrations (100 nM QC), these fibers were brightly and evenly fluorescent. Preliminary studies have shown that 100 µM mepyramine (an H_1-receptor antagonist) will block the aforementioned fluorescence (50 nM QC) whereas 100 µM cimetidine (an H_2-receptor antagonist) had no effect. These results suggest that QC may be binding to histamine receptors and/or histaminergic neurons in the CNS.

127.15 GLYCINE RECEPTOR LOCALIZATION IN RAT BRAIN BY RADIOHISTOCHEMICAL METHODS. M.A. Zarbin*, J.K. Wamsley and M.J. Kuhar. Depts. of Pharmacology and Psychiatry, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

Glycine receptors have been identified in the CNS by the direct binding of radiolabeled strychnine to homogenates. We have labeled glycine receptors in mounted tissue sections for the purpose of localizing the receptor by light microscopic autoradiography. The binding of radiolabeled strychnine to tissue sections was kinetically and pharmacologically identical to its binding to homogenates: the binding was saturable, of a high affinity, had the appropriate regional distribution, and the binding of strychnine to tissue sections of spinal cord was displaced by glycine but not by serine, proline, or GABA. Autoradiographs were generated by the apposition of emulsion coverslips as described by Young and Kuhar (Brain Res., 179:225, 1979).

Glycine receptors were concentrated in the spinal cord, medulla and pons. The receptor was widely distributed in the gray matter of the spinal cord. Levels were especially high around motoneurons in the ventral horn and in the substantia gelatinosa in the dorsal horn (laminae II and III of Rexed). In the medulla, high levels of glycine receptors were found in the nuclei of the cranial nerves V (trigeminal) and XII (hypoglossal). In addition receptors were concentrated in the gracile and cuneate nuclei; in the lateral reticular nucleus; in the nucleus intercalatus; and in portions of the inferior olivary nucleus. The lateral reticular nucleus of the medulla (pars ventralis and pars dorsalis) and the nucleus reticularis gigantocellularis showed significant but less striking densities of receptors. In the forebrain, the density of glycine receptors was generally very low or undetectable. Some areas of high receptor density, however, were noted: the parafascicular nucleus of the thalamus and the zona incerta. The nucleus of the lateral geniculate body (pars ventralis) contained a moderately dense population of glycine receptors. These studies should be useful for mapping glycinergic pathways in the brain and suggest an association of glycine receptors with sensory as well as motor pathways in the CNS.

127.16 RELATIONSHIP BETWEEN GABA AND BENZODIAZEPINE RECEPTORS: QUANTITATIVE AUTORADIOGRAPHIC STUDIES. J.R. Unnerstall, J.M. Palacios and M.J. Kuhar. Depts. of Pharmacology and Psychiatry, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

The pharmacological effects of the benzodiazepines (BZ) may be mediated through interactions with the GABA receptor. We have localized both the high affinity GABA receptors and the BZ receptor by light microscopic autoradiography in the rat CNS. The autoradiographic procedure involves the in vitro labeling of mounted tissue sections and the generation of autoradiograms by the apposition of emulsion-coated coverslips. By exposing suitable standards along with these labeled sections, one can relate the autoradiographic grain density to receptor density in terms of pmoles/g tissue.

Standards were constructed by mixing known amounts of non-volatile radioactive compounds with brain tissue ground to a paste. Blocks of tissue paste containing layers of different concentrations of radioactivity were frozen onto microtome chucks. Autoradiographic studies of sections of these blocks (4-10 uM in thickness) revealed that grain density increased linearly with time and concentration of radioactivity up to certain limits. Our routine receptor autoradiographic studies are normally within these limits.

GABA and BZ receptors were labeled as previously described (Palacios, J.M., Young, W.S., III and Kuhar M.J., J. PNAS 77:670, 1980; Young, W. S., III and Kuhar, M.J., J. Pharmacol. Exp. Ther. 212:337, 1980). The in vitro labeling of tissue sections for autoradiography allows for the careful control of the binding parameters. It was clear that the distribution of high affinity GABA and BZ receptors was different. For example, in the diencephalon, there were high densities of GABA receptors in the thalamus while BZ receptor density was high in the hypothalamus. Biochemical studies with our mounted tissue sections showed that GABA potentiated BZ receptor binding in agreement with other laboratories. Autoradiographic studies of the sites of this potentiation revealed that not all regions showed the same increase. For example, BZ receptor binding in the external plexiform layer of the olfactory bulb increased 40% upon exposure to 0.1 mM GABA while the increase in the molecular layer of the cerebellum was about 230%. There results suggest that there is no simple fixed-ratio relationship between the GABA and BZ receptors revealed in these studies. The effect may involve subpopulations of the receptors or even different receptors than the ones labeled under the conditions used in these studies.

127.17 OPIATE RECEPTOR BINDING IN RAT BRAIN SUBCELLULAR FRACTIONS, Bryan L. Roth*, Michael Laskowski and Carmine J. Coscia*, Depts. of Biochemistry and Physiology, St. Louis University School of Medicine, St. Louis, MO 63104.

Recent binding studies involving opiate receptors have utilized crude membrane preparations isolated in hypotonic buffers with little attempt at subsequent purification. Binding phenomena associated with these membranes cannot accurately reflect neuronal processes but are accepted as an approximation. Accordingly, in an effort to contribute to an understanding of the mechanism of action of opiates at the molecular level, we have initiated an investigation aimed at characterizing opiate receptor binding in purified subcellular fractions of rat brain. We have found that two distinct subcellular classes of receptors exist--one associated with a highly purified synaptic plasma membrane (SPM) fraction and the other with a crude microsome preparation (P3). In both fractions, receptor binding was enriched approximately 4-6 fold over crude homogenates. Furthermore, [^{3}H]naloxone and [^{3}H]dihydromorphine displayed high affinity binding with Kd's for naloxone of 1.3 nm (SPM) and 2.9 nm (P3) obtained by Scatchard analysis. The β_{MAX} for SPM and microsomes was 1.08 and .36 pmol/mg protein respectively. Marker enzyme assay revealed opiate binding was highly correlated with acetylcholinesterase activity and desmethylimiprimine-sensitive NE uptake. No correlation was observed with microsomal (NADPH-cytochrome-c-reductase, RNA), mitochondrial (monoamine oxidase), glial (2',3'-cyclic nucleotide phosphohydrolase), or cytosolic (LDH) enzyme activities. Subfractionation of the P3 preparation by continuous sucrose density gradients (18-28%, 200,000 x g, 10 h) revealed 5 distinct protein bands, two containing acetylcholinesterase activity. Additionally, fractions have been monitored by electron microscopy. In conclusion high affinity binding sites for opiate agonists and antagonists have been found to be associated with purified SPM as well as with microsomal preparations. (Supported by NS-12342)

127.18 DIFFERENTIAL DISTRIBUTION OF TYPE I AND TYPE II OPIATE RECEPTORS IN MONKEY CEREBRAL CORTEX. M. E. Lewis,* E. Bragin,* M. Mishkin, C. B. Pert and A. Pert. Biological Psychiatry Branch and Laboratory of Neuropsychology, NIMH, Bethesda, MD 20205

Although opiate receptor density is reportedly low in rat cerebral cortex, some regions of monkey cerebral cortex have been found to contain a relatively high concentration of opiate receptors. Because of the large literature emphasizing the functional and anatomical heterogeneity of monkey cerebral cortex, a detailed study of the cortical distribution of two types of opiate receptors was carried out. Type I and Type II opiate receptors (C.B. Pert and D.P. Taylor, in Endogenous and Exogenous Opiate Agonists and Antagonists, E.L. Way (Ed.), New York, Pergamon, 1980, pp. 87-90) are labeled under appropriate assay conditions by [^{3}H]naloxone and [^{3}H]D-Ala^2,D-Leu^5-enkephalin, respectively.

Rhesus monkeys were anesthetized with sodium pentothal before the brains were removed and dissected over ice into 39 areas which could be ordered into several functional hierarchies (cf. M. Mishkin, Neuropsychologia 17, 139-151, 1979). For example, in the visual system, neuroanatomical, electrophysiological and behavioral evidence indicates that visual information is processed sequentially through a series of cortical loci corresponding to von Bonin and Bailey areas OC (striate cortex), OB (lunate and inferior occipital sulci), OA (prestriate cortex), TEO (posterior inferotemporal cortex), TE (anterior inferotemporal cortex), and ventral TG (temporal pole). The density of stereospecific Type I opiate receptors increased in a gradient along this system from primary sensory cortex (OC) to the temporal pole regions (TG) which relay sensory information to the amygdala. The relative opiate receptor density observed was 1 (OC), 1.3 (OB), 1.7 (OA and TEO), 2.5 (TE) and 4.2 (ventral TG). A similar progression was apparent in the auditory cortical system, with a 3-fold increase in Type I opiate receptor density in the temporal pole (lateral TG) over that in the supratemporal plane (TB and TC). Evidence for receptor gradients was also obtained in the somatosensory and motor systems and in the prefrontal cortex. This pattern of distribution of Type I opiate receptors contrasts markedly with the distribution of Type II receptors labeled by [^{3}H]D-Ala^2,D-Leu^5-enkephalin. The enkephalin-labeled receptors were relatively evenly distributed throughout the cerebral cortex, showing less than a 2-fold variation among the 39 regions. Therefore, the two ligands label clearly different populations of opiate receptors in the monkey cerebral cortex. Discussion will focus on the possible functional implications of the gradients of Type I opiate receptors within hierarchically organized cortical systems.

127.19 OPIATE RECEPTOR DISTRIBUTIONS IN BRAIN SUGGEST "OPIATERGIC" TRACTS. S. Moon Edley,* M. Herkenham, C. B. Pert. Lab. of Neurophysiology and Biological Psychiatry Branch, NIMH, Bethesda, MD 20205

Autoradiographic visualization of specific, high-affinity [^{3}H]naloxone binding to slide-mounted tissue slices shows anatomical localization of opiate receptors in brain. In vitro incubation of serially cut fresh-frozen brain sections in a 4°C medium containing [^{3}H]naloxone in 0.05 M Tris buffer (pH 7.4), 100 mM NaCl and protease inhibitors is followed by rinsing in 4°C phosphate buffer solutions, rapid drying, hot paraformaldehyde vapor fixation and routine autoradiography (Herkenham and Pert, PNAS, in press). The results of this new method compare favorably with previously published techniques, as judged by examination of labeling in the caudate nucleus, where receptor patches stand out in sharp contrast to unlabeled areas. The ease with which in vitro labeling is accomplished suggests that this technique has general applicability for studying receptors in any tissue, including human brain. In rat brain, light microscopic resolution is so striking that close concordances between opiate receptor distributions and patterns of termination of some known tracts can be noticed, suggesting numerous, often sequential "opiatergic" pathways. A previously described five-link neural connection originates in the accessory olfactory bulb and passes to the medial and posterior cortical nuclei of the amygdala and then is sequentially relayed to the bed nucleus of the stria terminalis, the border of the medial and lateral habenular nuclei and, finally, the interpeduncular nucleus and median raphe. This linkage is noteworthy for the close correspondence of patterns of dense opiate receptor labeling with the patterns of termination of these tracts.

Another striking and general phenomenon is that opiate receptors are found within most primary and many secondary sensory nuclei, and are localized to superficial and/or molecular layers in laminated structures. Dense labeling in the superficial laminae of the spinal cord dorsal horn is one example, but localization of receptors in the superficial layer of the superior colliculus and the dorsal cochlear nucleus and in the glomerular and outer plexiform layers of the main and accessory olfactory bulbs are other examples. The "opiatergic" neurons whose axons are presynaptic to these receptors have not been identified but would be expected to functionally affect sensations at early stages of processing. Opiate receptors are also prominent in limbic cortical areas. By their laminated appearance in layers I and III of frontal and cingulate cortices, layer VI of the entorhinal area, and dense localization in the presubiculum, the possiblity of "opiatergic" thalamic or intracortical pathways terminating at these receptor sites can be surmised.

127.20 COMPETITIVE BINDING OF INSULIN TO BOVINE CEREBRAL MICROVESSELS. I. Gozes, Y. Gozes*, T.B. Strom* and M.A. Moskowitz. Lab. of Neural and Endocrine Regulation, MIT, Cambridge, MA 02139, and Immunology Lab. and Section of Neurology, Department of Medicine, Peter Bent Brigham Hospital, Boston, MA 02115.

Insulin receptors have been identified by competitive binding assays within the brain and spinal cord of several mammalian species. A relatively high proportion of these receptors appear by radioautography to be associated with sites on cerebral arterioles and capillaries where they may be important in the regulation of cerebral or cerebrovascular metabolism. In order to examine further the nature of hormone-receptor interaction, we have studied the binding of insulin and its various analogues to a highly purified preparation of isolated arterioles and capillaries from bovine cerebral cortex.

Bovine cerebral microvessels were isolated by isopycnic sucrose gradient centrifugation and molecular sieving and were shown by light and electron microscopy as well as by biochemical criteria to be free of contaminating neuronal and glial cells. The insulin binding to homogenized cerebral microvessels was measured utilizing a competitive ^{125}I-insulin radioreceptor assay. Final separation of microvessel-bound from free insulin was accomplished by centrifugation of the incubation mixture through oil. There was virtually no contamination of the microvessel fraction by free insulin.

Our data show that the amount of ^{125}I-insulin bound by the microvessel homogenate was proportional to the microvessel protein added to the incubation mixture. Between 20-35% of total bound counts was specific, however the displacement of pg amounts of ^{125}I-insulin required the addition of µg amounts of the cold polypeptide. Biologically less potent insulin analogues such as proinsulin or desoctapeptide appeared more active than insulin in their ability to compete with isotopically-bound insulin to the microvessel homogenate. In several preliminary experiments, nerve growth factor (NGF 2.5S and 7S) exhibited the most marked ability to displace insulin from this tissue. Our results suggest that insulin does not bind with high affinity to brain microvessels. However, we cannot rule out the possibility that there are vascular receptors for related molecules such as NGF or somatomedin.

128.1 EVIDENCE FOR ASCENDING ENDORPHINERGIC INHIBITION OF DISTRESS VOCALIZATION. N. Najam*, B.H. Herman* and J. Panksepp (SPON: W. Nelson), Dept. of Psychology, Bowling Green State Univ., Bowling Green, OH 43403.

Electrical brain stimulation (ESB) was employed to map brain distress vocalization (DV) loci in adult guinea pigs, and the inhibitory effects of brain endorphins and serotonin (5-HT) on these DV sites was evaluated.

DVs resembling natural separation DVs were produced by stimulating the dorsomedial thalamus (DMT) and septum/preoptic (POA), whereas stimulation of sites immediately surrounding the mesencephalic periventricular grey (PVG) produced "pain-like" screams. Other areas such as the cortex were free of vocalization loci. Thus, there appear to be specific subcortical emotional vocalization zones in the guinea pig brain.

In other studies, we examined the effects of a variety of drug and ESB mannipulations on DMT and septum/POA DVs. Naloxone increased the frequency of these forebrain derived ESB DVs by about 50% over saline baseline, whereas morphine and quipazine (5-HT agonist) decreased ESB DV frequency. In previous investigations, we found that separation DVs of infant guinea pigs are also increased by naloxone and decreased by morphine (B.H. Herman and J. Panksepp, Pharm. Biochem. Behav., 9: 213, 1978). Therefore, endorphins are inhibitory to natural or brain-elicited DVs.

Analgesic PVG stimulation inhibited DMT and septum/POA DVs by about 50%, and naloxone blocked the effects of analgesic PVG stimulation on DMT DVs. These data provide evidence for ascending endorphinergic inhibition of DMT DV sites, and extend the observations of others indicating that pain as well as brain-elicited DVs are under endorphinergic modulation.

Stimulation of nonanalgesic mesencephalic sites surrounding the PVG produced increases in the frequency of anterior elicited ESB DVs, and these effects were additively potentiated by naloxone pretreatment.

128.2 AFFERENT AND EFFERENT CONNECTIONS OF THE ORGANUM VASCULOSUM OF THE LAMINA TERMINALIS: A HORSERADISH PEROXIDASE (HRP) STUDY. Arturo Camacho* and M. Ian Phillips (SPON: W.J. Steele). Dept. of Physiology, Univ. of Iowa, Iowa City, IA 52242.

The organum vasculosum of the lamina terminalis (OVLT) is a single structure in the anterior ventral part of the brain lying immediately above the optic chiasm and below the anterior commissure. The OVLT has been proposed as a receptor site for the central dipsogenic, blood pressure and antidiuretic effects of angiotensin II (AngII).

In the present report, we have approached the OVLT ventrally through the optic chiasm to eliminate damage to structures dorsal to the OVLT and pressure injected 10-15 nl HRP (20% w/v) using a 1 µl Hamilton syringe with a glass micropipette glued to the needle. Following a 24 hour post-injection period, the animals were transcardially fixed (Karnovsky fixative) and brains removed. The rat brains were cut in 40 µ sections coronally, sagittally, or horizontally, and processed by the tetramethyl benzidine (TMB) method, with alternate sections near the site of injection processed by the diaminobenzidine (DAB) method. The brain sections were counter-stained with neutral red for the TMB sections and with methylene blue for the DAB sections. Table I summarizes the results of 12 male Sprague-Dawley rat brains.

TABLE I

Brain Area	Cell Bodies	Fibers
Subfornical organ	+++	+
Nucleus medianas	++	+++
Medial preoptic	+++	++
Supraoptic	+	++
Ventromedial nucleus	++	
Lateral hypothalamus	++	
Arcuate nucleus	+	
Pericallosal region		+++
Lateral preoptic	+++	+++
Hippocampus		+
Septum	+	+++
Locus coeruleus	+	
Central gray	+	

In conclusion, the HRP-positive perikarya and fibers confirm a neural connection between the OVLT and the subfornical organ (Miselis et al., Science 205:1022, 1979), both of which have been reported to be AngII receptor sites. The retrograde and anterograde transport of HRP revealed hypothalamic as well as extrahypothalamic connections of the OVLT, which may be related to the homeostatic functions of this structure.

128.3 NEONATAL HANDLING STRESS AND ACTH 4-10 ADMINISTRATION AFFECT ADULT ACTH-INDUCED GROOMING BEHAVIOR IN RATS. D.L. Colbern*, S.M. Dray, A.N. Taylor and E.G. Zimmermann. Neuroscience Program, Brain Research Inst. and Depts. of Psychology and Anatomy, UCLA and Brentwood V.A. Med. Ctr., Los Angeles, CA 90024.

Drug or environmental manipulations of neonatal rats alter adult behavioral and physiological responsivity to stressful stimuli. The present study examined effects of neonatal handling stress and exposure to ACTH 4-10 on adult grooming behavior induced by intracerebroventricular (ICV) injection of ACTH 1-24 in male Sprague Dawley rats.

Two types of early handling stress were produced by daily injection of 0.1 ml saline sc on postnatal days 7-9, using either 1) a standard injection procedure where pups are removed from the nest, placed on a heating pad, injected and returned as a group to the dam, or 2) a huddled injection procedure where the dam is removed from the cage, the pups injected in the nest under an external heat source and the dam returned at the end of the procedure. Rats, unhandled neonatally, served as additional controls. At 85 days of age, all animals were implanted with a polyethylene cannula and, 6 days later, injected ICV with 0.3 µg ACTH 1-24 in 2 µl saline or 2 µl saline. Animals were placed individually into novel observation chambers and, beginning 15 min postinjection, grooming was measured for 50 min using a time sampling technique.

Animals given saline neonatally by the standard injection procedure failed to show adult ACTH-induced grooming when compared to controls given ICV saline ($p > .05$) and they exhibited less peptide induced grooming than did unhandled controls ($p < .01$) or animals injected with saline in the huddle ($p < .05$). The huddle-injected animals did not differ from the unhandled controls ($p > .05$), both groups showing marked increases in grooming response to ICV ACTH 1-24 when compared to their ICV saline injected controls ($p < .01$).

In preliminary studies, pups given 10 µg ACTH 4-10 in 0.1 ml saline on days 7-9 showed intact adult excessive grooming to ICV ACTH 1-24 when compared to controls which were either unhandled or injected with saline in the huddle. Thus, in contrast to animals given saline on days 7-9, those given ACTH 4-10 by the standard injection procedure showed unimpaired adult grooming levels.

These findings demonstrate that neonatal handling stress can modify adult peptide-induced behavior and that quality and/or quantity of the early stress is important for the manifestation of this long-lasting peptide induced behavioral effect. Moreover, neonatal exposure to ACTH 4-10 seems to interfere with the action of early stress on the development of such effects. These findings support previous hypotheses that protracted neuroendocrine and behavioral effects of neonatal stress and ACTH 4-10 are mediated by altered functional organization of the brain. (Support: March of Dimes Birth Defects Fdn. and USPHS Grant NIAAA-03513.)

128.4 EFFECT OF BOMBESIN ON BODY TEMPERATURE IN AWAKE AND HIBERNATING GROUND SQUIRRELS. Delphi M. Toth. Dept. of Anat. Sci., Coll. of Med., Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK 73190.

There is considerable evidence that numerous brain and gastrointestinal peptides, including the opioid peptides, have potent effects on body temperature (T_b) in non-hibernating species. Bombesin, a tetradecapeptide isolated from anuran skin, has been shown to be one of the most potent substances affecting thermoregulation. At doses as low as 1 ng administered intracisternally or intraventricularly, bombesin produces dramatic reductions in T_b in cold-exposed rats. Bombesin hypothermia is reversed by naloxone. However, the effect of bombesin on hibernation is unknown.

Mammalian hibernation represents a highly effective strategy for prolonged survival under adverse climatic conditions of cold and starvation. From spring through early fall, these mammals are active and euthermic, maintaining a T_b of approximately 38°C. During the winter these same mammals appear to abandon euthermia as T_b drops to near 0°C and they become dormant. Throughout the winter they hibernate in bouts of 7-12 days duration, with a return to a T_b of 38° during the brief arousals between bouts. The ability to rewarm from nearly 0° to about 38° against the thermal gradient at any time (e.g., in response to sensory stimuli or adverse conditions) distinguishes hibernation from poikilothermia or hypothermia.

In order to determine the effect of bombesin on T_b throughout the hibernation cycle, cannulae were implanted into the cisterna magna of adult golden-mantled ground squirrels (*Spermophilus lateralis*). Ground squirrels were then placed into a cold room (5°C) and permitted to hibernate. Thoracic temperature, heart and respiratory rates, and oxygen consumption were monitored continuously, before and after administration of the peptide.

Bombesin produced a sharp and prolonged decrease in T_b when administered to animals during periods of wakefulness between bouts of hibernation. On several occasions, animals re-entered hibernation without regaining euthermia, but the ensuing bout of hibernation did not appear to be unusual. In hibernating animals, bombesin produced only slight decreases in T_b, however these animals continued to hibernate for approximately one week beyond the expected time of re-awakening. These protracted bouts of hibernation ended in death in 1/4th of the cases, apparently due to an inability to arouse against the thermal gradient. Animals rewarmed artificially proceeded to the next bouts of hibernation without ill effect. Further, hibernating ground squirrels receiving bombesin could not be made to arouse by intense sensory stimuli, as can untreated hibernators. This may have been due to the known analgesic effect of bombesin.

128.5 ENDOGENOUS OPIOID PEPTIDES MAY REDUCE SELECTIVE ATTENTION. Amy F.T. Arnsten and David S. Segal. Psychiatry Dept., Sch. of Med., Univ. of Calif., San Diego, La Jolla, CA 92093.

The effects of morphine and naloxone were examined on the behavioral response pattern of rats in a novel environment. After injection of saline, naloxone, or morphine, rats were monitored for locomotion and frequency and duration of contact with stimuli in a multicompartment chamber. In agreement with previous studies, naloxone at doses as low as 0.25 mg/kg increased both the total duration of contact and the average time spent per contact with stimuli in the environment. Conversely, morphine induced a dose-related reduction in both total duration contact and the average time spent per contact with these stimuli. This reduction was apparent at doses of morphine which produce hyperactivity (0.5-2.0 mg/kg) and hypoactivity (5 and 10 mg/kg), thus indicating the effect is independent of locomotor response. The concurrent administration of 0.25 mg/kg naloxone and 10 mg/kg morphine produced a response indistinguishable from saline controls. In addition, the enantiomer (+)-naloxone (0.5 mg/kg), which is devoid of opiate antagonism, had no effect on stimulus interaction. These results indicate a role for endogenous opioid systems in environmental stimulus interaction. Furthermore, these data suggest that opioid peptides may be involved with selective attention. The time spent per contact with stimuli index can be viewed as a model of selective attention; longer contacts, such as those induced by naloxone, are associated with focused activity, while the briefer contacts exhibited by morphine treated rats are affiliated with distraction. This hypothesis is supported by clinical reports that morphine produces an inability to concentrate in humans. The effects of naloxone on human selective attention and the involvement of locus coeruleus neurons in the naloxone response will be discussed. (Supported by USPHS Grants DA-01994-02 and MH-30914-03 and NIMH Research Scientist Award MH-70183-07 to D.S.S.)

128.6 DRUG-INDUCED SELF-BITING IN RODENTS AS MODELS FOR SELF-MUTILATION IN HUMANS. K. Mueller[a]. Dept. of Psychology, Univ. of Arizona, Tucson, AZ. 85721.

Self-mutilation is a behavioral characteristic of two syndromes associated with physiological abnormalities, the de Lange syndrome and the Lesch-Nyhan syndrome. Several drugs have been reported to produce self-biting in rats or mice. If the behavioral characteristics of drug-induced self-biting in rodents are similar to those of self-mutilation in humans, the same neurochemical mechanisms may be involved in both. Self-biting was induced in rats by oral administration of 140 or 220 mg/kg pemoline or by chronic caffeine (185 mg/kg/day) and in mice by 40 mg/kg clonidine. Pemoline reliably induced self-biting in rats; self-biting occasionally became so severe that animals were euthanized before completion of testing. Self-biting was behaviorally indistinguishable from stereotyped grooming and the most common targets were the medial digits or the dorsomedial aspect of the foreleg. Self-biting was accompanied by highly stereotyped behaviors, "hyperactivity", abnormal social behavior, abnormal sensorimotor behavior, and unresponsiveness or avoidance of moderate levels of sensory stimulation. Self-biting was very persistent but was somewhat environmentally modifiable. De Lange patients are also hyperactive, exhibit stereotyped behaviors, and exhibit abnormal social behaviors. Their self-biting can be controlled by punishment. Preliminary data indicated that intracranial hypoxanthine reduced the severity of pemoline-induced self-biting and normalized behavior to some degree, perhaps due to its benzodiazepinergic actions. Lesch-Nyhan patients exhibit high cerebrospinal fluid hypoxanthine levels and their self-biting cannot be controlled by punishment.

14 days of caffeine administration resulted in very mild self-biting of the dorsomedial aspect of the foreleg of 7% of treated rats. Behavior of these animals appeared normal. Clonidine induced relatively brief self-biting of the medial digits of the foreleg of 30% of treated mice. Self-biting only occurred in the absence of other objects to bite. This behavior was accompanied by a severe tremor and by sympathetic arousal.

Caffeine-induced self-biting is a poor animal model for practical reasons. Clonidine-induced self-biting appears to be a poor model because of the importance of biting per se. Pemoline-induced self-biting appears to be a good model for the behavioral aspects of the de Lange syndrome. A combination of pemoline and hypoxanthine may provide a behavioral model for the Lesch-Nyhan syndrome.

128.7 A MULTIVARIATE APPROACH TO THE CLASSIFICATION OF PSYCHOACTIVE DRUGS USING OPERANT RESPONSE MEASURES. Cynthia H. Walker*, William O. Faustman*, Stephen C. Fowler, and David B. Kazar*. Department of Psychology, University of Mississippi, University, MS 38677.

The aim of the present research was to evaluate the classificatory power afforded by the conjoint measurement of response rate and response duration as opposed to a univariate analysis based exclusively on response rate. Chosen for study in this context were several psychoactive drugs (chlorpromazine, haloperidol, chlordiazepoxide, & pentobarbital) which, despite their pharmacological differences, produce similar dose-related decreases in rate of responding on simple fixed-ratio schedules of reinforcement. The two multivariate techniques of factor analysis and linear discriminant analysis were used to describe the data. Factor analysis was employed to assess the relationships among the two operant variables, their higher-order components, and their nonadditive components regardless of drug class, and linear discriminant analysis was applied to the data to determine the usefulness of these variables in separating the four different drugs from one another.

Twenty-four rats were divided into four groups of six animals each and were administered either chlorpromazine (1.0, 2.0, & 4.0 mg/kg), haloperidol (.06, .125, & .25 mg/kg), chlordiazepoxide (2.5, 5.0, & 10.0 mg/kg), or pentobarbital (2.5, 5.0, & 10.0 mg/kg), with each group receiving only one drug. All drugs were administered intraperitoneally 30 minutes prior to the operant session, and three drug-free days (including one saline control day) separated the drug assessments. The reinforcement schedule which maintained the lever pressing behavior was a simple fixed-ratio 10, with a session length of 10 minutes.

Factor analysis demonstrated that there were no major redundancies between the rate and duration variables--a finding which indicates that useful and nonoverlapping information regarding the drug effect was provided by both response rate and response duration. Further, linear discriminant analysis clearly separated the four drugs into three distinct classes: neuroleptic, chlordiazepoxide, and pentobarbital. Under the conditions of this experiment discriminant analysis was not able to separate chlorpromazine from haloperidol.

These findings demonstrate the importance of considering operant response duration along with response rate in characterizing the differences in behavioral effects produced by various pharmacological agents. Moreover, the present work also points up the appropriateness of applying multivariate statistical techniques to data obtained in behavioral pharmacology experiments.

128.8 EFFECT OF PRENATAL HALOPERIDOL TREATMENT ON THE ONTOGENY OF LOCOMOTOR ACTIVITY IN RAT PUPS. James M. O'Donnell* and Lewis S. Seiden. Department of Pharmacological and Physiol. Sciences, The University of Chicago, Chicago, IL 60637.

Prenatal administration of haloperidol causes alterations in the ontogeny of locomotor activity in rat pups. It has been proposed that the normal development of locomotor activity in the rat depends on the development of dopaminergic pathways in the brain. This suggests that prenatal alteration of the developing dopamine systems could lead to profound changes in the ontogeny of locomotor activity. This prompted us to investigate the effect of prenatal treatment with the dopaminergic receptor antagonist haloperidol on the development of locomotor activity in rat pups. Haloperidol (vehicle, 0.5,1.0,2.0 and 4.0 mg/kg/day) was administered s.c. twice daily to female rats from the fourth day of pregnancy until the birth of the pups. Male pups were selected for experimental use and were fostered with vehicle-treated mothers. Locomotor activity was measured daily in one hour sessions. Pups were temporarily removed from the mother and placed in individual stabilimeter cages. Vehicle-treated pups showed the characteristic pattern of locomotor activity ontogeny. Locomotor activity increased progressively between ages 8 and 15 days, and then gradually decreased with further increases in age. We found that: 1) prenatal treatment with haloperidol from 0.5 to 2.0 mg/kg/day dose-dependently increased the peak level of locomotor activity during its development while 4.0 mg/kg/day caused a slight reduction; 2) prenatal haloperidol administration shifted the locomotor activity peak to later ages in a dose-dependent manner; 3) the within-session distribution of locomotor activity was altered by prenatal haloperidol treatment at those days of age when the experimental pups were hyperactive in that experimental pups had a greater proportion of activity counts in the latter portions of the session than did controls. These results suggest that pharmacological manipulation of the central dopaminergic systems with prenatal haloperidol treatment can alter the ontogenetic pattern of locomotor activity. Such a finding provides support for the hypothesis that dopamine neurons are involved in the ontogeny of locomotor activity. (Supported by USPHS Grants MH-11191; RSA MH-10562).

128.9 ANTICHOLINERGIC AND ANTICHOLINESTERASE EFFECTS ON A REPEATED ACQUISITION BASELINE. D.M. Penetar* (SPON: J. McDonough), USA Biomedical Laboratory, Aberdeen Proving Ground, MD 21010.

The operant learning paradigm of repeated acquisition has been the subject of much psychopharmacological research (Harting & McMillan, Psychopharmacology, 1976, 49, 245; Thompson & Moerschbaecher, Environ. Health Persp., 1978, 26, 77). Representative drugs from the stimulant, sedative-hypnotic, major and minor tranquilizer classes have been systematically studied for their effects on learning and performance behaviors during this paradigm. The anticholinergics and anticholinesterases have received scant attention however.

Cynomolgus monkeys were trained to emit a four member chain of key presses. Three backlit pushbutton keys were simultaneously transluminated with either red, yellow, green or blue stimulus colors (in that order). A correct response advanced the color sequence. Four repetitions of the sequence (16 correct responses) was required for reinforcement to occur. Correct sequences changed daily. Session length was 100 reinforcers. The effects of atropine (0.014, 0.044, 0.14, 0.44 mg/kg) and physostigmine (0.025, 0.050, 0.075 mg/kg) were assessed. Preinjection times were equated for onset of central effects. Atropine was injected 45 min prior to the session while physostigmine was injected 15 min prior.

Four measures of learning and performance were analyzed: 1) Session Time - minutes required to earn 100 reinforcers: 2) Trials to Criterion - the number of 16 response chains (trials) required to emit three consecutive chains at 90% correct or better; 3) Errors to Criterion - the number of incorrect responses emitted until criterion was reached; 4) Performance Errors - the number of incorrect responses emitted during the session after the learning criterion was reached. Results are summarized below:

Atropine	Baseline	0.014	0.044	0.14	0.44 mg/kg
Session Time (minutes)	42 ± 3	44	36	45	203
Trials to Criterion	7 ± 0	6	5	5	15
Errors to Criterion	25 ± 2	33	14	17	78
Performance Errors	23 ± 16	25	16	44	295

Physostigmine	Baseline	0.025	0.050	0.075 mg/kg
Session Time (minutes)	39 ± 7	46	50	111
Trials to Criterion	7 ± 1	10	6	12
Errors to Criterion	26 ± 6	46	49	81
Performance Errors	15 ± 9	20	22	41

The physostigmine results do not support reports of enhanced learning by anticholinesterase compounds. Atropine results indicate that anticholinergic compounds may have a biphasic effect on learning.

128.10 DIFFERENTIAL ACTIONS OF "CLASSICAL" AND "ATYPICAL" ANTIPSYCHOTIC DRUGS ON NEURONS IN THE AMYGDALOID COMPLEX. Kevin D. Alloway, George V. Rebec and Theodore R. Bashore. Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

Whereas haloperidol and other "classical" antipsychotic drugs produce immobility, rigidity, and other motor dysfunctions, "atypical" antipsychotics like clozapine are devoid of these effects. We have previously shown that despite these behavioral differences haloperidol and clozapine exert comparable effects on neuronal activity in the neostriatum and nucleus accumbens (Rebec et al., Pharmacol. Biochem. Behav., 1979, 11:529; Neuropharmacology, 1980, 19:281). To further elucidate the brain mechanisms underlying the differential behavioral actions of these antipsychotics, we extended our analysis to the amygdaloid complex. Single unit activity, recorded from immobilized, locally anesthetized rats (350-450g), was amplified and displayed by conventional means. Data were obtained from 70 amygdaloid neurons recorded bilaterally from 48 experimental animals. Haloperidol, clozapine, or d-amphetamine was injected via an in-dwelling intraperitoneal catheter.

At a dose known to elicit catalepsy in rats (2.0 mg/kg), haloperidol failed to change the firing rate of 12 of 13 neurons (the activity of 1 unit was increased by the drug). In contrast, 20.0 mg/kg clozapine, which is devoid of extrapyramidal side effects, produced a prolonged increase in activity in 10 of 19 neurons (7 neurons were unresponsive and 2 units were inhibited by clozapine). In a separate series of animals, 1.0 mg/kg d-amphetamine inhibited the firing rate of 28 of 38 neurons in the amygdaloid complex (3 units were accelerated and 7 neurons were unresponsive to the drug). A subsequent injection of 2.0 mg/kg haloperidol failed to block the amphetamine-induced depression in 8 of 9 neurons, whereas 20.0 mg/kg clozapine reversed this response in every case.

Our results indicate that in sharp contrast to the similar effects of haloperidol and clozapine on unit activity in the neostriatum and nucleus accumbens, neurons in the amygdaloid complex are more responsive to "atypical" than to "classical" antipsychotic drugs. It is conceivable, therefore, that the differential behavioral effects of these drugs are mediated, at least in part, by the relative inability of the "classical" antipsychotics to alter neuronal activity in the amygdaloid complex.

This research was supported, in part, by USPHS Grant DA-02451-02 from the National Institute on Drug Abuse.

128.11 ACUTE EFFECTS OF NEUROLEPTICS ON LOCOMOTOR ACTIVITY IN RATS. Gerald J. Schaefer and Richard P. Michael, Dept. Psychiatry, School of Medicine, Emory University and Georgia Mental Health Institute, Atlanta, GA. 30322.

We have previously examined (Psychopharmacology, 67, 9-15, 1980) the acute effects in rats of a series of neuroleptic drugs on brain self-stimulation current thresholds. The titration procedure allowed us to distinguish between the effects of neuroleptics on central reinforcement thresholds and on behavioral performance. The present experiments were performed to evaluate further this series of neuroleptics on motor behavior. The locomotor activity of rats was recorded during 10-min sessions in a circular open-field apparatus after the administration of vehicle or drug. Dose-response curves were obtained for five neuroleptic drugs alone and in combination with 1.0 mg/kg of d-amphetamine. Pretreatment times for the neuroleptics were between 45 min and 4 hr as previously described and d-amphetamine was administered 15 min before the start of the test session. Haloperidol (0.01-0.10 mg/kg) produced a dose-dependent decrease in locomotor activity, as well as a dose-dependent blockade of the increase in locomotor activity produced by d-amphetamine. However, the lowest dose of haloperidol in combination with d-amphetamine resulted in a greater increase in locomotor activity than did d-amphetamine alone. Pimozide (0.1-1.75 mg/kg) and loxapine (0.03-0.56 mg/kg) produced marked reductions in locomotor activity over their entire dose-response curve, together with a marked attenuation of d-amphetamine's effects. Over the dose range 0.1-3.0 mg/kg, clozapine did not significantly reduce locomotor activity when administered alone, nor did it attenuate the increase in locomotor activity produced by d-amphetamine. Chlorpromazine (0.1-3.0 mg/kg) produced a dose-dependent decrease in locomotor activity as well as in the d-amphetamine-induced increase in locomotor activity. Thus, neuroleptics differ with respect to their effects on locomotor activity as well as in their effects on reinforcement thresholds. Further, the changes in locomotor activity described here did not necessarily correlate with the response rate measure previously observed in our brain self-stimulation procedure. These data suggest that, while the neuroleptics alter locomotor activity, the changes in central reinforcement thresholds produced by these drugs are not solely a reflection of such changes. Therefore, the data on locomotor activity help us further in interpreting the relation between the chemical and clinical potency of neuroleptics.

128.12 **POSTSYNAPTIC ACTION OF ANTIDEPRESSIVE DRUGS AS MEASURED BY ACUTE TREATMENT EFFECTS ON AN ANIMAL MODEL OF DEPRESSION.** **H. Nagayama*, J.N. Hingtgen* and M.H. Aprison. Institute of Psychiatric Research and Depts. of Psychiatry and Biochemistry, Indiana University School of Medicine, Indianapolis, IN 46223**

In order to reconcile the conflicting animal data and clinical data, i.e. suppression of animal behavior is caused by an increase in 5-HT in the synaptic cleft, whereas human depression is associated with a deficiency of the cerebral serotonin system, a new theory was developed. This theory suggests that in some types of human depression, a hypersensitive postsynaptic receptor develops in these individuals due to a decreased release of 5-HT. Then, at some later date, a stress factor causes an increased release of 5-HT which now interacts with the supersensitive postsynaptic receptors. In the animal model, excess 5-HT from its precursor also increases in the cleft. In both cases, an increased release of 5-HT occurs when compared to the normal state (Aprison et al., In: Neuropharmacology and Behavior, Plenum Press N.Y., 1978). One way to test this theory is to demonstrate that one or more of the currently used antidepressive drugs blocks the 5-HTP induced depression in our animals acting through postsynaptic rather than presynaptic mechanisms. Rats working on a variable interval one minute (VI 1) schedule for milk reinforcement and exhibiting behavioral depression following administration of 50 mg/kg 5-HTP (I.P.) were pretreated (one hr before the 5-HTP injection) with fluoxetine (5 mg/kg I.P.) or methysergide (5 mg/kg I.P.) to establish a behavioral basis for distinguishing between pre- and postsynaptic events, respectively. Fluoxetine, a known specific uptake blocker of 5-HT, potentiated the depressive effect of 5-HTP by about 200%. Methysergide, a postsynaptic blocker of 5-HT, almost completely (93%) abolished the depressive effect of 5-HTP. Pretreatment (a 5 mg/kg dose given one hr before the 5-HTP injection) with amitriptyline, one of the commonly prescribed antidepressive drugs, reduced the behavioral depression following 5-HTP by approximately 50%. These data indicate that amitriptyline can act as an antagonist of 5-HT at the postsynaptic serotonin receptor. The effects of amitriptyline were compared to those of other antidepressive drugs (imipramine, mianserin, and iprindole) when used with the same model of depression. The results of this study, as well as those recently reported from CNS membrane binding studies, suggest that the therapeutic effects of some antidepressive drugs may be explained by their postsynaptic rather than presynaptic properties at central serotonergic receptors. Thus, these studies support a major portion of the hypothesis noted above. (Supported in part by PHS Research Grant MH-03225-20 from NIMH).

128.13 CHRONIC SPIROPERIDOL OR THIORIDAZINE TREATMENT: DIFFERENTIATION IN EFFECTS ON PREFRONTAL CORTEX SELF-STIMULATION. T. B. Wishart. Dept. Psychology, Univ. Saskatchewan, Saskatoon, Saskatchewan, Canada, S7N 0W0.

Rats with electrodes implanted in the dopamine-rich area of the prefrontal cortex were trained to self-stimulate in a photo-beam interruption task. Each animal, in addition to controlling the total number of brain stimulations per test by stepping into and out of the photo-beam, regulated its own duration of brain stimulation per response. Following training and the establishment of baseline levels of responding the animals were divided into groups to receive chronic spiroperidol (0.05 mg/kg/day), chronic thioridazine (10 mg/kg/day) or chronic saline. Two self-stimulation tests were given daily, one immediately prior to drug administration, the second test one and one-half hours later.

Spiroperidol administration inhibited self-stimulation rates and durations by comparable amounts (40-60%) throughout the 28 days of chronic drug treatment. Rates and durations of self-stimulation in the daily pre-drug tests were 60-80% of baseline values.

Chronic thioridazine administration resulted in progressive deterioration of self-stimulation. Initial injections (days one and two) reduced rates and durations to 70% of baseline values but, with continued injections, rates and durations fell to below 10% of baseline levels. Daily pre-drug self-stimulation rates and durations also progressively diminished as chronic thioridazine administration continued, but at a slower rate and the depressions obtained in these tests (60-70%) were not as pronounced as those observed immediately after drug injections.

These results provide support for the supposition that atypical neuroleptics, more so than the typical antipsychotics, strongly affect the meso-cortical dopamine system.

128.14 DIFFERENTIAL EFFECTS OF 17β-ESTRADIOL, 5α-DIHYDROTESTOSTERONE, AND TESTOSTERONE ON DRUG-INDUCED LOCOMOTION IN CASTRATED RATS. F.S. Mennitti*, B. Rudorfer* and M.J. Baum. Department of Nutrition and Food Science, MIT, Cambridge, MA 02139.

The ability of testosterone (T), and its neural metabolites, 17β-estradiol (E_2) and 5α-dihydrotestosterone (DHT), to modulate the functional activity of mesolimbic, dopaminergic synapses was assessed in castrated male rats by studying the ability of chronic treatment with each steroid to affect locomotor activity induced by D-amphetamine sulphate or apomorphine sulfate. The stimulatory action of a single injection of D-amphetamine (1.5 mg/kg) on locomotor activity was significantly augmented in castrated rats implanted s.c. with silastic capsules containing E_2, but not in rats implanted with T or DHT. In another experiment castrated rats received bilateral injections of 6-hydroxydopamine into the nucleus accumbens. In subsequent behavioral tests the ability of apomorphine (1 mg/kg) to stimulate locomotion was significantly heightened in rats previously implanted s.c. with silastic capsules containing E_2, as opposed to T or DHT. This action of E_2 could not be duplicated by chronic infusion of 2 hydroxyestradiol from minipumps implanted s.c. in other castrated males. Groups of neurologically intact, castrated rats implanted with T, E_2, or DHT displayed equivalent levels of stereotyped behavior in response to increasing doses (1,2, or 4 mg/kg) of apomorphine, suggesting that these sex steroids had no differential effects on the metabolism of this dopamine receptor agonist. Taken together, the results suggest that estrogenic metabolites of T may facilitate functional activity at mesolimbic, dopaminergic synapses by augmenting postsynaptic neuronal responsiveness.

(Supported by N.I.H. grant HD 12002)

128.15 CHOLINERGIC AND SEROTONERGIC MECHANISMS AND PASSIVE AVOIDANCE LEARNING IN YOUNG CHICKS. Bruce A. Mattingly* and James F. Zolman. Physiology and Biophysics, Medical Center, University of Kentucky, Lexington, Ky. 40536.

The main objectives of this research were: a) to determine whether cholinergic and serotonergic mechanisms are involved in passive avoidance (PA) learning of the young chick; and b) to determine whether developmental changes in cholinergic and/or serotonergic functioning could account for the age-dependent changes in PA learning reported previously between 1- and 4-day-old chicks.

In six experiments, Vantress x Arbor Acre chicks were trained to key-peck for heat reinforcement when 4 days old and then administered response-contingent wing-shock during PA testing. Acute intraperitoneal (IP) injections of different doses of scopolamine and atropine were used to study cholinergic mechanisms, and chronic IP injections of different doses of para-chlorophenylalanine (PCPA) were used to study serotonergic mechanisms.

Major findings were as follows: a) chicks injected with .5 mg/kg scopolamine or 1.0 mg/kg atropine were disrupted in PA learning as compared to saline-injected control chicks; b) chicks pre-treated with PCPA (3- or 5-injections of 75- or 150-mg/kg) over the first three posthatch days did not significantly differ from saline control chicks during PA testing when 4 days old; c) PCPA pre-treatments did not significantly affect the scopolamine-induced disruption in PA learning; and d) scopolamine-treated chicks, like saline control chicks, suppressed responding less in PA tests when given delayed, rather than immediate, punishment.

These findings suggest that cholinergic, but not serotonergic, mechanisms are involved in PA learning in the young chick. Moreover, the significant delayed-punishment effect in scopolamine-treated chicks suggests that scopolamine does not interfere with the chick's sensitivity to the stimulus- and/or response-shock contingencies in PA tests, and therefore, the disruption in PA learning may be best explained as a scopolamine-induced decrease in the chick's ability to withhold a prepotent response. Finally, a comparison of the behavior of the scopolamine-treated 4-day-old chick with that of the untreated 1-day-old chick on these tasks suggests that the deficient PA performance of these two groups is related to deficits in different behavioral processes. Consequently, maturational changes in cholinergic mechanisms apparently cannot account for the age-dependent changes in PA learning observed previously in the chick.

128.16 SELECTIVE EFFECTS OF ACUTE AND CHRONIC CAFFEINE ON SCHEDULE PERFORMANCE IN RATS. P.S. McGuire, S.H. Snyder, and Z. Annau. Division of Toxicology and Department of Pharmacology, The Johns Hopkins University, Baltimore, MD. 21205

Caffeine is a central nervous system stimulant which is widely and chronically consumed. Chronic caffeine use may result in the development of a degree of tolerance, although this, and its other behavioral effects, are poorly understood. The differential-reinforcement-of-low-rates schedule (DRL) allows the determination of response and reinforcement rates, as well as response patterning (interresponse time (IRT) distribution), and is well suited for a behavioral assessment of caffeine.

Adult male Long-Evans rats were water deprived for 23 hr and trained to press a response lever for .05 ml water under a DRL >18-sec schedule. This schedule requires the rat to space its responses at intervals greater than 18-sec. In the dose response phase, rats received caffeine (2.9, 16.6, or 50.0 mg/kg, i.p.) prior to the experimental session, while rats in the chronic phase received daily caffeine (16.6 mg/kg, i.p.) injections prior to testing.

The dose-response experiment showed selective disruption of aspects of DRL performance as a function dose. Caffeine at 2.9 mg/kg had little effect on any behavioral measure, while 50 mg/kg decreased both responses and reinforcements. The 16.6 mg/kg showed selective behavioral disruptions, increasing the number of responses occurring before the end of the 18-sec interval, thereby decreasing the number of reinforcements obtained by the animal.

Rats receiving daily caffeine (16.6 mg/kg, i.p.) injection displayed an initial and selective tolerance to the drug on the second day. The measure of response rate, but not number of reinforcements, was sensitive to this tolerance effect. While response rate returned to normal, the number of reinforcements in the chronic caffeine group stayed below baseline during the 21 day treatment regimen. Thus, different behavioral parameters are uniquely sensitive to the development of tolerance to caffeine.

128.17 XANTHINES ALTER BEHAVIOR MAINTAINED BY INTRACRANIAL ELECTRICAL STIMULATION AND OPERANT SCHEDULES. Z. Annau, J.J. Valdes, P.S. McGuire, and S.H. Snyder. Division of Toxicology, and Department of Pharmacology, The Johns Hopkins University, Baltimore, MD. 21205

The widespread recreational and therapeutic use of caffeine and related xanthines has led to increasing concern regarding the health effects of these chemicals. In behavioral studies both response rate enhancing and attenuating effects have been described, depending on the dose of caffeine and the behavioral measure used. In the present experiments, intracranial self-stimulation (ICSS) and differential-reinforcement-of-low-rates of responding (DRL) for water were chosen because of their demonstrated sensitivity to psychotropic drugs.

Male Long-Evans hooded rats were used in all experiments. Rats in the ICSS experiment were stereotaxically implanted with unilateral bipolar stimulating electrodes in either the substantia nigra (SNC) or the medial forebrain bundle (MFB). They were trained to press a bar for electrical stimulation on a continuous reinforcement schedule for one hour per day. Injections of saline or xanthines (caffeine, theophylline, theobromine, or ethyl-7-theophylline-acetate) at doses of 1.0, 2.9, 16.6, or 50.0 mg/kg, i.p., were given 10 minutes prior to behavioral testing. Between days of drug injections, the rats were tested without drugs to insure that their performance had returned to baseline levels. Rats performing for water reinforcement on a DRL> 18-sec schedule required the rat to space its responses at least 18-sec apart.

Theobromine and ethyl-7-theophylline-acetate were ineffective at any dose, on any behavioral measure. Caffeine and theophylline exhibited dose-dependent potentiation of ICSS, with theophylline being more potent. Rats with implants in the SNC showed a greater enhancement of ICSS as a function of drug treatment than rats with implants in the MFB. Both caffeine and theophylline increased response rates and decreased reinforcements on the DRL>18 schedule although the magnitude of this effect was less than was seen in the ICSS paradigm. The ICSS measure was thus slightly more sensitive to alterations induced by the drug treatments. The different neurochemical substrates of ICSS maintained by stimulation in the SNC and MFB, along with appropriate pharmacological manipulations, have the potential for use in the assessment of the underlying biochemical and behavioral mechanisms of this class of drugs.

128.18 THE EFFECT OF TAIL PINCH ON THE ACOUSTIC STARTLE RESPONSE IN RATS. N. R. Swerdlow* and C. A. Sorenson, Neuroscience Program, Amherst College, Amherst, MA 01002.

The amplitude of the ASR appears to be modulated by CA neural systems. Previous studies have shown that treatment with apomorphine (Davis & Aghajanian, Psychopharm., 47: 217, 1976) or with amphetamine (Davis et al., Psychopharm., 47: 1, 1975) augments ASR and that this effect is blocked by treatment with haloperidol (Davis & Aghajanian, 1976), pimozide (Kehne & Sorenson, Psychopharm., 58: 137, 1978), or AMPT (Davis et al., 1975). A role for NE neurons is suggested by the observation that phenoxybenzamine lowers startle baseline and blocks the stimulating effects of apomorphine and l-amphetamine (Kehne & Sorenson, 1978). ASR amplitude can also be enhanced by presenting the acoustic stimulus during another stimulus (light for example) that has previously been paired with shock. This "potentiated startle reflex" has been reported to involve noradrenergic influences as well. It is enhanced by piperoxane, which increases LC unit activity, and is attenuated by clonidine, which depresses LC unit activity (Davis et al., Psychopharm., 65: 111, 1979).

It has recently been reported that a 2/sec pinch applied to the tail increases pars compacta activity (York et al., Fed. Proc., 35: 668, 1976) and increases cortical NE release (Antelman et al., Brain Res., 99: 319, 1975). Thus, it would be expected that tail pinch (TP) might also potentiate the magnitude of the ASR.

A test of this hypothesis revealed that TP actually depressed startle amplitude. This depression appears to be distinct from the production of TP-induced "stereotyped behaviors" (gnawing, licking, eating, grooming), since inhibition of DA transmission with 1.0 mg/kg pimozide, which disrupts TP-induced stereotyped behaviors (Antelman et al., 1975), does not prevent TP depression of ASR. Moreover, 2/sec stroking of the tail (tail rub) depresses startle amplitude but does not induce stereotyped behaviors. TP depression of ASR amplitude appears to involve the n. accumbens, since damage to this nucleus reduces the TP depression, and the amount of reduction correlates with the extent of damage. The effect of TP on the n. acc. appears to involve disruption of an inhibitory dopaminergic input into this nucleus, since the potentiation of the ASR normally produced by 8 mg/kg d-amphetamine is blocked by TP. The depression of startle amplitude during TP and tail rub may be a manifestation of a generalized state of decreased sensory reactivity, since TP and tail rub also depress responses to pin prick, foot shock, and air puff. These results are consistent with other observations that the n. acc. plays a role in the modulation of sensory responsivity. These results also suggest that TP is not anxiogenic, despite the increased turnover of cortical NE, which has been associated with species-specific fear display (Redmond et al., Brain Res., 116:502, 1976).

128.19 A SENSITIVE OPEN FIELD MEASURE OF ANXIOLYTIC DRUG ACTIVITY. D. R. Britton and K. Thatcher Britton*. Peptide Biology Lab, The Salk Institute, La Jolla, CA 92037.

Several drugs with demonstrated anxiolytic and anticonflict properties were tested for their ability to alter behavior of fasted animals in an open field. In this paradigm individually housed rats were fasted for 24 hrs prior to receiving a subcutaneous injection of drug or vehicle. Thirty min later, the animals were removed from their home cages and placed in a brightly illuminated open field (30 cm in diameter) which contained a single food pellet secured in the center. Animals were observed for 15 min and records were kept of the number of approaches to the food pedistal, the amount of food eaten, the amount of rearing and grooming and the incidence of urination and defication. Anxiolytic drugs such as diazepam (0.75 mg/Kg - 3.0 mg/Kg), chlordiazepoxide (10.0 - 30.0 mg/Kg), pentabarbitol (5.0 - 20.0 mg/Kg) and others increased the amount of food eaten during the 15 min test and increased the mean g of food eaten per approach to the food pedistal in a dose-related fashion. This latter measure appears to be the more sensitive measure of the anticonflict properties of drugs. As the amount of food eaten by fasted animals in their home cages over a 15 min test is not effected by these drugs, the results do not appear to reflect a hyperphagic action of the drug treatment. Haloperidol which has sedative but not anxiolytic properties, does not increase the amount of food eaten or the mean g eaten/approach. Daily handling of the animals for 8 rather than the standard 3 days prior to testing has the same effect as anxiolytic drugs significantly increasing both measures of food related behavior. This test is currently being used to assess both the anxiolytic and the anxiogenic potencies of a variety of compounds.

128.20 THE ACUTE AND CHRONIC EFFECTS OF IMIPRAMINE ON INTRACRANIAL SELF-STIMULATION. Marinelle Payton*, Howard S. Wheeling* and Conan Kornetsky. Laboratory of Behavioral Pharmacology, Boston University School of Medicine, 80 E. Concord St., Boston, MA 02118

Using the rate-independent procedure of Esposito and Kornetsky (Science, 195:189-191, 1977), the effects of single doses of imipramine HCl (2-32 mg/kg, i.p.) on intracranial self-stimulation (ICSS) thresholds were determined. Male albino rats were stereotaxically implanted with stainless steel bipolar electrodes in the medial forebrain bundle (MFB). Significant threshold increases were obtained only at the highest doses (16 and 32 mg/kg). We hypothesized that long-term administration of these high doses might produce tolerance followed by a decrease in ICSS thresholds. Thus, imipramine (either 16 or 32 mg/kg, i.p.) was administered on a daily basis for up to 37 days (mean 19 days). Although most subjects displayed tolerance to the initial threshold elevation, neither post-injection nor pre-injection thresholds were lowered beyond those obtained during preceding and subsequent control periods. These data do not support completely our hypothesis. It appears unlikely that the effect of imipramine on ICSS from the MFB models the therapeutic action of this antidepressant.

128.21 THE COMPARATIVE EFFECT OF SEVERAL TRYPTAMINE ANALOGUES ON PRIMATE SOCIAL AND SOLITARY BEHAVIOR. W.J. Heinze*, R.F. Schlemmer, Jr., C.B. Tyler, N. Narasimhachari, and J.M. Davis. (Spon: L.F. Eastman). Illinois State Psychiatric Institute, Chicago, IL 60612 and National College, Lombard, IL 60148

Some analogues of tryptamine possess potent psychoactive properties in mammals including psychotomimetic effects in humans. To further examine the behavioral effects of these agents, selected tryptamine analogues were studied in members of primate social colonies and primate dyads of adult Stumptail macaques. The drugs and doses tested were: N,N-dimethyltryptamine (DMT), 2 mg/kg, N,N-diethyltryptamine (DET), 2 mg/kg, 5-methoxydimethyltryptamine (5-MeODMT), 0.25 mg/kg, 5-methoxytryptamine (5-MeOT) 20 mg/kg, 4-hydroxydimethyltryptamine (psilocin), 0.4 mg/kg, d-lysergic acid diethylamide (LSD), 0.01 mg/kg, and 2-bromo-LSD (BOL), 0.10 mg/kg. All drugs were administered i.m. once daily for up to 5 consecutive days. Each experiment was preceeded by a baseline period where saline or vehicle was given. A "blind" observer quantified and recorded the behavior of each monkey in the colony or dyad for 1 hour daily. Upon gross appearance, LSD, psilocin, DET, 5-MeOT, and BOL appeared to sedate treated monkeys, whereas DMT and 5-MeODMT-treated animals appeared hyperalert. Upon acute administration, all agents except BOL induced limb jerks, a myoclonic spasm of an extremity, although 5-MeOT induced considerably less limb jerks than LSD, psilocin, DMT, DET, and 5-MeODMT. Only LSD, 5-MeODMT, 5-MeOT, and to lesser extent DMT induced body shakes (wet shakes). Checking (vigilance) scores were significantly increased by DMT, 5-MeODMT, DET, and psilocin, but not by LSD, BOL, or 5-MeOT. All of the tryptamine analogues studied decreased social interactions initiated by treated monkeys with the exception of submissive gestures. Upon chronic administration, partial tolerance developed to LSD, psilocin DET and 5-MeOT-induced emergent behaviors (limb jerks and body shakes) in monkeys. However, tolerance did not develop to DMT and 5-MeODMT-induced emergent behaviors. From these experiments, the following general structure-activity relationships can be drawn: 1) N-termal methylation of tryptamine greatly enhances psychoactive properties, 2) 4-hydroxylation or additon of a methoxy group at the 5 position increases the potency of dimethyltryptamines, and 3) substituting ethyl groups for the methyl groups of DMT does not alter the potency, but does alter the behavioral changes induced by the drug. Of the agents studied, LSD, 5-MeODMT, psilocin, DMT, and DET all are known hallucinogens in humans and also induce limb jerks in monkeys as an emergent behavior. Moreover, there is a significant correlation between the log hallucinogenic dose in humans and the log dose necessary to induce limb jerks in monkeys for these tryptamine compounds.

128.22 A COMPARATIVE EVALUATION OF MONKEY ECoG AND VI 60 LEVER PRESSING EFFECTS PRODUCED BY SELECTED ANTIPSYCHOTIC AGENTS. A.B. Davidson*, T. Smart* and K.L. Keim (SPON: W. Schallek). Dept. Pharmacology, Research Division, Hoffmann-La Roche Inc., Nutley, N.J. 07110

It was our purpose to comparatively determine the effects of chlorpromazine (CPZ, 0.25-1 mg/kg), haloperidol (HALO, 0.125-0.5 mg/kg), clozapine (CLOZ, 1.25-15 mg/kg), and a new pyrroloisoquinoline derived Roche antipsychotic agent (RO, 0.125-0.5 mg/kg) on the electrocorticogram (ECoG) during an operant procedure. Drugs were administered to food-restricted squirrel monkeys (80% ad lib body wt) on a VI 60 sec schedule of food reinforcement. The ECoG was telemetered from the anterior sigmoid gyrus of the unrestrained animal. A computer quantified and subdivided a range of ECoG frequencies (0-32 Hz) into 8 bands. Each monkey (n= 4 to 8 per drug dose level) was run on two consecutive days; a vehicle was given on Day 1 and a drug on Day 2. Occassionally, a vehicle was administered on the second day (n= 16) to evaluate the placebo effect. Effects on lever pressing rate and total 0-32 Hz ECoG activity are reported as percent change of Day 2 (drug) values compared to Day 1 (vehicle) values. Changes in the relative distribution of ECoG frequencies among the 8 bands within the 0-32 Hz spectra (expressed as percentage of total 0-32 Hz activity) are compared to the previous day vehicle administration. Drugs were administered intragastrically 60 min (CPZ, RO in 1 ml water) or 90 min (HALO, CLOZ in 1 ml 5% tartaric acid) prior to the 90 min VI session. Neither vehicle affected lever response rate or the ECoG.

The doses (mg/kg p.o.) which reduced the VI 60 lever response rate by 50% (ED50) were as follows: RO, 0.43; HALO, 0.51; CPZ, 0.73; CLOZ, 13.55. However, 2.5 and 5 mg/kg CLOZ increased responding rates by 35% ($p<0.01$) and 30% ($p<0.025$), respectively.

Spectral density analysis of the ECoG showed that only CLOZ at 7.5 and 15 mg/kg increased the total 0-32 Hz activity (>30%, $p<0.05$). At the doses tested, the other compounds caused only minor changes in total ECoG activity. However, all drugs altered the relative distribution of frequencies within the 0-32 Hz range. CPZ and HALO had a similar effect on the ECoG. That is, dose dependently, these agents decreased 0-8 Hz and increased 12-24 Hz activity (each $p<0.02$ at highest doses). RO, while reducing lever responding, did not significantly modify the ECoG, although at 0.5 mg/kg it tended to decrease 4-8 Hz and increase 16-30 Hz activity. As with lever pressing, CLOZ differed qualitatively from the other compounds tested. At 7.5 and 15 mg/kg, CLOZ increased 8-16 Hz ($p<0.01$) and decreased 20-30 Hz ($p<0.02$) ECoG activity.

128.23 COMPARATIVE EVALUATION OF FELINE EEG EFFECTS PRODUCED BY PSYCHOTROPIC DRUGS: ANALYSIS BY FREQUENCY SPECTRAL DENSITY ESTIMATES. K.L. Keim and E. Zavatsky*. Dept. Pharmacology, Research Div., Hoffmann-La Roche Inc., Nutley, New Jersey 07110

Frequency spectral analysis of multi-site EEG recorded from 38 acutely prepared cats was used to demonstrate that representatives of clinically therapeutic drug classes could be discriminated from vehicle and distinguished from each other. Diazepam (DZ, 0.04-1.25) and flurazepam (FZ, 0.32-5), chlorpromazine HCl (CPZ, 1-10), amitriptyline HCl (AMI, 0.32-10), d-amphetamine SO_4 (AMPH, 1.25-10), and phenobarbital Na (PHB, 1-20 mg/kg) were administered i.v. in cumulative, doubling doses at 13 min intervals. Monopolar electrodes were located on the anterior sigmoid gyrus (ASG) and in the ventral hippocampus (VH) and the caudate nucleus (CN) under ketamine/methoxyflurane anesthesia; animals were maintained by local anesthetics, decamethonium and artificial respiration. Blood pressure was recorded from the femoral artery. A computer estimated and subdivided the relative distribution of the EEG frequencies into 8 bands over the range of a 0-32 Hz spectrum. The EEG was recorded continuously for 3 hrs.

To varying degrees, cumulative doses of DZ, FZ, CPZ, AMI, and PHB generally increased total 0-32 Hz EEG activity in the ASG and CN by 35%; all, but CPZ, increased 0-32 Hz VH activity. In all brain areas AMPH decreased the 0-32 Hz feline EEG by 15% while saline-acacia vehicle administration reduced activity by 5 ± 3%. However, within certain frequency bands, differential EEG modulation occurred following the drugs. DZ and FZ increased 12-30 Hz activity by as much as 160% in brain areas studied; DZ was more potent than FZ. The 70% increase in 0-12 Hz activity induced by CPZ in the ASG and CN, was limited in the VH to the 0-2 Hz band. In all recordings, AMI caused a marked biphasic frequency shift: 0-2 Hz, +250%; 2-12 Hz, +100%; 16-30 Hz, -50%. While activity >4 Hz was attenuated after AMPH, a 50% increase was registered in 0-2 Hz activity in the ASG, VH, and CN. At all recording sites the predominant action of PHB was an enhancement of 0-2 Hz waves and a marked increase (>250%) of the midrange 8-16 Hz activity. When compared to predrug levels, only high doses of DZ, FZ, AMPH, and PHB significantly reduced mean arterial pressure amounting to a decrease of approximately 20%. CPZ, however, lowered mean arterial pressure by more than 45% at all tested doses; AMI at 5 mg/kg lowered the pressure by 54%.

Although classes of psychoactive compounds could not be differentiated based upon analysis of wide band, total 0-32 Hz integration of EEG activity, we conclude that estimates of selected frequency band densities from the acute feline EEG may provide the resolution for the characterization of different types of psychoactive drugs.

128.24 QUIPAZINE AND METERGOLINE ALTER THRESHOLDS FOR SEPTAL INHIBITION OF MURICIDE. J.L. Gibbons, M. Potegal, A.D. Blau,* S. Ross,* and M. Glusman. Dept. Behavioral Physiology, New York State Psychiatric Inst., New York, N.Y. 10032

Mouse killing behavior (muricide) in rats can be selectively inhibited by drugs which stimulate central serotonergic systems (Gibbons & Glusman, Fed. Proc., 1979, 38, 257) and by electrical stimulation of the septal nuclei (Potegal, Gibbons, & Glusman, Physiol. Behav., in press). The present study was designed to investigate whether these inhibitory effects interact, and specifically whether quipazine, a putative 5-hydroxytryptamine (5-HT) agonist, and metergoline, a putative 5-HT antagonist, alter thresholds for septal inhibition of muricide. 13 male Long-Evans hooded rats were selected for reliable mouse killing behavior within 2 mins. of presentation of a mouse. They were implanted unilaterally under barbiturate anesthesia with bipolar electrodes aimed at the medial and lateral septal nuclei. After a one week recovery period, the rats were food deprived to 80% of ad libitum weight and stimulation tests begun. Using each of the tips as cathode, the motor threshold was established as the minimum current which reliably elicited a motor response. Then the muricide inhibitory stimulation (MIS) threshold was established. Starting at one half the motor threshold, stimulation was incremented by a small amount every second trial until a rat failed to attack or kill a mouse during 2 consecutive 2 min. trials. That current value was designated as the MIS threshold. On subsequent test days, rats were injected with saline, or low doses of quipazine (0.75 or 1.5 mg/kg) or metergoline (.01, .05, 1.0, or 2.0 mg/kg) 15 mins. prior to testing. After the first trial (a non-stimulated control trial) the threshold for MIS was re-established.

The mean current threshold for eliciting a motor behavior was 101 ± 5 μa, and the behavior most frequently elicited was wet-dog shakes. At more than 90% of the tips, mouse killing behavior was inhibited below the motor threshold. Mean MIS was 72 ± 10 μa. In subjects treated with quipazine the MIS threshold was significantly reduced in a dose dependent manner. After injections of 1.5 mg/kg quipazine spontaneous killing was not affected, but MIS threshold was reduced by 50%. In subjects treated with metergoline, the MIS threshold was significantly increased in a dose dependent manner. At 2.0 mg/kg metergoline, spontaneous killing was not affected, but MIS threshold was increased by 148%. These results show that quipazine and metergoline, drugs which are believed to act on central serotonin systems, alter thresholds for septal inhibition of killing.

128.25 BRAIN LEVELS OF ACETYLCHOLINE AND NEOSTIGMINE DURING ANTAGONISM OF METHYLPHENIDATE INDUCED BEHAVIOR. J.J. Freeman, H.E. Ward,Jr.* J.W. Kosh. Div. of Pharmacology, Col. of Pharmacy, Univ. of South Carolina, Columbia, S.C. 29208.

The theory that dopaminergic and cholinergic systems in the brain are functionally antagonistic has been supported by studies in which stereotypy was blocked or reduced in intensity by cholinomimetics. The present study was designed to substantiate the role of acetylcholine (ACh) in the blockade of motor and stereotyped activity induced by methylphenidate. Behavioral evaluations (motor and stereotypy) were made for 3 hrs. following pretreatment with (1) methylphenidate (40 mg/kg i.p.) and (2) neostigmine (30 nmoles i.vt.) plus methylphenidate. Pretreatment with neostigmine (i.vt.) caused a significant blockade of motor and stereotyped behavior induced by methylphenidate. Neostigmine alone caused ataxia and anergia. Brain levels of neostigmine were measured following ion-pair extraction with dipicrylamine and thermal dequaternerization after injection into a gas-chromatograph. Simultaneous determination of neostigmine and ACh levels showed a temporal relationship for 3 hrs. between the blockade of behavioral activation and the increase in ACh levels. The predicted localization of i.vt. neostigmine in brain was verified by: its sustained level (4 nmoles) in the brain, a prolonged elevation of ACh and an extended inhibition of methylphenidate induced behavior. The half-life for disappearance of neostigmine in brain appeared to be biphasic with an initial half-life of 40 minutes. Pretreatment with hemicholinium (10 µg i.vt. 2 hrs) did not potentiate the behavioral effects of methylphenidate but resulted in a behavioral syndrome displaying characteristics of both drugs. This study supports the hypothesis that there is an adrenergic-cholinergic balance in the brain which is functionally antagonistic.

128.26 POST-SLEEP EFFECTS OF FLURAZEPAM, SODIUM PENTOBARBITAL AND TRIAZOLAM ON CEBUS MONKEY OPERANT BEHAVIOR. J.G. Canon*, J.M. Halperin and L.C. Iorio* (Spon: W. Gray). Schering - Plough Corp., Bloomfield, N.J. 07003.

A common side effect following the use of many hypnotics in humans is psychomotor impairment the following morning. This effect is frequently not predictable in new, potential hypnotics, until clinical studies are conducted. This study describes a procedure using an operant discrimination test in cebus monkeys that can detect changes in psychomotor performance at selected times after drug administration, and presents data on three standard hypnotics (flurazepam, sodium pentobarbital, and triazolam) evaluated the morning after treatment.

Water-deprived cebus monkeys, housed under a 16 hr/8 hr light/dark cycle, were shaped to press one of two levers when a cue light over the correct lever was illuminated; a correct response was reinforced with 0.5 ml unsweetened orange juice. Cue lights remained illuminated for either 0.25, 0.5, 1.0, 2.0, or 4.0 sec. Location of cue light and duration of illumination were randomized over 250 trials (50 trials per time duration; 125 trials correct on each lever) with a 20 sec intertrial interval. The percent of correct responses for each duration was determined and the reaction latency (RL50), defined as that duration during which the monkeys responded correctly 50% of the time, was calculated using linear interpolation. On test days, vehicle or drugs were administered orally 30 min prior to the onset of the dark period and testing began 8 hr 45 min later (15 min after the onset of the light period).

Vehicle-treated monkeys responded correctly almost always at the longer and seldom at the shortest time duration; discrimination errors (depressing the wrong lever) rarely occurred. The RL50 for vehicle treated monkeys ranged from 0.5 to 0.8 sec. All three drugs produced dose-dependent increases in RL50's on the following morning. Relative to their hypnotic potencies, triazolam, sodium pentobarbital, and flurazepam caused small, moderate, and large increases in the RL50 respectively. These were characterized by decreased ability to respond prior to the termination of the cue light, rather than discrimination errors.

The post-sleep deficits in performance of cebus monkeys following the administration of these drugs closely parallels those in man. If this correlation holds for other standard hypnotics, this procedure may serve as an index for predicting psychomotor impairment liability of new drugs in man.

128.27 NALOXONE SUPPRESSES BRAIN STIMULATION REWARD IN THE VNB, BUT NOT IN MFB. M.J. Lewis(SPON: L. Hicks) Dept. of Psychology, Howard Univ., Washington D.C. 20059.

The opioid antagonist naloxone was found to suppress the rate of response for brain stimulation reward (BSR) at a ventral tegmental mesencephalic site previously found to contain ascending norepinephrine fibers (Ventral Noradrenergic Bundle, VNB; Ungerstedt, Acta Phys. Scand., Suppl. 367, 1971) but was found to be ineffective on BSR at a hypothalamic medial forebrain bundle (MFB) site. Adult Charles River albino rats were implanted with bipolar platinum electrodes in either the VNB or MFB. All were trained to press a lever for BSR on a continuous reinforcement schedule. After stable response rates were attained, all received a series of 3 saline injections prior to a 15 minute BSR session. The animals then received injections of naloxone (Endo Lab, Garden City, N.Y.). The rate of response for BSR at the VNB site was suppressed by both the 1.0 and 5.0 mg/kg injections of naloxone over the saline baseline values. No suppression was observed in BSR performance at the MFB site with any of the doses of naloxone. These data are consistent with previous data (Lewis, Margules, Costa and Jacobowitz, Brain Res., 107, 156-167, 1976) indicating the involvement of the mesencephalic VNB in opioid effects.

(Supported in part by NIDA grant 02176).

128.28 STUDIES ON THE MECHANISM AND SITE OF ACTION OF THE DISCRIMINATIVE STIMULUS (DS) EFFECTS OF ARECOLINE AND NICOTINE. L.T.Meltzer* and J.A.Rosecrans, Dept. of Pharmacology, Med.Col.Va, Richmond, Va. 23298

These studies were designed to investigate three issues. The first is whether or not there is a presynaptic cholinergic innervation that impinges on the muscarinic and nicotinic receptors that mediate the DS effects of arecoline (ARE) and nicotine (NIC) respectively. The second issue addressed is, does NIC exert its DS effects through the release of endogenous ACh. Both of these issues were examined by studying the interaction of the cholinesterase inhibitor, physostigmine (PHY), with the DS effects of ARE and NIC. The third issue investigated was, what is the role of the midbrain reticular formation (RF) and dorsal hippocampus (HIP), two sites sensitive to cholinergic stimulation, in mediating the DS effects of ARE and NIC. The experimental subjects in these experiments were 24 male Sprague-Dawley rats. Twelve rats were trained to discriminate ARE (1.14 mg/kg,s.c.) from saline. The other twelve rats were trained to discriminate NIC(0.4 mg/kg,s.c.) from saline. The DS paradigm involved differentially reinforcing with sweetened milk, drug or saline appropriate responding on a VI-12" schedule, in a two-lever operant chamber. PHY(0.125mg/kg) pretreatment shifted the ARE dose-response relationship to the left but did not effect the NIC dose-response relationship. PHY (0.25mg/kg) after different antagonist pretreatments to block some of its peripheral and central effects, produced an approximately 30% generalization to the DS effects of NIC and a 70% generalization to the DS effects of ARE. The PHY effect in NIC trained rats could not be antagonized by mecamylamine, while atropine could block the PHY effect in ARE trained rats. These results suggest that 1) there is a lack of or a negligible cholinergic innervation of the central nicotinic receptors that mediate the DS effects of NIC compared to the cholinergic innervation of muscarinic receptors that mediate the DS effects of ARE, and 2) NIC does not exert its DS effects through the release of endogenous ACh. NIC injected directly into the RF and HIP produced generalization to the DS of peripherally administered NIC. The RF was more sensitive than the HIP. No generalization was observed to the DS effect of ARE when ARE was injected directly into these sites. This study points to a role of the RF and HIP in mediating the DS effects of NIC but not ARE.

(Supported by U.S.P.H.S. grant DA-07027).

128.29 ANTICHOLINERGIC DRUGS PROMOTE RECOVERY FROM SELF-STIMULATION DEFICITS PRODUCED BY BILATERAL BUT NOT UNILATERAL DOPAMINE LESIONS. R. J. Carey, Psychology Service, VA Medical Center, Syracuse, N. Y. 13210.

Twenty rats with bilateral medial forebrain bundle electrodes which generated comparable rate-intensity functions for self-stimulation were administered either unilateral or bilateral injections of 6-Hydroxydopamine (4 μg of a 2 μg/μl sol.). The nigral injections produced a virtual complete loss of dopamine in the injected hemispheres. The unilateral dopamine depletion was manifested behaviorally by ipsiversive turning and a prolonged partial bilateral deficit in self-stimulation. The bilateral dopamine depletion produced a severe akinesia and severe bilateral loss of self-stimulation. After 1 month postoperative the rats were given injections of the anticholinergic drug scopolamine HCl (0.125, 0.25 and 0.5 mg/kg). In the rats with a unilateral dopamine lesion the drug injections enhanced ipsiversive turning and bilaterally attenuated self-stimulation. In the rats with bilateral dopamine lesions, however, the scopolamine reversed the akinesia and produced recovery of self-stimulation. The results of these studies show that self-stimulation deficits produced by dopamine lesions can be attributed to motor dysfunction.

129.1 A NEWLY IDENTIFIED CLASS OF INTERNEURONS IN THE SPINAL CORD OF LAMPREY. J.T. Buchanan*. (SPON: C.M. Rovainen). Dept. of Physiol. and Biophys., Washington Univ., St. Louis, MO 63110.

Interneurons with axons projecting caudally on the contralateral side of the spinal cord (CC interneurons) were identified electrophysiologically in lampreys. They were tested for pre- and postsynaptic connections with other identified neurons and were stained by injection of horseradish peroxidase. One class of CC interneurons (CC_1) has an inhibitory function.

Intracellular stimulation of a CC_1 interneuron produced inhibitory postsynaptic potentials (IPSPs) in the following cell classes on the opposite side of the cord and within 2 cm caudally: myotomal motoneurons, lateral interneurons (a class of inhibitory neurons with caudally and ipsilaterally projecting axons) and other CC_1 interneurons. These IPSPs were probably monosynaptic as they occurred at a constant latency which was 2 ms longer than the conduction time along the CC_1 interneuron axon at 9°C. CC_1 interneurons were inhibited by rostral and ipsilateral lateral interneurons. CC_1 interneurons also received polysynaptic input from sensory dorsal cells in a pattern similar to that observed in motoneurons and lateral interneurons.

CC_1 interneurons may, therefore, participate in motor coordination in lampreys since they receive sensory input, are active during swimming (Cohen and Buchanan, Neurosci. Abst., '80) and inhibit motoneurons and lateral interneurons. CC_1 interneurons would contribute to the formation and propagation of body waves by being coactive with nearby motoneurons and lateral interneurons on the same side of the spinal cord and by inhibiting those same cell classes in nearby segments on the opposite side. In addition, the activity of ipsilateral cells would be promoted by disinhibition, since CC_1 interneurons inhibit contralateral CC_1 interneurons.

CC_1 interneurons receive monosynaptic EPSPs from the ipsilateral reticulospinal Müller cell, B_1. Tonic stimulation of B_1 at 50 Hz during D-glutamate-induced swimming produced a decrease in the contralateral ventral root burst intensity, consistent with CC_1 interneuron inhibition of contralateral motoneurons. Either increases or decreases in frequency of ventral root bursting were also elicited during B_1 stimulation at 50 Hz. This indicates that B_1 has access to the swimming pattern generator in the spinal cord.

129.2 ACTIVITY OF IDENTIFIED SPINAL NEURONS IN LAMPREY DURING "FICTIVE SWIMMING". A.H. Cohen and J.T. Buchanan*. Dept. of Physiol. and Biophys., Washington Univ., St. Louis, MO 63110.

Bathing the isolated spinal cord of the lamprey in Ringer solution containing D-glutamate elicits episodes of "fictive swimming", i.e., patterns of ventral root (VR) discharges identical to the EMG pattern seen in intact, swimming fish. Such episodes can be long-lasting and stable (Cohen and Wallen, in press) allowing intracellular recording from identified spinal neurons during the "fictive swimming". We present here a description of the activity of previously characterized spinal neurons (cf. Rovainen, Physiol. Rev. 59: 1007, '79) including myotomal motoneurons, fin motoneurons, lateral interneurons, edge cells, dorsal cells and giant interneurons, as well as the newly characterized CC_1 interneurons (Buchanan, Neurosci. Abst., '80).

1) Myotomal motoneurons exhibited oscillating membrane potentials (MPs) which reached a peak depolarization during the middle of the VR burst. 2) Fin motoneurons also showed oscillating MPs, but their depolarizations and hyperpolarizations were opposite, or antiphasic, to those of myotomal motoneurons. Many fin motoneurons simultaneously exhibited a much slower cyclic bursting pattern. 3) The MPs of lateral interneurons oscillated deeply and in-phase with nearby myotomal motoneurons, but most of these cells did not actually fire. 4) CC_1 interneurons had deeply oscillating MPs and often fired. They reached their peak depolarization at the beginning of the VR burst, slightly prior to the peaks in myotomal motoneurons and lateral interneurons. 5) Edge cells have a variety of axonal projections, but behaved similarly during "fictive swimming". Their MPs were not strongly modulated. Their peak depolarization occurred near the end of the VR burst. 6) Dorsal cells, large sensory neurons in the spinal cord, were all silent in the isolated preparation. However, a single action potential produced by intracellular stimulation in one type of dorsal cell was capable of disrupting the ongoing rhythm. 7) Giant interneurons showed no phasic modulation of their MPs, although they did exhibit many synaptic potentials not related to the VR bursting pattern. 8) An assortment of interneurons not otherwise identifiable were recorded during "fictive swimming". Most were active during the first half of the VR burst.

The cellular basis for swimming in lamprey has not yet been determined, but its nervous system offers a convenient preparation in the search for a vertebrate pattern generator.

129.3 ACTIVITY OF THE METATHORACIC AND METACOXAL MUSCLES DURING FLIGHT IN THE COCKROACH, PERIPLANETA AMERICANA. C. R. Fourtner, J. B. Randall*. Dept. Biological Sciences, SUNY/Buffalo, Buffalo, NY 14260.

Recent developments have shown that the flight system of the cockroach may present an excellent opportunity to study the neuromechanisms underlying stereotypic behavior (see Ritzmann, et al. this volume). Although the coxal and thoracic musculature of the cockroach has been well described, data are minimal regarding the activity of these muscles during flight (Pond, J. comp. Physiol. 1972). Using intracellular recording techniques in partially dissected specimens, we have determined some of the temporal relationships of several muscles in the flight cycle. The "wing-beat frequency" in these preparations ranged from 20 c/s to 28 c/s; this is comparable to intact tethered animals. Phase relationships between the FPSP's from muscle fibers and the onset of EMG's from either the elevator or depressor muscles were calculated. Muscles 155, 156, 157, 161, 162, 163, 174, 175, 176 (Notation Carbonell, Smith. misc. Coll. 1947) are active prior to the onset of wing elevation; muscles 153, 154, 164, 165, 167, 169 and 177C are active prior to wing depression. Fibers in each of the above muscles produce large EPSP's or spikes which approached 0mV. A third group of muscles, 159, 160, 170, 171, 172, are active during flight but do not fire synchronously with either the elevators or depressors; fibers in these muscles produce small summating FPSP's. The coxal muscles 181C and 182A-D are femoral flexors and are either continuously active during flight or produce two bursts per cycle. An interesting functional aspect of the activation of the coxal muscles is that 177A, an elevator, and 177C, a depressor, insert on the same apodeme and produce extension of the femur. However, during flight the femur is held in an extreme flexed position; presumably this is due to the continuous activity in 181C and 182A-D. This allows the action of muscles 177A and 177C to be directed on the tergum and episternum respectively to produce their indirect effects during flight. Using the cobalt-backfilling technique we have determined the location of the somata of the motor neurons innervating some of these flight muscles. This information on muscle function and innervation should give a good starting point for future electrophysiological studies on flight motor neurons and on the central control of flight behavior.

129.4 ANALYSIS OF INNERVATION PATTERN IN MESOCOXAL MUSCLES OF PERIPLANETA. Charles R. Morgan*, Paul R. Lennard, and Darrell R. Stokes*. Dept. of Biology, Emory Univ., Atlanta, GA 30322.

This investigation establishes a relation between the innervation, biochemical characteristics, and ultrastructural parameters of muscles in the mesothoracic coxa of the cockroach. The leg muscles used were the posterior coxal depressor (muscle 136) and a coxal branch of the main depressor group (muscle 135e'). Muscle 136 receives fast innervation from a single axon D_f; muscle 135e' receives a slow motor axon D_s, in addition to D_f. Although muscles 136 and 135e' were thought to be homogeneous with respect to fiber composition and innervation, our enzyme histochemical data revealed two separate and distinct populations of fibers within muscle 135e'; muscle 136 was found to be homogeneous (Stokes et al., Cell Tissue Res. 198: 175, 1979). Evidence corroborating the histochemical study was obtained in ultrastructural work upon muscles 136 (Morgan and Stokes, Cell Tissue Res. 201: 305, 1979) and 135e'. Based upon these studies, muscle 136 and the lateral compartment of 135e' appear to be fast contracting and fast fatiguing, whereas the medial compartment of 135e' is considered to be fast contracting and fatigue resistant.

These data suggest a differential innervation for the two compartments of fibers in muscle 135e'. Therefore, multiple intracellular recordings were performed to establish the innervation pattern of each population of fibers within this muscle. Since muscle 136 receives only one axon, D_f, this motor unit serves as a control for our analysis of the distribution of D_f and D_s in muscle 135e'; the time course and amplitude of e.j.p.s in different muscles receiving D_f being very similar. Three features of this system aid in the identification of fibers innervated by these motor axons: 1) axons D_f and D_s have different thresholds and are differentially activated by stimuli of varying duration; 2) the marked antifacilitation of the electrical response in muscles receiving D_f; and 3) the facilitation of the e.j.p.s elicited when D_s activity is invoked.

We will report on the correlation between the distribution of fast and slow electrical responses among the fibers of muscle 135e' and the biochemical and ultrastructural differences previously established.

129.5 SEROTONIN CAUSES OPPOSITE MODULATORY EFFECTS ON DIFFERENT BUCCAL MASS MUSCLES IN APLYSIA. G. Ajimal*, U. Shukla*, and Jeffrey L. Ram. Dept. of Physiology, Wayne State Univ., Detroit, Mi. 48201

Contraction of the accessory radula closer (ARC) muscle of Aplysia buccal mass is enhanced by serotonin (SER) or by excitation of the serotonergic metacerebral neuron (MCN), which has an axon in the nerve root innervating the ARC (Kupfermann, Fed. Proc. 38: 2095, 1979). Since the MCN also sends axons out other motor roots of the buccal ganglia (Weiss & Kupfermann, Br. Res. 117: 33, 1976), and the MCN has been suggested as a common path for behavioral changes associated with a food-arousal state, it seemed reasonable to inquire whether the contraction of other buccal mass muscles was similarly enhanced by SER.

Buccal mass muscles mounted in an aerated chamber contracted in response to injections of acetyl choline (ACh). ACh was washed out after 15 sec and not reapplied for at least 3-5 min.

In addition to the ARC, observations were made on extrinsic muscles E_1 and E_2 (nomenclature of Howells, Q. J. Microsc. Sci. 83: 357, 1942). The responses of E_1 and the ARC were similar: Contraction was produced by a threshold concentration of ACh of 10^{-5} to 10^{-6} M. SER (usually 10^{-8} M) did not cause a contraction by itself, but when applied for one min prior to ACh application, it caused a 2 to >10-fold enhancement of the ACh-elicited contraction. For E_1, the ACh contraction elicited while SER was in the chamber averaged 430% of the magnitude of the preceding ACh contraction ($p<.005$, paired t-test). ACh contractions elicited 5 and 10 min after washing out SER were 240% and 140% of the pre-SER contraction ($p<.005$ and $p<.05$, respectively, on paired t-tests), indicating a modulatory effect that outlasts the presence of SER.

In contrast to the enhancement of the ARC and E_1, SER caused a long-lasting inhibition of E_2. Contractions in E_2 were produced by 10^{-5} to 10^{-6} M ACh. ACh contractions elicited one min after SER (10^{-8} M) was injected into the chamber were reduced to 50% of the preceding ACh response ($p<.005$, paired t-test). ACh contractions elicited 5 and 10 min after washing out SER were 75% and 85% of the pre-SER contraction ($p<.005$ and $p<.05$, respectively, paired t-tests).

Although MCNs send axons out all buccal ganglia motor roots, it is not presently known whether their processes innervate the two extrinsic muscles studied here. If they do, MCNs may produce modulatory changes of opposite direction, as their neurotransmitter, SER, has been shown to do in the present study. This would imply that the role of the MCNs is not only to "arouse" the circuitry involved in feeding but also to change the coordination of muscles controlled by it.

129.6 IDENTIFIED DUM NEURONS IN THE FIREFLY: MORPHOLOGY, PHYSIOLOGY, AND CONTROL OF THE LANTERN. Thomas A. Christensen, Department of Neurobiology & Behavior, S.U.N.Y. , Stony Brook, N.Y. 11794.

The male firefly (Photuris versicolor) produces a triple - pulsed flash that is recognized by conspecific females during a courtship. The flash is initiated by a complex neural burst from the brain which activates the lantern primarily through the two most posterior abdominal ganglia, A6 and A7. When a male executes a spontaneous flash, all the thousands of photo - cytes in the lantern luminesce and extinguish in synchrony.

Morphological examination of A6 and A7 reveals a small cluster of large (30-75 μm diam.) dorsal unpaired median (DUM) neuron somata in each ganglion. Each soma gives rise to a single neurite which bifurcates into two bilateral axons exiting both sides of the ganglion. Within each ganglion, all the neurites arising from the cluster appear to fuse at a characteristic T - shaped juncture formed by the bifurcation of the neurites. The roots of A6 and A7 branch in the periphery to innervate all areas of the photogenic tissue, which occupies the sternites of the sixth and seventh abdominal segments.

The DUM somata clusters occupy sizable portions of the dorsal surfaces of A6 and A7, and their positions within the ganglia vary only slightly from one preparation to the next. The somata are therefore easily identified visually as well as physiologically. Staining with Neutral Red dye supports the suggestion that these neurons are octopaminergic.

Firefly DUM somata produce spontaneous double - component potentials characteristic of the axon spikes recorded from the soma of DUMETi in the metathoracic ganglion of the grasshopper (Heitler & Goodman, J. Exp. Biol. 76: 63, 1978). These spikes are small suggesting electrotonic spread from the bilateral axons down the neurite to the soma. As in the grasshopper, the compound nature of these potentials indicates separate zones of spike initiation on the axons lateral to the T - juncture formed by the bifurcating neurite.

The firefly DUM neurons with their characteristic bilateral axons are well - suited to the synchronous activation of all the photocytes on both sides of the lantern. The role of multiple spike initiation zones in these neurons however, remains unclear. Experiments intended to correlate these special membrane properties with the control of synchronous flashing are now in progress.

129.7 IDENTIFICATION AND ASYMMETRY OF LOBSTER CLAW MOTONEURONS. C. K. Govind and Fred Lang (deceased). Scarborough Coll., West Hill, Ont., Canada and Boston Univ. Marine Pgm., Woods Hole, MA 02543.

The paired claws of the lobster Homarus americanus are dimorphic, consisting of a slender, fast-acting cutter claw and a stout, slow-acting crusher claw. Since this asymmetry includes the composition of the paired closer muscles and their neuromuscular synapses, the question arises as to whether the motoneurons are asymmetric. Each muscle is innervated by a fast closer excitor (FCE), a slow closer excitor (SCE) and a closer inhibitor. In order to identify the somata of FCE and SCE in the 1st thoracic ganglion, an isolated claw-ganglion preparation was developed (cf. Wiens, T.J., J. Comp. Physiol., 112:213, 1976). Here the FCE and SCE axons can be positively identified at the periphery by differences in their conduction velocities and in the contractions they elicit. By selectively stimulating each axon at the periphery, a search can be made amongst the soma in the ganglion for an andridomic potential appearing after a suitable latency. Further corroboration as to the identity of the soma can be obtained by depolarizing it and eliciting axon spikes at the periphery. Using such physiological criteria the somata of the FCE and SCE motoneurons have been identified as two of the largest cells on the anterior ventral surface of the 1st thoracic ganglion. The FCE soma is larger (130 μm) than the SCE soma (100 μm) and lies immediately posterior to it. After identifying the soma, their responses to a standard sensory stimulus of the 2nd root with long, intense electrical pulses were compared. The SCE soma produced longer bursts and higher frequencies of spikes than the FCE soma of the same claw. This asymmetry between FCE and SCE somata is not unexpected as their axons conduct at different velocities and cause different contractile behaviours of the closer muscles. Of more interest was the asymmetry between homologous somata. Whereas the FCE soma on the cutter side responded with only an EPSP or a spike to the standard stimulus, its homolog on the crusher side gave a spike barrage lasting up to 1 s. Similarly the cutter SCE soma gave a short burst of low frequency spikes compared to its crusher homolog. Thus the FCE and SCE somata on the crusher side gave longer bursts and higher spike frequencies than their counterparts on the cutter side. Clearly the homologous claw motoneurons are asymmetric in their responsiveness to sensory (extrinsic) stimuli. Whether they are also intrinsically asymmetric remains an interesting question. Supported by grants from NSERCC and MDAC to C.K.G. and by NSF and NIH to F.L.

129.8 ELECTROPHORETIC RESOLUTION OF POSSIBLE FUNCTIONAL AND RECOGNITIONAL PROTEINS IN LOBSTER MUSCLE. D. E. Meiss, Dept. of Biology, Clark Univ., Worcester, MA 01610 and W. J. Costello, Dept. of Biology, Yale Univ., New Haven, CT 06520.

Recent studies have demonstrated histochemical differences in crustacean fast and slow muscle which may at least partially be ascribed to the pattern of fast or slow innervation. This suggests that the muscle fiber may contain proteins characteristic of muscle function as well as proteins which may serve as recognitional molecules for innervation during development and/or regeneration.

The protein composition of the claw and abdominal muscles of the lobster, Homarus americanus, was analyzed by SDS polyacrylamide electrophoresis. The gel protein patterns revealed consistent differences in several major bands that could be correlated with the physiological properties of the muscle fibers. Hence, all fast-type muscle, independent of innervation, showed a common pattern distinct from slow muscles which also had a common pattern of their own. This suggests that functional properties of the muscle fibers are expressed in their protein compositions. Some differences could be observed between different fast muscles and between different slow muscles in minor protein bands. This may be correlated with the specific axonal innervation of the different slow and fast muscles, perhaps serving a recognitional function.

These results add a new dimension to studying muscle fiber properties and innervation. Thus it will be useful for identifying differences among the diverse muscle types found in arthropods and perhaps for determining the genetic and neuronal factors responsible for this diversity.

129.9 PROPRIOCEPTIVE INTERACTIONS WITH A FUNCTIONALLY DIVERSE CRUSTACEAN MOTOR SYSTEM. R.L. Crabtree and W.H. Evoy. Lab for Quantitative Biology, Dept. of Biology, Univ. of Miami, Coral Gables, FL 33124.

The integrative basis for functional interactions between central motor programs and sensory feedback, reflected by resulting movements, has remained elusive in all animals studied. Control of crayfish leg movements for forward and backward walking offers unique opportunities for experimental examination of both motor and sensory components involved in locomotion. Because of its accessibility, we have concentrated on the thoraco-coxal neuromuscular system which underlies promotion of the crayfish limb during the powerstroke in backward walking and the returnstroke of forward walking. In this system, we are also able to isolate coxal proprioceptive elements which may be responsible for modifying motor output during locomotion.

A substantial role of proprioceptive feedback in the operation of a central program for limb movements is indicated by the failure of centrally stimulated commands to provide normal expression of the program in the absence of contact with the substrate (Bowerman and Larimer, 1974, J. Exp. Biol. 60, 119-134; Evoy, 1977, Identified Neurons and Behavior of Arthropods).

The override of inhibitory inputs from proprioceptive pathways and suppression of excitatory inputs to motor neurons of more distal leg segments by stimulation of central descending interneurons suggests that premotor modulation of the pathways is prevalent (Evoy and Crabtree, 1978, Neurosci. Abstr. 4, 192).

The promotor neuromuscular system of the crayfish 5th leg consists of three morphologically and functionally distinct heads. The anterior and posterior promotors share at least 11 axons, are rhythmically active during walking, and are composed predominantly of tonic muscle fibers based on ultrastructural criteria. The phasic lateral head is active during fast escape and defense movements and is innervated by 6 motor neurons, at least two of which are shared with the muscles used in walking.

Several proprioceptors putatively involved in aspects of motor control of these muscles have been examined to determine the nature of this interaction. These include 1) the non-spiking coxal muscle receptor, 2) a chordotonal strand mechanically in parallel with (1), and 3) a population of sensory fibers sensitive to distortion of the interarticular membrane of the thoraco-coxal joint. These three sensory elements each address specific components of the promotor and other systems. Their inputs to relevant motor programs and their contributions to the control of locomotion are being examined.

129.10 STUDIES ON A PARALLEL ARRAY OF CRAYFISH PROPRIOCEPTORS. B.G. Lindsey and H.K. Brown, Depts. of Physiol. and Anat., Univ. of South Florida Med. Ctr., Tampa, Fl. 33612.

Previous work (Lindsey and Gerstein, J. Neurophysiol. 42:383, 1979) has shown that crayfish (Procambarus clarkii) claw propodite-dactyl (PD) chordotonal organ proprioceptors operate as an ensemble of parallel channels. Individual receptors make divergent connections with two mutually excitatory claw motor neurons, the slow closer exciter (CE) and the opener inhibitor (OI). Collectively the PD receptors play a major role in the generation of complex motor neuron proprioceptive fields. Electron micrograph montages of cross sections of the nerve carrying PD receptor axons now indicate an average of 83±16 S.D.(N=9) axons/nerve. Frequency distributions of axon diameters are positively skewed and bimodally distributed. Diameters ranged from less than 1μ to 22μ. Inspection of the montages reveals that axons with smaller diameters tend to be clustered in one or more groups.

Multiple en passant hook-oil electrodes (Wilkens and Wolfe, Comp. Biochem. Physiol. 48A:217, 1974) placed along the nerve, in conjunction with spike sorting techniques utilizing differences in conduction velocity and waveform, have, to date, permitted analysis of up to 13 simultaneously monitored proprioceptor spike trains. This approach has allowed direct observation of the dynamics of recruitment and changes in firing rates of many proprioceptors as a function of changes in claw dactyl displacement parameters (acceleration, velocity,joint angle, direction) in a single animal and will allow an analysis of issues such as redundancy and variability within the receptor array. When claw motor neurons are also monitored, the relative efficacies of various input channels are measured using cross correlation techniques. In addition, a conditional cross correlation technique is being used to measure the joint influence of action potentials in parallel channels on OI and CE firing probabilities (Lindsey, Fed. Proc. 39:596, 1980). Supported by NIH 5 SO7 RR05749 and NS 14934.

129.11 NEGATIVE AND POSITIVE FORCE FEEDBACK FOR THE REGULATION OF CONTRACTION IN CRAYFISH MUSCLE. J.D. Marrelli* and J.L. Larimer, Dept. of Zoology, University of Texas at Austin, Austin, TX 78712

This report concerns the interaction of motor and sensory elements during early phases of attempted flexion at the meruscarpus (MC) joint. Prior to movement, there is force generated by the flexor muscle (F) against loads placed upon the limb which activates sensitive cuticular receptors (DR). There is parallel activation of the accessory flexor muscle (AF) which drives myochordotonal organ (MCO) receptors embedded in its proximal tendon. In these experiments the receptors of other joints were rendered ineffective by rigid fixation. While the MCO can respond to MC joint movement, this movement was prevented.

Three cases were studied during the first 400-500 msec. of a loaded flexion: 1)Intact animal, 2)All Distal receptors (DR) destroyed, 3)DR and MCO destroyed. Histograms were made of the EMG of the flexor (5 msec. bin, N=21) with reference to the point in time when 60 gm-cm. of joint torque was produced. In each case the development of EMG freq. with time (t) was fitted by a linear regression line. Case 1:Intact; EMG freq.=(40·t)PPS,ρ=0.79. Case 2: Only MCO intact;EMG freq.=(79·t)PPS,ρ=0.94. Case 3: Open loop, no DR or MCO; EMG freq.=(42·t)PPS,ρ=0.75. In case 3, no feedback was possible and the rate of rise of the EMG in this unmodified central program was 42PPS/sec. In case 2 when only the MCO was present this rate of rise doubled to 79PPS/sec.

These data imply that the MCO provides additional excitation to the central program during isometric contractions of the flexor due to positive feedback of force information from the co-contracting receptor muscle, AF , to the working muscle, F. In case 1, the presence of DR reproduces the curve of case 3, that is, the rate of rise of EMG frequency was reduced to 40PPS/sec by their presence.

These findings i.e., positive feedback from the MCO and the modification of this feedback by load sensitive distal receptors have several implications for the control of movement. It seems paradoxical that in the intact animal, increasing the load on the limb should result the reduction of the rate of rise of the EMG frequency. However, enhanced limb stability may be an important consequence of DR-MCO interaction. Reflex lag time tends to destabilize control systems and inertial loads increase this instability. One solution is to move inertial loads more slowly, i.e., reduce the rate of rise of the EMG freq. and thus the play out of the motor program. The observed DR-MCO interaction in the earliest phase of movement may provide temporal rescaling of motor programs for increased stability of movement during load manipulation.

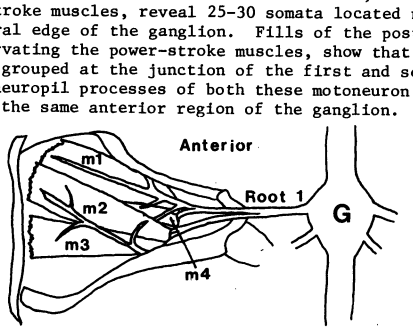
129.12 MOTONEURONS INNERVATING THE PRINCIPAL MUSCLES OF THE SWIMMERETS OF THE CRAYFISH, PACIFASTICUS. V. McDonald, D.H. Paul and B. Mulloney. Dept. of Zoology, University of California, Davis, CA 95616.

The swimmerets, paired appendages of the abdominal segments, are powered principally by four muscles that lie ventrally between the abdominal sternites. There are two power-stroke muscles (m2 and m3) and two return-stroke muscles (m1 and m4). This musculature is innervated by the first root of each ganglion which, in Pacifasticus, is split into anterior and posterior branches. Cobalt backfills of the anterior branch, innervating the return-stroke muscles, reveal 25-30 somata located near the anterio-lateral edge of the ganglion. Fills of the posterior branch, innervating the power-stroke muscles, show that there are 20-25 somata grouped at the junction of the first and second roots. The neuropil processes of both these motoneuron pools project into the same anterior region of the ganglion.

Dorsal view of swimmeret musculature and its innervation



Metachronal beating of the swimmerets is driven by hemisegmental oscillator networks. Previous work has shown that some of the motoneurons are an integral part of these networks (Heitler, 1978); however, the number and identity of these motoneurons is unknown.

Our aim is to identify the motoneurons that are part of the central oscillator. We use dye-filled microelectrodes to impale motoneuron somata in half-segment preparations with the innervation of the swimmeret muscles intact. Motoneurons are described on the basis of the following criteria: 1) their peripheral targets, 2) the sign of junctional potentials they elicit, 3) the dynamic characteristics of the neuromuscular junctions, 4) the effects on swimmeret motor pattern of current injection into the cells, 5) their firing characteristics in response to injected current pulses, and 6) location of soma and structure of neurites.

Supported by NSF Grant BNS 78-10516.

129.13 INVESTIGATION OF BURST FORMATION IN A CRAYFISH ABDOMINAL POSTURAL MOTONEURON. Mark D. Kirk and Raymon M. Glantz. Dept. Biol., Rice University, Houston, TX 77001.

The largest motoneuron (F6) innervating the tonic flexor muscle of each hemisegment in the crayfish abdomen patterns its impulses in the form of repeated bursts (Kennedy, D. and Takeda, K., J. Exp. Biol. 43:229-246, 1965b). This centrally generated pattern of activity is well matched to the properties of its peripheral neuromuscular junctions as well as the "faster" muscle fibers which it innervates (Gillary, H. and Kennedy, D., J. Neurophysiol. 32:608-612, 1969b; Velez, S. and Wyman, R., J. Neurophysiol. 41:85-86, 1978b). The present study was undertaken in order to extend a previous extracellular analysis of the mechanism of F6 burst generation (Gillary, H. and Kennedy, D., J. Neurophysiol. 32:595-606, 1969a). Combined intracellular and extracellular investigation of the tonic flexor motoneurons in the third and fourth abdominal ganglia enabled us to make the following observations pertaining to the mechanisms of burst formation in F6: 1) Synaptic coupling of suprathreshold activity within the tonic flexor "motor pool" is not sufficient by itself to produce the bursting output, 2) Depolarizing currents (over a restricted range) injected into the somata or neuropilar processes of F6 results in the clustered discharge characteristic of "command" or sensory induced activation, 3) The frequency-current (f-I) relationship reveals no increase in average sensitivity over this range of injected currents, 4) Both driven and spontaneous F6 bursts are associated with unpatterned synaptic activity, 5) All impulses generated during a burst are seen to arise from a distinct depolarizing afterpotential (DAP) which appears to arise from a passive invasion of dendritic membrane by the preceding impulse, 6) The DAP time course is closely paralleled by an increase in excitability seen by the spike initiating zone following a singlet action potential, 7) the excitability cycle following a rhythmic impulse is a good predictor of the "preferred" intradoublet (intraburst) intervals, 8) Each burst is terminated by a prominent postburst hyperpolarization (PBH), 9) F6 possesses two other features characteristic of many latent endogenous bursters-accommodative adaptation and posthyperpolarization rebound.

As suggested by the earlier extracellular work, our results imply that the characteristic of burst formation is endogenous to the motoneuron and not strongly dependent on patterned presynaptic input. The DAP, repetitive (i.e., tonic) firing nature of the axon, and PBH interact such that during intermediate levels of activation, F6 action potentials become clustered and its endogenous bursting character is revealed.

129.14 SCORPION WALKING LEG MOTONEURONS: PHYSIOLOGY AND MORPHOLOGY. Robert F. Bowerman and Malcolm Burrows. Department of Zoology, Cambridge University, Cambridge, England.

In the arthropods, the central neural mechanisms that underlie locomotion have been studied extensively in only two groups, the decapod crustaceans and orthopteran insects. Arachnid systems have not been described using currently available intracellular stimulating and recording techniques. Consequently, we decided to analyze the physiology and morphology of walking leg motoneurons in the scorpion Paruroctonus mesaensis. The preparation was mounted ventral surface uppermost so that the legs were free to move. The subesophageal ganglion was exposed and perfused with a constant flow of saline. Grass microelectrodes with D.C. resistances of 30-80 MΩ, filled with either 2M potassium acetate or 10% cobaltous chloride, could be driven across the sheath and into the ventrally situated motoneuron cell bodies, without pretreatment by proteolytic enzymes. Once penetrated, the motoneuron was characterized by which muscle it innervated, assessed either by electromyograms or direct observation of leg movement.

Orthodromic spikes have an amplitude of about 2-4 mv and a duration at half-height of 3-5 ms. Occasionally, spikes as large as 8 mv were recorded. The cell body also provides a window onto the synaptic potentials which are generated as a result of inputs from other neurons. Depolarizing and hyperpolarizing potentials, which appear to be unitary events, can have an amplitude as large as 0.5 to 1.0 mv. Resistance reflexes, in response to movements of individual leg joints, can also be recorded.

The cytoarchitecture of cobalt filled-silver intensified motoneurons was studied in whole subesophageal ganglia. Different motoneurons innervating different muscles were indistinguishable from one another. The cell body (30-80 µm diameter) gives rise to a single dorsally running process which has a diameter of 2-9 µm. This process is usually devoid of side branches for the first 150-200 µm of its course through the ventral neuropile areas. The main neurite then turns laterally and becomes somewhat broader, about 7-12 µm. It is from this broader region that most of the dendritic side branches arise. These side branches are distributed in a dorso-ventral orientation Before entering the peripheral nerve, the main neurite tapers to 2-5 µm. Once within the peripheral nerve, the diameter may again increase.

In summary, the scorpion motoneurons are similar to those in insects and crustaceans, both in terms of the electrical events that can be recorded at the cell body and in basic cell morphology. The differences which are noted, primarily in extent and orientation of the dendritic arborizations, reflect the way the motoneurons for all eight legs are packaged into the subesophageal ganglion.

130.1 MORPHOLOGY OF THE REGENERATING EYE OF STROMBUS LUHUANUS, A MARINE GASTROPOD. E.W. Gillary* and H.L. Gillary. Dept. of Physiology, University of Hawaii, Honolulu, HI 96822.

The retina of the mature eye of S. luhuanus exhibits several morphological cell types, arranged to form distinct layers of rhabdome, cell bodies and neuropile (Gillary & Gillary, '79). Following amputation of an eye, another is regenerated in its place. In the present studies, regenerates of animals reared at 28°C (normal ambient Tp) were examined by transmission e.m., to provide a morphological basis for the ontogeny of their electrophysiological responses to light (Gillary, '72). Within a day after amputation, an eyecup (0.2 mm dia) begins to form by epithelial invagination and closes off by 3 days. At this stage the cells (ca. 5 μ dia & 50 μ long) are all similar in appearance. Short microvilli (< 2 μ long) project from their apical ends at the eye's center, and the cytoplasm includes numerous 0.6 μ propigment granules and abundant rough e.r. No neuropile is present at this stage. The cytoplasm of the 4 day eye (0.3 mm dia) contains electron-opaque 0.6 μ pigment granules, as well as much rough e.r. and microtubules. A layer of neuropile comprised of processes 0.3 to > 1 μ dia. has begun to form near the capsule. Some cells possess apical bundles of cilia, but most exhibit apical membranous projections which appear involved in the secretion of lens material. The 5 day regenerate (0.3 - 0.4 mm dia) exhibits a layer of rhabdome (ca. 20 μ thick) comprised of microvilli eminating directly from the apices of cells filled with clear 50 nm vesicles characteristic of mature photoreceptors. Also found are glial cells, with bundles of tightly packed tonofilaments and abundant rough e.r., which is less conspicuous in the other cell types. The layer of neuropile is more like that of the mature eye, exhibiting more numerous and finer processes, and many synaptic-like structures. Retinal thickness, excluding the rhabdome, is ca. 80 μ, as in the mature eye. This stage regenerate can yield simple light-evoked potentials (H. Gillary, unpubl.). The rhabdome of the 7 day eye (0.4 mm dia) is comprised predominantly of photoreceptor distal segments, each with a central shaft (40 μ long) from which emanate closely packed microvilli, as in the mature retina. In the 11 day eye (0.7 mm dia) the distal segments are 70 μ long. The retina of the 14 day eye (0.8 mm dia) is very much like that of the mature eye (1-2 mm dia) in terms of the thickness of the rhabdome (80 μ), the complexity of the neuropile, and the appearance of 3 different cell types, in addition to glial cells, although the latter still display more cytoplasm and rough e.r. than mature glia. This stage of regenerate exhibits light-evoked potentials which are qualitatively similar to those of the mature eye (H. Gillary, unpubl.). (Supported by NIH Grant EY 01531.)

130.2 THE MORPHOLOGY OF NEURONS ARISING DE NOVO DURING METAMORPHOSIS IN THE TOBACCO HAWKMOTH, MANDUCA SEXTA. P.H. Taghert* and J.W. Truman (SPON: M.R. Meyer). Dept. of Zoology, Univ. of Washington Seattle, WA 98195.

During metamorphosis in Manduca, certain central neurons die, some are respecified and some arise de novo. Of the new neurons in the unfused abdominal ganglia, eight have axons in the segmental nerves and are therefore effector cells and not interneurons. However, intracellular depolarization sufficient to cause repetitive firing in these cells does not produce contraction of skeletal muscle. These cells all have somata along the mid-line of the ganglion and are arranged as four pairs. Each pair of neurons appears to arise from a nest of four cells that can be found in late stage larvae. All cells within a nest begin to enlarge two days before pupation; at pupation, however, two cells die and the remaining two continue differentiation. In the adult moth, all eight neurons have bilateral axons, spiking cell bodies and make 'blind' terminations in the neurohaemal transverse nerve. They appear neurosecretory in many respects, but their product is presently unknown. They may be analogous to cells of the Dorsal Unpaired Median group of orthopterans.

Within the ganglion, the new neurons project to discrete areas of the neuropile that are identical to those occupied by neurons previously found to contain the peptide hormone bursicon (Taghert and Truman, 1979, Soc. Neurosci. 5, 263). Bursicon neurons are fully differentiated in larval stages and do not undergo major dendritic reorganization during metamorphosis. The common neurosecretory neuropile is arranged as three dorso-ventral planes along the mid-line and along both lateral edges of the neuropile. Major dendrites connect these planes by way of specific routes along the dorsal-most and ventral-most surfaces of the neuropile. Like the associated bursicon neurons, the new neurons exhibit variabilty in the route and number of major dendritic branches. On the basis of branching number and frequency, we infer the presence of six organizing centers for the growth of these neurons. These centers are situated at the mid-line,just below the cell body layer and along the dorsal and ventral surfaces of the neuropile. All known secretory neurons in the abdominal ganglion - new pupal neurons, bursicon neurons and others not mentioned here - grow towards and branch at these sites. Therefore we conclude that during metamorphosis, neurons differentiating for the first time grow in response to set of morphogenetic signals that was already established during embryonic stages.

130.3 NEURITE GROWTH AND ITS RELATIONSHIP TO SYNAPTOGENESIS IN THE FLY'S VISUAL SYSTEM. A. Fröhlich and I.A. Meinertzhagen, Life Sciences Centre, Dalhousie University, Halifax, N.S. Canada.

The growth of neurites between immature neurons determines the numbers and combinations of elements which may communicate synaptically in the adult. In order to assess the exact extent of this influence we have examined the first optic neuropile, or lamina, of the developing visual system of the fly. Reconstructtions have been made from serial electron micrographs of individual cartridges, the unit synaptic compartments of this neuropile. Cartridges have been studied from animals between 55-100% pupal development. At these stages the positions of the component elements are identifiable with reference to their positions occupied in the adult cartridge, by which each element is uniquely identified. Thus, only the fine grain extension of processes between cartridge elements varies during this period. At the same time synapses emerge (Fröhlich and Meinertzhagen, Soc. Neurosci. Abstr. 5, 245, 1979).

Between stages 55-100%, processes of L1 and L2 extend radially in the plane of the cartridge cross section and simultaneously branch. By 95% all extant processes have spread to the cartridge exterior. Accompanying this lateral extension the processes also spread vertically, continuing to do so after the lateral spread has stopped. At the same time as some processes are extending, however, others are regressing. The total number of processes decreases steadily from 55-95% so that, overall, more neurites are resorbed than extend. After 74% processes which had hitherto not extended to the cartridge exterior are destined not to persist. Consequently, those neurites which fail to start growth early enough or to extend sufficiently by the 74% stage are not represented in the adult. Eventually some branching occurs in most processes but extensive branching is delayed till after 74%.

A further influence upon neurite growth and survival is mediated by the interaction between L1 and L2. Although the attrition of processes seen throughout development is approximately the same for both L1 and L2, the total number of processes is greater for L1 and L2 up till 95%. At this stage the processes of L1 and L2 assume, through the depth of the cartridge, their characteristic adult pattern of interdigitation. Before this time, however, this regular alternating sequence is not found. At 55% the sequence is still random, regular alternation appearing largely between 62% and 74%.

Between 62-74% the fastest extension of neurites to the cartridge exterior is paralleled by the greatest increase in numbers of synapse.

130.4 VARIABILITY IN THE PROSTERNAL SENSE ORGAN OF DROSOPHILA MELANOGASTER. David G. King. School of Medicine, Southern Illinois University, Carbondale, IL 62901.

The prosternal organ in dipterans is a sensory hair plate located on the anterior prothorax at the articulation with the head. The prosternal organ consists of a bilaterally paired cluster of mechanoreceptor bristles which presumably functions as a proprioceptor, similar to the more familiar hair plates located on the neck and leg joints of other insects (Pringle, J. Exp. Biol. 15:467-473, 1938).

In a wild-type population of Drosophila (Canton-S from R. Wyman, Yale Univ.) the variability in the number of sensilla in each cluster was surprisingly large. This number ranged from 12 to 21 around a median value of 15. (Mean = 15.16; standard deviation = 1.62; n = 166.) This large variation suggests that this hair plate may not provide precise quantitative information on joint position but may simply provide a qualitative indicator for joint movement.

The large variability was reflected not only in differences among individuals but also in differences between the left and right sides of single individuals. Although there was a correlation between the numbers of sensilla in left and right clusters, this correlation was weak (correlation coefficient = 0.40; n = 83). The two sides could differ by as many as 4 sensilla (or 33%); the mean difference between left and right was 1.42 bristles.

The variation between left and right sides indicates that the number of sensilla on each side is not closely coupled to systemic factors (such as body size) which would affect both sides equally and yield a higher correlation. Rather this side to side variability may indicate a developmental process which not only is regulated only within rather broad limits but which also is bilaterally independent.

To isolate the variability arising epigenetically during development from that due to genetic differences, isogenic flies (from W. Doane, Arizona State Univ., and T. Wright, Univ. of Virginia) were examined. Preliminary data from two isogenic lines indicates that in isogenic flies the left-right correlation is absent, while the variability although reduced is still considerable. The mean number of sensilla can differ significantly between strains. (Strain/mean/standard deviation/n: TW-a50/13.02/1.14/45; WD-CS/15.38/1.05/25.) Several more isogenic lines will be examined to determine to what extent the degree of variability in the prosternal organ is under genetic control.

130.5 EMBRYONIC DEVELOPMENT OF AN INSECT ANTENNAL NERVE. Alma Toroian-Raymond* and David Bentley. Neurobiology Group and Zoology Dept., Univ. California, Berkeley, CA 94720. (SPON: G. Westheimer).

In the antennae of grasshopper embryos, the first connection between the periphery and the central nervous system is made by two pairs of specialized cells termed peripheral pioneer neurons (Bate, '76, Nature, 260: 54). We have investigated the development of this afferent system throughout embryogenesis.

Antennae of staged embryos of S. nitens were observed with Nomarski optics in living embryos and stained whole-mounts, and with transmission EM. EM sections were taken at the antennal base at 5-10% intervals from 35% of embryogenesis through hatching. In micrographs, axon profiles were counted, and mean-diameters were plotted in histograms. Profiles ranged from 0.9 to 0.1 um, and histograms were increasingly skewed toward smaller diameters in older nerves. Pioneer axons did not form a group distinguishable by size or appearance.

Pioneer neuron somata were seen in antennae as early as 30%, but axon profiles were not found at the base until after 35%. At 40%, two pairs of 0.9um axons were present on opposite sides of the antennal lumen. They were associated with an a-cellular lamina lining the inner surface of the epithelial layer, and were not ensheathed. In the period from 40%-63%, the number of axon profiles in the two nerves increases steadily(40%=2/2; 45%=14/13; 15/uncounted; 55%=47/67; 58/56; 63%=78/95), and the nerves become ensheathed by glia. After 63%, a large number of axons appear in the nerves, which by 75% contain 4,421 and 4,894. This complement remains relatively unchanged through 87% (5,123/4,672), but rapidly increases again during the last part of embryogenesis. At hatching, the nerves contain 6,628 and 6,593 axons. All axons follow the path of the initial pioneer axon pair.

Embryonic appendages of grasshoppers form three cuticles (each preceded by a pulse of ecdysone; Lagueux, et. al., '79, J. Insect Physiol. 25: 709). The first arises before 40% and completes apolysis(separation from the epithelium) by 50%. The second begins forming after apolysis of the first and completes its apolysis by 80%. The third cuticle begins forming after 80% and is the cuticle of first instar nymphs.

Our data indicate that afferent cells arise concurrently with the formation of each cuticle. The first pioneer neurons appear at the time of formation of the primary cuticle. The second set of afferents (the first sensory neurons) arise during formation of the second cuticle; axons of these cells reach the antennal base before apolysis (their dendrites will innervate sensilla of the third cuticle). The third wave of afferents(second set of sensory neurons) appears concurrently with the formation of the third cuticle.

130.6 UNATTACHED PRE-SYNAPTIC TERMINALS IN A FLIGHTLESS MUTANT OF DROSOPHILA MELANOGASTER. Walter J. Costello. Dept. of Biol., Yale Univ., New Haven, Conn. 06511.

The interaction between nerve and muscle to form neuromuscular systems is much studied. Mutations which affect these systems serve as useful models to analyze their development. The stripe (sr) mutation in Drosophila affects only one set of the indirect flight muscles, the dorsal longitudinal muscles (DLMs). In its homozygous state (sr/sr) the DLMs are reduced to about 50% of their normal volume. The DLMs are completely absent in adult flies with only one copy of the mutant allele (genotype sr/Df(3)sr; one chromosome carries sr, the homologous one has a deletion at the sr locus).

In early stages (the first 30 hrs of pupation @ 25° C) the development of this muscle is no different from that of wild type flies (Costello, 1979, Neurosci. Abstr. 5:243). Subsequently, the DLMs in this mutant degenerate. Serial reconstruction of the thoracic ganglion reveals that the nerve supplying the DLMs, the posterior dorsal mesothoracic nerve (PDMN), persists even without its end target. As in normal flies, the PDMN exits the ganglion and sends a branch to the jump muscle. It then courses dorsally to where the DLMs would be normally located. Here it ends in a tangled mass of tissue, forming a "neuroma-like" structure. The PDMN at this point contains the five motor axons which normally innervate the DLMs. Many small diameter (sensory) axons are also present.

Ultrastructural analysis shows that hundreds of abnormal synapses are located within this structure (cf Hirano and Shin, 1979, Neuropathol. and Appl. Neurobiol. 5:63-70). Normal pre-synaptic elements are present: synaptic vesicles (not misshaped), T-bars, and pre-synaptic membrane thickening. However, no postsynaptic specialization exists. These unattached pre-synaptic terminals are formed onto glial elements as well as other axons.

Small clumps of highly disorganized muscle tissue (DLM remnants?) are also found in this structure. Myofilaments are organized into sarcomeres; the myofibrils look normal, but bundles of myofibrils run through the muscle mass in random orientations. A few neuromuscular synapses with normal postsynaptic specialization are present.

130.7 AXOTOMY INDUCES INCREASED CHOLINERGIC CHEMOSENSITIVITY. H. Meiri*, M.E. Spira* and I. Parnas* (SPON: J.H. Caldwell). Neurobiology Unit, The Hebrew University, Jerusalem, Israel.

Cholinergic chemosensitivity of intact giant axons of the cockroach Periplaneta americana is very low at the abdominal level (i.e., in ganglia A_2-A_5). This is demonstrated by bath application of 10^{-5}M nicotine, which causes a membrane depolarization of 10±2 mV and an increased membrane conductance of 10±2 percent.

When the axons are cut between ganglia A_2 and A_3, recovery of normal membrane properties (resting potential and input resistance, among others) occurs after about 8 days (Meiri et al.,Neurosci. Abstr. 5:680,1979). Cholinergic chemosensitivity of the axotomized giant axons then begins to increase gradually, reaching maximum values of 30±5 mV membrane depolarization and 85±8 % increased membrane conductance 22 days after the cut. Chemosensitivity remains high for at least 100 days. The effect of nicotine can be blocked by 10 µg/ml alpha-Bungarotoxin.

Local application of nicotine on each of the above ganglia (A_3-A_5) or on the connectives between them reveals that increased cholinergic chemosensitivity appears simultaneously in each of these ganglia despite their differential distances from either the cut end or the cell bodies. However, chemosensitivity in the connectives between the ganglia does not increase.

In order to localize the cholinergic responses more precisely, acetylcholine was applied iontophoretically. After axotomy, increases in responsive membrane surface (where acetylcholine produces direct depolarization) occur in each of the above ganglia, following a time course similar to that of increased chemosensitivity.

When a single axon, or two axons, are cut while the others remain intact, increased chemosensitivity appears only in the axotomized axons. In the neighboring intact giant axons, chemosensitivity remains low. It is therefore concluded that in this case chemosensitivity is increased directly by axotomy.

131.1 LOCALIZATION OF NERVE GROWTH FACTOR BOUND TO CULTURED SENSORY NEURONS. S.T. Carbonetto and R.W. Stach, Depts. of Pharmacology and Biochemistry, S.U.N.Y. Upstate Medical Center, Syracuse, NY 13210.

Neurons were dissociated from the dorsal root ganglia of 9 day chick embryos by trypsinization (0.025%) followed by trituration. The cells were cultured on collagen-coated culture dishes in growth medium consisting of: Eagles Minimal Essential Medium, 10% horse serum, 2% embryo extract and 10 ng/ml β nerve growth factor (βNGF). βNGF was labelled with ^{125}I by the lactoperoxidase procedure to a specific activity of approximately 2000 cpm/fmol.

After 2 days of growth 6 identical sets of cultures (3 experimental sets and 3 control sets) were removed from the incubator, washed 3 times with phosphate buffered Gey's balanced salts solution (PBG) and returned to the incubator for 1 hour in PBG. Experimental cultures were then incubated with ^{125}I-βNGF at 1 ng/ml, 5 ng/ml and 20 ng/ml. To determine the level of "non-specific" binding in experimental cultures, control cultures were incubated with the same concentrations of ^{125}I-βNGF plus 1000-fold concentration of unlabelled βNGF. After incubation for 30 min. at 23°C, all cultures were quickly washed in PBG and fixed in 2% paraformaldehyde/1% glutraldehyde in 150 mM phosphate buffer. The cultures were then dehydrated in alcohol (50%, 70%, 95%, 100%) and coated with Kodak NTB-2 emulsion. After approximately 2 weeks of exposure, the autoradiographs were developed and observed in a Zeiss photomicroscope with phase and bright field optics.

At both 1 and 5 ng/ml the binding of ^{125}I-βNGF in experimental cultures was highly specific and control cultures had little binding above background (background was estimated from cultures not exposed to ^{125}I-βNGF but autoradiographed as described above). Also, at 1 and 5 ng/ml the binding of ^{125}I-βNGF was highly selective for neurons (cells with refractile somata and long processes) with very little binding above background to non-neuronal cells such as fibroblasts. At 20 ng/ml the binding of ^{125}I-βNGF was greatly reduced in its selectivity for neurons, and its specificity.

At 5 ng/ml ^{125}I-βNGF bound extensively to neuronal somata and in the autoradiographs exposed emulsion grains could be found along the length of growing neurites and over growth cones. However, not all neurons bound the ^{125}I-βNGF to the same extent and within small clusters of neuronal somata it was possible to find heavily labelled cells adjacent to cells that had little or no label. Future experiments will be aimed at describing the localization of higher affinity ($K_d \sim 10^{-11}$ M) vs. lower affinity ($K_d \sim 10^{-10}$ M) binding sites for NGF, and whether the amount of NGF bound by neurons reflects their growth rate. This work was supported by NIH grant #NS 12325.

131.2 BINDING AND SEQUESTRATION OF ^{125}I-β NERVE GROWTH FACTOR TO EMBRYONIC SENSORY NEURONS. R.W. STACH, B.J. WAGNER* AND E.J. OLENDER* (SPON: J. Robson). Dept. of Biochemistry S.U.N.Y. Upstate Medical Center, Syracuse, NY 13210.

Nerve growth factor (NGF) is necessary for the growth and development of the sympathetic and embryonic sensory nervous systems. It has been shown that NGF binds to its responsive cells through a cell surface membrane receptor. Recently, it has been shown, for sympathetic neurons, that after NGF binds to the receptor, a time and energy dependent process occurs that makes the bound NGF inaccessible to the external milieu (Stach & Olender, J. Supermolec. Structure, Suppl. 4, 58, 1980). This inaccessible NGF has been termed sequestered NGF. We were interested in determining if a similar process occurred with sensory neurons.

Cell dissociates from 9 day embryonic (E9) chick dorsal root sensory ganglia were used in the studies. The binding of ^{125}I-βNGF was found to be of high affinity and saturable, with apparent dissociation constants of 2.6×10^{-11} M for the higher affinity (type I) sites and 3.6×10^{-10} M for the lower affinity (type II) sites. These dissociation constants are similar to those obtained by Sutter, et al. (J. Biol. Chem 254, 5972, 1979), and are also very similar to the dissociation constants obtained for sympathetic neurons. When E9 sensory nerve cells are incubated with ^{125}I-βNGF (3.8×10^{-10} M) for various times and then incubated with an excess of native βNGF for an hour, or longer, a certain amount of the specifically bound ^{125}I-βNGF can not be displaced. The sequestration process in sensory neurons is also time and energy dependent. The sequestration process is not temperature dependent as is also the sequestration process in sympathetic neurons. The energy dependence can not be explained as an affect on the binding of ^{125}I-βNGF to the sensory neurons; since in the presence of the metabolic inhibitor, sodium fluoride, and the uncoupler of oxidative phosphorylation, dinitrophenol, there is no observable effect on the binding. It also appears that the type I sites are involved to a greater extent in the sequestration process than are the type II sites. At low concentrations of ^{125}I-βNGF a higher percentage of the specifically bound NGF is sequestered than at high concentrations.

This work was supported by NIH grant #NS12325.

131.3 CAN HUMORAL FACTORS INDUCE ACETYLCHOLINE-RECEPTOR AGGREGATES IN CULTURED MUSCLE CELLS OTHERWISE FREE OF AGGREGATES ? J. Hooisma*, A.J.M. Blom*, T. Magchielse*, H. Muijser* and W.F. Stevens*. (SPON: O.L. Wolthuis) Medical Biological Laboratory TNO, Rijswijk (Z.H.), The Netherlands.

In cultured skeletal muscle cells acetylcholine (Ach) receptors are initially distributed uniformly on the cell membrane. After some time in culture clusters of Ach-receptors, socalled hotspots, are formed. Christian et al. (1978) have presented evidence that the number of hotspots can be increased by humoral factors released from neuronal tissue. For reasons unknown only a negligible number of hotspots are formed in muscle cells in our cultures which were conventionally prepared from leg or breast muscles of 11 day old chick embryo's.

Aggregates of Ach-receptors could be induced in our cultures when muscle cells were grown together with spinal cord neurons or neurons from the ciliary ganglion. No aggregates were formed in mixed cultures with neurons from dorsal root ganglia. Neurons were added as spinal cord explants or as whole ganglia. The density of Ach-receptor aggregates induced by spinal cord neurons decreased gradually with increasing distance from the neuronal tissue. It was observed that contact between muscle cells and neurites was not sufficient to induce aggregation of Ach-receptors. Neurites of the ciliary ganglion visualised by injecting the cellsoma with the fluorescent dye Lucifer Yellow (gift W.W. Stewart, Bethesda, U.S.A.) could be seen coursing over the muscle surface for long stretches apparently without inducing any aggregates. The gradient of cluster density observed in the presence of spinal neurons was lost when the mixed cultures were grown on a slowly rocking table that caused thorough mixing of the culture medium. Clusters then appeared throughout the culture. Conditioned medium obtained from such mixed cultures induced aggregates in cultures of muscle cells deprived of neuronal tissue. The latter observations can only be explained by the assumption that a humoral factor is involved. If such a humoral factor is released from the nerve ending it might be possible to influence the aggregation of Ach-receptors by electrical stimulation of the neurons. In fact a member of our group has shown that such stimulation during one week caused a reduction of the number of endplates (Magchielse et al. 1980). Presently we are investigating this hypothesis.

131.4 EFFECTS OF NEURONAL CELL FACTORS ON KINETICS AND AGGREGATION OF CULTURED RAT MUSCLE ACETYLCHOLINE RECEPTORS. S. Hasegawa*, H. C. Bauer*, and C. N. Christian* (SPON: D. Symmes). Lab. of Devel. Neurobiol., NICHD, NIH, Bethesda, Md. 20205.

Medium conditioned by cells of the neuronal cell line NG108-15(NG108-15 CM) increases the aggregation of the acetylcholine receptors(AChR) of cultured embryonic rat myotubes. We report here that NG108-15 CM also decreases the rate of AChR degradation of AChR and has little effect on the rate of AChR synthesis. Myotube cultures were treated for at least 10 hours with 20-fold concentrated CM, labelled with [^{125} I] alpha-bungarotoxin, and the release of radioactivity measured over 40 hours in the presence of CM. In untreated cultures the average half-time(T 1/2) of AChR is 22.5 hours. In cultures treated with NG108-15 CM, the total number of AChR was increased by 13%, and the T 1/2 of AChR degradation was increased by 33%. Myotubes similarly treated with medium conditioned by C6 glioma cells had no effect on the T 1/2 or the total number of AChR. We tentatively conclude that neuronal cells produce factors which both aggregate AChR and decrease the rate of degradation, and that these factors are not produced by glial cells. It remains to be shown whether the same factor which produces AChR aggregation also increases the metabolic stability of AChR.

The cellular mechanism of the modification of the rate of AChR degradation was studied by treating myotubes with agents known to affect the cross-linking of cell surface receptors or the metabolism of cells. Concanavalin-A treatment increased the T 1/2 of AChR by 100%, whereas succinyl Concanavalin-A was without effect. The cyclic nucleotides dibutyryladenosine cyclic monophosphate and dibutyrylguanosine cyclic monophosphate had no effect on the rate of AChR degradation. The T 1/2 of AChR degradation was increased 16% and 23% by 1mM adenosine 5'-triphosphate(ATP) and 1mM adenosine, respectively. A 24 hour treatment with the cholinergic agonist carbachol at a concentration of 10^{-5} M decreased the total number of AChR to 75% of control values, but had no effect on the subsequent rate of AChR degradation. The presence of neuronal factors and ATP at the neuromuscular junction may contribute to the metabolic stability of junctional AChR.

131.5 SUB-POPULATIONS OF CHICK SYMPATHETIC NEURONS RESPOND DIFFERENTIALLY TO THREE SURVIVAL FACTORS IN CULTURE.

David Edgar*, Yves Barde* and Hans Thoenen. Dept. Neurochemistry, Max-Planck-Institut,D-8033 Martinsried, West Germany.

Quantitative observations on the survival of sensory neurons in culture allowed as to define two classes of survival factors, differing funtionally in terms of the age of maximal neuronal responsiveness. (Barde et al., PNAS, 77:1199-1203, 1980). Thus, brain extracts or glioma conditioned medium (GCM) are distinct from the nerve growth factor (NGF): they support the survival of neurons dissociated from dorsal root ganglia taken from chick embryos older than those responding maximally to NGF.

We now show that such a differential effect is of more general applicability: neurons dissociated from embryonic chick paravertebral sympathetic ganglia become increasingly responsive to GCM throughout embryonic development, whereas NGF becomes less effective after embryonic day 12. It is shown that another commonly used neuronal survival factor present in heart cell conditioned medium (HCM, Collins, Dev. Biol., 65:50-57, 1978) is distinct from both NGF and GCM: the sympathetic neurons become maximally responsive to HCM at embryonic day 14 i.e. after NGF but before GCM.

That the factors are distinct is also supported by the observation that the combination of HCM with either GCM or NGF allows the survival of up to 90 % of the neurons plated, i.e. a greater proportion than those supported by saturating concentrations of any factor acting alone.

The results provided by this experimental approach further indicate that the sympathetic chain ganglia at any given stage of development consist of sub-populations of neurons which differ in their requirements for survival factors in culture.

131.6 NEUROTROPHIC FACTOR: DEPENDENCE OF IN VITRO MYOGENESIS ON A NEUROTROPHIC PROTEIN PRESENT IN CHICK EMBRYO EXTRACT.

T. H. Oh, and G. J. Markelonis. Dept. of Anatomy, Univ. of Maryland Sch. of Med., Baltimore, MD. 21201.

A neurotrophic protein (neurotrophic factor: NTF) purified from nerve tissue has been shown to enhance the morphological development and to promote the maintenance of skeletal muscle cells in vitro (Markelonis, G. J. and Oh, T. H., Proc. Nat. Acad. Sci., USA, 76: 2470-2474, 1979). We have elicited a specific antiserum against purified NTF in rabbits. Using this antiserum, we have examined whether NTF is also required for the initial differentiation of avian myogenic cells in vitro. Dissociated myogenic cells obtained from 12-day chick embryos were grown in the culture medium consisting of Dulbecco's modified Eagle's medium, horse serum and chick embryo extract (EE). NTF was found to be a component of EE, a constituent of culture medium required for myogenesis in vitro, by an immunodiffusion assay and by NaDodSO$_4$-gel electrophoresis. The removal of NTF from EE by immunoprecipitation with anti-NTF serum completely inhibited myogenesis. When myogenic cells were grown in culture medium from which NTF has been removed, the cells failed to differentiate beyond the myoblast stage. However, when NTF (25 µg/ml) was added to the NTF-absorbed culture medium, normal myogenesis ensued. Furthermore, myogenic cells underwent normal myogenesis in the absence of EE if NTF (25 µg/ml) was added to the culture medium. These results demonstrate that NTF is the component of EE required for myogenesis and that it influences the initial differentiation of myogenic cells in vitro.

131.7 ABSENCE OF ARGININE-ESTEROPEPTIDASE ACTIVITY IN HUMAN NERVE GROWTH FACTOR.

M. Blum*, C. E. Beck*, and J. R. Perez-Polo. Dept. Hum. Biol. Chem. & Genet., Univ. Tex. Med. Br., Galveston, Texas 77550.

Nerve Growth Factor (NGF) is one of a family of trophic factors required during the development of the vertebrate peripheral nervous system. The NGF protein has been isolated from the male mouse submaxillary gland, a number of snake venoms, guinea pig prostate and more recently from human placental tissue. In all species studied to date, NGF has been found to exist as a high molecular weight complex. Murine NGF, the most highly characterized form, consists of three different subunits, α, β and γ. This complex is weakly associated by noncovalent forces and can be dissociated either by a simple dilution or a shift in pH. The biological activity resides in the β subunit which has been found to be a basic protein with a molecular weight of ∿26,000 daltons. The γ subunit possesses an arginine-specific esteropeptidase activity. Presently no known biological activity has been associated with the α subunit.

NGF isolated from human placental tissue also appears to be associated in a high molecular weight complex with its biological activity residing in a basic subunit. However, we have failed to demonstrate an arginine-esteropeptidase activity like that demonstrated for the murine γ subunit. It has been reported for murine NGF that the enzyme activity of the γ subunit is present when it is dissociated from the complex and is inactive when bound to the β subunit. Therefore, our inability to detect enzyme activity from human NGF may be more of a reflection of an increase in affinity between the β subunit and a possible γ subunit, rather than the total absence of such a γ-like component.

Supported in part by NIH grants NS-15324 and NS-14034, Robert A. Welch Foundation grant H698, and a RCDA (NS00213) to J.R.P.

131.8 NEUROTROPHIC FACTOR: PURIFICATION AND CHARACTERIZATION OF A NEUROTROPHIC FACTOR FROM CHICKEN SCIATIC NERVES.

G.J. Markelonis, V.F. Kemerer* and T.H. Oh. Department of Anatomy, Univ. of Maryland School of Medicine, Baltimore, Maryland 21201.

A protein isolated from sciatic nerves of adult chickens promotes the morphological maturation and maintenance of embryonic avian skeletal muscle cells in the absence of innervation and is required for normal myogenesis in vitro. This neurotrophic factor (NTF) has been purified by ion-exchange column chromatography on DEAE cellulose followed by gel filtration on Sephadex G-100 superfine. NTF migrated as a single polypeptide chain of molecular weight (MW) 84,000 on sodium dodecyl sulfate-gel electrophoresis. The native MW of NTF as determined by sedimentation equilibrium centrifugation was 86,400. Amino acid analysis revealed that NTF is relatively deficient in tryptophan, histidine, glycine and arginine, but enriched in cysteine, methionine, alanine and lysine. Carbohydrate determination showed that NTF is composed of 11% sugar by weight with no detectable N-acetylneuraminic acid residues. Sedimentation velocity centrifugation studies revealed an $S^{o}_{20,w}$ of 5.11 with a frictional coefficient of 1.31. NTF had no detectable protease or acetylcholinesterase activity as determined by sensitive assays. The results of the present study provide new biochemical information on a macromolecule with biological activities similar to those of the "maintenance" group of growth factors which includes such proteins as insulin and nerve growth factor (NGF).

Supported by grants from the NIH (NS 15013 and 16076) the MDA and the Paralyzed Veterans of America.

131.9 NEURONAL SURVIVAL PROTEIN (NSP): A SUBSTANCE SUPPORTING SURVIVAL OF PARASYMPATHETIC NEURONS IN CELL CULTURE. J. B. Tuttle*, C. Greene*, G. Pilar and J. Lucas-Lenard*. (SPON: H. Swadlow). Physiol. and Biochem. and Biophys. Sections, Bio. Sci. Grp., Univ. of CT, Storrs, CT 06268.

We have attempted to isolate a substance capable of supporting long-term survival of dissociated ciliary ganglion neurons. Previous work (Tuttle, et al., Brain Res., 183 (1980) 161-180) showed that a saline extract of chick embryo contained survival-promoting activity. Thus, we sought to determine if any single component could substitute for extract in a survival bio-assay. The bio-assay consisted of pre-plating neurons for 24 hrs. at relatively low density (2-4,000 neurons/cm^2) in 80% modified MEM with 10% HS and 10% whole embryo extract. This medium was then replaced with 5% HS-MEM plus test substance. The number of neurons surviving up to three weeks was determined by counting under phase-contrast.

Ultrafiltration of whole extract indicated that a fraction of mol. wt. 10-30,000 supported survival equivalent to control. Further, this fraction was not permissive for non-neural cell growth, thus simplifying the assay. Polyacrylamide gel analysis on a 7% non-denaturing gel revealed a single band, while on a 15% SDS gel four major bands were stained (mol. wt. ≈ 17K, 12K, 10K, 7K). Sephracryl S-100 column chromatography in 0.1M buffer (pH 7.5) of the ultrafiltrate revealed a broad protein peak with a maximum m.w. of about 12K. Bio-assay revealed a corresponding activity peak at 12,000 m.w. The substance thus isolated is sensitive to trypsin, suggesting that it is a protein. It is stable at 4°C in dilute solution and active at nanomolar concentrations. Preliminary specificity tests suggest the substance supports survival and neurite extension from sympathetic neurons also. The substance has been tentatively named "neuronal survival protein" (NSP).

Several other laboratories have recently reported on substances with various "trophic" actions upon cholinergic neurons, and on ciliary ganglion neurons in particular (Helfand, et al., Expt. Cell Res., 113 (1978), 39-45; Collins, PNAS, 75 (1978) 5210; McLennan and Hendry, Neurosci Let. 10 (1978) 269-273; Manthorpe et al., J. Neurochem., 34 (1980) 69-75; Ebendal, et al., Neurosci. Let. 14 (1979) 91-95). The relationship, if any, between NSP and these other factors remains to be determined. However, we believe NSP to be the lowest m.w. substance yet isolated that supports long-term survival of dissociated parasympathetic (and other ?) neurons in culture. Investigations into the chemical nature, physiological activity and developmental significance of NSP are in progress. Supported by NIH NS10338, NS5382, The Univ. of Conn. Research Foundation, and the National Spinal Cord Injury Foundation (J.B.T.).

131.10 DEVELOPMENTAL STUDIES OF CHICK CILIARY GANGLIONIC CELLS IN VITRO. M. Manthorpe, R. Adler and S. Varon. Dept. Biology, Univ. of Calif., San Diego, La Jolla, CA 92093.

In vivo, the survival and normal development of chick embryo ciliary ganglion (CG) neurons depends upon the establishment of connections with their intraocular target tissues, i.e., the choroid and iris musculature. It has been shown that the in vitro survival of 8-day chick CG neurons depends upon the presence of exogenously added ciliary neuronotrophic factor (CNTF), which is highly concentrated in, and has been partially purified from, extracts of choroid-iris tissue (Science 204: 1434, 1979; Dev. Biol. 74: 401, 1980; J. Neurochem. 34: 69, 1980). We have now undertaken the examination of CG neurons with regard to developmental changes in CNTF requirements.

As a first step, adequate CG dissection procedures and a common dissociation method were developed for CG's from 5 to 14 day chick embryos. Total cell yields per ganglion rose from 10^4 at day 5 to 7×10^4 at day 14. Two cell types could be recognized in the dissociate after day 7, but not reliably before: i) small phase dark (SD) cells, possibly non-neurons and ii) large phase bright (LB) cells, presumptive neurons. Dissociates contained 10-11 x 10^3 LB cells per ganglion between days 7 and 9 and this number appeared to decline 50% by day 14. After 24 hours in vitro the number of non-neuronal flat cells increased dramatically in cultures from 9-14 day CG. LB cells were also present in 24 hour cultures from all stages when eye-CNTF was added to the medium. However, neuritic development could be observed in cultures from younger but not older CG. In the absence of added CNTF, no or very few LB cells were present in 24 hr cultures from 5-9 day CG. In contrast, the number of LB cells present at 24 hr in the cultures from older CG increased progressively, reaching for the 14 day CG the same number found in CNTF-supplied ones. Current work is attempting to investigate the basis for these different in vitro behaviors of older CG cells.

Supported by NINCSD grant NS-07606 and NEI grant EY-02854.

131.11 CHARACTERIZATION OF NEURITIC OUTGROWTH PROMOTING ACTIVITY OF CONDITIONED MEDIUM ON SPINAL CORD EXPLANTS. Lori B. Dribin and John N. Barrett. Dept. Physiol. and Biophys., Univ. of Miami Med. Sch., Miami, Fla. 33101.

Conditioned medium from a variety of nonneuronal primary cultures (rat skeletal muscle, fibroblast and lung) produces a 3-to4-fold increase in the area of neuritic outgrowth from rat spinal cord explants compared to explants grown in fresh, nonconditioned medium [Dribin, L.B. and Barrett, J.N. (1980). Dev. Biol. 74, 184-195]. The neuritic outgrowth promoting factor(s) in conditioned medium is a macromolecule and is stable when heated to 58°C for 30 min. (op cit). We report here attempts to further purify and characterize this factor(s).

Conditioned medium was collected from monolayer cultures of fetal rat lung and concentrated by molecular filtration (nominal molecular weight cutoff of 10,000 daltons). The concentrated conditioned medium was then subjected to column chromatography or trypsin treatment. The outgrowth promoting activity of each treated fraction was assayed by measuring the area of neuritic outgrowth around fetal (15 day) rat spinal cord slices after 7 days in vitro, and comparing this area to the area of outgrowth around matched slices grown in fresh, nonconditioned medium.

When the concentrated conditioned medium was analyzed by molecular gel chromatography with Ultrogel AcA 54 or AcA 34, the eluted fractions containing the highest neuritic outgrowth promoting activity were consistently found in a region corresponding to an apparent molecular weight of approximately 60,000 daltons, although fractions with lower activity were usually found in lower molecular weight regions.

The biologically active portion of the conditioned medium adsorbed to a Concanavalin A-Sepharose column, because the fraction of the conditioned medium that passed through the column displayed no biological activity. The active fraction of the conditioned medium could then be recovered from the column by elution with α-methyl mannoside.

The neuritic outgrowth promoting activity of the conditioned medium was destroyed by trypsin treatment (1 mg/ml, 1 hr., 37°C).

These results suggest that the factor(s) responsible for the increased neuritic outgrowth from spinal cord explants is a glycoprotein.

Supported by NIH Grant NS12207.

131.12 STAGE-DEPENDENT GROWTH INFLUENCES ON FROG TADPOLE DORSAL ROOT GANGLION NEURITES EXERTED BY SPINAL CORD EXPLANTS IN VITRO. E.D. Pollack, V. Liebig* and C.R. Reed*. Inst. for the Study of Developmental Disabilities and Dept. of Biological Sciences, Univ. Illinois, Chicago, IL 60680.

Each of the major components of the spinal reflex arc (spinal cord, dorsal root ganglion, limb muscle) can be represented as part of an interacting nerve-target complex during the growth of nerve fibers. A tissue culture system comprised of combinations of these tissues explanted from Rana pipiens tadpoles at several developmental stages has allowed a determination of stage-dependent influences of target tissues on the growth of neurites from neural tissues normally innervating those targets. An earlier study (Pollack and Liebig, Science 197:899,1977) reported that the appropriate target tissue for peripheral spinal fibers during development is the mesenchymal limb bud rather than differentiated muscle, as evidenced by enhanced and directed nerve fiber growth. We now report that the optimal stage for eliciting neurite growth from dorsal root ganglia (DRG) by its centripetal target, the spinal cord, is that characterized by a moderately differentiated hind limb lacking exteroceptive innervation (stage XI of Taylor and Kollros, Anat. Rec., 94:7, 1946). The maximal response on the part of DRG neurites occurs when both the DRG and explanted cord target are at stage XI. This is the same stage at which the DRG is also most responsive to the presence of limb tissue, also at stage XI (Pollack, et al, J. Cell Biol., 83:135a, 1979). Unlike the cord, which presents maximal neuritic outgrowth in the presence of undifferentiated limb bud tissue, the DRG requires a substantial degree of limb differentiation, i.e., muscle, in order to respond in vitro. The DRG exhibits no outgrowth in the absence of target tissue in the serum- and extract-free medium in these studies (Muhlach and Pollack, TCA Manual 4:875,1978). The percentage of DRG explants showing outgrowth increases as the stage of both DRG and cord advance. However, the extent of outgrowth remains sparse to modest until the DRG has attained stage XI after which the response to different cord stages decreases. It is suggested that the target tissue for nerve fibers, whether neural or non-neural, can exert critical stage-dependent influences on the extension of nerve fibers in vitro with in vivo correlates. The nature of the influence is hypothesized to be nerve growth factor (NGF) of target origin for the DRG, and an as yet uncharacterized factor of limb mesenchyme origin for the cord neurites. (Supported by NIH grant NS 13814 to E.D.P.)

131.13 FACTORS AFFECTING THE APPEARANCE OF JUNCTIONAL AND PERIJUNCTIONAL ACH RECEPTORS IN ORGAN CULTURE. Anthony Olek and Norman Robbins
Dept. Anat. Sch. Med. Case Western Reserve Cleveland, O. 44106

A rapid, nerve stump dependent appearance of acetylcholine receptors (AchR) had been previously reported to occur after 42 hours following the introduction of rat phrenic nerve-diaphragm preparations into organ culture (Olek and Robbins, Soc. Neurosci. Abt. 1979, 5,2585). Approximately 2 x 10^6 or more AchR (assayed by I^{125}-alphabungarotoxin binding) appeared in the junctional region between 42-44 hrs. of denervation in organ culture, while only approximately 5 x 10^5 AchR appeared in an equivalent surface area of extrajunctional membrane during the same time. The presence of a long nerve stump prevented the increase of AchR specific to the endplate region, but had no effect on the appearance of extrajunctional AchR.

Further studies have revealed: 1) The increase in junctional region AchR is composed primarily of junctional receptors. Autoradiographic examination of I^{125}-alphabungarotoxin (*BTX) binding indicated that approximately 75% of the increase in binding is confined to the endplate, and approximately 25% to a region within 300μ of the endplate. 2) The increase in junctional region receptors reflects the new appearance of AchR. Prior labelling with cold BTX does not prevent the subsequent appearance of junctional region AchR after 42 hrs. 3) The newly appeared AchR demonstrate pharmacologic specificity. Binding of *BTX to newly appeared AchR (after 42 hrs.) can be blocked with cold BTX. 4) The appearance of AchR is sensitive to block of RNA synthesis. Actinomyosin D prevents the appearance of junctional region AchR if applied before 24 hrs. of culture, but has no effect on the AchR increase after that time. 5) The increase in AchR does not depend on muscle activity or nerve impulse transmission. The nerve stump dependent appearance of AchR persists with the application of tetrodotoxin, cold BTX, and pan-curonium. 6) Stimulation of the nerve stump produces an earlier appearance of junctional region AchR in culture. Stimulating the nerve stump at 10 hz for 1 hr. in the presence of curare, followed by washout of the stimulated media, results in an increase in enplate region AchR found at 24-32 hrs. of culture.

The present findings suggest that junctional and extrajunctional AchR are controlled by different neuronal mechanisms and that junctional receptors are subject to rapid alteration.

131.14 THE DEVELOPING HIPPOCAMPUS IN CELL CULTURE

W. Seifert, N. Buckley*, B. Ranscht*

Friedrich-Miescher-Laboratorium, Max-Planck-Institute, Tübingen, W-Germany

The hippocampus consists of only a few classes of well characterized neurons: the pyramidal neurons CA_1-CA_4, the granular neurons of the dentate gyrus, and the inhibitory basket cells. At a certain developmental stage of the fetal rat brain, only pyramidal neurons will survive and develop in dissociated cell cultures of the hippocampus, together with glial cells and other non-neuronal cells (1). With this culture system we are studying 1) the morphological and biochemical development of pyramidal neurons, 2) the control of possible synapse formation and 3) the trophic interactions between neuronal and glial cells.

We have isolated the hippocampus from fetal rats at day 18 and followed the morphological development of dissociated cultures under various conditions. Identification of cell types was carried out by morphology and by binding of immunocytochemical markers: tetanustoxin for neuronal cells, antiserum against GFAP for astrocytes and antiserum against galactocerebroside for oligodendrocytes. In addition a monoclonal antiserum was used for identification of neurons, and a monoclonal antiserum produced in our laboratory for identification of oligodendrocytes.

After defining optimal conditions for long term neuronal cultures (2-3 months), our goal is to study the development of neurons in a controlled environment in order to evaluate the contributions of genetic programs versus environmental influences such as direct cell-cell interactions or soluble trophic factors. For this purpose we are studying changes in morphology and in the appearance of specific antigens in parallel with some biochemical markers: ganglioside pattern and neurotransmitter uptake (GABA, glutamate).
Trophic effects of glial conditioned media and gangliosides on neuronal cells have been described previously in our laboratory (2,3). We are now investigating such trophic effects in this culture system of the developing hippocampus.

131.15 COMPARISON OF THE GROWTH AND DIFFERENTIATION OF SYMPATHETIC NEURONS GROWN IN A BIOCHEMICALLY DEFINED MEDIUM AND IN SERUM-CONTAINING MEDIUM. J. E. Freschi. Neurobiology Department, Armed Forces Radiobiol. Research Inst., Bethesda, MD 20014.

For the past several years we have successfully grown sympathetic neurons in culture over several months using modified Ham's F12 medium supplemented with 5% fetal bovine serum and nerve growth factor (NGF). Recently we have had success in growing these neurons in the biochemically defined medium of Bottenstein and Sato. Beyond cell survival, however, changes in medium composition may have marked effects on differentiated neuronal functions such as electrical membrane properties, neurotransmitter synthesis, chemosensitivity, and synapse formation. In order to compare neurons grown in defined medium (N1) with those grown in serum-containing medium, neurons dissociated from neonatal rat superior cervical ganglia were plated in F12 + 10% fetal bovine serum (FCS) + NGF + antibiotics for less than 24 hrs. They were then fed either N1 + NGF or F12 + 5% FCS + NGF. Neuronal survival appeared to be approximately the same after the first week. In serum, fibroblast proliferation was rapid, and Schwann cells formed overlying aggregates with interconnecting bundles of neurites. In N1, however, fibroblast proliferation was slow. Schwann cells formed a more diffuse meshwork, and neurites showed less tendency to form bundles. In serum, nearly every cell showed many spontaneous EPSPs and action potentials. Recording from neuron pairs showed evidence of widespread complex neuronal networks. In N1, fewer cells showed spontaneous EPSPs, and the amount of synaptic activity on a given cell was less than on neurons in serum. Nevertheless, spontaneous synaptic activity was seen in about half of the neurons studied grown in N1. In both sets of cultures spontaneous synaptic activity was blocked by nicotinic antagonists. Neither serum nor N1 grown neurons showed specific catecholeamine fluorescence between 2 days and a month in culture. The incidences of Ca++-dependent, K+-mediated spike after-hyperpolarizations and iontophoretically evoked muscarinic acetylcholine potentials were similar in the two groups of neurons.

I conclude that sympathetic neurons can be grown in good condition in a biochemically defined medium. This will be of value in studying the influence growth and trophic factors on sympathetic neuronal differentiation.

131.16 SYNERGISTIC EFFECTS OF NERVE GROWTH FACTOR AND CYCLIC AMP IN PC12 CELLS. G.E. Landreth, P.W. Gunning, M.A. Bothwell* and E.M. Shooter. Dept. of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

A clonal line of rat pheochromocytoma cells (PC12) respond to nerve growth factor (NGF) by cessation of division and development of a number of properties characteristic of mature sympathetic neurons. These cells undergo morphological differentiation and extend neurites over a period of days in response to NGF by a transcriptionally-dependent process. When PC12 cells are exposed to NGF (50 ng/ml) or dibutrylcyclic AMP (dbcAMP, 1mM), 10% and 26% of the cells develop neurites within 24 hrs. respectively. If the cells are exposed to both agents 70% of the cells extend neurites within 24 hrs. The synergistic neurite outgrowth is dependent on the NGF concentration, and is maximal at 0.5 - 1 ng/ml NGF. The dose-dependent stimulation of neurite outgrowth is identical to that observed in a neurite regeneration assay from differentiated PC12 cells.

Potentiation of neurite outgrowth occurs as a function of the simultaneous exposure to both agents, neurites induced by dbcAMP were not maintained after replacement of the dbcAMP by NGF. The initiation of neurite outgrowth in the presence of both dbcAMP and NGF is independent of RNA and protein synthesis, in contrast to that caused by NGF alone.

The response was specific for cAMP, as cholera toxin together with NGF produced the same response as that observed with dbcAMP.

Cellular RNA concentration increased in response to NGF and dbcAMP within 24 hrs, however, in the presence of both agents the increase was additive or greater.

These results are inconsistent with a common mechanism of action for NGF and cAMP, since maximally stimulating concentrations of both produce additive or synergistic effects when added together. The data suggest that cAMP relieves the transcriptional dependency of NGF-mediated neurite outgrowth, permitting rapid reorganization of the PC12 cytoskeleton.

131.17 MORPHOLOGICAL AND BIOCHEMICAL CHARACTERIZATION OF HUMAN NEUROBLASTOMA AND SYMPATHETIC GANGLION CELLS IN SERUM-FREE SUPPLEMENTED MEDIUM. D.W. Burmeister*, G.K. Zeevalk*, J.M. Carroll* and K.M. Lyser. Dept. of Biological Sciences, Hunter College of the City University, New York, NY 10021.

Cells of the clonally derived continuous line SK-N-SH-SY5Y (SY5Y) (Biedler et al., Cancer Res. 38:3751, 1978) have been cultured in Bottenstein and Sato's N2 medium (Proc. Natl. Acad. Sci. 76:514, 1979), in N2 without selenium (N2A), or in medium with 10% fetal calf serum (FCS). As observed by phase, scanning and transmission electron microscopy, SY5Y cells cultured in defined medium showed an altered morphology from cells cultured in FCS. The cells became less adherent to the substrate with only a few areas of the cell periphery making close contact. They developed more surface ruffling and formed more cell clumps at comparable densities. Ten to 20% of the cells developed distinctive processes, which were generally non-adherent to the substrate along their length and adhered preferentially to other cells. The processes were rich in microtubules as well as ribosomes and mitochondria. The differences occurred with or without FCS or fibronectin on the substrate.

The specific activity of dopamine-β-hydroxylase (DBH) in cultures maintained for 1 week in N2, N2A, or N2A plus 50 ng/ml β-nerve growth factor (NGF) was the same as that in the presence of FCS. SY5Y carried in N2 for 90 days maintained this level of DBH activity.

For comparison, human fetal ganglion cells, which are the normal counterparts of the tumor cells, were cultured in N2 plus 10 ng/ml NGF and in serum-supplemented medium containing chick embryo extract and NGF for at least 2 weeks. The human fetal neurons maintained their cytological differentiation in vitro and formed extensive, typical axons with microtubules and neurofilaments. In defined medium, neuronal cells showed good survival and differentiation with extensive neurite outgrowth and formation of fiber bundles. There was a marked reduction in non-neuronal cells, in contrast to cultures in medium with FCS, which were rapidly overgrown with fibroblasts. Exogenous NGF was required for survival of the sympathetic neurons in either medium. The level of DBH in these cells is currently being investigated.

The use of defined medium now allows investigation of the effects on human neuronal cells of a variety of factors (cAMP, NGF, glial factors) without the complications contributed by serum.

Supported by PSC-BHE Research Award 13052 from the City University.

131.18 DORSAL ROOT GANGLION NEURONS STIMULATE DIFFERENTIATION AND MYELIN FORMATION BY OLIGODENDROCYTES DERIVED FROM EMBRYONIC SPINAL CORD. P.M. Wood* and R.P. Bunge. Dept. of Anatomy & Neurobiology, Washington Univ. School of Medicine, St. Louis, MO 63110.

We have previously shown that cultured networks of dissociated dorsal root ganglion neurons (DRGN) induce myelin formation by oligodendrocytes (ODC) derived from optic nerve sections taken from 7-14 day postnatal rats (Wood, P., Okada, E., Bunge, R.P., Brain Research, In Press). These optic nerve sections would have already contained mature ODC, which could have accounted for the myelin found. In more recent experiments, spinal cord tissue from 14 day rat embryos has been tested as a source of ODC. ODC differentiation and myelin formation do not occur until after birth in the rat; this embryonic tissue, therefore, contained only ODC precursors.

Neonatal rat dorsal root ganglia were dissociated, cultured for 2 weeks in medium containing fluorodeoxyuridine (10^{-5}M) to suppress Schwann cell ensheathment and fibroblast proliferation, and subsequently maintained for one week in serum rich drug-free medium. At 3 weeks spinal cord tissues from 14 day rat embryos was added to the DRGN networks either as 1) small fragments or as 2) suspensions of mechanically dissociated cord cells. Cultures were fixed at 2 and 4 weeks after cord tissue addition and stained with Sudan Black for light microscopic analysis. ODC type myelin was found at 2 weeks in all cultures of DRGN networks that had received either fragments or cells in suspension but not in control cultures of cord tissue alone. More extensive myelination of axons within DRGN fascicles was observed at 4 weeks in all cultures with both DRGN networks and added spinal cord tissue; in cultures containing just cord fragments, myelin was found only within, or immediately adjacent to the fragments themselves. ODC myelin formation was not observed in dissociated spinal cord cultures in the absence of DRGN networks. These results indicate that both the differentiation of immature ODC precursors into ODC, and myelin formation by ODC were induced (or stimulated) by the presence of stable mature DRGN networks. The proliferation of residual Schwann cells and the formation of Schwann cell myelin was markedly or completely inhibited in areas of the network occupied by glial cells; in contrast DRGN networks not receiving glial cells often became heavily myelinated by Schwann cells by 4 weeks. This culture system demonstrates the importance of a stable neuronal population capable of inducing myelin formation in the study of factors influencing ODC differentiation.

131.19 RELEASE OF PLASMINOGEN ACTIVATOR FROM CULTURED MUSCLE CELLS. M. Patterson*, K. Romstedt* and B.W. Festoff. (SPON: D.K. Ziegler). Dept. of Neurology, Univ. of Kansas Med. Ctr. and Neurobiology Res. Lab., VA Med. Ctr., Kansas City, MO 64128.

We have been exploring mechanisms of maintenance and development of synaptic connections at the neuromuscular junction (NMJ). One recent model proposed is that muscle cells produce and release proteolytic enzyme (PE) activity augmented by nerve terminal-released acetylcholine (ACh). PE are thought to degrade surface molecules and to be involved in extracellular matrix (ECM) metabolism. Elimination of polyneuronal innervation of muscle fibers in neonatal animals may require PE. This model may be applicable to certain disease states of man such as amyotrophic lateral sclerosis (ALS) and others. Interest in release of plasminogen activators (PA) from cells in various tissues has developed because of involvement of PA's in numerous signal biologic processes. Report of their release from nerve and Schwann cells have appeared this past year. PA release from muscle has not yet been reported.

Chick primary muscle cultures (PMC) and G-8 cells, a fusing cell line spontaneously transformed from mouse myoblasts, were evaluated by the fibrin over-lay and ^{125}I-fibrin plate methods. Plasminogen was purified from human plasma and dog serum; fibrinogen from bovine serum. Clones of PA secreting cells were identified and sub-cultured from G-8 cells plated at low density. PMC, before 6 days in vitro, did not produce detectable PA without media additions. However, after 7 days in culture or with 10^{-5}M ACh (with eserine) PA was detected in media. A dose response curve then demonstrated that half-maximal response was approximately micromolar. We next evaluated dibutyryl cyclic AMP (dbcAMP), adenosine and PGE_2. Slight increase in PA activity was found with all. Using SDS gel analysis of ^{125}I-labelled plasminogen incubated with conditioned medium from G-8 cells producing PA, both heavy and light chains of labelled plasmin were detected. Study of the kinetics of release of PA from cloned G-8 cells is in progress. This evidence suggests that PA released from muscle cells, cleaves plasmin, thus providing a potential extracellular mechanism for turn over of surface molecules at the NMJ that may play roles in plasticity, denervation and disease. The role of nerve in regulating such activity, by direct inhibition perhaps in the synaptic cleft or indirectly by "trophic" regulation of synthesis, transit to the surface or release deserves further exploration.

131.20 DEVELOPMENT OF CHOLINERGIC SYMPATHETIC INNERVATION OF ECCRINE SWEAT GLANDS IN RAT FOOTPAD. S.C. Landis and D. Keefe*. Dept. of Neurobiology, Harvard Med. Sch., Boston, Mass. 02115.

Sympathetic principal neurons dissociated from ganglia of newborn rats become cholinergic if grown with certain nonneuronal cells or medium conditioned by them. This induction occurs in immature adrenergic neurons which have acquired the ability to synthesize, store and take up catecholamines (CA); as the neurons acquire cholinergic properties, they lose the ability to synthesize CA but are still able to take up and store exogenous CA. In vivo a minority of principal neurons are cholinergic and some of these innervate sweat glands of cat and rat footpads. We have examined the development of these cholinergic sympathetic fibers in vivo to determine whether they undergo a similar transition from adrenergic to cholinergic function.

In the adult rat, acetylcholinesterase(AChE)-positive fibers form a loose plexus in the SG. In thin sections, AChE-staining surrounds axons which run in bundles partially ensheathed by Schwann cells. Axonal varicosities are separated from the myoepithelial and secretory cells of the SG by a thick basal lamina and often also by fibrocyte processes. In adults, no fibers contain histochemically detectable endogenous CA; however, if 1-10mg/kg α-methylNE is injected ip, a plexus of fluorescent fibers is present and corresponds in position and density to the AChE-stained plexus. CA uptake is blocked by prior injection of DMI (30mg/kg) and is absent from parasympathetic cholinergic fibers in irides and salivary glands of ganglionectomized rats. Thus this CA uptake is specific and a special property of cholinergic sympathetic neurons.

SGs form shortly after birth in the hindfeet. AchE-stained fibers are found in the forming gland at 7 days and increase in number and staining intensity as the SG differentiates during the next two weeks. At 7, 10 and 14 days, endogenously fluorescent fibers are also found in all developing glands and their distribution matches that of the AChE-positive fibers. At 21 days, only an occasional and faintly fluorescent fiber is observed in the absence of exogenous CA. One interpretation of these observations is that a single population of terminals is present, that cholinergic sympathetic neurons in vivo as in vitro initially possess adrenergic properties and that some of these properties are lost as cholinergic ones appear. An alternative possibility is that early-arriving adrenergic terminals retract or degenerate, leaving behind a second population of cholinergic terminals which constitute the adult innervation. Ultrastructural studies are in progress to distinguish these possibilities. Supported by ROI NS 15549. E. Lamperti participated in early studies.

132.1 ONSET OF HORMONAL REGULATION OF ODC ACTIVITY IN THE PERINATAL RAT. S. J. Geyer*, C. M. Kuhn* and S. M. Schanberg. Laboratory of Neuropharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Rapid cell proliferation and tissue growth is closely associated with elevated ornithine decarboxylase activity (ODC). It has been shown that levels of ODC activity in developing rats are altered by a variety of hormones and neural substances and that different organs show varying responsiveness to drug treatment. Recent data from our laboratory suggest that the regulation of tissue ODC activity by hormones changes during development. We have shown in rat pups as young as 2 days of age that a SC injection of growth hormone stimulated liver and brain ODC activity after 4 hr. However, growth hormone had no effect on tissue ODC activity when given SC to 17-21 day old fetuses in utero, whereas, placental lactogen effectively stimulated fetal tissue ODC activity (Hurley, T. W., Endoc. Soc. 1979). In the present study the changing regulation of ODC activity during development was examined by testing the sensitivity of liver and heart ODC activity to hormones and drugs in perinatal rats. ODC activity in fetal liver was found to increase 10 fold (per organ) between 15 and 17 days of gestation while a 10 fold surge in fetal heart ODC activity occurred later, between 17 and 20 days of gestation. Despite the dramatic increase of basal tissue ODC activity occurring in fetal tissues between 15 and 20 days of gestation, fetal liver and heart tissue was found to be completely insensitive to a variety of agents which we have shown markedly enhanced ODC activity in 8 day old pups. Phenylephrine, dexamethasone, dbcAMP, vasopressin, angiotensin II, insulin and PGE_1 were all ineffective when administered SC or IP to fetuses (15-20 days) in utero 4 hr before tissue collection. Furthermore, liver and heart ODC of 0-24 hr rat pups which were delivered naturally or by C-section on the 21st day of gestation also were unresponsive to SC administration of phenylephrine, dbcAMP, vasopressin and PGE_1. However, by 2 days of age, modest ODC increases (200% of control) were elicited in heart and liver tissue by phenylephrine and in the liver by dexamethasone. Starting at 3 days of age the ODC activity response to these drugs was more marked (300-500% of control). These results suggest that although basal tissue ODC activity is changing during the rapid growth phase of gestation, hormonal and neurotransmitter regulation of ODC activity characteristic of an adult develops only after several days of postnatal life. 132.2 SEXUALLY DIMORPHIC NUCLEUS IN THE RAT SPINAL CORD: RESPONSE TO ADULT HORMONE MANIPULATION, ABSENCE IN ANDROGEN INSENSITIVE RATS. S. Marc Breedlove and Arthur P. Arnold, Dept. Psychology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

There is a sexually dimorphic, androgen accumulating motor nucleus in the fifth and sixth lumbar segments of the rat spinal cord, consisting of motoneurons innervating two striated perineal muscles, the levator ani and the bulbocavernosus. This nucleus, the spinal nucleus of the bulbocavernosus (SNB), is diminished or absent in female rats (Breedlove & Arnold, in press). We now report 1) the number of neurons in the SNB is not altered by adult gonadectomy or treatment with testosterone propionate (TP), 2) the size of SNB neurons is increased in the presence of androgen, 3) genetically male Tfm mutant rats with reduced androgen receptors do not have an SNB. These results support the hypothesis that the dimorphic nature of the SNB depends not on the adult hormone state, but on the interaction of androgens with their receptors early in development.

Adult male and female Sprague-Dawley rats were either gonadectomized or sham operated. Sham operated animals were given s.c. injections of vehicle, while the gonadectomized rats were injected with either vehicle or TP, 200 µg/100 g body weight/day for 28 days. Using thionin-stained 50 µm transverse sections, a blind observer made corrected counts of the number of nuclei of densely staining cells in the region normally occupied by the SNB. At least 10 cells from each animal were outlined using a camera lucida, and areas of the neurons and their nuclei calculated.

Across all three treatment groups, male rats had more and larger neurons with larger nuclei in the SNB region than females (2-way ANOVA, $p < .001$). Adult hormone manipulations had no significant effect on the number of neurons counted. Hormone treatment did have a significant effect on neuronal size ($p < .05$), with exogenous or endogenous androgen associated with larger neurons, although the 4 week treatment with TP was insufficient to bring the size of these neurons in gonadectomized females to the level of vehicle injected castrated males. Adult hormone state seems to have little effect on the dimorphism of the SNB, since TP treatment does not affect the number of cells, and only partially compensates for the sex difference in neuronal size.

Seven adult King-Holtzman male rats with the testicular feminization mutation which results in few androgen receptors, and seven normal male littermates were sacrificed and examined as above. Tfm males do not have an SNB, unlike their normal male littermates. In the SNB area, normal males have more and larger cells with larger nuclei than the Tfm rats (t-tests, $p < .001$).

132.3 GLUCOCORTICOIDS INHIBIT MYELINATION IN DEVELOPING RAT. V.L.Friedrich,Jr. and M.C.Bohn. Lab. of Neuromorphology, Dept. of Biobehavioral Sciences, Univ. of Connecticut, Storrs, CT 06268

Glucocorticoids are known to affect the generation of neurons in vivo and of glial cells in vitro. Our study was undertaken to determine the effects of glucocorticoid treatment on myelination in vivo, using optic nerve as a model.

Most oligodendrocytes in rat optic nerve are formed during the second and third weeks after birth(Skoff et al., J.comp.Neurol. 169:313). Therefore, rats were injected daily with hydrocortisone acetate(HCA)(10 µg/g body weight, limited to 200 µg/injection), from postnatal days 7 to 18. Animals were sacrificed at 21 days after birth to determine acute effect of the treatment and at 60 days to assess lasting effects. Untreated litters were used as controls to avoid possible effects of increasing endogenous steroids through the stress of repeated injections. Animals(3 per group) were prepared for electron microscopy and the optic nerves analyzed by standard stereological techniques.

At 21 days after birth, the total amount of myelin (per whole nerve cross section) was reduced in the treated animals by 40%. This reduction was due entirely to a reduction in the proportion of axons myelinated, from 75% in the normal animals to 46% in the treated ones. The total number of axons, average size of myelinated axons, and average size of unmyelinated axons were not affected. In spite of the large deficit in myelin, the average amount of myelin per myelinated axon was normal, suggesting that myelination of individual axons proceeded normally once initiated.

At 60 days after birth, the total amount of myelin was normal, indicating a striking recovery from the substantial deficit at 21 days. This recovery reflected an increase in the proportion of axons myelinated, to the normal value(100%). The total number of axons, amount of myelin per axon, and average axonal size were also normal at 60 days.

To assess possible effects of HCA on gliogenesis, we injected tritiated thymidine on day 19 and sacrificed animals at 60 days. The total number of oligodendrocytes was normal. However, twice as many oligodendrocytes were labeled in the treated group as in the controls. We conclude that more oligodendrocytes were formed in the treated animals than in the controls, after day 18.

Our results show that glucocorticoid treatment of postnatal rats inhibits myelination of optic nerve. Following termination of treatment, we observed late generation of oligodendrocytes and complete recovery of myelination. Our findings raise the more general possibility that glucocorticoid treatment at any age may inhibit myelination or remyelination.

132.4 THE CELLULAR NATURE OF THE CRITICAL PERIOD FOR SEXUAL DIFFERENTIATION IN THE ZEBRA FINCH. Mark E. Gurney Div. of Biology, California Institute of Technology, Pasadena, CA 91125

Within telencephalic brain nuclei which participate in the efferent motor pathway for song in the zebra finch (Poephila guttata) it has proved possible to follow over time the ability of individual neurons to undergo morphological sexual differentiation as a consequence of exposure to 17β-estradiol (E_2). The number of neurons in the nucleus robustus archistriatalis (RA) which are able to differentiate under the influence of exogenous E_2 declines exponentially with increasing age, while the magnitude of their growth response does not change. Such data may suggest that the critical period transition of RA neurons from E_2-responsive to E_2-unresponsive is autonomous to these cells.

Exposure of female zebra finch chicks to E_2 at hatching masculinized the cytoarchitecture of RA. When administered to one-year-old, gonadally intact adult females on the other hand, E_2 had no effect on RA's cytoarchitecture. To investigate the temporal constraints on responsiveness to E_2, female finches were implanted subcutaneously with a Silastic pellet which contained 50 µg of E_2 (Gurney and Konishi, Science, in press) either at hatching, at 3, 6, 9, 15, 30, or at 40 days of age, and then sacrificed for histological examination when sexually mature at 90 days of age. The morphological assay of the ability of RA neurons to respond to E_2 consisted of measurement of their maximum somal diameter and average packing in Nissl-stained material. The distribution of somal diameter for RA neurons in either males or females was unimodal and nonoverlapping. In males the somal diameter of RA neurons averaged 17.9 µm and in normal females averaged 8.2 µm. In females exposed to E_2 at hatching the distribution of somal diameter remained unimodal, but was shifted to an average diameter of 15.9 µm. In females exposed to E_2 at 40 days of age, the pattern of response to E_2 was quite different: neurons which responded to E_2 with an increase in somal size comprised only a fraction of the total neuronal population in RA and were confined within the core of the nucleus. The distribution of somal diameter was thus bimodal with a peak of responsive neurons at 14.6 µm while unresponsive neurons remained 8.7 µm in diameter. The maximum somal diameter attained by E_2-responsive neurons in RA was equivalent in all of the different treatment groups, while the number of E_2-responding neurons within RA fell exponentially with increasing age. The half-life with which RA neurons lost E_2-responsiveness was 17.3 days.

132.5 NEONATAL PROGESTERONE AND SEXUAL BEHAVIOR OF RATS. E. M. Hull. Department of Psychiatry & Behavioral Sciences, University of Texas Medical Branch, Galveston, Texas 77550.

My coworkers and I have demonstrated an antiandrogenic influence of perinatally administered progesterone, manifested as decreased sexual and aggressive behaviors, improved active avoidance and impaired maze performance of intact male rats. We have also demonstrated that pre- and neonatally administered progesterone increased monoamine oxidase activity in whole brain homogenates of rat fetuses and neonates, respectively.

The present experiment investigated the effects of neonatal progesterone treatment on both masculine and feminine sexual behavior of both genders. Lactating females received daily injections of 3.3 mg/kg progesterone or oil, and their offspring were gonadectomized in adulthood and tested for both masculine and feminine sexual behavior elicited by estrogen, progesterone and testosterone regimens.

Progesterone treated males exhibited significant impairment of masculine behavior elicited by both estrogen and testosterone regimens. Latency and frequency of mounts and intromissions of those males which did engage in sexual behavior were not significantly different for the two groups; the major difference was in number of animals which did mount and/or intromit. Males exhibited insufficient feminine behavior for meaningful statistical analysis, though there was a slight preponderance of progesterone treated animals which showed lordosis responses. Progesterone administered to estrogen primed males did not facilitate feminine behavior in either group. There were no statistically significant differences between progesterone treated and control females in either masculine or feminine behavior tests, though there were trends toward reduction in masculine behavior of progesterone treated females during the testosterone regimen. Estradiol benzoate sufficient to elicit considerable feminine behavior failed to elicit any masculine behavior of females. There were no differences in body weight at any time nor in testis or accessory organ weights of males.

The results of this experiment confirm our previous finding of reduced sexual competence of male rats treated neonatally with moderate doses of progesterone, and indicates that this effect is not the result of diminished adult hormone levels. This finding is consistent with the hypothesis that progesterone interacts with testosterone's effects on developing neural circuits, though alterations in sensory mechanisms or in peripheral metabolism of hormones have not been ruled out. Neonatal progesterone appears to have minimal or no effect on feminine behavior patterns of rats.

132.6 THE INFLUENCE OF NEONATAL GONADECTOMY AND ANDROGENS ON THE SEXUALLY DIMORPHIC NUCLEUS OF THE PREOPTIC AREA. R.A. Gorski, C.D. Jacobson, J.E. Shryne* & V. Csernus*. Dept. Anat. & Brain Res. Inst., UCLA, Los Angeles, CA. 90024

The volume of the Sexually Dimorphic Nucleus of the Preoptic Area (SDN-POA), which is larger in the male, is influenced by androgen during the first week of postnatal life. To evaluate the role played by gonadal steroids during this period, we compared for each sex the influence of different doses of testosterone propionate (TP) or of a gonadal graft in the neonatally gonadectomized (Gx) rat on the volume of the SDN-POA in the adult. On day 1 of postnatal life (the day of birth) male (♂) and female (♀) Sprague-Dawley pups were Gx, sham operated (SHAM) or served as untreated controls (CONT). Additionally, Gx-♂ and Gx-♀ were given sc testicular or ovarian grafts. On day 2, Gx pups which did not receive grafts were given a single injection of either vehicle (OIL), 100µg or 1mg TP. On day 45, rats which had gonads were Gx, all other rats were subjected to sham surgery. When adult, rats were sacrificed and perfused with saline and with 10% formalin. Brains were frozen sectioned at 60µ, stained with thionin, and coded so that all analyses were performed blind. The volume of the SDN-POA for each rat was determined as previously described. In all cases, there is a sex difference in SDN-POA volume for rats which received the same treatment. In the ♂: SDN-POA volume in the CONT and SHAM groups is significantly greater than that in the Gx+OIL group. Also, 100µg or 1mg TP or testicular grafts reverses the effects of Gx since SDN-POA volume in these rats is equal to that of the SHAM group. However, an ovarian graft did not affect the resulting volume of the nucleus of the Gx rat. In the ♀: the volume of the SDN-POA in the Gx+OIL group does not differ from that of the SHAM, or Gx+ gonadal grafted rats. There is a similar pattern of response to TP in the ♀ as seen in the ♂. Gx+TP significantly increases SDN-POA volume as compared to that of the Gx+OIL group. These data confirm the importance of the steroidal environment in the ♂ during the first week of postnatal life since a single injection of TP or testicular implant in the Gx-♂ replaces the endogenous hormone which is normally present during the critical period for maturation of the SDN-POA. In addition, a single injection of TP increases SDN-POA volume in the Gx-♀. However, a testicular graft was not able to alter SDN-POA volume in the Gx-♀. The differing response of the developing ♂ and ♀ SDN-POA to the presence of a testicular graft indicates a differential sensitivity to the steroidal environment since in both sexes a larger amount of androgen is able to affect nuclear volume. Also, the steroidal milieu produced by an ovarian graft can not replace the testes in the ♂, or enhance the volume of the SDN-POA in the ♀. (NIH Grant HD-01182 & the Ford, Grant & Kroc Foundations.)

132.7 REGIONAL DIFFERENCES IN INTRANEURONAL α-FETOPROTEIN, ALBUMIN, AND TRANSFERRIN LOCALIZATION WITHIN THE DEVELOPING MOUSE BRAIN. D. Toran-Allerand. Center for Reprod. Sci. and Dept. of Neurol., Columbia Univ., Coll. of P&S, New York, NY 10032.

Immunofluorescence studies have shown the intraneuronal localization and coexistence of immunoreactive α-fetoprotein (AFP), albumin, and transferrin within the same neurons of the late fetal and post-natal mouse brain. These observations have important implications for the process of sexual differentiation of the brain. The intraneuronal presence of estrogen-binding plasma proteins (AFP, albumin) must bring estradiol (E_2) into the cell, forcing reconsideration of the concept that extracellular AFP protects the female rodent brain from exposure to maternal estrogens and providing support for the hypothesis of a need for E_2 per se in neural differentiation. The present study documents the unusual topographic distribution of these proteins with respect to the E_2-concentrating regions of the hypothalamus, preoptic area and the amygdala of the developing mouse. Antigen localization was carried out by single and double label immunofluorescence (combined direct and indirect method). 3-4um serial coronal sections of the brains of E-18, newborn and P-8 mice of both sexes were exposed to antibodies to mouse AFP, albumin, transferrin, or IgG, followed by goat anti-rabbit- or rabbit anti-goat IgG conjugated to either fluorescein or rhodamine, or to antibodies to mouse albumin directly conjugated to fluorescein. All appropriate controls were without fluorescence. Localization and coexistence of all three plasma proteins was observed in diverse cell groups throughout the brains of both sexes. In the hypothalamus, preoptic area (POA) and the amygdala, however, certain nuclear regions were rendered anatomically distinctive by the complete or almost complete and bilaterally symmetrical absence of fluorescence. These regions include: the diagonal band of Broca, the medial POA, the suprachiasmatic, arcuate, ventromedial, ventral premamillary nuclei of the hypothalamus, and the medial and cortical amygdaloid nuclei. These are all regions in the developing rodent that have been shown to contain E_2-receptors by ^3H-E_2 autoradiography. The significance of this staining pattern is unknown. It is unlikely that it is an artefact, however, since it has been observed in both sexes of different ages and in the newborn rat. By its association with presumed target regions of estrogen during the critical period for sexual differentiation these regional differences in staining raise intriguing questions regarding the role of E_2-binding proteins as mediators of steroidal effects on the developing brain. (Supported in part by grants from NIH (HD-08364); NSF (BNS 79-24775); W.T. Grant Foundation; The March of Dimes Birth Defects Foundation; and NIMH Research Scientist Development Award (MH-00192).

132.8 NEUROGENESIS OF THE SEXUALLY DIMORPHIC NUCLEUS OF THE PREOPTIC AREA. Carol D. Jacobson and Roger A. Gorski. Dept. Anatomy and Brain Research Inst., UCLA, Los Angeles, CA 90024.

The Sexually Dimorphic Nucleus of the Preoptic Area (SDN-POA), is larger in volume in the male and hormone dependent early in postnatal life. Presently, we compared for each sex the time course of neuroblast proliferation which forms SDN-POA or adjacent medial preoptic area (MPOA) neurons, and the temporal gradient of production of neurons in relation to their final position within the SDN-POA of Sprague Dawley rats. Sperm in the vaginal smear defined day 1 postfertilization (PF). On day 13PF each pregnant rat was implanted with a right atrial cannula through which 3H-thymidine (*thy; 5µCi/g B.Wt.) was given on day 14,15, 16,17 or 18PF. Pups were sacrificed and perfused with neutral formalin when 30 postnatal days old. After histological processing, 6µ sections were coated with NTB-2 emulsion and stored in the dark at 4°C for 30 days, developed for autoradiography and stained with cresyl violet. All further analyses were performed blind. Three sections of the SDN-POA (anterior, middle and posterior) were analysed. Neurons were rated as either labeled or not. On each section neurons within the MPOA, but lateral to the SDN-POA were also analysed. Data were converted into the percent (%) neurons which were labeled. In the MPOA and the SDN-POA the % labeled neurons decreases as the day of injection of *thy approaches the end of gestation, but the time period in which neuroblast divisions occurred is markedly different for the SDN-POA as compared to that of the MPOA. DNA synthesis occurs as late as day 18PF for neurons which form the SDN-POA but ceases on day 16PF for those destined for the MPOA. There is a sex difference in neuronal production on both day 14 and 17PF for neurons destined for the SDN-POA. After injection on day 14PF the % labeled neurons is larger in the female than in the male, but after injection on day 17PF this is reversed. Analysis of SDN-POA neurons in relation to their final position within the nucleus revealed that the posterior section has a higher % labeled neurons than that seen in the anterior section after *thy injection on day 16,17 or 18PF, and after injection on day 14PF there is a higher incidence of division of neuroblasts which form the anterior SDN-POA. These data illustrate that the specific neurons which comprise the SDN-POA in both the male and female are being produced as late as day 18PF, whereas neurons located in the MPOA but not in the SDN-POA have all been born by day 16PF. Neuroblast division which produces the neurons of the SDN-POA may begin earlier and terminate sooner in the female than in the male. The difference in neuronal birth may partially account for the sexual dimorphism seen in the volume and neuronal number of the SDN-POA of the adult rat. (Supported by NIH grant HD-01182 and the Ford, Kroc and Grant Foundations.)

132.9 AGE-DEPENDENCY OF CORTICOSTEROID-INDUCED CHANGES IN BRAIN GROWTH

J. A. Devenport*, L. D. Devenport & F. A. Holloway (SPON: W. C. Orr). Dept. Psychiat. & Behav. Sci., Univ. Okla. Health Sci. Ctr., Oklahoma City, OK 73190.

The wet and dry brain weight of adult adrenalectomized rats is greater than that of sham-operated animals, and this difference holds for both hind- and forebrain (Devenport, Behav. Neur. Biol. 27:218, 1979). We have since found that this effect is mediated by the adrenal cortex. In the adrenalectomized rat, exogeneously administered corticosterone decreases both brain weight and body weight; deoxycorticosterone reverses corticosterone's effect on the body, but not its effect on the brain. We have found a combined dose of these hormones which, when administered daily to adrenalectomized rats, almost exactly duplicates the brain and body characteristics of intact animals.

Using this dose, we investigated the sensitivity of rat brain growth to the presence or absence of the hormones during two other stages of brain development: That occurring across ages 25-45 days, and that occurring across ages 45-65. This was accomplished in a design that also permitted assessment of the extent to which the effects of hormones or their absence are reversible.

Sprague-Dawley rats born and reared in our laboratory were adrenalectomized when 25 days old and maintained with isotonic saline. Some received daily s.c. hormone replacement (corticosterone, 8 mg/kg; deoxycorticosterone, 1 mg/kg in oil) or vehicle until 45 days old, after which conditions for some remained the same or, for others, hormonal conditions were reversed for another 20 days. Other animals were sacrificed at 45 days, and the remainder at 65 days of age. Perfused brains were removed and coded for "blind" weight determinations.

Brains of animals which received vehicle throughout the 40 day period were 12% heavier than those of rats receiving hormones during the same period. Of this differential growth, about 70% was accomplished in the second 20 day phase. Withdrawal of hormones during the first 20 days increased brain weight by only about 3.6% when sampled at the end of that phase. We conclude that for a time immediately following weaning, and perhaps before, the rat brain is relatively resistant to the atrophic action of corticosteroids, this resistance being lost with the approach of adulthood. Apart from this, evidence of reversibility of brain growth changes was also found.

133.1 INTRACEREBRAL INJECTIONS OF NERVE GROWTH FACTOR ALTER GLIAL RESPONSE TO BRAIN INJURY. D. G. Stein, A. C. Firl* and C. Craig*. Brain Research Lab., Clark Univ., and U. Mass. Medical Center. Worcester, MA 01610.

In a previous experiment, we noted that single injections of NGF facilitate behavioral recovery from caudate nucleus (CN) lesions. An analysis of the brain sections (6 months post lesion) revealed that the NGF treated rats had fewer glial cells in the area of the lesion than the control group. Because of the possibility that glial cells might play a role in mediating behavioral recovery after brain damage, we have examined the time-course and extent of glial reaction to brain injury after NGF treatment.

Bilateral, radiofrequency lesions were placed in the anterior CN of mature, albino rats. Immediately after, the rats received unilateral intracaudate injection of 2.5S NGF and, in the contralateral CN, an injection of saline solution. Following surgery and injections, groups of 4-5 rats were allowed to survive for 0, 10, 20, 30 and 60 days. Their brains were subsequently prepared for frozen sectioning, cut at 30 microns and then stained with the Cajal gold-sublimate method for reactive astrocytes. Astrocytes were counted in the lesion area and in the corpus collosum overlying the lesion area. Also, measurements of astrocyte size were taken by counting number of processes. Our preliminary analysis of size was not significant for any of the postoperative survival times, despite the fact that the NGF treated CN tended to have larger astrocytes in rats that survived 30-60 days after treatment. The measurements of astrocyte numbers did reveal effects--no differences between the saline and NGF-treated side of the brain up to 20 days post-operatively, but in those rats that survived 30 and 60 days, the CN treated with NGF had significantly more reactive astrocytes than the saline-treated side in the 2 areas we examined. Finally, as a control measure, 10 rats divided into groups with the same survival times as above, were given NGF on one side of the brain and saline on the other, but no lesions were inflicted. For all groups, analysis revealed no significant differences between the two sides of the brain in number and size of astrocytes.

It appears, therefore, that a single injection of NGF stimulates the reaction of astrocytes to brain injury but does not enhance glial proliferation in the absence of trauma. This response, however, was apparent only after 30 days following experimental treatment.

We thank Dr. Gordon Guroff for a generous supply of NGF.
Research supported by NIA 2 R01 AG 00295-04.

133.2 ONTOGENESIS OF NERVE GROWTH FACTOR (NGF) AND EPIDERMAL GROWTH FACTOR (EGF) IN MALE MOUSE SUBMAXILLARY GLAND (SMG). P. Walker*, M.E. Weichsel, Jr., D. Eveleth*, and D.A. Fisher* Fetal-Maternal Res. Lab., Harbor-UCLA Medical Center, Torrance, CA 90509

NGF and EGF are found in highest concentrations in adult male mouse SMG. Little is known, however, of the postnatal ontogenetic pattern of accumulation of the two proteins. Using sensitive and specific radioimmunoassay (RIA) techniques, we measured SMG NGF and EGF concentration in SMG of 2,5,8,11,17,18,21,28,32,40 and 60 day old male Swiss-Webster mice. RIA sensitivities were 13 pg/tube and 21 pg/tube for NGF and EGF respectively. SMG extracts exhibited parallel displacement in both RIA systems and there was no significant displacement of radiolabeled NGF by unlabeled EGF or radiolabeled EGF by unlabeled NGF. SMG NGF and EGF content decreased from ages 2 to 8 days, the half-lives of disappearance being approximately 8 days and 5 days respectively. Mean EGF concentrations exceeded NGF concentrations from 2 through 8 days of age. SMG NGF and EGF concentrations increased exponentially after 11 days of age with 3 phases of increase being apparent for both proteins. Mean SMG NGF concentration increased 543 fold between 11 and 21 days of age from 0.19 $\pm$ 0.02 ng/mg protein to 0.1 $\pm$ 0.05 µg/mg protein, the greatest increase being observed between 18 and 21 days of age where NGF concentrations increased 314 fold. Mean EGF concentration also increased markedly from 0.24 $\pm$ 0.01 ng/mg protein at 11 days to 0.09 $\pm$ 0.005 µg/mg protein at 21 days, a 368 fold increase. Again, the greatest increase (218 fold) was observed between 18 and 21 days of age. The second phase of increase was noted between 21 and 32 days where NGF and EGF concentrations increased 26 and 28 fold respectively. In the third phase, (32-60 days of age), increases in mean SMG NGF (7.6 fold) and EGF (8.1 fold) concentrations were noted. Mean NGF and EGF concentrations were similar at all ages after 21 days. Conclusions: The postnatal period is characterized by three phases of increase in SMG NGF and EGF concentrations. Initially (11-21 days) NGF increases to a 50% greater extent than EGF. Since we have noted that thyroxine (T4) administered to adult female mice elevates SMG NGF to levels of 50% greater than EGF (unpublished), it is possible that this initial pronounced increase is thyroid hormone mediated. Whereas the factor(s) responsible for the second phase of increase between 21 and 32 days of age (to levels comparable to those in the adult female) cannot be explained, the third phase of increase between 32 and 60 days is most likely androgen dependent. Thus, the control mechanisms responsible for the observed developmental pattern of SMG and EGF appear to be similar, although the predominant factor(s) during early postnatal life may be different from those operative in mature animals.

133.3 A NEUROTROPHIC EFFECT UPON THE PHOSPHORYLATION OF CYTOSOLIC PROTEIN IN SKELETAL MUSCLE. S.P. Squinto*, J.A. McLane, H.C.* Yeoh and I.R. Held. Loyola Univ. Med. Ctr. and VA Hospital, Hines, IL 60141.

Many physiological responses induced by extracellular stimuli mediated by such diverse substances as hormones, neurotransmitters and perhaps neurotrophic factors may commonly act through phosphorylation of endogenous protein substrates by cyclic AMP dependent protein kinases. In an earlier study (Trans. Am. Soc. Neurochem. 11:118, 1980), we found that when the transmission of nerve impulses and unidentified neurotrophic factors to skeletal muscle are disrupted by denervation, the in vitro phosphorylation of a 40,000 dalton polypeptide from cytosolic fractions of the denervated muscle is increased. In this investigation, we have extended this finding by evaluating the endogenous phosphorylating activity of cytosolic fractions (105,000g supernatants) from rat soleus muscles which were denervated for 1,3,12,24,36,48,54, 60,66 and 72 hr by cutting the left sciatic nerve either at a low level of 2 mm or less, at a mid level of 17-20 mm or at a high level of 32-35 mm before its insertion into the muscle. When the nerve was cut distally at either the low or mid levels, a proximal cut was also made at the high level. Control samples were obtained from sham-operated, contralateral muscles. ^{32}Cytosolic phosphorylating activity was determined as fmoles ^{32}P incorporated into TCA-precipitable material/mg protein after incubation of 30-50 µg supernatant protein for 5 min in a phosphorylating media (pH 7.5) containing 2mM $MgCl_2$ and [γ-^{32}P] ATP (3000 Ci/mmole). We found that the cytosolic phosphorylating activity was similarly increased 75-100% whether the nerve was cut at the low, mid or high levels and remained significantly stimulated for as long as 12 hr. There was a marked difference, however, in the length of time after cutting the nerve at these three levels before the period of increased cytosolic phosphorylating activity was seen. With the shortest possible nerve stump of 2 mm or less the cytosolic phosphorylating activity was significantly increased at the 12 and 24 hr denervation periods. Marked increases were not seen, however, until 48 and 66 hr with the mid and high nerve stumps, respectively. The results of this investigation demonstrate that the cytosolic phosphorylating activity may be dependent upon a temporal alteration in the supply of axonally transported neurotrophic factors and not solely related to the contractile activity of the muscle.

133.4 NEURONAL CONTROL OF METABOLIC TURNOVER OF JUNCTIONAL ACETYLCHOLINE RECEPTORS. R.H. Loring, T.A. Levitt* &M.M. Salpeter Lab. of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853.

After denervation the junctional acetylcholine receptor turnover rate increases while the average receptor site density does not change (Loring and Salpeter, PNAS, April 1980). We report here (using gamma counting after labelling with ^{125}I-α-bungarotoxin) that this increased receptor turnover rate is time-dependent and that by fifteen days the half-life of the denervated junctional receptors reaches thirty hours. We found however, that the acetylcholine receptors which are present at the junction prior to denervation increase their turnover rate only slightly over a fifteen day post-denervation period. Calculations show that these data are compatible with the hypothesis that there is a composite population of receptors at the denervated junction, and that as the original junctional acetylcholine receptors are degraded they are replaced by receptors with a half-life of about one day. EM autoradiographic analyses indicate that over this period there is no shift in the relative distribution of acetylcholine receptors between the tops and bottoms of the junctional folds. Thus, after denervation the junctional acetylcholine receptors are slowly replaced with metabolically unstable receptors, while their anatomical stability, as reflected by high density clustering on the specialized region at the tops of the junctional folds, remains.

133.5 EXTRAJUNCTIONAL MEMBRANE PROPERTIES OF DENERVATED SKELETAL MUSCLES REINNERVATED BY INTACT AND IMPULSE-BLOCKED NERVES. A.Cangiano, L.Lutzemberger* and P.C.Magherini*.Istituto di Fisiologia, Università di Pisa,56100,Italy.

Impulse activity, nerve borne "neurotrophic" factors, the neurotransmitter acetylcholine have all been proposed as mechanisms of regulation of the extrajunctional membrane properties of skeletal muscles. Part or all of these factors might be responsible for the return to normal of the extrajunctional membrane properties of skeletal muscles upon reinnervation. If impulse conduction is blocked in the rigenerating nerves, reinnervation cannot restore muscle activity and the possible normalizing action of nerve-borne chemical factors can be studied in isolation. For these purpose we have crushed in rats the nerves to the soleus and the EDL muscles of one side at a few mm of distance from the muscles without exposing their surface. The muscles of the contralateral side were denervated and reinnervation prevented by removal of a sciatic nerve segment. Eight days later, that is when reinnervation is beginning, a chronic blockade of nerve impulses of the sciatic nerve was established on the crushed side by implanting a tetrodotoxin impregnated silastic cuff. In a control group of rats with crushed nerves, cuffs were not implanted. After 9-11 days of chronic conduction block (i.e., 17-19 days since the initial crush) EDL and soleus muscles of the reinnervated and the denervated sides were examined in vitro for the resting membrane potential (RMP) and the extrajunctional resistance of the action potential to tetrodotoxin (TTX). In control muscles reinnervated by intact nerves,the TTX resistance characteristic of the denervated muscles had already practically disappeared whereas in the majority of the muscles reinnervated with blocked nerves it had retained high values comparable to those of the contralateral denervated muscles. Similarly, the RMP of the reinnervated paralized muscles had the same low values of the denervated muscles. Furthermore, no significant correlation was observed between the amount of TTX resistance measured in each reinnervated paralyzed fiber and the frequency of its miniature end-plate potentials (which is related to the age of the synaptic contact). Thus, muscle activity appears to be the principal factor that induces the return to normal of the extrajunctional membrane properties of denervated muscles upon reinnervation. Occasional failure of the long-lasting conduction block appears therefore to be the most likely explanation for the moderately lower TTX resistance observed in a minor number of reinnervated muscles in respect to their denervated counterparts, although the contribution of nerve-borne chemical factors cannot be entirely excluded. (supported by grants from the Muscular Dystrophy Association of America and the Consiglio Nazionale delle Ricerche of Italy).

133.6 THE ROLE OF ACH TRANSMISSION IN THE NEURAL REGULATION OF MUSCLE RESTING MEMBRANE POTENTIAL. E.F. Stanley, D.B. Drachman,* A. Pestronk,* D.L. Price*. Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD 21205

An intact motor nerve is necessary for the maintenance of many muscle properties. Elimination of the nerve's influence by surgical denervation results in changes in the morphological, physiological and biochemical properties of muscle fibers. However, the mechanisms by which the nerve regulates muscle properties are not clearly understood.

In this study we have examined the role of cholinergic transmission in the regulation of one muscle property, the resting membrane potential (RMP). A fall in the RMP is one of the first changes to occur in muscle following denervation. We have compared in vivo the effect of denervation with that of complete blockade of ACh transmission.

The soleus muscle of the rat was denervated by cutting the soleus nerve close to its point of entry into the muscle. Neuromuscular blockade was achieved by injecting 8 µg of purified α-bungarotoxin (α-BuTx) in Ringer solution directly into the muscle. In order to maintain an effective post-synaptic blockade, α-BuTx was infused into the muscle at a rate of 0.4 ug/hr by means of an implanted osmotic pump. RMPs were recorded from the soleus muscle in vivo after 6 to 48 hours of treatment.

The RMP began to fall 18 hours following denervation, as reported previously with in vivo recording (Stanley and Drachman, Exp. Neurol., in press). This fall reached a plateau of -65 mV by 42 hours. With α-BuTx treatment the onset, time course and extent of the fall in RMP were identical to the changes observed following denervation.

In order to exclude the possibility that α-BuTx also damages the nerve terminals, the muscles were examined by light and electron microscopy. Following 48 hours of α-BuTx treatment there were no changes in the structure of nerve terminals whereas denervation resulted in marked degeneration.

The effect of α-BuTx treatment on the RMP was identical to that of denervation. The only known action of α-BuTx at the neuromuscular junction is the blockade of ACh receptors. Cholinergic blockade is therefore equivalent to denervation and it is unnecessary to hypothesize that denervation involves the interruption of other neuroregulatory factors. Hence it is likely that the motor nerve normally regulates the RMP through ACh neurotransmission.

133.7 ACCELERATED DEGRADATION OF JUNCTIONAL α-BUNGAROTOXIN-ACETYLCHOLINE RECEPTOR COMPLEXES IN DENERVATED RAT DIAPHRAGM. R.S. Brett, S.G. Younkin, M. Konieczkowski* and R.M. Slugg*. Dept. of Pharmacol., Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106.

We labelled innervated and 5-day denervated hemidiaphragms in vivo with ^{125}I-α-bungarotoxin (BTX) and measured toxin binding 5 days later. Denervated hemidiaphragms contained only 17% of the BTX found in innervated hemidiaphragms. Because of the rapid degradation of extrajunctional toxin-receptor complexes essentially all of the toxin remaining 5 days after labelling is bound to junctional AChR. The decrease in junctional toxin binding seen could occur if denervation (1) decreases the number of junctional AChR, (2) interferes with the in vivo labelling of AChR or (3) accelerates the degradation of junctional toxin-receptor complexes. To evaluate junctional AChR in denervated muscle we microdissected AChE-stained endplates (mean length = 80 µM) from single fibers labelled with BTX. Innervated diaphragm labelled in vitro under saturating conditions bound 1.51 x 10^{-17} M BTX per endplate and 5-day denervated muscle bound 1.85 x 10^{-17} M per endplate, so denervation for 5 days did not reduce the number of junctional toxin binding sites. One day after labelling in vivo innervated muscle bound 0.44 x 10^{-17} M BTX per endplate whereas 5-day denervated muscle bound 0.23 x 10^{-17} M per endplate, so denervation appears to interfere with the in vivo labelling of junctional AChR. One day after in vivo labelling, 5-day denervated muscle contained 52% of the junctional toxin-receptor complexes found in innervated muscle. By 5 days after labelling, denervated muscle contained only 17% of the junctional toxin-receptor complexes found in innervated muscle. This suggests that junctional toxin-receptor complexes are degraded more rapidly in denervated muscle. To confirm this, innervated and 5-day denervated rat hemidiaphragms were labelled in vivo and toxin binding was examined 1,3,5, and 8 days after labelling. After correction for toxin binding to extrajunctional AChR we found that the loss of junctional toxin-receptor complexes in denervated muscle (t 1/2 = 2.0 days) was significantly faster than that in innervated muscle (t 1/2 = 10.7 days). In a separate experiment we labelled AChR in vivo immediately after denervation. This procedure was advantageous because it avoided both the denervation-induced interference with toxin binding and the need to correct for toxin binding to extrajunctional AChR. In this experiment the degradation of junctional toxin-receptor complexes in denervated left hemidiaphragms was apparently normal for three days and then increased significantly (t 1/2 = 3.7 days, 3-13 days after denervation). Taken together these results support the concept that continuous innervation is needed to maintain the stability of junctional AChR.

133.8 COMPARATIVE CHANGES IN THE MOLECULAR FORMS OF ACETYLCHOLINESTERASE DURING POSTNATAL DEVELOPMENT IN SOLEUS AND EXTENSOR DIGITORUM LONGUS MUSCLES FROM RAT. Douglas E. Groswald* and Wolf-D. Dettbarn. Dept. of Pharmacology, Vanderbilt Univ. Sch. of Med., Nashville, TN 37232.

Previous studies have shown that acetylcholinesterase (AChE, EC 3.1.1.7) from various mammalian tissues exists in a number of molecular forms. These molecules, which may be characterized by their approximate sedimentation coefficients in sucrose gradients as 4s, 10s and 16s are present in skeletal muscle and the 16s form appeared to be associated with the muscle endplate.

It is generally accepted that physiological and biochemical characteristics of fast twitch and slow twitch muscles are different. However, nothing is known about differences in regard to AChE in these two muscle types.

The present study demonstrates the existence of a different molecular form of AChE between a slow tonic (Soleus-SOL) and a fast phasic (Extensor digitorum longus-EDL) muscle during postnatal development in the rat. Total AChE activity rapidly increases in both muscle types during the first two weeks postnatally and then decreases to adult levels by six weeks postnatally. A correspondingly rapid increase is seen in the larger molecular form (16s) of AChE in both muscle types, but in addition to the intermediate molecular form (11s) in the EDL and SOL muscles, a heavy intermediate (13s) appears in the soleus by two weeks postnatally and increases to its adult level by 10 weeks postnatally. As the molecular forms (11s and 4s) decrease in the soleus the 13s molecular form increases. The smaller molecular form (4s) which remains elevated in the EDL progressively decreases in the soleus. Decreases are evident in all the molecular forms, as total AChE activity decreases during development, but in a qualitatively different manner. These findings suggest that the specific cholinesterases in fast and slow muscle types may be under different regulatory mechanisms.

133.9 COLCHICINE CONTAINING SILASTIC NERVE CUFFS ACT UPON THE NERVE TRUNK AND NOT THE TONGUE TO ELIMINATE TASTE RESPONSES AND TASTE BUDS. H. Sloan*, L. B. Jones* and B. Oakley (SPON: R. E. Davis) Div. Biol. Sci., Neuroscience Lab. Bldg., Univ. of Mich., Ann Arbor, MI 48109.

The effects of blocked axonal transport upon fungiform taste buds of the Mongolian gerbil were evaluated by placing silastic cuffs, containing 0-1% colchicine, around the combined lingual-chorda tympani nerve. Electrophysiological recordings were made from the chorda tympani proper in response to taste solutions applied to the tongue. Eight to fifteen days after cuff implantation ipsilateral taste responses were reduced or eliminated and fungiform taste buds were partially or wholly degenerated. Normal taste responses and taste buds were observed contralaterally to the cuffed nerve and with cuffs lacking colchicine. To determine whether the colchicine was acting at the level of the nerve trunk or the tongue, 1% (w/v) colchicine cuffs containing 0.79 μCi-7.86 μCi ^{3}H-colchicine (specific activity 10.1 Ci/mmole) were used. Liquid scintillation counting of aliquots of solubilized left and right halves of the tongue revealed closely similar colchicine levels. We conclude that colchicine acted at the level of the nerve trunk and not the tongue to eliminate ipsilateral chorda tympani taste responses and fungiform taste buds. Supported in part by NIH Grant NS-07072.

133.10 SPINAL CORD TRANSECTION INTERFERES WITH NORMAL DEVELOPMENT OF SYMPATHETIC PREGANGLIONIC NEURONS. Leonard L. Ross, Arnold J. Smolen and Joan Cherry*. (SPON: L. Pubols). Department of Anatomy, The Medical College of Pennsylvania, Phila., PA 19129.

The formation of a normal complement of synapses in a peripheral autonomic ganglion is dependent on the presence of an intact afferent input to the preganglionic neurons innervating the ganglion. Following neonatal spinal cord transection there is a marked reduction (>60%) in the number of ganglionic synapses formed, as demonstrated by biochemical studies in the rat (Hamill, Bloom and Black, 1977) or morphometric studies in the chick (Ross and Cosio, 1979). And, in the chick, this reduction in peripheral synapses is not accompanied by any loss of cells in the spinal cord preganglionic nucleus.

However, preganglionic neurons probably represent only 25% of the cell population of the nucleus (Caserta, Johnson and Ross, 1977). Therefore, the aim of the present study was to examine the effect of spinal cord transection on the sympathetic preganglionic neurons specifically innervating the adrenal medulla of the rat. The spinal cords of three-day old rats were transected between T5 and T7 and the animals were maintained until 16 or 24 days of age. At these times, the left adrenal was injected with horseradish peroxidase (HRP, 30% in saline). Following a 48-hour survival, the animals were sacrificed, perfusion-fixed and the spinal cords were cut serially at 50 microns. HRP reaction product was demonstrated in every fifth section between T9 and T11 using tetramethyl benzidine. The number of labeled cells were counted and compared with control animals of the same ages. These three segments were chosen because they have been shown to provide the major preganglionic input to the adrenal medulla (Ross, Glazer and Sparling, 1979).

In the spinal cord-transected animals, the number of retrogradely labeled neurons was reduced by 75% when compared with controls of the same age. Since transection does not appear to affect the number of neurons in the preganglionic nucleus, the most likely explanation for these results is an impairment of the cells' ability either to transport or to take-up and transport HRP. Thus, the reduction in the number of labeled cells could indicate that most preganglionic neurons fail to form an adequate number of synapses in the target organ or could be indicative of a general metabolic effect as a result of the transection.

133.11 AXON TRANSPORT INHIBITION IN THE DEVELOPING VISUAL SYSTEM. M.A.Matthews, W.J.Cornell*, D.B.Clarkson*, L.West*, T.Alchediak* and D. Siegenthaler-Matthews*. Dept. of Anat., LSU Med. Ctr., New Orleans, La. 70119.

Establishment and maintenance of neuronal differentiation requires synchronized formation of appropriate synaptic arrays by which a physiological interdependence among functionally-related neuronal groups is created. The importance of proper synaptic input has been emphasized by studies in which surgical destruction or functional deprivation in primary afferent pathways results in retardation of growth patterns in neurons of secondary receiving centers. It has been proposed that "trophic" factors, carried by axon transport mechanisms, may mediate this long-term metabolic influence. Therefore, the developing visual system of the rat has been employed as a model to examine the effects of intraocular administration of axon transport inhibitors upon the differentiation of neurons in the dorsal lateral geniculate nucleus and superior colliculus.

Colchicine or anisomycin, (a protein synthesis inhibitor), was injected into the posterior chamber of rats ranging in age from neonate through 20 days postnatal and in doses ranging from 10^{-2}M – 10^{-5}M. EM analysis of the retina revealed swelling or dissolution of the lamellar plates of photoreceptors, a decrease in thickness of the plexiform layers, the appearance of cytoplasmic vacuoles, dilation of the endoplasmic reticulum and minimal ribosomal degranulation in ganglion cells, although quantitative analysis of these cells demonstrated no abnormal reduction in population density. Axon transport rates were determined by liquid scintillation spectroscopy following intraocular injection of ^{3}H Proline or Fucose 24 hours after colchicine injection. Fast and slow components of transport were inhibited in relation to dosage and the maturity of the animals. The optic nerve leading from the injected eye was reduced in diameter but EM studies revealed no evidence of axon degeneration.

Golgi analysis of relay neurons within the dorsal lateral geniculate nucleus revealed alterations in branching patterns as shown by Sholl methodology as well as a diminution in complexity of the post-synaptic component of the glomerular synaptic terminal of retinofugal fibers. A correlated EM study showed vesicular enlargement together with a reduction in size of these terminals but no evidence of degeneration. These findings support the efficacy of a deprivation model designed to address the role of axon transport in the maturation of neurons in functionally related centers.

Supported by NIH research grant NS 14699.

133.12 TROPHIC INTERACTIONS OF CRAYFISH GIANT AXONS.
Robert M. Grossfeld, George D. Bittner, Martis L. Ballinger*, and Terry A. Viancour. Department of Zoology, University of Texas, Austin, TX 78712 and Department of Biology, North Carolina State University, Raleigh, NC 27650.

The severed stumps of crayfish medial giant axons (MGAs) usually remain morphologically intact and functionally competent for 4-6 months. This survival is associated with hypertrophy and hyperplasia of glial sheath cells. Compared to intact axons, the sheaths of severed MGAs incorporate more labeled amino acid acids into proteins and the axoplasm contains more labeled protein (Meyer and Bittner, Br. Res. 143:145-211,212-232,1978; Ballinger and Bittner, Cell Tis. Res. in press,1980). We now report that both the ultrastructural appearance and the putative transfer of labeled proteins is not uniform along the entire length of a severed MGA. For example, labeled proteins often accumulate in the sheath or axoplasm near adaxonal glial cells. Furthermore, Lucifer yellow CH appears in all glial cells of the adaxonal layer within a few minutes after intracellular injection into an MGA. All these data suggest that glial cells and MGAs mutually exchange many substances, perhaps by exocytosis-pinocytosis of plasmelemma vesicles. However, we find that a decrease in extracellular [Ca^{++}] does not block the putative transfer, as reported in squid giant axons (Lasek et al, J. Cell Biol. 74:501-523,1977).

The severed stumps of crayfish lateral giant axons (LGAs) often survive for over 12 months with little or no change in axoplasmic or sheath morphology. However, LGA segments degenerate within one week if separated from both their own cell body and from LGAs in adjacent segments. After lesioning, the gap junctions largely disappear between adjacent LGAs, the coupling resistance between adjacent LGAs dramatically increases, but many 20-40 nm vesicles remain in the region of apposition between adjacent LGAs (Bittner et al. JEZ 189:13-36,1974; Anderson and Bittner, Br. Res. 184:224-228, 1980; Bittner and Ballinger, Cell Tis. Res, in press,1980). We now report that an entire set of adjacent LGAs can survive for many months if only one LGA remains connected to its cell body. Furthermore, horseradish peroxidase stain injected into one LGA appears in the vesicles and cytoplasm of adjacent LGAs within 30 minutes. All these data suggest that adjacent LGAs mutually exchange many substances, perhaps by exocytosis-pinocytosis of cytoplasmic vesicles which release or obtain their contents from the extracellular space. In fact, such a process may be a ubiquitous mechanism for trophic exchanges between various cell types in many organisms (Bittner, p. 507-532, Trophic interactions of crustacean neurons in Identified Neurons and Behavior, G. Hoyle, Ed, 1977). (Supported by an NIH RCDA 00070 and NINCHDS research grant to GDB).

134.1 ULTRASTRUCTURE OF REGENERATING CENTRAL NERVOUS CONNECTIONS AND IMPLANTED GANGLIA IN THE SNAIL MELAMPUS. Stacia Moffett. Dept. of Zoology, Washington State University, Pullman, WA 99164.

In the pulmonate snail Melampus behavioral and physiological studies have shown that neuronal circuitry necessary for restoring normal reflex responses is formed following transection of the cerebral commissure or removal of one cerebral ganglion (Moffett, Neurosci. Abs. 5, 254, 1979). Regenerating cerebral commissures have been examined eight days, two weeks, one month and four months postoperative and compared with cerebral commissures of control animals. In early stages of regeneration the commissure is composed of a relatively small number of large and medium sized axons (.1 micron up to 2 microns) very loosely associated with one another. In more advanced stages there is a progressive tendency for axons to be grouped together in bundles and smaller diameter axons (less than .1 micron) become increasingly common in the commissure profile. The cerebral ganglia of snails in early stages of commissure regeneration contain patches of degenerating tissue in close proximity to normal tissue. The rough endoplasmic reticulum is particularly well developed in many cells.

After the removal of one cerebral ganglion the nerves, connectives and commissure that were associated with it grow together and form an enlargement, the ganglion bud (Price, Cell Tiss. Res. 180, 529-36, 1977). The ultrastructure of the neuropile within this bud is indistinguishable from neuropile of control ganglia, except that axon tracts are lacking. The sheath covering the bud contains dense droplets characteristic of normal ganglion sheaths and neurosecretory release sites are present. In the margin of the ganglion buds a few neuron cell bodies have tentatively been identified, but because the distinction between glial cells and neurons is based primarily on the morphology of the nuclei, the presence of neurons in the ganglion buds is inadequately substantiated to date.

Cerebral ganglia implanted in host snails form connections with the host snail's nervous system and with peripheral structures. The connections have not been evaluated functionally but the ultrastructure of the cell bodies and neuropile of ganglia cultured two months indicates that the implants are viable. The gross appearance of ganglia cultured in vitro for two years is also normal.

134.2 AXOTOMY INDUCES OUTGROWTH FROM CELL BODIES OF GIANT INTERNEURONS. E. Roederer* and M. J. Cohen. Dept. of Biol., Yale Univ., New Haven, CT 06511.

An insect central neuron characteristically possesses a rounded cell body from which a single initial process emerges to form both the dendritic tree and the axon. We report here that axotomy induces a proliferation of neurite-like outgrowths from cell bodies of identified central interneurons in the cricket Acheta domesticus. Approximately 40 days after transecting their axons in the abdominal nerve cord, the cell bodies of 7 identified giant interneurons in the terminal abdominal ganglion begin to form at least one additional large neurite that emerges opposite the initial process. These cytoplasmic extensions are irregular in shape and may reach lengths of 100µm. Homologous cell bodies of contralateral intact interneurons in the same ganglion appear normal. Intracellular recording indicates that the soma of the normal medial giant interneuron (MGI) does not support regenerative action potentials. The electrical properties of the soma membrane in the axotomized MGI do not seem substantially altered at 40 days after transection.

Sprouts emerge from the proximal axonal stumps of these interneurons as early as 2 days after transection and continue to grow for only 2-3 weeks. These sprouts never cross the site of transection into the distal stump of the sectioned connective. They follow an irregular path and each sprout ends in a terminal swelling that contributes to a neuroma formed at the proximal stump. Only well after the axonal sprouting stops does the outgrowth of neurites from the cell body of the same neuron begin.

Interrupting the giant axons by crushing a connective leads to axonal regeneration from the proximal stump across the lesion into the distal stump of the neural connective. This regeneration may continue through several abdominal ganglia. Cell bodies of regenerating interneurons whose axons have been crushed do not show the neurite-like outgrowth that is seen following axonal transection.

Cutting or crushing the axons do not modify the primary dendritic morphology of these giant interneurons as seen in whole mounts intracellularly stained with Lucifer Yellow or horseradish peroxidase. Intracellular recording from the medial and lateral giant interneurons indicates that synaptic input from cercal receptors is not obviously modified up to 72 days after axotomy.

Supported by NIH Training Grant HD 07180 and NIH Research Grant PHY 5 ROl NS08996-09S1.

134.3 ANATOMICAL REGENERATION AND FUNCTIONAL RECONNECTION OF AN IDENTIFIED NEURON IN THE CNS OF A VERTEBRATE. Matt T. Lee. Biology Dept., UCSD, La Jolla, CA 92093.

The Mauthner (M) neurons are paired cells located in the medulla of fish and amphibians. Each cell gives rise to an axon that crosses the midline in the medulla and runs caudally in the ventral spinal cord. The large size, characteristic location, and morphology of the M cells make them readily identifiable. Consequently, they provide a potential system for the study of axonal regeneration and the re-establishment of functional synaptic contacts by an individual vertebrate central neuron.

In tadpoles of the African clawed frog, Xenopus laevis, the two M axons are clearly visible in the isolated brain and spinal cord, when examined with interference contrast optics. Each axon can be impaled with a microelectrode for intracellular stimulation, recording, and dye injection. In normal tadpoles at Nieuwkoop & Faber stages 49-54, current injected into the M axon produces a spike in that axon, followed by a short-latency compound action potential recorded from ipsilateral ventral roots. Intracellular recording from individual motor axons in these roots reveals a postsynaptic potential (psp) and spike following M excitation. The brief latency of the psp indicates a monosynaptic connection between M axon and motor neuron.

The spinal cords of tadpoles at stages 46-49 were transected completely at the level of the 5th myotome. At various times thereafter, the CNS was isolated and the fluorescent dye, Lucifer Yellow, was injected into each M axon. By 2 days following transection, fine processes can be seen emerging from the end of the proximal segment of the axon, which has usually retracted 1-3 segments from the lesion site. The first sprouts to cross the lesion can be seen within one week in some animals. Tadpoles examined at later times (3½-6 weeks) may have axonal sprouts that extend for 10 or more segments caudal to the lesion; this dye spread is comparable to that seen in M axons of normal animals. However, regenerating axons are often morphologically abnormal; they may branch at the lesion, and branches may run rostrally or caudally on either side of the cord.

By 3½ weeks after cord transection, firing of the M axon rostral to the lesion often elicits spikes in ipsilateral ventral roots caudal to the lesion. These spikes have a latency close to that observed in normal animals, and have been recorded as much as 10 segments caudal to the lesion. These results indicate that regenerating M axons are capable of re-forming functional synaptic contacts with their normal postsynaptic target cells. Occasionally, a regenerating axon will cross over to the opposite side of the cord at the lesion and synapse with motor neurons on that side. Thus, there is no apparent left-right specificity concerning trunk motor neurons as targets for these regenerating axons.

134.4 INCREASED ACTIVITY OF ORNITHINE DECARBOXYLASE FOLLOWING OPTIC NERVE CRUSH IN THE GOLDFISH. Shinichi Kohsaka* and Bernard W. Agranoff. Neuroscience Laboratory, University of Michigan, Ann Arbor, MI 48109.

We have previously demonstrated an increase in tubulin mRNA and tubulin labeling, as well as the activities of a number of enzymes of RNA precursor metabolism in the goldfish retina after its optic nerve had been crushed. Since it is generally believed that polyamines play an important role in RNA metabolism, we investigated effects of unilateral nerve crush on the activity of ornithine decarboxylase (ODC), a rate-limiting enzyme of polyamine synthesis.

ODC levels were measured in 6-7 cm goldfish at various times following optic nerve crush. Unlike the completely unilateral nature of biochemical alterations previously seen, ODC was increased in both retinas, although the activity was significantly higher on the side of the crush. Measurable increases in retinal ODC were seen 3 days following crush, peaked by day 5, and had returned to control values by day 7. ODC was also increased in brain and kidney. Various other treatments such as sham operation and behavioral stress secondary to electrical shock produced relatively minor increases in ODC compared with that seen following nerve crush. Unilateral eye enucleation resulted in increased ODC in the remaining eye and in the brain similar to that seen following nerve crush. A related study (Schwartz, Kohsaka and Agranoff, abstracts in this meeting) reveals that the addition of mouse ß-NGF to retinal explants leads to increased ODC activity in vitro.

The various results suggest that both local and humoral factors may participate in the retinal response to axotomy.

134.5 RETINAL GANGLION CELL RESPONSE TO AXOTOMY AND NERVE GROWTH FACTOR ANTISERUM TREATMENT IN THE REGENERATING VISUAL SYSTEM OF THE GOLDFISH: AN IN VIVO AND IN VITRO ANALYSIS. J. E. Turner, R. K. Delaney* and J. E. Johnson. Dept. of Anatomy, Bowman Gray School of Med., Wake Forest Univ., Winston-Salem, NC 27103.

In vitro nerve growth factor (NGF) antiserum (anti-NGF) treatment was found to severely inhibit retinal ganglion cell neurite outgrowth in goldfish explant culture. Goldfish retinas, conditioned by a 14-day prior optic nerve crush, demonstrated a significant dose response inhibition of neurite outgrowth (i.e., up to a 50% reduction) if incubated with various concentrations of the antiserum (i.e., concentrations from full strength to 1:100 dilutions) before explantation for tissue culture. NGF (100 ng/ml) added to the culture medium containing antiserum (1:1.5 dilution) eliminated the inhibition of neurite outgrowth during the first four days of explant culture. Antiserum treatment at the higher concentrations (i.e., full strength and 1:1.5 dilution) caused a cessation of nerve growth from explants between culture days 3 and 4. However, preimmune serum controls at this time still exhibited vigorous neurite outgrowth.

In vivo treatment with anti-NGF administered intraocularly at 7 DPA) was found to reduce significantly the size and complexity of the retinal ganglion cell nucleoli when analyzed morphometrically at 14 DPA. No other cell parameters measured were found to be affected by the single antiserum treatment.

134.6 A PREPARATION OF DISSOCIATED ADULT GOLDFISH RETINAL CELLS CAPABLE OF NEURITE OUTGROWTH IN CULTURE. James E. Johnson, James E. Turner and Rebecca K. Delaney*. Dept. of Anatomy, Bowman Gray Sch. of Med. of Wake Forest Univ., Winston-Salem, NC 27103.

The goldfish visual system represents a model of successful vertebrate central nervous system (CNS) regeneration. Retinal ganglion cells are capable of establishing functional connections with the optic tectum following optic nerve axotomy (Attardi and Sperry, Exp. Neurol., 7, 1963). Recent studies suggest that nerve growth factor (NGF) may effect the retinal ganglion cell response to axotomy in both the newt (Turner, Brain Res., 171, 1979) and in the goldfish (Turner, Brain Res., in press). We are reporting the development of cultures prepared from dissociated goldfish retinas as a model for further studies of neurotrophic phenomena.

Retinas from common goldfish (Carassius auratus) which had received either (1) an optic nerve crush 7, 14 or 21 days prior to placement in culture or (2) no prior lesion, were dissociated in 0.05% trypsin (Sigma). Following trypsinization, two million cells were seeded on poly-L-lysine (type VI B, Sigma) coated 35mm culture dishes in a Leibovitz (L-15, GIBCO) nutrient medium supplemented with 10% fetal calf serum (FCS, GIBCO), 20mM HEPES (pH 7.2, Sigma) and gentamycin sulfate (0.1 mg/ml, Sigma).

Highly refractile cells with neurite outgrowth were counted and examined by phase contrast, light and transmission electron microscopy. Preliminary results indicate that a population of cells dissociated from the goldfish retina were capable of attachment and extensive neurite outgrowth. Outgrowth from several large refractile cells were often found to form fascicles. Ultrastructural examinations of these cells and their processes also revealed the presence of microtubular complexes and organelle characteristics which are indicative of neurons. After three weeks in culture, retinas treated with an optic nerve crush 14 days prior to dissociation exhibited a 14-fold increase in the number of phase bright cells with neurite outgrowth over preparations which received no prior lesion. These results indicate that the administration of a prior optic nerve crush facilitates a significantly greater neurite outgrowth in dissociated cultures.

A dissociated cell population established from an adult vertebrate CNS tissue has demonstrated the capability for neurite outgrowth in culture. This in vitro preparation, represents a model for the analysis of possible neurotrophic phenonmena in successful CNS regeneration.

Supported by NIH research grant NS12070. J. E. T. is also the recipient of NIH Research Career Development Award NS00338.

134.7 INCREASED RATE OF REGENERATION IN GOLDFISH OPTIC AXONS RESULTING FROM INTRAOCULAR INJECTION OF CALCIUM IONOPHORE A-21387. Bernice Grafstein and Hamutal Meiri*. Department of Physiology, Cornell University Medical College, New York, NY 10021

At three and five days after the goldfish optic nerve had been crushed in the orbit, 3×10^{-10} moles of A-23187 in 3 µl of 10% ethanol-Ringer was injected into the eye. The rate of outgrowth of the regenerating axons was increased by about 30% compared to control animals which had been injected with 10% ethanol-Ringer. This was evident from the following observations:

a) The mean time for recovery of visual function (reappearance of the startle reaction to sudden illumination following 20 min of dark adaptation) was decreased from 14.2 ± 1.0 (SEM) days to 10.3 ± 0.6 days ($p < 0.001$).

b) The rate of advance of regenerating axons stained by cobalt filling, measured between 5 and 14 days after the lesion, was increased from 0.058 mm/day to 0.072 mm/day.

The proportion of retinal ganglion cells containing nucleoli, measured at 22 days after the lesion, was increased by the ionophore treatment from 73.9 ± 1.0 % to 89.8 ± 3.1 % ($p < 0.002$). The mean number of nucleoli per cell increased from 0.84 ± 0.03 to 1.15 ± 0.05 ($p < 0.001$). These findings indicate an enhanced level of ribosomal RNA synthesis accompanying the faster rate of regeneration.

The effect of the ionophore appeared to be dose-dependent, since doses smaller than 3×10^{-10} moles were less effective, as tested by the recovery of visual function. Doses of 10^{-9} moles and higher caused corneal opacity, intraocular bleeding, and bulging of the eye.

We conclude that modulation of the calcium level in the retinal ganglion cell may be an important factor in regulation of axonal outgrowth.

134.8 ALTERED INTRACELLULAR TRANSPORT OF NEWLY SYNTHESIZED PROTEINS IN PERIKARYA OF REGENERATING GOLDFISH RETINAL GANGLION CELLS. Mark H. Whitnall and Bernice Grafstein. Dept. of Physiology, Cornell University Medical College, New York, NY 10021

Intracellular transport of newly synthesized proteins through the perikaryal organelles of regenerating goldfish retinal ganglion cells was studied using electron microscopic autoradiography. Retinas were removed 14 days after optic tract cut or sham operation, incubated in medium containing [^{3}H]proline for 5 min, and then incubated in chase medium containing unlabeled proline for up to 55 min, fixed and processed according to standard techniques. Organelle labeling was analyzed in terms of "crude relative specific activity", i.e., % grains ÷ % effective area (Williams, M.A., in Glauert, A.M.(ed.), Practical Methods in Electron Microscopy, vol. 6, pt. 2. Amsterdam: North Holland, 1977. Thus labeling time courses refer to relative concentrations, not absolute amounts of label.

The time courses for rough endoplasmic reticulum labeling were almost identical in regenerating and control cells, showing sharp decreases during the first 15 min of chase. Subsequently, a major portion of the label appeared in two main cell compartments: the Golgi apparatus, and a general category containing a combination of cytosol, free polyribosomes and small vesicles below the resolution of the autoradiographic technique. A greater proportion appeared in the Golgi apparatus in regenerating cells, suggesting a rerouting of newly synthesized proteins during regeneration. Also observed in regenerating cells, but not in controls, was a rise in plasma membrane labeling between 35 and 55 min of chase, indicating increased perikaryal plasma membrane turnover during regeneration. Since glycosylation in the Golgi apparatus is an important step in the preparation of plasma membrane proteins, the increase in plasma membrane turnover may be related to the observed increase in Golgi processing.

Between 35 and 55 min of chase, a significant increase in nuclear labeling occurred in regenerating cells but not in controls, showing that influx of newly synthesized protein into the nucleus increases during regeneration, possibly due to increased formation of ribonucleoproteins and/or other nuclear proteins involved in the regulation of the regenerative response.

134.9 RAPIDLY TRANSPORTED PROTEINS IN THE REGENERATING OPTIC NERVE OF GOLDFISH. L.I. Benowitz, V.E. Shashoua and M.G. Yoon. Depts. of Psychiatry and Biological Chemistry, Harvard Medical School, McLean Hospital, Belmont, MA 02178; Dept. of Psychology, Dalhousie University, Halifax, Nova Scotia (M.G.Y.).

In the goldfish, a severed optic nerve will regenerate within a few weeks of being cut, re-establishing the original pattern of connections between the eye and the brain and restoring visually-guided behaviors. To understand the molecular events which underlie this phenomenon, we have developed a double-labeling method to identify specific proteins whose metabolism is differentially altered during the regenerative process. Particular attention was paid to proteins which move down the optic nerve in the rapid phase of axoplasmic transport; this phase contains material which becomes added to the growing axon terminals and which is likely to play a role in such phenomena as intercellular recognition and synaptogenesis. Intraocularly injected [^{3}H]- and [^{14}C]-proline were used as precursors for contrasting the labeling spectra of proteins in a regenerating optic nerve and in the unoperated, contralateral side. Preliminary experiments to validate the method demonstrated that the eye gets labeled as a separate channel (i.e., no isotope cross-over occurs), and that no asymmetric uptake of the two labels occurs. The labeling time used, 5 h, was selected to exclude from our analysis most of the slower moving common structural elements of the axonal matrix. Among the rapidly transported proteins, our results showed the labeling pattern to shift radically during regeneration, with relative changes in the labeling of various proteins varying over a 3-fold range. Eight days after crushing the optic nerve, the greatest relative increases were found for species migrating on SDS-polyacrylamide gels with apparent molecular weights of 135,000 and 50,000 daltons; later in the regenerative process these peaks declined, and by day 29 the greatest relative change in labeling was seen for material with an apparent M.W. of $\sim$ 105,000 daltons. In general, the more common protein species of the optic nerve, i.e., those which stain prominently or which incorporate most of the label, were not among the ones whose metabolism was most altered. By day 62, the labeling spectrum on the regenerating side reverted to that of an unoperated eye. Our results demonstrate that regeneration involves a selective, time-dependent shift in the synthesis and transport of particular molecular species, rather than a nonspecific overall increase in the normal complement of transported proteins. 134.10 QUANTITATIVE TWO-DIMENSIONAL GEL ANALYSIS OF SPECIFIC PROTEIN INDUCTION DURING OPTIC NERVE REGENERATION. M. Deaton*, J. A. Freeman, M. Willard*, and J. H. P. Skene*(SPON: M. I. Johnson). Depts. of Anatomy, Ophthalmology, and Physics, Vanderbilt Univ., Nashville, TN 37232; and Depts. of Anatomy-Neurobiology and Biological Chemistry, Washington Univ., St. Louis, MO 63110.

We have constructed a computer-controlled densitometric scanner to analyze and compare two-dimensional electrophoretic autoradiograms of radioactively labeled proteins. Regions of interest on the autoradiograms are scanned (512 x 512 points) and the data are stored in a mini-computer (PDP-12). A system of programs (similar to that described by Lutin, Kyle and Freeman, Electrophoresis '78, N. Catsimpoolas,ed., Elsevier, 1978) was developed which permitted the data to be smoothed transposed and plotted as contour maps or three-dimensional perspective displays. The computer also resolved individual polypeptide components from overlapping peaks and computed their concentrations.

We applied this analytical procedure to the identification and quantification of growth-associated proteins (GAPs) in the retinal ganglion cells of toads (Bufo marinus). During optic nerve regeneration in toads, the rapid axonal transport of three membrane-associated polypeptides (mol. wts. 24K, 43K, 50K), termed GAPs, is dramatically and specifically increased in retinal ganglion cells (Skene and Willard, submitted). Quantitative two-dimensional analysis of these GAPs labeled 9 days after the optic nerve was crushed showed that their relative labeling increased as follows: GAP-50, 14 fold; GAP-43, 5 fold; GAP-24, 35 fold. This method is also being used to study specific changes in gene expression during axon growth and synaptogenesis in the goldfish visual system, and it should be applicable to many other problems involving the analysis of changes in polypeptide compositions.

134.11 **ANOMALOUS GROWTH OF FROG OPTIC NERVE AXONS INTO THEIR OWN PIGMENT EPITHELIAL LAYER AFTER NERVE INJURY.** **R. Bohn*and P. Reier, Dept. of Anat., Univ. of Maryland Sch. of Med., Baltimore, 21201.**

As regenerating axons emerge from the proximal stump of injured peripheral nerves, they frequently exhibit variable patterns of outgrowth which appear to depend on the type and severity of the lesion and surrounding connective tissue response. Studies in this laboratory have also noted the formation of complex neuromas and aberrant bundles of fibers during initial stages of regeneration of the transected optic nerve in Xenopus tadpoles and adults. Whether such highly variable elongation of axons is due to altered patterns of outgrowth in the proximal (retinal) segment or to the cellular organization of the lesion zone has not been extensively studied. We describe here preliminary observations of an unusual growth pattern of axons in the retinal stump of adult Xenopus following resection of a 1 mm segment of the intraorbital portion of the optic nerve. During the first post-operative week the proximal stump was characterized by unmyelinated axons, reactive glial elements and myelin debris resulting from an initial retrograde response to injury. At 2-4 weeks the original nerve stump became circumscribed by a distinct peripheral zone of axons oriented longitudinally and fasciculated by radial glial processes. Near the eye, however, the outer ring of fibers changed from a longitudinal to a circumferential orientation and radial glial processes were no longer apparent. Circumferentially-oriented fibers were most apparent within the intrascleral portion of the nerve while fibers in the central region of the stump were still aligned parallel to the nerve's longitudinal axis. At the optic nerve head, bundles of axons emerged from the circumferentially-oriented fibers and entered the pigment epithelial layer of the retina. These fibers extended in some cases as far as the ciliary margin and generally grew between the epithelial cells internal to Bruch's membrane and the basal lamina. Penetration of more internal retinal layers by these axons did not occur. This novel pattern of axonal orientation has been seen following section of the nerve within the orbit and at the chiasm but not after ablation of the contralateral tectum. Moreover, this phenomenon has not been observed in either nerves from unoperated or sham-operated animals. Based on these initial findings, the observed growth pattern may represent a recurrent growth of axons from the lesion site along the subpial margin of the nerve. These results thus suggest that in addition to influencing the random orientation of fibers within the lesion zone, local environmental conditions at the cut end may compromise the emergence of fibers and induce retrograde growth. (Supported by NIH Grant NS-13836 and the Paralyzed Veterans of America)

134.12 REGENERATION OF OPTIC AXONS IN THE CHICK RETINA. S. Goldberg* and B. Frank* (SPON: J. de la Torre). Dept. of Anatomy, Univ. of Miami Sch. Med., Miami, 33101.

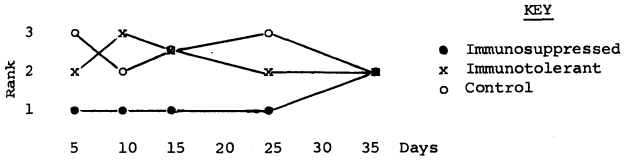
Lesions were produced in the retinas of newly-hatched chicks. Optic axon sprouting began within 2-3 days. Three types of growth patterns were observed. Optic axons that were deflected deep (sclerad) to the ganglion cell fiber layer (GCFL) grew randomly with no tendency to stick to one another. Some optic axons grew along the wound edge. Other axons made hairpin turns, remained within the GCFL, and grew in reverse direction, toward the retinal periphery. On the central side of the lesion, centrifugal axons behaved similarly, in mirror-image fashion. As compared with lesions in 5 day-old chick embryos (Goldberg, '77), axons in newly-hatched chicks showed a lesser degree of elongation, greater randomness of growth, and less tendency to adhere to other optic axons. Axons did not appear to bypass the lesion, as they did in embryos.

Anterograde and retrograde degeneration of optic axons proceeded more rapidly in newly-hatched chicks than in those 14 days post-hatching. More rapid degeneration of optic axons in neonates, as compared with older animals, has also been observed in the mouse retina (Goldberg and Frank, '80).

134.13 BASAL LAMINA AT THE SITE OF CNS INJURY IN TREATED ANIMALS. T. F. Kowalski, E. R. Feringa, H. L. Vahlsing*. Depts. Path. & Neurol. VA Med. Ctr. & Univ.Mich., Ann Arbor, MI 48105 & Dept. Neurosci., UCSD & VA Med. Ctr. San Diego, CA 92161.

After injury, functionally significant regeneration of long tract axons in mammalian spinal cord is not attained. Basal lamina (BL) caps the transected end of the rat spinal cord at the CNS-scar interface 20 days postsurgery. BL may impede the progress of growing axons. Since this BL cap is formed before regenerating axons would be expected to cross the transection site, we felt it might impede regeneration. To test this, we studied BL after two treatments which facilitate axon regeneration.

Fifteen adult (6 wk. old) rats immunosuppressed with 75 mg/Kg I.P. cyclophosphamide 48 hours after spinal cord transection were compared with 15 rats made immunologically unresponsive to CNS antigens by daily injections of 75 mg of emulsified isogeneic spinal cord on the first day of life and weekly until spinal cord transection at age 6 wks. These two groups and a 15 animal control group were studied at 5, 10, 15, 25 and 35 days post-transection with an epithelial BL specific immunohistochemical stain to determine the amount of BL present at the lesion site. At each time interval, animals from the 3 groups were ranked in a numerical hierarchy for the amount of BL observed at the CNS-scar junction. The group with the least BL was graded 1; the group with an intermediate amount, 2; and the group with the greatest amount, 3. These rankings were tested for significance by Students paired t test. The graph below shows the rankings of the groups at time intervals studied.



No significant difference exists between the immunotolerant animals and the controls. However, those animals treated with cyclophosphamide have a significant ($p < 0.05$) decrease in BL at the CNS-scar interface as compared to controls or the immunotolerant group.

Treatment of spinal cord transected animals with cyclophosphamide significantly slows the development of the BL cap over the transected end of the spinal cord. This delay may allow the earliest few axons to regenerate across the transection site. Later, a completed BL cap may block the remaining axons which attempt to regenerate.

134.14 REGENERATION OF VOMERONASAL NERVES INTO THE MAIN OLFACTORY BULB. P.C. Barber*. (SPON: J. Nagy) Laboratory of Neurobiology, National Institute for Medical Research, Mill Hill, London NW7 1AA

It has been previously shown (Barber, P.C. and Raisman, G., Brain Res., 147: 297, 1978) that after section of the vomeronasal nerves, the neurosensory cells of the vomeronasal epithelium undergo retrograde degeneration and die. They are subsequently replaced by newly-formed neurosensory cells, which arise from a stem cell present in the epithelium. In the present study, it is demonstrated that vomeronasal nerve section results in orthograde degeneration of neurosensory cell axons and their terminals in the glomeruli of the accessory olfactory bulb. The glomerular organisation collapses and the external plexiform layer of the accessory bulb becomes covered by glial lamellae. Re-innervation of the accessory bulb by vomeronasal axons does not occur, at survivals as long as 150 days. However, autoradiography of axonal transport after application of [^{3}H]-proline to the regenerated vomeronasal epithelium reveals that vomeronasal axons arising from newly formed neurosensory cells in the regenerated epithelium are able to innervate the main olfactory bulb, in regions where it is damaged or deafferented, and form glomeruli which resemble those of the accessory bulb. Electron microscope autoradiography shows that the regenerated vomeronasal axons within these glomeruli form morphologically normal terminals, with synapses contacting dendrites of the nearby main bulb neurons.

134.15 EM AUTORADIOGRAPHIC STUDY OF REGENERATING LOCUS COERULEUS FIBERS INTO IRIS TISSUE IMPLANTS IN THE RAT MESENCEPHALON. Amy Rothman Schonfeld, Cedric S. Raine and Robert Katzman, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Regenerative sprouting of adult central monoaminergic (MA) fibers after mechanically or chemically induced injury has been well documented light microscopically using histofluorescence and histochemistry. One model which has proven particularly suitable for demonstrating axonal regeneration involves implantation of peripheral tissue, especially the iris, into the brain or spinal cord (Svendgaard et. al., Adv. anat. embryol. Cell Biol. 57:7, 1975). A previous ultrastructural report from this laboratory revealed the presence of newly formed nonmyelinated axons and varicosities containing either dense or clear core vesicles within iris implants in the rat mesencephalon (Katzman et. al., Brain Res. 138:423, 1977) and light microscopic (LM) autoradiography established the locus coeruleus as the source of at least some of the fibers (Schonfeld and Katzman, Soc. Neurosci. 5:682, 1979). The aims of the present study were: (1) to determine what proportion of regenerating fibers within an implant are of locus coeruleus origin and (2) to establish the location and terminal arrangements of these fibers by electron microscopic (EM) autoradiography.

For this, heterologous iris implants were inserted in the caudal mesencephalon in the region of the dorsal tegmental bundle (DTB) in female rats previously subjected to ipsilateral superior cervical sympathectomies, a procedure known to sever the DTB (Katzman et. al., 1977). Approximately 2 weeks later, animals were injected with ^{3}H-leucine into the ipsilateral locus coeruleus and sacrificed 2 days later. After fixation with paraformaldehyde-glutaraldehyde, the areas of the implant and injection site were dissected out, post-fixed in 1% osmium tetroxide and processed for EM. One micron Epon sections were cut and prepared for LM autoradiography according to the method of Cowan et. al. (Brain Res. 37:21, 1972). Thin sections from selected blocks were prepared for EM autoradiography according to the method of Salpeter and Bachmann (J. Cell Biol. 22:469, 1964).

At the LM level, numerous labelled fibers were observed within iris implants and traversing between brain and implant, as previously reported (Schonfeld and Katzman, Brain Res., in press). Labelled fibers showed an affinity for smooth muscle and walls of blood vessels. Ultrastructurally, a number of fibers, predominantly thinly myelinated by Schwann cells or unmyelinated, were found to be labelled. The presence of labelled regenerated axons within the previously denervated implants further confirms that central adult MA fibers retain the capacity to regenerate. A morphologic analysis of this phenomenon will be presented.

134.16 CELL PROLIFERATION IN AREAS OF INTRASPINAL SCHWANN CELLS. S. A. Gilmore, J. K. Heard and T. J. Sims. Depts. of Anatomy and Pathology, Univ. Arkansas Med. Sciences, Little Rock, AR 72205.

Intraspinal peripheral nervous tissue (IPNT), consisting of Schwann cells, myelin, and connective tissue components, develops in immature rats following exposure of the spinal cord to x-rays (Gilmore and Duncan, '68; Beal and Hall, '74; Blakemore and Patterson, '75; Heard and Gilmore, '80). Areas of IPNT consistently occur by 2 weeks post-irradiation (P-I), when many of the intraspinal Schwann cells are labeled by ^{3}H-thymidine (Gilmore, '71). IPNT occurs first in the dorsolateral portion of the dorsal funiculus, and by one month usually extends throughout this structure and into the dorsal gray matter. At two or six months P-I, IPNT still occupies the dorsal portion of the spinal cord. Factors limiting the development of IPNT could reside within this tissue itself and/or in the normal constituents of the spinal cord. The present study was undertaken to examine the proliferative potential of cells in areas of IPNT.

Three-day-old Charles River CD^R rats were x-irradiated. A single exposure (4000R) was administered to a 5-mm length of lumbosacral spinal cord. Fifteen to 45 days P-I, groups of irradiated and sham-irradiated rats were injected with ^{3}H-thymidine and perfuse-fixed 1 hour later. Spinal cords were removed, and interrupted serial sections were prepared for light microscopic and autoradiographic evaluation. Spinal cords from other rats were used for ultrastructural studies.

The light microscopic appearance and the distribution of IPNT was the same as that reported previously from this laboratory. Labeled cells were noted throughout the IPNT at 15 and 20 days P-I, when IPNT was usually restricted to the dorsal and/or dorsolateral portions of the dorsal funiculi. By 25 and 30 days P-I, IPNT extended deeper into the dorsal funiclui and into the dorsal gray matter. The labeled cells occurred throughout the IPNT, but there was a tendency toward concentration of the labeled cells in the deeper portions of the IPNT, i.e., closer to the interface between central nervous system structures and IPNT. Labeled cells were present at 45 days P-I. These cells tended to be concentrated toward the depths of the IPNT, and sizeable areas of IPNT contained no labeled cells.

These data indicate that cell proliferation is in progress in areas of IPNT as late as 45 days P-I, a time when active Schwann cell myelination can be demonstrated ultrastructurally. Animals killed at longer post-irradiation intervals are under study, and the cellular composition of the areas of IPNT is being examined ultrastructurally.

(Supported by NIH Grant NS 04761.)

134.17 GROWTH OF OLFACTORY SENSORY AXONS INTO TRANSPLANTED BRAIN SLABS. P.P.C. Graziadei and G.A. Monti Graziadei* Department of Biological Science, Florida State University, Tallahassee Fla. 32306

After bulbectomy, olfactory sensory neurons are known to regrow into several portions of the spared forebrain, where they form glomeruli-like structures (Graziadei, Levine and Monti Graziadei, 1978, 1979). To test the ability of the olfactory sensory neurons to establish contacts with several neuronal populations of the C.N.S., besides the ones which can be reached after bulbectomy, we have resorted to the technique of transplantation.

In host mice 1 to 10 days old the olfactory bulb has been partially or totally removed. Brain slabs of medulla oblongata, cerebellum and occipital cortex, removed from donor mice embryos at 15 days of gestation, were positioned in the cavity resulting from bulbectomy. Care was taken to position the transplants immediately adjacent to the lamina cribrosa. After proper dressing of the surgical wound the animals were left to survive up to 6 months. The host mice were then perfused, the head embedded in paraffin and serial sections obtained. Alternate slides, with 4 sections per slide, were stained with iron hematoxylin and Bodian silver methods. Intermediate slides, judged of interest, were stained with the unlabeled antibody method (Sternberger et al. 1970) for the demonstration of the olfactory marker protein. The presence of this specific protein has allowed the recognition of the sensory axons and their terminals in the invaded, transplanted tissue.

It has been observed that the olfactory sensory axons can invade all the transplanted C.N.S. portions. When partial bulbectomy is performed the sensory axons can form glomeruli in the spared portions of the bulb, in the forebrain and in the transplanted tissue. A demonstation will be provided of the modalities of penetration of the sensory axons in the transplants and of the connections of these axons with the local neurons, as these contacts can be demonstrated at light microscope level.

(This research was supported by Grants from the National Science Foundation (BNS 77/16737) and the National Institutes of Health (5/T/32 NS 07010).

134.18 MATURATION OF FETAL SPINAL CORD IMPLANTS IN THE LATERAL CEREBRAL VENTRICLES OF ADULT RATS. P. J. Reier, M. J. Perlow and L. Guth (SPON: A. A. Zalewski). Dept. Anatomy, Univ. Maryland, Sch. of Med., Baltimore, MD 21201 and Unit on Geriatric Psych., Lab. Clincial Psychopharmacology, N.I.M.H., St. Elizabeths Hospital, Washington, D.C. 20032.

Implantation of fetal neural tissue to various regions of the adult rat brain has been shown to represent an important approach in the analysis of cellular mechanisms associated with development and regeneration. Although most regions of the CNS survive and differentiate as embryonic grafts, some variability has been noted in the extent of normal development achieved by various CNS structures. Notably, grafted segments of fetal spinal cords have been reported to develop an intrinsic cytoarchitecture which significantly departs from the normal cellular organization of the mature cord. Since the transected spinal cord in immature rodents has also been shown to have a limited regenerative capacity, the following histological and ultrastructural study was undertaken to examine further the degree to which injury compromises development of the spinal cord in the neural tissue transplantation model. Segments of cervical and lumbar spinal cord, 1-4mm long, were obtained from 15-day-old Sprague-Dawley rat fetuses, and several pieces of tissue were stereotaxically injected into the lateral cerebral ventricles of 600-800gm males. The recipients were sacrificed at intervals from 5 days to 7 months after implantation, and tissues were examined by light and electron microscopy. In all cases, the implanted cord segments survived and were extensively revascularized; no tissue rejection was evidenced. By 5 days the fetal cords exhibited numerous immature neurons, glioblasts and a well-developed neuropil in which early stages of synaptogenesis were evident. By 1½ months the implants had increased in size and closely approximated the parenchyma of the hosts' brains. Silver-stained sections revealed numerous axons traversing the interface between host tissue and implant. At this time, the grafts consisted of many identifiable neurons, including large motoneurons, glia, myelinated fibers and a highly differentiated neuropil with numerous synapses. Several distinct zones of white and gray matter were formed in the implants, although specific development of dorsal and ventral horns did not occur. Similar patterns of maturation were noted in grafts which were situated in regions of injured cerebral cortex near the initial site of tissue injection; however, axons extending between host parenchyma and implant were less apparent in these areas. Studies are currently in progress to define the nature of host-implant interactions and environmental factors which may influence neuritic outgrowth from grafted segments of fetal spinal cords. (Supported by NIH grants NS-13836,-12847 and The Paralyzed Veterans of America).

134.19 UNILATERAL LESIONS IN THE SUBSTANTIA NIGRA INDUCE PROJECTIONS FROM THE CONTRALATERAL SUBSTANTIA NIGRA TO THE IPSILATERAL THALAMUS. M. Pritzel* and J.P. Huston. Institute of Psychology III, University of Düsseldorf, Düsseldorf, FRG.

The efferent organization of the substantia nigra (SN) to the striatum, thalamus and superior colliculus is limited to ipsilateral connections. We recently found that hemidetelencephalization, which leads to transient ipsiversive turning in rats, also induces the development of crossed projections to thalamic nuclei which normally receive only ipsilateral projections. The present study sought to determine whether the development of crossed projections would follow other interventions known to produce behavioral asymmetries.

Rats were given a unilateral injection of 4 µl (4 mg/ml) 6-OHDA into the SN. The resulting ipsiversive turning had ceased by 6-8 days post-lesion. The animals were then administered an injection of HRP (Boehringer, grade I, 30-50%, 0.02-0.04 µl) into the ventrolateral/ventromedial thalamus, which is one of the projection sites of the SN. In addition to the ipsilateral nigro-thalamic projections that were spared by the lesion, we found mirror image contralateral projections from the SN to the ipsilateral thalamus. Similar results were obtained after unilateral lesions of the SN with kainic acid (2 mg/ml, 0.5 µl) alone, or in combination with 6-OHDA (which leads in both cases to contraversive turning).

We prefer to interpret these results in terms of morphological reorganization underlying behavioral reorganization following 'sensori-motor' asymmetries induced by unilateral insults to the brain.

134.20 HISTOFLUORESCENT OBSERVATIONS OF MONOAMINE AXONAL ELONGATION IN TRANSECTED RAT SPINAL CORD. Nylén, E., D.D. Rigamonti, W. Prominski* and L. Sigmund*. Department of Anatomy, Georgetown University School of Medicine, Washington, D.C. 20007.

Axonal growth of CNS monoamine (MA) fibers intrinsic to the brain stem has been documented following mechanical and chemical axotomies. The bulbospinal MA system also progressively regenerates following toxic lesions and "sprouting" is observed subsequent to mechanical induced injuries when the cord, meninges and the vascular supply has been interrupted. An improved spinal cord surgical transection technique which maintains the meningeal blood supply is currently being used in reconstruction experiments. Results from an anatomical study in the rat suggest that there is sprouting of primary afferents into an autologous peripheral nerve graft and also growth of intrinsic CNS neurons near the implant (Richardson et al., Nature, 284:264, 1980.) Our experiments were designed to study the reaction of fluorescent fibers, presumably descending MA bulbospinal axons, in the subpially transected adult rat spinal cord. In all, 16 animals were operated and observed at 21, 42 and 142 days. One group of animals received a sciatic nerve implant between the midthoracic cord stumps while a second group were subpially transected and left with no reconstruction. All animals showed MA fibers converging at the cranial side of the lesion, some of which projected into the transection area. Some fibers were also observed throughout the extent of the transection site. Immediate implantation of sciatic nerve segments in the transected area mainly influenced the pattern of MA growth which was then more uniform, and to a lesser extent the relative abundance of fibers in the distal zones of the transected area. We suggest that the maintenance of the meningeal vasculature is critical for axonal elongation and reconstruction experiments. (Supported by NIH Grant RR5360)

134.21 CEREBELLAR REGENERATION AFTER IMMUNOTHERAPY FOR GRAFT VERSUS HOST DISEASE. W.S.T. Griffin and J.R. Head*. Dept. of Cell Biology, The Univ. Tx. Health Science Center, Dallas, Texas 75235.

A tool with which cerebellar histogenesis could be turned off and then turned back on in vivo holds promise for the study of 1) events occurring during uninterrupted histogenesis and 2) the potential for regrowth and plasticity of developing CNS structures. Graft versus host disease (GVHD) induced alterations in rat cerebellar cell proliferation and function and the reversal of these alterations by therapeutic intervention affords such a tool. For this study, Fischer (FI) rat litters of not more than 12 pups were initially divided into two groups. One group contained one-third of the pups and received no treatment at birth. The other group contained two-thirds of the pups, and each of these pups was grafted by an intravenous injection of 20 x 10^6 lymph node cells from an allogeneic donor, viz., a DA adult rat. This latter group was further subdivided so that one-half of these pups received 3 injections, on postnatal days 11, 12 and 13, of syngeneic serum containing high titers of antibodies to their allogeneic graft, i.e., FI anti-DA serum. One-half of the control group also received three daily injections which had no apparent effect. Analysis of diseased animals on day 11 revealed that cerebellar DNA synthesis and total DNA content were significantly less than unmyelinated controls and further analysis indicated that synthesis and content of RNA were similarly affected. Histological analysis revealed that the mantle area which contains the newly formed cells of the external granular layer was smaller at day 11. These same kinds of analyses were performed on 14-day-old animals with GVHD, deprived of immunotherapy (E); animals "saved" from GVHD by treatment with alloantiserum (I); and littermate controls, both treated and untreated with alloantiserum (C). Analysis of cerebellum from E animals at 14 days revealed that DNA synthetic capacity had worsened between days 11 and 14 and DNA content was markedly less than the value from either I or C. DNA synthesis and content in I was significantly greater than E but remained less than C by a small but significant amount. RNA synthesis and content in 14-day-old E animals was significantly less than that in C at day 14, but synthesis of RNA from I (after only 3 days of alloantiserum treatment) was significantly greater than E and was similar to C. However, RNA content in 14-day-old I was still less than 14 days old C.

We conclude that the CNS has the ability to acquire new cells in an accelerated fashion when stress is imposed and then lifted and that this acquisition is accompanied by increased cellular functional capacity.

135.1 CROSSED HINDLIMB REFLEXES DURING FICTIVE LOCOMOTION IN ACUTE SPINAL CATS. S. Rossignol and C. Julien*. Centre de Recherche en Sciences Neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec, Canada, H3C 3J7.

In decerebrate cats walking on a treadmill, a high intensity stimulation of the superficial peroneal nerve (SPN) on one side can evoke on the other side a crossed extension response during stance or a crossed flexion during swing (Rossignol, S. and Gauthier, L., Soc. Neurosci. Abstr., 4, 304, 1978). In the present work, similar stimuli were given during fictive locomotion in spinalized (th13) and paralyzed cats pretreated with Nialamide (50 mg/kg) and L-DOPA (50-70 mg/kg). Trains of 10 to 20 pulses at 100 Hz were delivered to the SPN at an intensity sufficient to induce contralateral responses recorded in the extensor Gastrocnemius or flexor Semitendinosus nerves by means of cuff electrodes. The innervation of the limbs was left intact except for the recorded nerves which were ligated distally to the recording site. Both limbs were placed in a standing position. The stimulation produced an ipsilateral flexion response in all phases of the step cycle. However, in the contralateral limb, crossed extension responses occurred when stimuli were given just before or during the first half of the locomotor extensor burst. Crossed flexion responses were seen with stimuli delivered towards the end of the extensor burst and during the first half of the flexor burst. Stimuli in the second half of the flexor burst often gave no response in either nerve, whereas stimuli in the second half of the extensor burst gave either an extension or a flexion. In periods when crossed flexion or crossed extension responses were usually elicited, mixed responses were seen on occasion. They consisted of a short inhibition in the ongoing locomotor burst and a short response in the antagonist after which the ongoing activity resumed and the burst was completed. Stimuli given during the crossed flexion burst shortened the cycle whereas stimuli during crossed extension lengthened it. The overall distribution of crossed responses and the effects of stimuli on the duration of the step cycle during fictive locomotion are strikingly similar to those observed in the cat walking on a treadmill except for the mixed responses which we have never seen in the latter. This suggests that crossed reflex pathways to extensor and flexor motoneurons are largely selected centrally during rhythmic activity and that afferent information originating from the walking limbs provides a corrective reinforcement of that selection to insure that the responses are appropriate for the phase of the movement.

135.2 NEURAL FEEDBACK RESPONSES TO HAND PERTURBATION. Robert N. Stiles. Dept. of Physiology and Biophysics, University of Tennessee Center for the Health Sciences, Memphis, TN 38163.

Damped oscillations of the extended hand in response to a pulse perturbation occur at the frequency of postural hand tremor, when these are detected under similar conditions of added mass, displacement amplitude, and with rest between runs. Also, each kind of oscillation is accompanied by amplitude modulation of wrist extensor EMGs (forearm pronated) at the frequency of the oscillation, modulation that can be interpreted as resulting from neural feedback. Certainly the timing (or phase) of this EMG activity and the hand motion may be important relative to the amplitude of these hand oscillations. Hagbarth and Young (Brain 102: 509-526, 1979) noted that the repetitive EMG bursts tended to occur later in the oscillation cycle as the damped oscillations decreased in amplitude. The present report also considers the timing (and phase) between muscle activity and the damped hand oscillations that occur in response to a pulse perturbation.

Using a small accelerometer (phase and amplitude calibrated) and bipolar EMG electrodes, damped oscillations of the extended hand and surface EMGs from two wrist extensors were detected from each of ten normal human subjects. Damped oscillations of each subject's hand were produced by repetitively applying a downward pulse of force (a tap) at about 1/sec for 16 sec. The timing between the demodulated EMG and the negative of hand acceleration was obtained by cross-covariance analysis, and by the method of averaged transients.

The time (designated Δt) between when the peak upward position of the oscillating hand occurred and the time later that the maximum extensor activity occurred was consistently between 30-45 msec for all ten subjects. Visual analysis of the averaged transients indicated that Δt was relatively constant for each cycle of the damped oscillation. Further, the first average EMG response was a pulse of increased activity at 30-45 msec after the initial pulse of downward acceleration. With 100 g added mass, the maximum extensor activity at the frequency of the motion occurred at about the time of maximum downward velocity of the hand. With 600 g added mass, the oscillation frequency was reduced, Δt was little changed, and the extensor EMG maximum occurred prior to the maximum downward hand velocity. In all, the results suggest that: 1) Only one reflex pathway mediated the oscillatory EMG modulation. 2) The feedback delay varied little with oscillation amplitude. 3) The receptors that mediated this EMG response produced maximum afferent activity at the time when the muscle was maximally shortened. (Supported in part by USHPS Grant NS 14730.)

135.3 TIME-DEPENDENT EFFECTS OF SURAL NERVE STIMULATION ON EXTENSOR MOTOR POOL ORGANIZATION. H. P. Clamann and A. J. Robinson*. Dept. of Physiology, Med. College of Virginia, Richmond, VA 23298

It has been suggested that cutaneous nerve stimulation may have differential effects on select sub-populations of a motoneuron pool, and produce changes in the size-dependent recruitment order. The present study was designed to seek and quantify any changes in the recruitment order of monosynaptically activated medial gastrocnemius (MG) motoneurons produced by a conditioning train of stimuli to sural nerve. In cats anesthetized with chloralose, the sural nerve and MG muscle nerve were cut and placed on electrodes for stimulation or recording. Monosynaptic reflexes were evoked in MG by stimulation of L7 and S1 dorsal roots and reflex magnitudes were measured from the volleys recorded at the muscle nerve. The response of a single motoneuron was recorded with a microelectrode driven into its axon in a ventral root. A 10 msec train of pulses at 200 pps to sural nerve produced a brief inhibtion of a monosynaptic reflex initiated 1-2 msec after the end of the train; this inhibition was graded with conditioning stimulus intensity. In contrast, a 100 msec conditioning train to sural nerve facilitated a subsequent MG monosynaptic reflex.

When the sural nerve conditioning train was timed so as to facilitate MG, some changes in the recruitment thresholds of individual motoneurons were produced but these did not appear to be related to the conduction velocities of the cells. Sural nerve facilitation of MG did not alter the over-all size dependent recruitment order established in the monosynaptic reflex, but did reduce the correlation between recruitment order and conduction velocity.

When the sural nerve conditioning train was timed so as to inhibit MG, that inhibition appeared to occur selectively in motoneurons of low conduction velocity, causing their initially low recruitment thresholds to rise sharply. The same conditioning volley appeared to facilitate units of high conduction velocity, causing their initially high recruitment threshold to fall. This is supported by the following observation: when MG was tetanized to increase its monosynaptic reflex responses, 10 msec trains of sural nerve conditioning stimuli increased these responses further. As the effect of PTP wore off, the same sural nerve conditioning shocks produced inhibition of the smaller MG responses.

The nature of the effect of sural nerve stimulation (excitation or inhibition) depends in part on the level of activity of the MG motoneuron pool. This could contribute to the response of extensor muscles seen in 'phase dependent reflex reversal' of spinal cats during locomotion.

135.4 TEMPORAL RELATIONS BETWEEN MOTOR CORTICAL AND ELECTROMYOGRAPHIC RESPONSES TO IMPOSED FORELIMB DISPLACEMENTS IN THE CAT. A.G.E. North* and W.G. Tatton, Playfair Neuroscience Unit, University of Toronto, Toronto, Ontario, Canada, M5T 2S8.

Imposed displacements of upper limb joints in the monkey evokes activity in motor cortical neurons (MCN's) that is appropriately timed to contribute to the "M2" response in the EMG activity recorded from the stretched muscles. Despite the appropriate timing, recent transection studies (Ghez, C., Shinoda, Y., Exp. Br. Res., 32, 55-69, 1978) do not support the proposal that the MCN output contributes to a second reflex EMG response peak in cat forelimb muscles considered to be analogous to the monkey "M2".

Simultaneous area 4 microelectrode and triceps EMG recording was carried out in nine chronically prepared cats. A "receiving" zone in area 4 containing MCN's responding to imposed displacements of the elbow was mapped for each animal. MCN afferent latencies ranged from 10 to 28 msec with two distinct modes at 14 and 18 msec. The latencies were constant within ± 2 msec despite variation of the initial displacement velocity by as much as ten fold (60 to 600 degrees/second) and variation of the initial included joint angle from 130° to 70°. Intracortical microstimulation at loci within the "receiving" zone was shown to evoke activity in triceps brachii. The EMG showed three response peaks identical to those of Ghez and Shinoda at latencies ranging from 10 to 14, 34 to 52 and 60 to 85 msec respectively. The latencies of the second peak varied by ± 10 msec depending on the velocity of the displacement and/or the initial joint angle.

Following chronic recording for 2 to 3 weeks, five of the cats were anaesthetized with chloralose and stimulation ($< 50\mu$amps) of the cervical cord at the C2 level was carried out to determine the antidromic conduction time to MCN's in the "receiving" zone and the efferent conduction time to triceps. Antidromic conduction times ranged from 1.0 to 7.0 msec (mode 1.0 - 2.0 msec) and efferent times to triceps of 4.0 to 7.0 msec. Calculation of the summed afferent-efferent times establish that MCN activity in the "receiving' zone does not contribute to the generation of the 2nd EMG response peak in support of the transection studies and in contrast to MCN activity related to the M2 response for monkey distal upper limb musculature.

135.5 STRETCH REFLEX AMPLITUDE VARIATION IN PRIMATES.
J. R. Wolpaw and M. G. Sanders*. Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Monkeys maintained elbow angle at 90° (±1.5°) against constant extension force. Elbow angle and biceps EMG (from chronic intramuscular stainless steel wire electrodes) were monitored by computer. If correct angle was maintained for a randomly selected 1- to 2-sec period, and if the average absolute value of biceps EMG (sampled at 10 kHz) for the final 0.5 sec of the period fell within a preset range, a stimulus consisting of a 20-msec pulse of additional extension force occurred at the end of the period. It transiently extended the elbow (3-4°), eliciting a stretch reflex. The computer determined the amplitudes of the M1 and M2 components of the reflex. M1 amplitude was defined as the average absolute value of the EMG occurring 12.5-21.5 msec after stimulus onset, minus pre-stimulus EMG amplitude. M2 amplitude was defined as the average absolute value of the EMG occurring 31.5-56.5 msec after stimulus onset, minus pre-stimulus EMG amplitude. The computer also followed stimulus-induced elbow angle change. Under the Control condition, liquid reward was given 70 msec after stimulus onset. Under the M1+ or M1- condition, reward was given only if M1 amplitude was greater than (M1+), or less than (M1-), a preset value.

In initial work, data were obtained from four animals over continuous recording periods of up to 3 months. The computer tabulated number of trials, average pre-stimulus EMG amplitude, average M1 and M2 amplitudes, and average course of stimulus-induced elbow angle change, at hourly and daily intervals. Animals usually completed 3,000-10,000 trials per day. For each animal, EMG electrodes, pre-stimulus EMG amplitude, constant extension force, stimulus amplitude, and stimulus-induced change in elbow angle, remained unchanged over the recording period.

Marked acute (hourly) and chronic (daily and weekly) changes occurred in average M1 amplitude independent of change in average pre-stimulus EMG amplitude. These preliminary studies suggested: (1) When animals working in constant light complete equal numbers of trials around the clock, a clear circadian variation in M1 amplitude often occurs. M1 may be up to 40% greater at midnight than at noon. (2) Under the impetus of the M1+ or M1- condition, animals appear to be able to alter M1 amplitude progressively over a period of several days. (3) Without change in reward conditions, acute and chronic changes in M1 and M2 amplitudes can occur with considerable independence from each other.

In awake behaving primates, M1 amplitude at a given muscle length does not appear to bear a fixed relationship to alpha motorneuron tone. Whether the present findings are attributable to change in gamma motorneuron tone, other intra-segmental changes, and/or humoral effects on muscle spindle sensitivity, remains to be determined.

135.6 RELATION BETWEEN STIFFNESS AND FORCE IN THE ACTIVE CAT SOLEUS MUSCLE. T. M. Hamm* and L.D. Partridge. (SPON: B. R. Botterman). Dept. Physiol. Biophys., Univ. Tenn. Center Health Sci., Memphis, TN 38163.

In the active muscle, the relations between force and stiffness give insight into both current theories of contraction and the constraints imposed by muscle mechanics on the control of movement. The present report describes the relation between force and stiffness of the active soleus muscle (stimulated via sectioned sciatic nerve at 25 Hz) under isometric and anisometric (dynamic) conditions. Stiffness was measured as the ratio of force to length changes produced by small amplitude (< 0.2mm) vibration (200 Hz) imposed by an electromagnetic puller on the isometric muscle, and during 2-3 mm triangular and random stretches (< 8 Hz). By use of low- and high-pass filters, it was possible to separate low frequency changes in force and length from the high frequency changes used for the stiffness measurement.

"Shortrange stiffness" as described by Rack and Westbury (J. Physiol. Lond. 240: 331-350, 1974) was observed during triangular stretches. However, stiffness, as presently defined, was found to increase with force throughout the full duration of such stretches. In general, stiffness was found to be proportional to force under both isometric and dynamic conditions. At or near L_0, the slope of stiffness to force was similar for isometric and dynamic tests. At shorter lengths, (ascending limb of length-tension curve) this slope was greater for dynamic tests.

The dynamic relation between stiffness and force was examined by calculation of the cross-spectral density function of these two variables from records of random movements. At higher frequencies, the amplitude ratio of stiffness to force decreased, and stiffness began to lag force in phase.

In summary, the present results indicate that the mechanical properties of active muscle vary continuously with changes in force and length.

135.7 A MODEL OF MEDIAL GASTROCNEMIUS MOTOR UNIT ACTIVATION PATTERNS IN THE STRETCH REFLEX OF THE DECEREBRATE CAT. P.J. Cordo and W.Z. Rymer. Neurological Sciences Inst., Portland, OR 97209 and Northwestern Univ. Medical School, Chicago, IL 60611.

Single motor unit recruitment and rate modulation data obtained from the medial gastrocnemius (MG) of the decerebrate cat during stretch reflexes was used to reconstruct a whole-muscle force-EMG relationship. This predicted relationship was compared to the measured force-EMG relationship to test whether the motor unit sample was representative of the population. Using the motor unit activation parameters quantified in these experiments (1), the model incorporated the following features: 1) a muscle of 150 motor units with 75 S and 75 FR twitch types (2), 2) a 5 mm, 5 mm/sec ramp stretch reflex commencing from an initial force of 100 g and rising linearly with time to a peak of 1600 g, 3) a single unit recruitment function (force threshold distribution) $N=150-150e^{-.0019xF}$, 4) an initial firing rate proportional to the units' force thresholds, 5) a smooth increase in firing rate of each recruited unit of 2.0 pps/100 g force increase up to a saturated rate, and 6) a step increase in firing rate at stretch onset of 4.6 pps for units which were active before stretch began.

Comparison of actual and predicted force-EMG plots revealed a recording bias for larger motor units had occurred. By adjusting the recruitment function to include an initial step in recruitment (c.f. the dynamic component of the IA afferent response to muscle stretch) and a slightly steeper decay ($e^{-.003}$), a good correlation between predicted and measured force-EMG relationships was obtained. The initial abrupt rise in multiunit EMG which was observed during stretch reflexes supports this alteration of the recruitment function. The adjusted model was then combined with isometric twitch tension data (2) to reconstruct the force trajectory of the experimentally observed stretch reflexes. The force trajectory predicted by the model generated substantially more force than actually observed suggesting that, at least initially, the net force production capability of isometric muscle exceeds that of lengthening muscle. More interesting, the predicted force trajectory had an early, marked discontinuity in it which may correspond to the early loss of muscle stiffness ("yield") which has been demonstrated in the electrically stimulated cat soleus (3). If the correspondence is real, this finding strongly suggests that the mechanical properties of the reflexly activated portion of MG (slow twitch units) are qualitatively similar to those of the soleus and that, under reflexive conditions, these stiffness discontinuities are largely compensated for by rapid and substantial motor unit recruitment.

135.8 Stimulation of and recording from axons within their myelin sheaths: A stable and nondamaging technique for studying single motor units. D.L. Zealear* (SPON: M. Hast). Dept. of Otolaryng., Northwestern Univ. Med. Sch., Chicago, Ill. 60611.

The contractile properties and motoneuron spiking patterns of single laryngeal motor units were studied by stimulating and recording intracellularly from their motoneuron cell bodies. Since these experiments were conducted in the brainstems of lightly anesthetized, spontaneously breathing cats, considerable difficulty was encountered in holding cell bodies with micropipettes. An alternative approach was therefore taken, that of penetrating motoneuron axons in the recurrent laryngeal nerve; this was found to be a very stable technique. In most axon penetrations, sudden d.c. voltage shifts were not recorded, indicating that axon axolemmas were intact. In such cases, activation and recording of action potentials occurred from the myelin sheaths of axons. As described previously (Tasaki, I., Jap. J. Physiol. 3:73:1952), myelin sheath penetrations were functionally similar to actual axon penetrations. Threshold activation occurred with small anodal current pulses (a few namps in magnitude), and positive action potentials were recorded, but were graded in size with the depth of sheath penetration. Activation from a myelin sheath, therefore, had the functional advantage of an intracellular approach: stimulus current sufficient to activate a motoneuron being recorded from was too small to activate other motoneurons. Myelin sheath penetrations were, nevertheless, physically outside motoneurons and circumvented damage or conduction block, which could occur when using an intracellular approach. Because of the stability and noninjurious nature of the myelin sheath approach, motor units have been studied for over an hour on a routine basis, and for as long as three or four hours in many instances. The factors which contributed to the success of the approach will be described.

135.9 FREQUENCY ANALYSIS OF SHIVER IN HUMANS. R. S. Pozos, P. A. Iaizzo* and S. A. Burgstahler*. Dept. of Physiology, Univ. of Minn.-Duluth Sch. of Med., Duluth, MN 55812.

Shivering may be considered an involuntary oscillation similar to a reflex clonus but with possibly some central regulatory component (Perkins, J. F., Am. J. Physiol., 145: 264-271, 1946). However, the role of segmental as well as supraspinal reflexes on the generation of shiver and its maintenance and synchronization is still not well understood (Stuart, D. et al., Am. J. Physiol. Med., 45(2):61-102, 1966). The present study was undertaken to quantitate the frequency of shiver in humans using spectral techniques.

Human male and female subjects were seated in an environmental chamber set at 0°C. Surface electrodes had been placed on the masseter (M), pectoralis major (PM), trapezius (T) and soleus (S) muscles. An accelerometer was placed on the dominant knee of the seated subject, who held his leg in a plantar flexed position with the heel 2-4 cm off the floor. Core temperature was monitored using a rectal thermocouple and surface temperatures were recorded from thorax and abdomen regions. Signals were recorded on an FM tape recorder and later analyzed on a PDP-12 computer. Spectral as well as cross spectral techniques were employed to detect frequency and phase relationships between the various signals. Once an overall shiver was evident, subjects stayed in the chamber an average of 25 minutes. In most cases, core temperature rarely fell lower than 1°C. Peripheral temperatures, however, varied greatly depending on the amount of subcutaneous fat.

The analysis of the EMGs showed a number of major peaks. All the muscles oscillated in a range between 6-13 Hz. Accelerometer recordings of the ankle ranged between 5-8 Hz. In the case of the masseter, the EMG frequencies changed from one high frequency of 10 Hz to a higher one of 13 Hz. Throughout all records, there was a persistent major frequency of 4-6 Hz. Initially there was no significant coherence between the various EMGs and/or the accelerometer recording. However, as the shiver increased in intensity, significant coherence between the various EMGs (M, S, PM, T) as well as motion occurred at a frequency range of 5-6 Hz. At this time spectral analyses of the EMG usually showed at least two major peaks, one in the low range of 4-6 Hz and one at approximately 10-14 Hz.

This data indicates that during the initial stages of shiver the musculature is oscillating at a number of frequencies independent of each other. Eventually, as the shiver increases in intensity, there seems to be more synchronization between the various EMG signals.

135.10 COORDINATION OF ARM MOVEMENTS AND ASSOCIATED POSTURAL ADJUSTMENTS IN STANDING SUBJECTS. L. M. Nashner and P. J. Cordo. Neurological Sciences Inst., Portland, OR 97209.

It has been shown that, prior to a voluntary arm movement, activation of the trunk and leg muscles occurs in such a way as to compensate for the destabilizing effect of the intended arm movement (1). We have examined the characteristics of these associated postural responses (APR's) during arm movements with a view toward determining some organizational features of the interaction between voluntary and APR activities.

Standing subjects held a handle in the right hand and either pulled (using elbow flexion) as quickly as possible following an auditory signal or were instructed either to resist or not to resist the perturbation. In one group of trials the subjects were allowed to lean their chests against a rigid cross-beam support ("supported trials") and in another group they stood unsupported ("free-standing trials"). Surface EMG electrodes recorded the activity of biceps brachii and involved muscles of the ipsilateral calf and thigh while mechanical transducers monitored anteroposterior sway angle and handle force.

During free-standing trials, APR's in leg muscles preceeded tone-triggered biceps activity by 10-40 ms. When the handle pulled unexpectedly upon the subject's arm, APR's occurred 50-60 ms following the onset of displacement (both instructions). These latter APR latencies were at least 40-50 ms faster than the fastest reaction times, possible when subjects intentionally activated either leg or arm muscles following a tone. When instructed not to resist, EMG activity in biceps was rarely discernable preceeding the APR, while an instruction to resist vigorously almost always resulted in biceps activation at myotatic (25-30 ms) latencies. During all supported trials, APR's were rarely discernable and biceps reaction times to tones were 10-150 ms shorter compared to unsupported trials. Biceps responses to unexpected pulls usually occurred at myotatic latencies (25-30 ms), regardless of the prior instruction. Finally, when subjects supported themselves with the handle during platform movements, APR's occurred in arm muscles at 50-60 ms latencies, while normal postural adjustments in leg muscles (90-110 ms latencies) were attenuated.

These findings suggest: 1) a hierarchically low level of organization of APR's because of their rapid action and versatility of organization, 2) the magnitude of the APR appears to be modulated by the "postural set" of the subject since it is markedly reduced or absent when postural demands are reduced, 3) an interdependence of APR's and voluntary movements because both voluntary reaction and stretch response times in biceps were delayed with an increase in the postural demands of the task. (1) El'ner, A.N. Biophysics 18, 966-971 (1973).

135.11 EFFECT OF CHLORPROMAZINE ON H-REFLEX RECOVERY CURVE. John Metz, Henry H. Holcomb*, and Herbert Y. Meltzer. Laboratory of Biological Psychiatry, Illinois State Psychiatric Institute and Dept. Psychiatry, University of Chicago, Chicago, Ill.

We have found that the recovery curve of the H-reflex, an electrically evoked monosynaptic spinal reflex, is abnormally high (fast) at intervals from 50 to 300 msec in about 25% of schizophrenic and affective disorder patients (Metz et al., Psychological Medicine, in press). We are now conducting a series of acute pharmacological studies in order to understand the neural transmitter mechanisms which may underlie this abnormality. Here we report that chlorpromazine (CPZ) significantly decreases the H-reflex recovery curve in a dose-related fashion in normal young adults.

We administered saline, 12.5 mg CPZ, or 25.0 mg CPZ intramuscularly to a total of 16 paid volunteers, 5 males and 11 females, aged 22 to 34 (median 27). Most subjects received all 3 doses on different days, with at least 3 days intervening between treatments. All subjects abstained from food, cigarettes, and caffein throughout the experimental day and for at least 9 hours preceding the first test. Subjects were tested on the H-reflex recovery curve according to standard procedures between 9 and 11 A.M. (baseline condition); they were then given an injection of CPZ or saline and were retested 2 hours later (drug condition). In each condition, we determined the ratio of an H-reflex to an equal stimulus reflex (at maximum H amplitude) at 10 interstimulus intervals between 50 and 300 msec. The average of these 10 values constituted our measure of recovery for that condition.

There were no statistically significant differences in the conditioning reflexes or direct muscle responses between baseline and drug conditions at any of the doses used. There were no recovery differences among baseline values obtained on saline, 12.5 mg or 25.0 mg CPZ days. There was also no difference between the baseline and saline condition. In contrast, both groups which received CPZ had recovery values significantly lower than baseline ($F=7.06$, $p<.005$; Scheffe comparison to saline, $p<.05$ for 12.5 mg group, $p<.01$ for 25.0 mg group). Eight of the 10 subjects who received both 12.5 mg and 25.0 mg CPZ had markedly lower recovery at the higher dose.

The dose-related reduction in H-reflex recovery following CPZ suggests that the excitability of the alpha-motoneurons may be controlled by catecholamines acting at either spinal or supraspinal levels. This finding is also consistent with an interpretation that abnormally high recovery curves in unmedicated psychiatric patients may be related to higher than normal catecholamine activity or sensitivity in these patients.

135.12 EFFECTS OF BACLOFEN, GABA MIMETICS AND ADRENERGIC AGENTS ON THE FLEXOR REFLEX OF THE CHRONIC SPINAL RAT. J.G. Nutt, A.M. Marquez* and W.R. Woodward. Dept. of Neurology, Univ. of Oregon Health Sci. Ctr., Portland, OR 97201.

The antispasticity agent, baclofen, reduces flexor spasms (electrophysiologically analogous to the flexor reflex) in cord injured humans. As baclofen has some structural and physiological similarities to both GABA and phenylethylanine, we have compared the effects of baclofen with those of GABA-mimetics and adrenergic agents on the flexor reflex of chronic spinal rats.

The reflex was studied in rats three or more weeks after midthoracic cord transection when extensor spasms and hyperactive flexor reflexes were present. The rat was immobilized in a plexiglass restrainer, the flexor reflex elicited by constant current stimuli applied to the foot and the respnse measured by a force transducer attached to the leg. The parameters examined included maximum force, integrated force and duration of reflex response, as well as, threshold for eliciting the reflex. In chronic spinal animals, the maximum force of the flexor reflex is decreased and the duration increased as compared to that of intact rats.

Baclofen (3 and 6 mg/kg, i.p.) dose dependently reduced duration, and integrated force, increased threshold stimulus and slightly augmented maximum force. The "GABA facilitator" and antispasticty agent, diazepam (0.5 and 1.0 mg/kg), reduced maximum force, duration and integrated force of the reflex and increased threshold stimulus in a dose responsive manner. The GABA agonists, muscimol (up to 4 mg/kg) and THIP (5,10,and 20 mg/kg), produced catatonia and sedation respectively, without altering the parameters of the flexor reflex. The GABA transaminase inhibitor vinyl GABA (1000 mg/kg), doubled dorsal spinal cord GABA concentration but did not influence the reflex.

The α_2 adrenergic agonist, clonidine (0.06 to 0.5 mg/kg) increased the maximum force in a dose dependent manner and reduced the reflex duration but with no evident dose dependency. At low doses of clonidine the reflex force profile was similar to that produced by baclofen. In addition, preliminary studies indicate that the α_2 adrenergic antagonist, yohimbine (1mg/kg) antagonized the actions of baclofen and low doses of clonidine on the reflex.

In conclusion, the effects of baclofen on the flexor reflex of the chronic spinal rat did not resemble those of GABA-mimetics. There are, however, similarities between the actions of baclofen and those of the adrenergic agonist clonidine. The clinical implication is that GABA-ergic agents are unlikely to benefit patients with flexor spasms but that α_2 adrenergic agonists deserve further investigation.

135.13 PHYSIOLOGICAL TESTS FOR THE STUDY OF SKELETOFUSIMOTOR (BETA) INNERVATION IN THE CAT. Léna Jami*, K.S.K. Murthy and J.E. Petit* (SPON: H.H. Kaufman). Laboratoire de Neurophysiologie, College de France, 75231 Paris-5, France.

Recent studies employing the technique of glycogen-depletion of muscle units have uncovered the existence of skeletofusimotor (beta) innervation by fast conducting alpha motoneurones in addition to the well established slow beta axons (Harker et al. J. Neurophysiology 40: 791-799, 1977). It is thus of interest to establish the physiological tests necessary for the adequate identification of beta fusimotor action exhibited by an alpha motor axon.

Experiments were performed on cats anesthetized with sodium pentobarbital. Up to ten muscle spindle afferents from peroneus tertius were isolated in dorsal roots L_7 or S_1. Single alpha motor axons isolated from ventral root filaments which increased the rate of discharge of any of the spindle afferents were subjected to a detailed investigation involving the following tests:

1. Test for the ability of the spindle afferent to respond to a sudden increase in stimulus rates, well above the frequency for maximal extrafusal tension.
2. Test for the occurrence of unfused "frequencygrams" of the spindle afferents (Bessou et al. J. Physiology 196: 37-45, 1968), when the motor axon was stimulated at rates above the tetanic fusion frequency for extrafusal tension.
3. Test for fusimotor action during a concurrently applied muscle stretch.
4. Test for difference in the fatiguability of junctional transmission between extrafusal and intrafusal end plates by repetitive high frequency tetanic stimulation.

A total of 116 motor units were studied. Thirty-six of these (31%) were identified as beta with the fusimotor actions of static versus dynamic in the ratio of 2:1. Static beta axons were found among the faster conducting alpha population (76-104 m/sec) compared to the dynamic beta axons which were exclusively among the slower conducting units (56-79 m/sec).

135.14 DISCHARGE PROPERTIES OF MUSCLE SPINDLE AFFERENTS IN FATIGUED MUSCLE. D. L. Nelson* and R. S. Hutton, Dept. of Kinesiology, University of Washington, Seattle, WA 98195.

Fatigue to 60-50% maximum tetanic tension was induced in the isolated gastrocnemius muscle in five cats by sustained, 7xthreshold electrical stimulation (100Hz) of the cut L_7VR and S_1VR. Group Ia and II afferent responses to ramp stretches (5mm) and vibration (100Hz) applied to the Achilles tendon were monitored before and immediately after muscle tetany. Firing characteristics were similar when results from slower (summarized below) and faster (25mm/s) ramp stretches were contrasted.

Muscle Spindle Afferent Responses to Ramp Stretch (5mm/s) in Fatigued Muscle

	Resting Discharge				Static Response		
	↑	↓	NC	NA	↑	↓	NC
Ia	24	8	3	14	10	32	7
II	12	5	0	9	9	14	3
Sum(%)	36(48)	13(17)	3(4)	23(31)	19(25)	46(61)	10(14)

	Dynamic Sensitivity (Mean Frequency)			Dynamic Response (Peak)		
	↑	↓	NC	↑	↓	NC
Ia	30	12	7	19	22	8
II	15	6	5	14	11	1
Sum(%)	45(60)	18(24)	12(16)	33(44)	33(44)	9(12)

	Vibration Response				Response Latency		
	↑	↓	NC	NA	↑	↓	NC
Ia	42	3	3	0	3	45	1
II	19	3	2	2	1	22	3
Sum(%)	61(82)	6(8)	5(7)	2(3)	4(5)	67(90)	4(5)

↑ (increase), ↓ (decrease), NC (no change), NA (not active)

During muscle fatigue, both afferent types predominantly decreased in response latency to displacement and increased in resting discharge, mean frequency during stretch and frequency of firing to vibration. Static responses were generally lower indicating a decrease in position sensitivity. Resting muscle force and passive peak muscle stiffness were consistently higher following contraction. Under the same experimental conditions, we have previously reported (Med. Sci. Sport, 11:76, 1979) that group Ib excitability to passive stretch or muscle twitch is depressed for several seconds after sustained muscle tetany. It is therefore proposed that the sum effect of these adjustments in proprioceptive afferent and intrinsic muscle responses would be to reflexly and mechanically increase muscle stiffness during subsequent perturbations.

135.15 SPIKE TRIGGERED AVERAGING OF EMG AS AN INDICATOR OF SKELETOFUSIMOTOR ACTION ON MUSCLE SPINDLE RECEPTORS. W. Zev Rymer, F.R. Edwards* and C.L. Cleland (Spon: A.R. Gibson), Depts. of Physiology and Neuroscience Program, Northwestern University Medical School, Chicago, Illinois 60611.

In previous presentations, we have argued that changes in muscle spindle receptor discharge arising above extrafusal threshold are legitimately attributed, at least in part, to actions of skeletofusimotor neurons on intrafusal muscle fibers. However, these arguments were indirect in nature, and more direct evidence supporting skeletofusimotor action is to be preferred. If skeletofusimotor innervation arises simply as branches from ordinary (i.e., skeletomotor) axons, then it follows that changes in intrafusal state should be paralleled by discernible changes in skeletomotor state. Such changes in intrafusal state would be expected to induce modifications in spindle receptor discharge.

We examined the discharge of primary spindle receptor afferents from the soleus muscle of the decerebrate cat preparation. This discharge was recorded from small natural dorsal root fascicles; most of the dorsal roots were left intact. Muscle force and length were recorded by appropriate transducers, and emg by extensively bared intramuscular nichrome wires (.005" diameter). Afferent discharge was recorded during spontaneous or reflexively induced changes in muscle force, under both isometric conditions and during changes in muscle length.

Evidence for skeletofusimotor discharge was sought by compiling a spike triggered average of soleus emg, force and length, using the afferent fiber spike to trigger this average. In approximately 50% of the primary endings, this spike was associated with an increase in emg activity in the soleus muscle arising about 5.0 msec. before the afferent spike. There was also typically a correlated force increase, peaking shortly after the spike occurrence.

It is argued that the prior increase in emg is precisely what would be expected if the intrafusal fibers were induced to contract by a descending impulse which also activated extrafusal muscle fibers. The increase in intrafusal tension would heighten the probability of discharge of the spindle receptor, while the impulse to extrafusal fibers would give rise to correlated emg and force increases.

135.16 STRETCH DURATION DETERMINES THE RATIO OF VELOCITY TO PROPORTIONAL SENSITIVITY IN PRIMARY MUSCLE SPINDLE RECEPTORS. R.E. Poppele. Lab of Neurophysiology, University of Minnesota, Minneapolis MN 55455.

The behavior of primary endings of deefferented cat spindles to relatively large amplitude stretches was explored using randomly applied stretches and ramp-and-hold stretches. The response of the primary endings was expressed as a ratio of its dynamic to static responses to a ramp-and-hold stretch (see below). For a linear device, this fraction (d/s) should be proportional to the velocity-amplitude ratio (v/a) of the stimulus, so that the fraction (d/s / v/a) should be constant. For the spindle, that fraction is not constant, but depends on the amplitude to velocity ratio of the applied ramp or its rise time as plotted below for three stretch amplitudes.

The finding is confirmed with random stretches. Applied as a filtered Poisson process, the mean stretch velocity per unit amplitude could be varied by suitable choice of filter time constant and shot amplitude. A frequency domain analysis was done to determine the ratio d/s of the response. This was divided by the mean velocity to mean amplitude ratio of the stretch and is plotted as a function of the mean rise time of the random stretches below.

The results suggest that the primary endings, in the absence of fusimotor influence, provide predominantly velocity feedback in the presence of slow stretches and predominantly proportional feedback for rapid stretches.

135.17 TENDON ORGAN RESPONSE TO RANDOM ACTIVATION OF SINGLE AND MULTIPLE MOTOR UNITS. E. K. Stauffer, G. P. Moore, and R. A. Auriemma*. Univ. Minn.-Duluth Sch. Med., Duluth, MN 55812 and Dept. Biomed. Engr., USC, Los Angeles, CA 90007.

Previous studies of motor unit-tendon organ (TO) interactions have tended to emphasize the stereotyped responses of these receptors to isolated twitches or short tetani. In this report we examine the effect of patterns of motor unit activity in which summation of individual twitch forces over time and between different motor units associated with a single receptor can take place.

Single slow twitch motor units from the cat soleus were functionally isolated from ventral rootlets at the L7-S1 level. Single TO afferents were identified and isolated from corresponding dorsal rootlets. Afferent responses were recorded during periodic (2 Hz) stimulation of each motor unit and PST histograms were constructed to show the average response of the TO spike train to periodic motor unit contractions. Average motor unit twitch force also was calculated. Following this the same TO was tested as motor units were stimulated with random Geiger counter driven pulse trains at mean rates of about 10 Hz for periods of 10-20 minutes duration, either singly or with multiple, concurrent, and independent stimulus trains.

When the firing pattern of one or more slow twitch motor units produces forces which exceed some minimum load, the TO undergoes a transition from a basically silent receptor with transient responses to a receptor more or less tonically active whose firing rate is modulated by the force pattern. Only when summation of random twitches from a single motor unit takes place is there distinguishable a time varying effect of each motor unit twitch on the TO firing probability, an effect characteristic of that motor unit and relatively unaffected by the existence or particular pattern of concurrent firing in other motor units.

Thus the average Ib afferent response has 1) a baseline discharge rate related to the mean total force coupled to the receptor capsule; 2) a transient burst associated with and characteristic of the rate of change of each motor unit's development; and 3) a slower, more prolonged response that closely follows the entire force profile of the twitch.

A striking nonlinear effect of twitch summation within a single motor unit was revealed by a new two dimensional PST histogram technique. Less dramatic nonlinear interactions were revealed when two or more motor units activated a common tendon organ. The random stimulus technique shows for the first time the dependence of tendon organ discharge on the entire twitch waveform (and hence type) of the motor units connected to its capsule and on the detailed firing pattern by which each is activated.

136.1 RECIPROCAL INHIBITION IN THE MEDULLARY RESPIRATORY NETWORK. Stephen R. Muza* and Donald T. Frazier. Department of Physiology and Biophysics, University of Kentucky, Lexington, KY 40536

A current notion with respect to the genesis of the respiratory rhythm involves the existence of two separate pools of brainstem neurons which are reciprocally inhibitory. If the hypothesis is true, maneuvers which increase inspiratory neural activity should cause expiratory neurons to receive more inhibition and vice versa. To test the hypothesis, experiments were conducted in dial-urethane anesthetized cats. Firing patterns of inspiratory (nucleus tractus solitarius-NTS) and expiratory neurons (nucleus retro-ambigualis-NRA) were recorded with extracellular glass microelectrodes. Inspiratory and expiratory neural activity was independently modulated by adding graded airway resistances either on inspiration or expiration. Since inspiratory and expiratory neural activity is 180° out of phase, the hypothesized inhibition would be arriving during the respective cell's silent period. However, when a cell is silent an extracellular electrode cannot distinguish whether the cell is silent because of lack of excitation or the presence of inhibition. Therefore glutamate, which raises the excitability of respiratory neurons, was used to unmask the existence of inhibitory inputs. L-glutamate was microiontophoretically applied to produce neural activity in the normal silent phase. Thus a reduction of the L-glutamate induced activity during resistive loading in the opposite respiratory phase would indicate the presence of an inhibitory input. The data was analyzed on a PDP 8/e computer which provided inspiratory (T_I) and expiratory (T_E) durations and plotted unit activity histograms. The presence or absence of an inhibitory input was statistically evaluated using the Sign Test. Application of L-glutamate substantially increased the firing rate of a single respiratory neuron throughout the entire breath but did not alter the animal's respiratory activity. As previously shown in our laboratory, inspiratory and expiratory resistive loading increased T_I and T_E respectively. Induced inspiratory unit activity during the normal silent period was decreased by expiratory resistive loading. Likewise, induced expiratory neuron unit activity was decreased by inspiratory loading. The occurrence of inhibition of the L-glutamate induced activity during resistive loading in the opposite phase was highly significant. The results suggest that NTS inspiratory and NRA expiratory neurons receive phasic inhibitory inputs during the opposing phase of respiration and are consistent with the reciprocal inhibition hypothesis.

136.2 RESPIRATORY AND MORPHOLOGIC CHANGES FOLLOWING KAINIC ACID (KA) LESIONS OF THE VENTROLATERAL NUCLEUS OF THE SOLITARY TRACT (v1-NTS). Albert J. Berger and Karen A. Cooney*. Dept. Physiology and Biophysics, Univ. of Washington, Seattle, WA 98195.

KA may destroy CNS neurons having glutamate receptors while sparing axons in passage (Coyle et al. J. Comp. Neur. 180:301, 1978). Medullary respiratory neurons are markedly excited by glutamate (Denavit-Saubié et al. Brain Res. 155:55, 1978). Therefore we used KA to destroy neurons within the v1-NTS, which is known to contain a major concentration of respiratory neurons. These neurons may have a role in respiratory pattern generation.

Under anesthesia we exposed the dorsal medullary surface and using a microsyringe injected stereotaxically KA dissolved in mock cerebrospinal fluid (CSF). At 0, +1, and +2 mm rostral of obex 0.3 or 0.5 µg of KA was injected at each site, either unilaterally (2 cats) or bilaterally (5 cats). In 2 control cats mock CSF was injected. Two mos. later the medulla was removed. Cells of somal diameter ≥ 20 µm and lying in a quadrant of 300 µm radius placed ventrolateral to the tractus solitarius from 0-2 mm of the obex were counted. In two unilaterally lesioned cats the total number of cells was reduced from 305 and 353 cells on the unlesioned side to 74 and 81 cells on the lesioned side, respectively. The ipsilateral solitary tract and the dorsal motor vagal nucleus appeared normal, while the number of cells in the XII n. nuc. was also reduced.

Hyperoxic breathing patterns were determined before and after lesion placement during wakefulness and under pentobarbital anesthesia. Awake studies were done on 4-5 separate days prior to lesion and usually at 1, 2, 4, 6, and 8 weeks post lesion. Anesthesia studies were done 2 weeks prior to and 2 months post lesion. During wakefulness control and unilaterally lesioned animals did not have significant ($P > .01$) changes in any respiratory variable pre vs. post lesion. Some bilaterally lesioned animals did have significant ($P < .01$) changes: ventilation ($\dot{V}$) reduced (2 of 5); tidal volume (V_T) reduced (1 of 5); breathing rate (f) reduced (3 of 5); inspiratory time (T_I) increased (2 of 5); expiratory time (T_E) increased (2 of 5). All anesthetized unilateral and bilateral but not control lesioned animals exhibited marked reductions in $\dot{V}$ and f and marked increases in T_I and T_E, but no consistent change in V_T for any group. These results demonstrate that: 1) KA can destroy most of the v1-NTS. 2) During wakefulness rhythmic respiration is sustained and in some but not all animals is not significantly altered following bilateral KA lesion of the v1-NTS. 3) Anesthetized unilaterally and bilaterally lesioned animals have altered rhythmic respiratory patterns. We suggest that during wakefulness or anesthesia the v1-NTS is not solely responsible for respiratory rhythmogenesis. (Supported by USPHS Grant NS 14857 and RCDA NS 00378.)

136.3 ABSENCE OF FAST PERIODIC OSCILLATIONS IN PNEUMOTAXIC AREA NEURONAL DISCHARGE DURING SLEEP. Gary C. Sieck*, and Ronald M. Harper. Dept. of Anatomy and Brain Research Inst., UCLA Sch. Med., Los Angeles, CA 90024.

High frequency oscillations (HFO; 60-110 Hz) are present in phrenic activity and medullary respiratory unit discharge (Cohen, M. I., Acta Neurobiol. Exp. 33:198-218, 1973). Periodic stimulation of the nucleus parabrachialis medialis (NPBM; Pneumotaxic Area) can drive the HFO of both phrenic activity and medullary respiratory neuron discharge, suggesting that HFO of the respiratory system are effected by oscillatory input from the pneumotaxic area. Moreover, HFO appears to be susceptible to the state of arousal of the animal, as is the discharge of NPBM neurons (Sieck, G. C. and Harper, R. M., Exp. Neurol. 67:79-102, 1980.). The purpose of the present study was to examine the discharge of NPBM neurons during different sleep and waking states to determine whether the activity of this area displayed fast periodic oscillations that might drive the HFO of the respiratory system.

Adult cats were instrumented with electrodes for monitoring sleep and waking states. A bundle of 10 fine wire electrodes (62 µ insulated nichrome wire) was implanted in the NPBM through the guide tube of a miniature microdrive. During recording sessions, the animals were unrestrained except for a recording cable coupled to a connector atop the animal's head. The physiological signals were recorded both on analog tape and polygraph paper, and the two records were synchronized using a time code. Segments of the polygraph record were selected that represented samples of each sleep-waking state. The corresponding analog tape records were replayed, and the neuronal spike data were passed through a Schmitt trigger circuit. The times of occurrences of the neuronal events were stored in a computer file and periodicities in neuronal discharge were assessed by calculating autocorrelation functions (bin width=1 msec) on these data. The activity of a total of 60 NPBM neurons was recorded during each sleep-waking state. Fast periodic activity was not observed in the discharge of any NPBM neuron during any sleep-waking state, despite the presence of respiratory-related activity in many of these cells (N=27). In contrast, recordings of the activity of medullary respiratory neurons (N=10) in awake intact cats show the presence of HFO in the discharge of these neurons. Thus, these data indicate that fast periodic oscillations in activity present at several levels of the respiratory system are not present at the level of the pneumotaxic area. (Supported by Grant HL-22418-02 from the NIH, and by NS05349-03 PHS Research Fellowship Award to G.C.S.)

136.4 IS RESPIRATORY ACTIVITY EVERYWHERE? A. Netick* and J. Orem. Psychology Dept., Calif. State Univ., Hayward, CA 94542 and Dept. of Physiology, Texas Tech Univ. Sch. of Med., Lubbock, TX 79430.

After recording 800 mesencephalic neurons, none of which was ostensibly respiratory, we began to doubt the claim by Vibert and his colleagues (Neuroscience Letters,11:29,1979) that 38.5% of the cells in this region are respiratory modulated. Although there were differences in the preparations (our animals were intact, chronic and unanesthetized while theirs were semi-chronic and locally anesthetized with bilateral vagotomy and spinal section, these differences seemed less significant than the fact that both preparations avoided the use of general anesthetics. A more important difference between the studies was that they used computer techniques to discriminate respiratory cells while we simply looked at and listened to the neuronal activity. With this in mind, we tested the respiratory modulation index (RMI) developed by these authors to discriminate respiratory neurons (RMI≥.7). Computer simulations revealed that the RMI is an inadequate statistic that can and often does characterize nonrespiratory activity as respiratory.

We compared RMI with two standard statistical techniques: a parametric test, the analysis of variance (F), and a nonparametric test, Friedman's analysis of variance for ranked scords (χ^2). We used a Monte Carlo technique of drawing repetitively samples from simulated distributions of neuronal activity and allocating them to successive bins (n=22) representing the respiratory cycle. Allocation to bins was made randomly so that only a chance relationship existed between the simulated activity and the respiratory cycle. For F and χ^2, the theoretical rate of false positives was set at 5% using standard statistical tables. Over wide variations in sample size and in the shape of the distribution of spike activity, the actual rate of false positives conformed closely to the expected rates. In contrast, RMI, under the same conditions, wildly fluctuated with up to 100% false positives. Similarly when respiratory activity was simulated, χ^2 and F proved more sensitive to the relationship than RMI.

The RMI evaluated 54% of a sample of 41 midbrain cells as respiratory. In fact, only 12% and 7% were actually respiratory as determined by F and χ^2 respectively. These latter values are possible chance events, and although there may be some small percentage of respiratory cells in this region, the high incidence as reported by Vibert and coll. for this and other brain regions (Bertrand et al., Exp. Brain Res. 16:383, 1973) is based upon the faulty RMI and is highly questionable.

136.5 DIFFERENTIATION OF CENTRAL AND PERIPHERAL ACTIONS IN SOMAN-PRODUCED RESPIRATORY ARREST. D.L. Rickett, M.L. Adams*, K.J. Gall*, S.F. Rybczynski*, and T.C. Randolph*. Physiology Branch, US Army Biomedical Laboratory, Aberdeen Proving Ground, MD 21010.

Soman (1,2,2-trimethylpropyl methyl-phosphonofluoridate), an organophosphorus anticholinesterase, resists treatment with atropine and/or oximes. This is thought to be due to the rapid rate at which the soman-acetylcholinesterase complex ages. The lethality of this agent is generally attributed to respiratory arrest. Recent demonstrations of the efficacy of the quaternary carbamate pyridostigmine (3-dimethylcarbamoyloxy-1-methyl-pyridinium bromide) in raising the subcutaneous LD50 of soman have raised questions concerning the relative importance of the central and peripheral effects of soman in producing respiratory arrest. The present study was designed to differentiate acute central and peripheral effects of soman in Dial anesthetized cats. Medullary respiratory-related unit activity, contralateral phrenic nerve activity, diaphragmatic electromyographic activity and contractions, blood pressure, and airflow were monitored. Soman was infused via the femoral vein at the rate of 1 ml/min (15 ml equivalent to an iv LD50). Soman infusion was stopped when spontaneous respiration ceased. At that time, neuromuscular blockade was tested by administration of supramaximal stimulation of the phrenic nerve. The results show that at the time of soman-produced respiratory arrest there was a loss of synchronous firing of respiratory-related units. Furthermore, contractions elicited by phrenic nerve stimulation demonstrated that the neuromuscular junction was not blocked. These contractions were subsequently blocked by Flaxedil. The present data support the notion that soman-produced respiratory arrest is mediated centrally and that, while soman's peripheral effects may be important, they are not the primary cause of respiratory arrest. The central actions of soman remain to be elucidated.

136.6 THE NEUROCHEMICAL MECHANISM BY WHICH AMINOPHYLLINE STIMULATES RESPIRATION. R. A. Mueller, D. B. A. Lundberg* and G. R. Breese. Departments of Anesthesiology, Pharmacology and Psychiatry, Univ. of N. Carolina, Chapel Hill, NC 27514, and Dept. of Anesthesiology Sahlgrenska Sjukhuset, Göteborg, Sweden.

Aminophylline has been employed for several years as a respiratory stimulant in infants displaying the neonatal apnea syndrome. The present study examined the neurochemical basis of the aminophylline-induced increase in respiratory activity using halothane-anesthetized rats. Male Sprague-Dawley rats with cannulae in the tail artery, the trachea, the esophagus, and the peritoneal cavity were given 0.7% halothane in O_2 and placed in a closed body plethysmograph for recording of tidal volume, respiratory frequency, blood pressure and heart rate. After 20 min of the above mixture, the response to 5% and 10% CO_2 in oxygen was measured for 2 five min periods and hypoxia (10% oxygen, 90% nitrogen) for 5 min. After aminophylline administration (i.p.) the hypercarbic and hypoxic tests were repeated 15 min later. Brain concentrations of norepinephrine, dopamine, and serotonin were measured at the conclusion of these respiratory tests with aminophylline. Aminophylline increased basal and hypercarbia or hypoxia induced respiratory stimulation. Division of the ninth cranial nerve together with removal of the carotid body did not alter the response, whereas vagotomy changed the response from one of increased frequency to an increase in tidal volume. Both awake and anesthetized rats evidence a decrease in $PaCO_2$, and in awake animals a decrease in brain stem dopamine content was observed.

Treatment of infant rats with 6-hydroxydopamine, which selectively reduced brain stem dopamine content to less than 30% of control, abolished the effects of aminophylline on both basal and CO_2, or hypoxia-induced respiration when tested as adults. Neonatal treatment with 5,7-dihydroxytryptamine, which reduced brain stem serotonin content to less than 30% of vehicle treated controls, potentiated the effects of aminophylline on basal and stimulated respiratory parameters. Since haloperidol, a dopamine antagonist, blocked the response to aminophylline it is possible that aminophylline may stimulate respiration by indirectly altering dopamine receptor activation in the brain. Alternatively, aminophylline could be stimulating respiration by blunting the effects of tonic inhibitory serotonin receptor activation.

137.1 ANTAGONISM OF THE REGIONAL ELECTRICAL EFFECTS OF GAMMA-HYDROXY-BUTYRIC ACID BY PETIT MAL ANTICONVULSANTS. L. J. Bearden and O. C. Snead. Neurosciences Program, Dept. of Pediatrics, and Dept. of Biomedical Engineering, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

Gamma-hydroxybutyric acid (GHB) is known to be a normal constituent of human and animal brain. An increase in the concentration of GHB in the brains of animals has been found to produce an unresponsive state which is characterized by a fixed gaze, and an accompanying spike-wave pattern in the electroencephalogram. These behavioral and electroencephalographic effects are quite similar to those observed during petit mal seizures. The similarity between the GHB induced behavioral depression and petit mal seizures is increased by the fact that clinically effective petit mal anticonvulsants also antagonize the behavioral and electrical effects of GHB. Since GHB has been found to inhibit the firing of dopaminergic cells in the pars compacta of the substantia nigra (Roth et al., in "Frontiers in Catecholamine Research", p. 567, 1973), this inhibition (via GABA receptors, Roth and Nowycky, Biochem. Pharmacol. 26:2079, 1977) has been proposed as the means by which the behavioral and electrical effects of GHB are achieved. However, this inhibition was not specific for dopaminergic cells. In addition, more recent experiments have shown that the inhibitory effects of GHB on nigral and neocortical cells are not mediated via activation of bicuculline sensitive GABA receptors (Olpe and Koella, Eur. J. Pharmacol. 53:359, 1979). Therefore, the mechanism of action and the neural origin of the behavioral effects of GHB remain undefined. The present experiments were conducted to examine the subcortical electrical effects of GHB and the alterations of these effects by petit mal anticonvulsants. Power spectral analysis of the electrical response of cortex, hippocampus, caudate-putamen, and ventral thalamus to GHB indicates a variable sensitivity of these tissues to the effects of this compound.

137.2 CHANGES IN LOCOMOTOR ACTIVITY IN RATS "KINDLED" IN THE AMYGDALA AND NUCLEUS ACCUMBENS SEPTI. C.L. Ehlers*, G.F. Koob, S.J. Henriksen, and F.E. Bloom (SPON: W. Vale). A.V. Davis Ctr. for Behav. Neurobiol., Salk Inst., La Jolla, CA 92037.

"Kindling" is a process whereby a progressive increase in neural and behavioral responsivity develops during spaced and repeated epileptogenic stimulation of specific brain sites. In the present study we sought to determine if changes in interictal behavior, initially assessed by monitoring locomotor activity, accompanies the development of "kindling" following electrical stimulation of the amygdala (AMYG) or Nucleus Accumbens Septi (NAS). Wistar rats were stereotaxically implanted with bipolar electrodes aimed at either the AMYG or NAS. Additional screws were placed in the calvaria over the frontal and occipital cortex. The kindling stimulus (a 1 sec train of 1 msec biphasic square wave pulses, 60 Hz, 200 A) was applied once daily until 3 fully-kindled convulsions were observed. Although fully kindled responses in NAS and AMYG animals were similar, the order of presentation of behavioral signs during the development of kindling was different, as was the number of stimulations necessary to produce fully-kindled responses. Control animals were implanted and handled but not electrically stimulated. Locomotor activity of kindled and control rats was assessed in hanging wire cages equipped with 2 photocell beams. Activity was measured as total beam interruptions counted and recorded every 10 minutes over 4 hr test sessions. NAS and AMYG kindled animals exhibited a significant decrease in interictal locomotor activity compared to implanted controls. Significant decreases in locomotor activity were also found post-ictally in rats monitored for 2 hours immediately following a kindled seizure. NAS and AMYG kindled animals also exhibited a significant attenuation of the locomotor-stimulating effects of amphetamine (0.5 mg/kg) administered post-ictally. All these effects were more prominent in NAS kindled animals compared to those kindled in AMYG or controls. These results suggest that interictal changes in behavior accompany the development of kindling in the rat, and that a differential response is seen in NAS vs. AMYG kindled animals (supported by DA 01785 and the Klingenstein Foundation).

137.3 KINDLING PHENOMENON: PHARMACOLOGICAL AND ELECTROPHYSIOLOGICAL CORRELATES. R.L. Borison, R. Kowatch*, P.J. Maple* and B.I. Diamond. Illinois State Psychiatric Institute, Mount Sinai Hospital, and Rush Medical College, Chicago, IL 60612.

The kindling phenomenon was first described electrophysiologically as repeated subconvulsive stimulation inducing generalized seizure activity. Pharmacological kindling has now been described behaviorally for drugs which work via brain dopamine systems, such as L-DOPA. We now report experimental studies correlating pharmacological kindling and behavior, with electrophysiological events. Subjects were white male Sprague-Dawley rats, with recording electrodes stereotactically placed bilaterally into the caudate-putamen nucleus and the nucleus accumbens (NA). Animals were treated daily with either d-amphetamine (dA) (3.75 mg/kg) or phenylethylamine (PEA) (50 mg/kg) in doses per se subthreshold for producing behavior. Both of these drugs are capable of producing stereotyped behavior and psychosis in man. After drug injections, the EEG was recorded while the animal was freely moving. We found that repeated injection of PEA or dA resulted in a gradual increase in stereotyped behavior during the first three weeks and plateauing at five weeks. The EEG records showed that acute or subacute dA or PEA failed to affect electrical activity. However, by week three, there was a significant increase in fast, high amplitude activity lateralized to the right caudate in dA treated animals, and the right NA in PEA treated animals. At five weeks, PEA treated animals showed bilateral high amplitude activity in the NA, whereas dA treated animals showed similar activity, but localized to the caudate-putamen. The behavior induced by dA and PEA are identical, yet the EEG indicates differing sites of origin. Moreover, changes in behavior were correlated with changes in EEG activity, indicating that electrical kindling is coincidental with behavioral kindling.

137.4 LATERALIZATION OF STATE-DEPENDENT LEARNING PRODUCED BY HIPPOCAMPAL KINDLED CONVULSIONS. K. A. Stokes* and D. C. McIntyre* (SPON: Dr. Metuzals). Physiological Psychology Labs, Carleton University, Ottawa, Ontario, Canada, K1S 5B6.

Convulsions kindled from the amygdala readily produce state-dependent learning. The hippocampus also kindles easily, and because of its implication in learning and memory, it was decided to study the state-dependent effects of hippocampal kindling. Electrodes were implanted in either the left or right hippocampus of 87 male Wistar rats and kindling was begun. One week after the fifth generalized convulsion, the rats were trained in an inhibitory avoidance task under one of two conditions: normal (N) or convulsed (C). Testing took place 24 hours later under either the same or changed state conditions. Thus, there were four groups for each hemisphere: N/N, C/C, N/C and C/N. Results showed that animals trained and tested in the normal state, for both hemispheres, could learn and retain the task adequately. For both hemispheres, animals trained in the normal state while tested in the convulsed state were severely impaired in their retention. Differences between the two hemispheres occurred in the C/N and C/C conditions. Left C/N animals showed markedly impaired retention, while right C/N animals were less impaired, although significantly different from normals. Left C/C animals were somewhat impaired in their retention, while right C/C animals were comparable to normals and controls in their retention. Seizure data could not adequately account for these differences beyond a tendency for the left hemisphere to give longer electrographic afterdischarge than the right hemisphere. Thus, a convulsion produces an encoding deficit as well as a recall deficit in the left hemisphere, but only a recall deficit in the right hemisphere, except if the state remains the same at training and testing. The results were interpreted as a hemispheric asymmetry, either in terms of relative impairment of function after a convulsion (functional lesion effect) or in terms of lateralization of information processing.

137.5 INCREASE IN SENSITIVITY TO CONVULSANTS FOLLOWING INTRAVENTRICULAR INJECTION OF GANGLIOSIDES. Karpiak, S.E. and Rapport, M.M., Div. of Neuroscience, N. Y. State Psychiatric Inst. and Depts. of Psychiatry and Biochemistry, Columbia Univ., New York, 10032.

Several studies (1-4) have implicated brain gangliosides in seizure activity. Work in our own laboratory showed that the intracerebral injection of antibody to GM1 ganglioside induces recurrent epileptiform activity. Both Westmoreland et al. and Yu et al. have reported increases in ganglioside content in animals following chemically induced seizures. Recently Kostic et al. reported ganglioside changes in the CNS following pentylenetetrazol (Metrazol) induced seizures in the rabbit. The following study was undertaken to determine if an intraventricular injection into the rat brain of brain gangliosides would decrease or otherwise alter seizure thresholds to Metrazol. Metrazol thresholds were determined (5) in rats (Sprague-Dawley, 250 grams) on Day 1. On Day 2 the rats were given (under ether anesthesia) an intraventricular injection of 10 mg of total brain ganglioside in saline (10 µl). Controls were injected with saline. On Day 3 Metrazol thresholds were redetermined. Animals injected with gangliosides showed a decrease in threshold ($p<0.01$) whereas thresholds of controls were unaffected. The results indicate that gangliosides injected into the brain can alter the properties of neurons in such a way as to increase seizure susceptibility. Since the mechanism of action of Metrazol is hypothesized to be that of a "synaptically acting convulsant" which activates excitatory synapses rather than blocking inhibitory synapses (6), exogenously administered gangliosides may be exerting their effect on excitatory synaptic pathways. It will be of interest to see if gangliosides affect seizure thresholds induced by convulsants which block inhibitory pathways.

137.6 DENDROTOXIN: CONVULSANT AND POSSIBLE ANTICHOLINERGIC ACTION IN FROG SPINAL CORD. P.A. Smith, A.L. Padjen, M. Quik* & B. Collier. Dept. of Pharmacology, McGill Univ., Montreal, H3G 1Y6, Quebec.

Several fractions of the toxin (DTOX) isolated from the venom of Dendroaspis viridis (the green mamba) have been proposed as ligands for the study of nicotinic receptors in the nervous system (1). In the present study the sucrose gap technique was used to record potentials from the dorsal and ventral roots of the isolated hemisected frog spinal cord. Fractions of DTOX were tested as potential antagonists of synaptic and amino acid evoked responses. A fraction of DTOX resembling 4.11.3 of Banks et al. (2) induced spontaneous and stimulus coupled rhythmic convulsant discharges in both roots (cf.1). These convulsions, which appeared within 7 min of toxin exposure, were not the result of the antagonism of neutral amino acids since DTOX did not block dorsal and ventral root responses to GABA, glycine, β-alanine or to glutamate and aspartate (measured in the presence of tetrodotoxin or high calcium low magnesium Ringer). This same toxin fraction also completely antagonised the ventral root evoked dorsal root potential (cf.1) (VR-DRP). Unlike its convulsant action, this second action of DTOX occurred only after 30-50 min exposure to the toxin and could be partly reversed after 24 hours washing. The convulsant action of the toxin persisted even after 40 hours washing. This may indicate that these two actions of the toxin occur through independent mechanisms. Since DTOX was ineffective in antagonising responses to putative amino acid neurotransmitters it is possible that its selective blockade of VR-DRP resulted from an action at the cholinergic synapse of the polysynaptic VR-DRP pathway. We were unable, however, to protect the VR-DRP from the action of the toxin with the nicotinic antagonist dihydro-β-erythroidine. These experiments therefore raise some doubt as to the value of DTOX as a ligand for central nicotinic receptors especially since we were unable to reduce the binding of I^{125} DTOX to brain or spinal cord members with the cholinergic ligands, nicotine or d-tubocurarine (10^{-4}M). We also found that DTOX did not block nicotinic receptors in bullfrog sympathetic ganglia. If, however, DTOX does block VR-DRP by an action at the cholinergic synapse this may indicate a differential sensitivity of central vs. peripheral synapses to this substance.

137.7 KAINATE NEUROTOXICITY IS SUPPRESSED BY SOME ANTICONVULSANTS BUT NOT OTHERS. Terry A. Fuller and John W. Olney. Washington University School of Medicine, St. Louis, MO 63110.

Systemically administered kainic acid (KA), a potent excitotoxic analog of glutamate, induces convulsions and acute neuronal necrosis in several regions of the adult rat brain, including hippocampus, amygdala, olfactory cortex and lateral septum. Previously we reported that pretreatment with diazepam (20 mg/kg) effectively inhibits seizures and markedly suppresses the brain damage so that only mild histopathology was detected in the CA3 and CA4 regions of the hippocampus and occasionally in the lateral septum or the amygdaloid complex. Others have reported that the neurotoxicity induced by direct intra-hippocampal injection of KA is suppressed, not only by diazepam, but by other anticonvulsants, including phenobarbital (PB), and diphenylhydantoin (DPH). Here we report that phenobarbital (PB), like diazepam, suppresses both the convulsions and the brain damaging effects of systemically administered KA but large doses of DPH or valproic acid (VA) do not suppress either phenomenon.

Adult male Sprague-Dawley rats were injected subcutaneously(sc) with KA (12 mg/kg). Pretreatment 15 min to 1 hr earlier was either with an anticonvulsant sc or an equal volume/weight of H_2O sc. Brain regions of interest were examined by light microscopy at survival times of either 4 or 24 hrs. In control animals receiving only KA + H_2O (n=27) the incidence of both convulsions and brain damage was 96%. In animals pretreated with 50 mg/kg PB (n=16) there were no convulsions and brain damage, restricted to very mild changes in the CA3-CA4 hippocampal region and occasionally lateral septum or amygdaloid complex was detected in 62.5%. DPH at 50 mg/kg (n=13) or 100 mg/kg (n=6) and VA at 27 mg/kg (n=6), 100 mg/kg (n=7) or 400 mg/kg (n=7) exerted no suppressant effect on either convulsions or brain damage; 100% of animals in all groups sustained both convulsions and brain damage. In a subgroup of rats (n=3) we administered DPH (50 mg/kg) chronically for 8 days prior to KA treatment and this chronic pretreatment regimen also was ineffective in suppressing either convulsions or brain damage.

Our finding that the potent convulsive property of KA is inhibited by diazepam and phenobarbital but not by diphenylhydantoin or valproic acid and that the agents which suppress convulsions also suppress KA-induced brain damage, suggest that KA-induced convulsions and brain damage are closely associated phenomena. These findings lend additional credence to the usefulness of KA as a tool to study epilepsy and the condition known as "epileptic brain damage" that has been reported in human epilepsy. 137.8 NEUROPATHOLOGIC AND BLOOD BRAIN BARRIER CHANGES IN KAINIC ACID INDUCED LIMBIC SEIZURES. D.K. Zucker, E.W. Lothman and G.F. Wooten; Depts. of Neurology & Psychiatry; Wash. Univ. Sch. Med., St. Louis, MO 63110.

Electrical and 2-deoxyglucose autoradiographic studies have shown that intravenous kainic acid (KA) is a reliable means of selectively provoking seizures in limbic centers. The severity of the seizure activity varies with the dose of KA, and can be graded with behavioral markers (Neurology:30, 386, 1980). Injections of greater than 7 mg/kg of KA cause neuropathologic changes in the same regions as the electrical seizures (Soc. Neurosci. Abstr. 4:712, 1978).

We have done a dose/time study of the neuropathologic changes associated with intravenously administered KA in adult rats. These changes were correlated with the animal's behavior and changes in the blood brain barrier permeability, studied with α-aminoisobutryic acid (αAIBA). Animals received 1, 4, 7 or 12 mg/kg of KA and were observed over intervals from 1/2 hour to 7 days. At the end of the given interval they received 10µCi of ^{14}C-α-AIBA (New England Nuclear, 51.6 mCi/mmol) intravenously. Ten minutes later the animals were perfused and decapitated. The brains were studied with ^{14}C-autoradiography, and Nissl and H. & E. Stains.

Behavioral response to KA was variable at a given dose level. Necrosis of neurons and neuropil was seen in entorhinal cortex, hippocampal formation, amygdaloid nuclei, and thalamic nuclei in the animals who had major motor seizures. Only scattered neuronal changes were seen in animals with seizures of lesser intensity. Increased blood brain barrier permeability to α-AIBA was seen acutely only in those animals who had major motor seizures. These changes were seen as early as 1 hour after injection. The distribution of the increased permeability seen acutely conformed to the pattern of necrosis recognized after longer survival in other animals with major motor seizures. Minor seizures did not lead to changes in blood brain barrier permeability.

These results show that, with a given dose of KA, behavior is a reliable prediction of ultimate neuropathologic findings. It is suggested that, in the KA model, the breakdown of blood brain barrier is an epiphenomenon to tissue necrosis.

137.9 FACILITATION OF PENICILLIN-INDUCED INTERICTAL SPIKES BY ATROPINE
Jeffrey H. Goodman*and R. M. Lebovitz. Dept. of Physiol., Univ. Texas Health Sci. Center at Dallas, Dallas, Texas 75235

Recent experiments have shown that atropine increases the interictal spike rate in the amygdala of kindled rats. This effect of atropine is believed to be mediated through a cholinergic mechanism (Fitz and McNamara, Brain Res.,178:117, 1979). It is unclear to what degree this result can be generalized to other forms of experimental epilepsy. The purpose of this study was to determine the effect of atropine on another seizure model,viz., the interictal spikes of epileptic foci created by the topical application of penicillin.

The left hippocampus of Long-Evans rats was exposed under nembutal anesthesia. Sodium penicillin was applied to the CA1 region of the dorsal hippocampus and this area was then covered with warmed artificial cerebrospinal fluid (CSF). Once a baseline interictal spike rate was established, the hippocampus was superfused with atropine sulfate dissolved in artificial CSF. The concentrations of atropine tested ranged from 10^{-5}M to 10^{-2}M. It was observed that atropine in doses ranging from 3×10^{-4}M to 10^{-2}M significantly increased the interictal spike rate. The latency of this facilitatory effect was dose dependent and the increased rate continued after the atropine was removed. Repeated washing with atropine-free artificial CSF did not cause a reversal of any facilitatory effect. Furthermore, subsequent superfusion with acetylcholine dissolved in CSF (10^{-2}M) did not reverse this effect.

When atropine was administered IV no facilitation of the interictal discharges was observed. In only one out of four animals in which atropine was injected IP (50mg/kg) did an acceleration of the interictal spike rate occur. This effect was not long-lasting.

It is well established that atropine has convulsive properties of its own (Daniels and Spehlmann, Electroenceph. Clin., Neurophysiol., 34:83,1973). Whether this apparent pacing of the penicillin focus is due to the epileptogenic action of atropine or through a direct cholinergic mechanism remains to be determined.

137.10 EFFECTS OF BEMEGRIDE ON THE SENSORY RESPONSES OF NEURONS IN THE RETICULAR FORMATION AND HIPPOCAMPUS.
C.L. Faingold, W.E. Hoffmann* and J.D. Stittsworth Jr. Department of Pharmacology, Southern Illinois University School of Medicine, Springfield, IL 62708.

Studies from this laboratory have shown that the sensory responses of brainstem reticular formation (RF) neurons are greatly enhanced following administration of subconvulsant doses of pentylenetetrazol or strychnine (Faingold, Neuropharmacology, 19:53-62, 1980. Soc. Neurosci. Abs. 4:142, 1978). This investigation was undertaken to examine further the generality of this action. The effects of bemegride (1.9 mg/kg/min i.v.) were evaluated on the neuronal responses of locally anesthetized, paralyzed and respired cats using poststimulus time histogram (PSTH) analysis. Many RF neurons which were not clearly responsive to visual, auditory or somatosensory stimuli before drug became responsive to one or more modalities of stimulus after subconvulsant doses of bemegride. Initially responsive RF neurons became more responsive after bemegride as shown by increases in amplitude and/or duration of the peaks in the PSTHs. This occurred in both mesencephalic and bulbar RF regions. Most hippocampal neurons examined thus far have shown relatively minor changes in response to sensory stimuli with bemegride, although a small number of hippocampal neurons showed some response enhancement at high doses. Some increase in stimulus-induced inhibition of firing of hippocampal neurons and modest decreases in PSTH peak latency were also observed. Simultaneously held RF neurons showed extensive response enhancement. These data suggest that hippocampal neurons are considerably less involved than RF neurons in the initiation of seizure generalization by sensory stimuli under these conditions. This finding and the observation of minimal convulsant-induced changes in lateral geniculate neuronal responses (Faingold and Stittsworth, Electroenceph. clin. Neurophysiol. 1980 in press) suggest a relative selectivity of the effect for the RF.

Bemegride-induced enhancement of the responses of RF neurons is quite similar to that seen with strychnine, pentylenetetrazol, and in preliminary studies with physostigmine. This neuronal mechanism subserves the enhancement of sensory evoked field potentials induced by these agents. These findings suggest that the 14 other convulsant drugs which also enhance sensory evoked field potentials (Faingold, Prog. Neuro-Psychopharmacology, 2:401-422, 1978) may also produce such neuronal response enhancement. These data further support the concept that the enhancement of RF neuronal responses to sensory stimuli is a general action of convulsant drugs which can contribute to the initiation of sensory-induced seizures.

137.11 KINDLING AND CYCLIC NUCLEOTIDES: EFFECTS OF THEOPHYLLINE, DIBUTYRYL-cAMP, AND 8-BROMO-cGMP.
Donald P. Cain and Carol A. Routhier. Department of Psychology, University of Western Ontario, London, Ontario, Canada N6A 5C2.

The cyclic nucleotides have been implicated recently in cellular processes that could be involved in the neuroplastic changes thought to underlie the kindling effect. Thus, the effects of manipulations of cyclic nucleotide levels on the development of kindled seizures was assessed in male hooded rats. The animals carried bilateral amygdala electrodes and were electrically stimulated with low intensity square wave currents at 60 Hz following i.p. or intracerebral administration of one of the following drugs: theophylline, dibutyryl-cAMP, or 8-bromo-cGMP. Control groups received either the vehicle or artificial CSF. This procedure was repeated at 24 or 48 hour intervals until a generalized seizure developed.

The theophylline group developed seizures more rapidly and displayed longer afterdischarges relative to controls. The dibutyryl-cAMP and 8-bromo-cGMP groups also developed seizures significantly more rapidly than their respective control groups, but did not display longer afterdischarges. Various control procedures showed that the accelerated kindling was not due to a pharmacological kindling effect, and that the resulting kindling was permanent.

The results suggest that the cyclic nucleotides may play a role in the neuroplastic changes thought to underlie kindling.

Supported by a grant to D.P.C. from the Natural Sciences and Engineering Research Council of Canada.

137.12 AUDITORY AND VESTIBULAR PATHOLOGY OF SEIZURE-PRONE CHICKS.
Mary M. Beck and Wayne J. Kuenzel *. Dept. of Poultry Science, University of Maryland, College Park, MD 20742.

The mutant sex-linked lethal recessive px (paroxysmal) gene, expressed in White Leghorn chicks (Gallus domesticus) causes seizures beginning on approximately day eight posthatching. Seizures are spontaneous and induceable by auditory but not by photic stimulation. Prior to seizure onset px chicks are indistinguishable from non-px siblings. With seizure onset is a decrease in food intake which causes deterioration and death by 4-8 weeks of age. In a preliminary histological study conducted on 22-day-old chicks, brains were perfused and treated according to an improved cupric-silver staining technique. Nuclei and fiber tracts of px auditory and vestibular systems were extensively degenerated; control brains showed essentially no degeneration. A second experiment was performed on 5, 10, 15, and 20-day-old chicks to determine whether and to what extent degeneration occurs prior to seizure onset. Nuclei of px cerebellum appeared to be the first affected (5 days of age). Extent of degeneration progressed steadily over time through 20 days of age, by which time all components of the 2 systems were maximally affected. In a third experiment, one group of px and control chicks was raised in a quiet to low-level noise environment; a second group was subjected to systematic noise stress from day of hatching. Noise did not affect onset or extent of degeneration, nor did it affect onset of seizures. A sequel study indicated that GABA levels are implicated in abnormal auditory function of px chicks.

137.13 REDUCED SUSCEPTIBILITY TO DRUG-INDUCED SEIZURES AFTER SOMATOSENSORY DEAFFERENTATION IN THE CAT. S.S. Bowersox* & M.B. Sterman. Brain Research Institute, University of California, Los Angeles & V.A. Medical Center, Sepulveda, CA 91343

We have evaluated the effects of somatosensory deafferentation on monomethylhydrazine (MMH)-induced seizures in adult cats. Enforced restraint was shown previously to decrease susceptibility to MMH seizures in cats (Bowersox, Siegel & Sterman, Exp. Neurol 61:154, 1978) and infrahuman primates (Sterman & Kovalesky, Exp. Neurol., 65:78, 1979). It was hypothesized that reduced somatosensory inflow contributed to these effects.

To test this hypothesis, eleven adult cats equipped with indwelling cortical and subcortical electrodes, received bilateral lesions of the dorsal columns at either high cervical (C_1-C_3) or low cervical (C_5-T_1) levels. After a three week postsurgical period, each animal was administered an intraperitoneal injection of monomethylhydrazine at the established convulsive dosage of 10 mg/kg. Behavior was monitored continuously, and seizure latency was measured from the time of drug injection to onset of tonic-clonic convulsions. Latency data were compared with those obtained from a similar group of non-lesioned animals. Results are given below:

	Range of Latencies (min)	Group Mean (min)
Intact (N=18)	41-80	59.5±4.05
Low Cervical (N=5)	60-93	81.4±6.29
High Cervical (N=6)	70-222	134.0±22.04

Data showed a progressive increase in seizure latencies with more encephalad transection of the dorsal columns. Multiple t-test comparisons of individual group data revealed significant differences between intact group latencies and those of both lesion groups (Intact vs. Low: $t=-2.10$; $p<0.05$, Intact vs. High: $t=-4.26$, $p<0.05$). There was no significant correlation, however, between extent of damage to the dorsal columns at each level and latency to seizure (Spearman Rank Correlation Coefficient; High: $r_s=-.77$, $p>0.25$, Low: $r_s=.58$, $p>0.25$).

Two possibilities might account for these findings. First, somatosensory deafferentation was associated with significant enhancement of specific electrocortical patterns known to correlate with the inhibition of motor functions (e.g., sensorimotor rhythms). Resistance to seizures observed here might relate to the facilitation of these patterns. Alternatively, protection against seizures might be provided by the reduction of cutaneous and proprioceptive input which normally constitutes a source of convulsion inducing excitatory feedback.

137.14 ON THE LOCALIZATION OF STRUCTURES RESPONSIBLE FOR SEIZURE ANTAGONIZING EFFECT OF A MIDBRAIN TEGMENTAL LESION. R. A. Browning and F. J. Turner*. Southern Illinois University, School of Medicine, Carbondale, IL 62901.

We have previously reported that bilaterally-placed mechanical lesions of the midbrain tegmentum inhibit the hindlimb extensor (HLE) component of both maximal electroshock (MES)-and maximal pentylenetetrazol-induced seizures (Neurosci. Abst. 4, 139, 1978). These lesions were produced by lowering a stainless steel rod (1.2 mm diameter) 9 mm below the surface of the brain, 6 mm posterior to the bregma and 1 mm lateral to the midline. Histological evaluation of the lesion revealed damage to the superior colliculus and its commissure, periaquaductal gray (PAG), the dorsal and ventral noradrenergic (NA) pathways, superior cerebellar peduncles, lateral aspects of the tectospinal tract, and the reticular formation. In an attempt to determine which of the damaged structures is responsible for the seizure antagonizing effect of the lesion, we varied the location of the lesion within the midbrain in separate groups of rats, and examined the response to MES 2 weeks later. Histological evaluation of each lesion was also carried out. The present findings show that inhibition of the HLE component of the MES seizure is observed only if the lesion is bilateral, and only if the damage extends ventrally beyond the superior cerebellar peduncles (7-7.5 mm below surface of brain). Movement of the lesion 1 mm in the lateral direction, while retaining the same AP and ventral coordinates, spares the PAG and the NA fibers, but still produces seizure antagonism. Furthermore, movement of the lesion 2 mm in the anterior direction interrupts the ascending NA fibers, and the PAG, without producing seizure antagonism. On the basis of these findings we can suggest that the following structures are not involved in the seizure antagonizing effect of our original lesion: superior colliculus and its commissure, PAG, NA pathways, and the tectospinal tract. This leaves the superior cerebellar peduncles and the reticular formation as probable candidates. Studies are currently underway to determine whether either or both of these are involved.

137.15 AUTORADIOGRAPHIC IDENTIFICATION OF THE CORTICAL LAMINAE INVOLVED IN THE GENERATION OF A DISCRETE INTRACORTICAL EPILEPTIC FOCUS. A.B. Chatt and J.S. Ebersole. Dept. of Neurology, Yale Univ. School of Medicine, New Haven, Ct. 06510 and Neurology Service, VA Medical Center, West Haven, Ct. 06516.

Previously, we have described an in vivo model of epileptogenesis within the cat striate cortex induced by picoliter volumes of pressure-injected sodium penicillin (NaPen). These methods produced an epileptic focus that was: discrete, progressive, temporary and repeatable. Since response activity was being driven by natural visual stimuli, this model allowed neurons or neuron populations of interest to be characterized before, during, and after the development of an epileptic focus. Our objective, here, was A) to determine whether the methods used to induce this highly localized electrocorticographic epileptic focus could also be employed in determining whether a laminar sensitivity to NaPen exists within the striate cortex and, if so, B) to identify the cortical depths and layers (using 14-C) which are most sensitive to NaPen.

In the first series of experiments, ejections were made at each of several cortical depths (200,600,1100,1600,2000μ)within an animal and responses were recorded at the level of ejection. Using these methods, we have been able to isolate a band of intracortical tissue that is most sensitive to the epileptogenic effects of penicillin. This band is confined to cortical depths located roughly between 700-1600μ during relatively large volume ejections and to approximately 1000-1300μ when smaller more discrete volumes are employed. Penicillin ejections made either superficial to or deeper than these values were not effective in producing an epileptic focus. Since the site of maximal penicillin sensitivity always occurs where the response to visual driving is greatest, we feel that cortical layer IV may be the site of penicillin focus generation. It is in this layer that the sensory-specific subcortical afferents terminate most densely.

In our autoradiographic studies, microejections were made at these same cortical depths but were limited to 1 depth/animal. Following ejection and 3 minutes of recording time, the brain area of interest was excised immediately and prepared for autoradiographic analysis. The results, thus far obtained, support the preceeding data in demonstrating the largest concentration of [14-C] NaPen in cortical layers IV and V whenever epileptogenic abnormalities were seen. Discrete ejections made in other laminae (I-III,VI), which were unsuccessful in producing epileptogenesis, were largely confined to those layers with only an occasional sparse labeling of IV and V.

Future work will correlate the spatial extent of [14-C] NaPen with the level of epileptic abnormality induced.

137.16 MULTIPLE VS SINGLE HYPERTHERMIA-INDUCED CONVULSIONS IN THE DEVELOPING RAT. Corinne Manetto*, James A. McCaughran, Jr.*, and Nisson Schechter. (SPON: I. Fand). Departments of Psychology, Psychiatry and the Long Island Research Institute, SUNY at Stony Brook, Stony Brook, New York 11794.

We have proposed a model for human infantile febrile convulsions using hyperthermia-induced convulsions (HICs) in the rat pup. In this study, we compared the effects of a single HIC (SHIC) to multiple HICs (MHICs) to determine if additional changes in the parameters of the convulsion or later susceptibility to pentylenetetrazol (PTZ) will occur.

At 5, 10, 15, or 20 days of age rat pups were subjected to a SHIC, hyperthermia alone, or handled. In another group, pups were subjected to 7-10 HICs starting from 5 days of age and ending at 20 days of age. No more than 1 HIC was induced per day in the MHIC group of pups.

The latency to the HIC increased with age in both the SHIC and MHIC groups. However, at 15 and 20 days in the MHIC group the latency was significantly shorter than that of 15 and 20 day pups in the SHIC group (means = 8.8 min and 8.4 min vs 10.9 min and 11.5 min, respectively). The duration of the convulsion between the SHIC and MHic groups did not differ significantly at any age point. Within each group the duration of the convulsion in the 15 and 20 day pups was significantly longer than that of the 5 and 10 day pups ($ps < .01$). Furthermore, within each group the rectal temperature associated with the start of the HIC was generally higher in the older pups.

Rats subjected to a SHIC were more susceptible to the convulsant effects of PTZ as adults than rats that had been subjected to hyperthermia alone or handled (means = 9.5 min vs 11.7 and 12.1 min, respectively). Infants that had been subjected to MHICs were found to not only be more susceptible to PTZ as adults than rats from their control groups (means = 6.9 min vs 11.4 min, respectively) but were also more susceptible to PTZ than rats that had undergone a SHIC (means = 6.9 min vs 9.5 min, respectively).

Overall, the parameters of the MHIC are similar to those of the SHIC with the following exceptions. Although the rectal temperature did not differ between the MHIC and SHIC groups, the latency to the HIC in the 15 and 20 day MHIC pups was shorter than that of similar rats in the SHIC group. This is discussed in terms of a 'kindling-like' effect or a breakdown of the thermoregulatory ability of the rat. Furthermore, MHICs have a greater effect on the later susceptibility to PTZ than a SHIC. This result is discussed in terms of its similarity to human infantile febrile convulsions.

137.17 HYPERTHERMIA-INDUCED CONVULSIONS IN THE RAT PUP: AN ANIMAL MODEL OF HUMAN INFANTILE FEBRILE CONVULSIONS. James A. McCaughran, Jr.* and Nisson Schechter. (SPON. R.E. Whalen). Departments of Psychology, Psychiatry and the Long Island Research Institute, SUNY at Stony Brook, New York 11794.

Infantile febrile convulsions are a serious pediatric neurological problem. Although the incidence of these convulsions is second only to head injuries in the United States, little experimental work has been done towards elucidating the underlying causes of this problem. To a large extent this can be attributed to the lack of an experimental animal model of the disorder. In the present report data is presented that supports the use of hyperthermia-induced convulsions (HICs) in the developing rat as a useful model of human infantile febrile convulsions.

At 5, 10, or 15 days of age rat pups were subjected to a single HIC, hyperthermia alone, or handled. The latency to the convulsion in the HIC group was significantly influenced by age with the youngest rats displaying the shortest latencies ($ps < .01$). The duration of the convulsion was also affected by age. Pups of 15 days of age had longer convulsions than either the 10 day or 5 day old rats ($ps < .01$). Although the older pups generally had higher rectal temperatures associated with the start of the convulsion, the effect of age on the rectal temperature was not significant.

Male and female rats that had been subjected to a HIC were more susceptible to the convulsant effects of pentylenetetrazol (PTZ) as adults ($ps < .01$). When the data were analyzed according to the age at which the HIC was elicited, only the 15 day old males differed from their appropriate control groups. These males were more susceptible to PTZ ($ps < .01$). The duration of the PTZ-induced convulsion was not different between any of the groups ($ps > .05$).

Induced hyperthermia using infrared radiation is a reliable and quantifiable technique for eliciting convulsions in infant rats. The parameters of the convulsion are age-related and are similar to human infantile febrile convulsions. The clinical data indicate that younger children are more susceptible to the convulsant effects of a febrile illness than the older children. We have found that younger rats are more susceptible to the convulsant effects of hyperthermia than older rats. Clinical reports also indicate that epilepsy is a major neurological sequela to severe febrile attacks. In the present study, a single hyperthermia-induced convulsion in infancy increased the susceptibility of adult rats to the convulsant effects of PTZ. These results indicate that a long-term change in the physiology of the central nervous system resulted from this early convulsion.

137.18 SELF-INDUCED REDUCTION OF INTER-ICTAL HIGH VOLTAGE SHARP WAVES BY EPILEPTIC PATIENTS. W.J. Jackson, A.V. Nelson*, D.W. King* and J.L. Veal*. Depts. of Physiology, Biomedical Engineering and Neurology, Medical College of Georgia, Augusta, GA 30912

Several epileptic patients having prominent high-voltage sharp waves in their inter-ictal EEG's were given cues (4 hrs. per day for 7 days) upon the occurrence of the spikes. The spike detection circuitry was an expansion of techniques described by Whisler, et al. (Proc. Epilepsy International Symposium, Vancouver, 1978). During the training, the patients were instructed to accomplish two objectives: (1) To attempt recognition of mental events associated with the high-voltage sharp waves and (2) To attempt to reduce the frequency of the sharp waves by self-inducement of the mental state during which (in the patients' evaluation) the least number of sharp waves occurred.

Findings were concurrent with Stevens, Milstein, & Dobbs (EEG & Clin. Neurophysiol., 23: 57-66, 1967) in that none of the patients could recognize any mental event concurrent with the sharp waves. On this basis Stevens, et al. had hypothesized that operant conditioning would not be effective in reducing such sharp waves, but did not actually make the attempt. To the contrary, however, most of our patients demonstrated that they could reduce the numbers of sharp waves even without recognizing them. All successful patients reported that their strategy was to remain alert and to avoid drowsiness. Subsequent analysis of the patients' EEG's verified that there were more spikes present against a background EEG of 1-8 Hz than were present against a background of 8-16 Hz or 16-24 Hz.

137.19 EATON-LAMBERT SYNDROME: DECREASED QUANTUM CONTENT OF NEUROMUSCULAR TRANSMITTER RELEASE PRODUCED BY SERUM FACTORS. Yong I. Kim,* Donald B. Sanders and T.R. Johns, (SPON: G.R. Hanna) Department of Neurology, University of Virginia School of Medicine and the University of Virginia Jerry Lewis Neuromuscular Center, Charlottesville, Virginia 22908.

The Eaton-Lambert syndrome (ELS) is a defect of neuromuscular transmission, frequently associated with carcinoma of the lung, characterized by a reduced number of acetylcholine (ACh) quanta released per nerve impulse. We wished to determine whether serum factors from a patient with this condition could produce in vitro a neuromuscular blockade resembling that found in that patient. Our findings show that ELS serum, when applied to rat skeletal muscle in vitro, produces a pronounced neuromuscular block as a result of decreased quantum content of the evoked transmitter release.

Using intracellular microelectrode recording techniques, direct quantal analysis was performed on rat flexor digitorum longus muscles bathed in a physiologic buffer solution containing a high magnesium concentration (10mM Mg^{++}). Control measurements were made of miniature end-plate potentials (MEPPs) and indirectly stimulated end-plate potentials (EPPs) from 10-15 end-plates. Similar measurements were repeated in the same muscle as it was perfused with the high-magnesium control solution containing either ELS or normal human serum.

Perfusing the muscle with normal serum produced no significant effect on the amplitudes of MEPPs and EPPs, and thus had no effect on the calculated ACh quantal content. ELS serum, however, applied under the same conditions, produced a marked reduction in the EPP amplitude, with no change in MEPP amplitude. Thus there was a reduction in the number of ACh quanta released from the motor nerve terminals. This prejunctional blockade of neuromuscular transmission was only partially reversed by prolonged washing with the control solution. Although normal and ELS sera caused a slight decrease in the frequency of MEPPs, neither had an effect on the resting membrane potential of the end-plates.

This study demonstrates that serum from a patient with ELS contains a factor that diminishes the release of ACh quanta from motor nerve terminals and can produce the physiologic abnormality characteristic of the syndrome. Future investigations are aimed at confirming this observation within a larger group of patients with the Eaton-Lambert syndrome.

137.20 NEUROMUSCULAR BLOCKING PROPERTIES OF SUXAMETHONIUM AND DECAMETHONIUM IN NORMAL AND MYASTHENIC RAT MUSCLE. Bruce R. Johnson*, Yong I. Kim*, and Donald B. Sanders. Department of Neurology, University of Virginia School of Medicine and the University of Virginia Jerry Lewis Neuromuscular Center, Charlottesville, Virginia 22908.

The neuromuscular blocking properties of suxamethonium (Sux) and decamethonium (Deca) were compared in forelimb flexor digitorum longus muscle from normal rats, and from those with experimental autoimmune myasthenia gravis (EAMG). EAMG was induced by immunization with an initial subcutaneous injection of 50 µg Torpedo acetylcholine receptor protein in Freund's complete adjuvant and a booster injection of 25 µg given at least two weeks before experimentation. Conventional intracellular recording techniques were used to measure endplate depolarization and miniature endplate potential (MEPP) amplitude.

In normal muscle at 1, 5, 10, and 25 µM concentrations we found that Sux produces a greater depolarization than Deca. Depolarization with Sux was typically maintained until a saline wash. Depolarization produced by Deca tends to reverse after reaching its peak despite continued application of the drug. With both drugs MEPP amplitude reduction is maintained until a saline wash and begins and ends more quickly than does the depolarization. EAMG endplates respond in a similar qualitative manner to each drug. However, the induced depolarization is significantly less in EAMG than in normal muscle; it occurs and recovers at a slower rate than in normal muscle; and it appears to be proportional to the MEPP amplitude measured before drug application. When MEPP amplitude was reduced in normal muscle by treatment with 0.03 µg/ml d-tubocurarine, the depolarization induced by Sux and Deca was similar to that in EAMG muscle. In both EAMG and normal muscle neostigmine (1 µM) antagonized the MEPP amplitude reduction produced by Sux and Deca.

In human myasthenic muscle, the blocking effects of Sux and Deca are less than in normal muscle. Neostigmine potentiates the depolarizing effects of Deca in normal muscle, but reverses the neuromuscular block produced by Deca in myasthenic muscle. We have shown that curarized normal rat muscle and EAMG muscle also have diminished sensitivity to Sux and Deca. However, we found no differences in neostigmine and depolarizing drug interaction between normal and EAMG rat muscle. Thus, while EAMG may mimic myasthenia gravis in some respects, differences such as those observed in this study should be considered when extrapolating from the animal model to human myasthenia. (Supported by a Center grant from the Muscular Dystrophy Association.)

137.21 THE EFFECTS OF AZATHIOPRINE AND CYCLOPHOSPHAMIDE ADMINISTRATION ON THE PATHOGENESIS OF EXPERIMENTAL AUTOIMMUNE MYASTHENIA GRAVIS. I. J. Griffith and N. L. Norcross*. Dept. of Microbiology, New York State College of Veterinary Medicine, Cornell University, Ithaca, New York 14853.

Myasthenia gravis (MG) is an autoimmune disease affecting humans. As clearly shown in the animal model for MG, antibodies capable of binding to the nicotinic acetylcholine receptor (AChR) are critical to the pathogenesis of the disease. Due to the disease's immune nature, many current therapies for MG involve the use of immunosuppressive agents. It is possible to use the animal model, designated as experimental autoimmune myasthenia gravis (EAMG), to evaluate the mechanisms of immunosuppression and effectiveness of these therapies in controlling disease pathogenesis. We report here the effect of two immunosuppressive agents, azathioprine (Imuran®) and cyclophosphamide (Endoxan®), on the pathogenesis of EAMG in the rat.

As previously described (Soc. Neurosci. Abstr. 4:397, 1978), rats inoculated with AChR purified from Torpedo characteristically develop two distinct periods of decreased activity corresponding to the recognized acute and chronic phases of EAMG. This activity assay was used as a sensitive and objective method with which to evaluate the effects of drug therapy on the development of the clinical weakness during disease pathogenesis. Activity was also correlated with levels of antibodies capable of binding to both Torpedo and rat AChR, AChR content of the limb muscles, and percentage of endogenous AChR complexed with antibody.

Azathioprine (AZA), an antimetabolite, has been used effectively in the treatment of many patients with MG. However, the drug had no effect on the pathogenesis of EAMG in rats when administered biweekly in intraperitoneal injections of 160 mg/kg beginning 9 days after inoculation with Torpedo AChR. This is in contrast with the finding that AZA can block the induction of EAMG when administered shortly after inoculation with AChR (J. Immunol. 117:225, 1976).

The intraperitoneal administration of cyclophosphamide (CY) at a dose of 100 mg/kg (60% LD_{50}) 14 and 28 days after inoculation with AChR had a pronounced effect on disease expression. This was reflected in activity, AChR content of limb muscles, and level of endogenous AChR complexed with antibody. CY administration did not affect the levels of antibodies capable of binding to Torpedo AChR in vitro.

The implications these studies have for understanding the pathogenesis of MG will be discussed.

137.22 MOLECULAR FORMS OF ACETYLCHOLINESTERASE IN DYSTROPHIC MOUSE SKELETAL MUSCLE. K.A. Skau & W.S. Brimijoin, Mayo Foundation, Rochester, MN. 55901

It has been suggested that murine muscular dystrophy may be related to a "functional denervation" of muscle fibers leading to an abnormality of locomotion as well as to biochemical changes. Denervation of normal muscle results in a variety of biochemical changes including profound alterations in the distribution of the molecular forms of the enzyme acetylcholinesterase (AChE). We have examined the forms of AChE in both intact and surgically denervated dystrophic mouse muscle as compared to muscle from normal littermates to test the possibility that dystrophic muscle resembles denervated muscle. The hemidiaphragms and extensor digitorum longus (EDL) muscles from REJ/129 (dys/dys) mice and their normal (+/?) littermates were homogenized in tris buffered medium containing 1% Triton X-100 and 1M NaCl to solubilize AChE. Low speed supernatants from these homogenates were centrifuged on 5-20% linear sucrose density gradients as described by Hall (J. Neurobiol 4:343, 1973) to resolve the AChE molecular forms. In hemidiaphragms we found no difference in total AChE activity between dystrophic and normal littermates; however, the distribution of the molecular forms of AChE differed markedly. In the normal littermate muscles three peaks of AChE activity were evident sedimenting at 4S, 10S and 16S. In dystrophic muscle only the 4S and 16S forms showed clear-cut peaks; small but consistent peaks indicated that presence of minor amounts of 13.5S AChE, not observed in controls, and 10S enzyme. Although 16S activity was slightly lower in dystrophic muscle (118 ± 7.0 units) vs control (148 ± 16 units), the pattern did not resemble changes induced by surgical denervation of muscle. AChE activity in dystrophic EDL was significantly lower than control EDL (168 ± 22 vs 394 ± 29 units) and, as with hemidiaphragms, exhibited major peaks at 4S and 16S. The percentage of 16S enzyme in dystrophic EDL was slightly less than the percentage in control muscle; however, in one week surgically denervated muscles the reduction of 16S AChE was similar in both types of muscle (dys = 32% vs control = 34%). Since 16S AChE is generally regarded as an endplate marker and declines upon surgical denervation, the data suggest that dystrophic muscle is not exhibiting denervation-like effects. The unusual distribution pattern of AChE further indicates a biochemical abnormality of enzyme synthesis that may be related to neuronal or muscular aberrations or both. (Supported by NIH grants NS11855 and NS14304. WSB is a recipient of Research Career Development Award NS 00119 from NIH.)

137.23 STUDY OF A FATAL AUTOIMMUNE DISEASE. L.-P. Chao, K.-S.K. Kan and C. Angelini. Dept. Neurol. Sch. Med. UCLA, Los Angeles, CA 90024 and Clin. Neurol. Padova Univ., Padova, Italy.

When a fraction of choline acetyltransferase (ChAc) was injected weekly into guinea pigs with complete Freund's adjuvant, the animals showed progressive weakness, weight loss, reduction of respiratory rates, signs of cyanosis and then died about 14 days from the initial injection. These results suggest that the death is from respiratory failure. The incidence of the disease is 100% and reproducible. Some animals were sacrificed 3-6 days after the second injection. The brain, spinal cord, sciatic nerve, liver, intestines, lung, heart and various muscles, the diaphragm, soleus, biceps, gastrocnemius and iliopsoas, were removed for histological and histochemical studies. Guinea pigs injected with saline substituted for ChAc were used for controls. These animals appeared normal throughout the experimental period. They were sacrificed and tissues were removed for histological and histochemical examinations. Histological studies involved: a) Hematoxylin and eosin staining for all sections; b) Silver and myelin stains were performed on sections of nervous tissue. Histochemical staining of muscle sections included succinic dehydrogenase; adenosine triphosphatase at pH 9.4, 4.6 and 4.3; NADH-tetrazolium reductase; alkaline phosphatase and acid phosphatase. The histological and histochemical results showed various degrees of muscle atrophy and lymphocyte infiltration in certain areas of the muscles. However, the infiltration was found to be concentrated at the neuromuscular junctions and not randomly distributed. In addition, we recently localized ChAc in the presynaptic nerve terminals and axons of the neuromuscular junctions (Muscle & Nerve in press). Therefore, the pathogenesis of this autoimmune disease is most likely from denervation and may be considered a presynaptic neuropathy. Some lymphocyte infiltration was also observed in the lung, liver and intestines. No significant abnormality was found in the central nervous system of the injected animals. The control guinea pigs revealed no pathological changes.

137.24 NON-HEME INTRACELLULAR IRON IN MULTIPLE SCLEROSIS BRAINS. Michael W. Migdal* and William Craelius, Dept. of Biology, Lafayette College, Easton, Pa., 18042.

Elemental analyses of multiple sclerosis (M.S.) brains indicated that unaffected areas of M.S. white matter had elevated concentrations of calcium, iron, manganese and zinc compared with controls. M.S. plaques were particularly concentrated with these elements. Histochemical confirmation of non-heme iron contained within cells of M.S. brains is reported in this study.

Cerebral cortex samples of 5 victims positively diagnosed with M.S. and of 6 controls of similar ages, were fixed in 10% Formalin at autopsy and processed identically. White and grey matter samples were dissected out with glass knives, embedded in paraffin, and sectioned for light microscopy. Serial sections were stained with either luxol fast blue to show myelin or with Perl's acid ferrocyanide to demonstrate reactive ferric iron bound to hemosiderin and ferritin.

Sections from 6 control brains, processed simultaneously with the M.S. brains, showed no positive ferric iron (Prussian blue) reactions. In each of 5 M.S. brains examined, positive Prussian blue reactions were observed in certain myelinated areas. Numerous hemosiderin-loaded cells were observed in some areas of the cortex, which appeared to be large macrophages. Staining was heaviest along the cell perimeter. Myelin staining of adjacent sections indicated that the iron containing macrophages were within circumscribed areas of white matter of variable myelin density. Hemosiderin, apparently in association with myelin, was also observed following along axonal tracts. Perivascular lymphocytes were also found to contain hemosiderin.

Further confirmation of the iron deposits was obtained using Mallory's hematoxylin stain for non-heme iron. Serial sections of tissue which stained positively with Prussian blue were also positively stained with Mallory's. Preliminary ultrastructural observations on unstained sections of M.S. brains demonstrated electron dense particles along the perimeter of cells similar in appearance to the iron loaded macrophages seen histochemically.

The iron-loaded macrophages are similar in morphology to spleen macrophages described previously. The iron deposits observed in association with axons and lymphocytes are novel and unexplained.

137.25 GLUTAMATE TOXICITY IN HUNTINGTON'S DISEASE FIBROBLASTS. P.N. Gray and P.C. May*. Dept. of Biochem. and Molec. Biol., Univ. Oklahoma Coll. of Med., Oklahoma City, OK 73190.

Fibroblast cultures derived from persons with Huntington's Disease (HD) show loss of cell viability, with cell degeneration, when treated with L-glutamic acid (Glu). Control fibroblast cultures, after similar treatment, do not respond in the same manner. The cell degeneration is apparently a specific response to L-Glu and occurs at concentrations of Glu in the range of normal neural levels. Huntington's disease (HD) is a progressive neurodegenerative genetic disorder. Pathologic examination of the brain reveals degeneration in the neostriatum and cerebral cortex. This degeneration is accompanied by consistent decreases in the levels of glutamate decarboxylase and γ-aminobutyric acid. Intrastriatal injections of two excitatory amino acids, glutamic acid and its analog kainic acid (KA), cause degeneration of neostriatal neurons in rats and mice which mimic the neuronal degeneration observed in HD brains at autopsy. Preliminary experiments indicating an increased Glu uptake in HD fibroblasts, and the KA and Glu induced neuronal cell degeneration in rats led us to examine the effects of these compounds on HD skin fibroblasts in cell culture. The effects of Glu, at concentrations up to 50 mM, were determined on nine HD fibroblast cell cultures. Non-HD cultures, matched for sex, approximate age, and passage were tested in parallel. All HD cell cultures showed characteristics of cell degeneration, within 16 hrs following treatment with Glu in excess of 20 mM. HD cells grown in Glu concentrations equal to or less than 10 mM decreased in viability by only 20%. Glutamate at 30 mM and 50 mM was extremely toxic to HD cultures with significant loss of viability occurring 10 to 12 hrs after treatment. Cell death and degeneration were not observed in any of the matched control cell cultures grown in 30 mM Glu. HD cells did not show cell degeneration in the presence of 30 mM D-glutamic acid, pyroglutamate, γ-aminobutyric acid, aspartic acid, cysteic acid, proline, glutamine, asparagine, ornithine or sodium chloride. Kainic acid, 30 mM, was also nontoxic to all cells tested. The present studies with HD skin fibroblasts indicate that specific toxic effects can be induced in non-neural tissues and that the effects can be blocked by Gln. The data here provide evidence pertinent to both the primary membrane defect and the cause of cell degeneration in the HD brain; namely, an excessive effect of glutamate on neurons that may have defective membrane functions.

This research was funded by a grant from the DHEW, NINCDS #NS 14642.

137.26 DISTRIBUTION OF LYMPHOCYTIC CHORIOMENINGITIS VIRUS (LCMV) ANTIGENS IN THE CEREBELLA OF NEONATAL RATS DURING THE ACUTE PHASE OF INFECTION. Robert L. Stoughton[1], Manuel del Cerro[1,2] and Andrew A. Monjan*[3]. 1) Center for Brain Research, Univ. of Rochester Med. Ctr., Rochester, NY 14642. 2) Center for Visual Science, Univ. of Rochester, Rochester, NY 14627. 3) Dept. of Epidemiology, School of Hygiene and Public Health, The Johns Hopkins Univ., Baltimore, MD 21205.

LCM virus infection of neonatal rats produces an acute, destructive immunoneuropathy of the cerebellum which has previously been studied with immunofluorescence (Monjan et al., 1973). We thought it worthwhile to re-examine the spread of the infection using the much more sensitive unlabeled antibody technique applied to 1 μ sections, and to correlate the results with optical microscopy of 1 μ sections and with electron microscopy. Rats were infected intracerebrally with LCMV at age 4-5 postnatal days (PND) and subsequently sacrificed by intracardial perfusion with a variety of aldehyde fixatives at several ages up to 21 PND. Slices of cerebellar vermis were post-fixed in OsO_4, stained with uranyl acetate, and embedded in Spurr's resin. Unlabeled antibody immunocytochemistry was performed on 1 μ sections (del Cerro et al., 1980), with adjacent sections being stained for optical microscopy. Finally, the blocks were trimmed and thin sections for electron microscopy were cut.

The antisera used were raised in rabbits against a 20% suspension of LCMV in mouse brain. To control for the staining of various brain antigens, 1 μ sections of non-infected cerebella were also prepared for immunocytochemistry; these did, indeed, reveal a diffuse staining pattern. However, when compared to the non-infected tissue, infected cerebella clearly showed a pattern of staining "superimposed" on the background diffuse staining. The most prominent staining appeared in the white matter. At 13 PND, a band of white matter nearest to the internal granular layer (IGL) stained, while by 17 PND much more of the white matter stained. Electron microscopy of these areas revealed an increased extracellular space filled with a flocculent material. A grainy distribution of labeling appeared over the IGL. The vasculature and hematogenous elements yielded variable results. Some endothelial cells were unstained, while others appeared to be faintly labeled. Occasional labeled monocytes were seen within the lumens of vessels. Slightly more frequently, foamy cells in the neural parenchyma showed label. A striking finding was the staining associated with cell-free perivascular areas, especially in the meninges.

Supported by grants MH 14577, EY 02632, and HRC 9-075.

137A.1 MODELING OF RECURRENT CYCLIC INHIBITION IN NETWORKS OF NON-SPIKING NEURONS. W. Otto Friesen and Charles E. Mitchell*. Dept. of Biology, University of Virginia, Charlottesville, VA 22901.

Experiments to identify the physiological basis of repetitive animal movements are now beginning to provide some insights into the neuronal mechanisms generating the underlying rhythms. These experiments have been especially fruitful in the invertebrates where both specific neuronal circuits as well as specific mechanisms for rhythm generation have been identified. Swimming movements in the leech, for example, were shown to result from the phasic activity of interneurons whose interactions form a network of inhibitory rings. Modeling studies have shown that phasic activity in such inhibitory rings can replicate the rhythmic activity observed in leech neurons and that the origin of phasic activity results from the mechanism of recurrent cyclic inhibition (Friesen, Poon and Stent. J. exp. Biol. 75: 45-63, 1978). In insects as well, rhythmically active interneurons occur which function to generate rhythmic movements. Unlike in the leech, however, the rhythmic activity appears to result from interactions of non-spiking interneurons (Pearson and Fourtner. J. Neurophysiol. 38: 33-52, 1975). We report here on experiments using neuromimes, designed to examine rhythm generation by the mechanism recurrent cyclic inhibition in networks of such non-spiking neurons.

The modeling was carried out with a system comprised of two types of analog circuits. One circuit type, the spike analog (SA), is designed to simulate membrane potentials near the spike initiating zone. The potential of this SA circuit is controlled by its input from the second circuit type, the integrative analog (IA), which simulates the neuronal integrative region. The IA potential is in turn, controlled by the potential of the SA. Thus activity in neuronal networks can be simulated by suitable interconnections of SA and IA circuits. Three of the SA circuits were interconnected via inhibitory IA circuits to form an inhibitory ring. In addition, a common source of non-phasic excitation was provided to each of the SA circuits. Action potentials in the SA's were eliminated by setting thresholds to the maximum values. The results show that with sufficient excitation the SA circuits exhibit phase-locked voltage oscillations similar to those observed in such networks of spiking neuromimes (Friesen and Stent. Biol. Cybernetics. 28: 27-40, 1977). However the activity in non-spiking circuits differs from that observed previously in two important respects: the cycle period of the oscillations in non-spiking circuits is much reduced and the cycle period for non-spiking networks is nearly independent of the level of extrinsic excitatory drive. (Supported by the UVA-NIH Biomedical Sciences Support Program and by NIH grant NS 14965).

137A.2 ROLE OF CA^{2+} IN CYCLIC NUCLEOTIDE ALTERATION OF ACTIVITY IN APLYSIA NEURONS. P. F. Drake and S. N. Treistman, Dept. Biology, Bryn Mawr College, Bryn Mawr, PA. 19010.

Bursting pacemaker activity of cell R15 of Aplysia is altered by synaptic and hormonal stimulation, and this alteration may be mediated by cyclic nucleotides (Treistman and Levitan, Nature, 1976; PNAS, 1976). Cyclic nucleotide agents are capable of inducing bursting activity in normally silent neurons (Treistman and Drake, Brain Research, 1979). Steady state I-V plots under voltage clamp indicate that the induction of activity in the silent metacerebral giant cell (MCC) with 8-benzylthio cAMP is associated with an increased Na^+-dependent negative slope resistance (NSR) and an increased conductance to hyperpolarizing pulses. In cell R15 the 8-benzylthio cAMP derivative enhances only the conductance to hyperpolarizing pulses.

We have investigated the possible role of Ca^{2+} in the cyclic nucleotide-induced alterations. Steady state voltage clamp data is examined under two circumstances: 1) EGTA injection and subsequent nucleotide treatment, and 2) Ca^{2+}-free perfusion followed by cyclic nucleotide perfusion. These procedures should inhibit intracellular accumulation of Ca^{2+} and transmembrane Ca^{2+} fluxes, respectively. The I-V plot of cell R15 shows that the injection of EGTA moderately increases the conductance to hyperpolarizing pulses. Upon subsequent perfusion of 8-benzylthio cAMP the slope conductance to hyperpolarizing pulses is further increased. The injection of EGTA into the MCC linearized the I-V curve. Perfusion of the cAMP derivative returns the hyperpolarized portion of the I-V curve to control values and dramatically enhances an NSR region in the depolarized portion of the I-V plot.

Perfusion of cell R15 with Ca^{2+}-free ASW has two primary effects: 1) an increased conductance to hyperpolarizing pulses, and 2) an increased magnitude of the NSR. Subsequent perfusion of the cAMP derivative caused a further enhancement of the slope conductance to hyperpolarizing pulses suggesting that the action of cAMP does not require a transmembrane Ca^{2+} current. Perfusion of the MCC with Ca^{2+}-free ASW induces bursting activity and the I-V curve exhibits a marked enhancement of the NSR. This enhanced NSR is further increased when 8-benzylthio cAMP is added to the bathing solution. In addition to an enhanced NSR in Ca^{2+}-free ASW, an increase in the slope conductance to hyperpolarizing pulses is observed; this effect also increases when the cAMP derivative is introduced. (Supported by PHS Grant #NS15195-01.)

137A.3 PARAMETER CONSTRAINTS FOR OSCILLATORY NETWORKS. D.K. Hartline, W.M. Roberts‡ and C.L. Baker Békésy Lab, U. Hawaii, Honolulu, HI.

A study was made of repetitive bursting in neural network models to help assess the origin of such behavior in real nets. Constraints on "emergent" oscillations were examined in a series of models ranging from a physiologically detailed computer simulation to a simplified but analytically solvable model still retaining the important aspects of the physiology.

A simple N-cell linear network model was generated by solving:

(1) $f_i(t)=e_i(t) + \sum_j \int_{-\infty}^{t} p_{ij}(t-t')f_j(t')dt'$

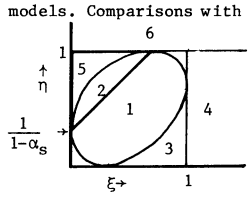
where f is the response (V_m or frequency); e=excitation; $p_{ij}(t)$= interaction time-course = $(\alpha_{ij}/\tau_{ij})H_o(t)\exp(-t/\tau_{ij})$ where H_o is the step function, α_{ij} the PSP area, and τ_{ij} its time-constant (Ratliff et al PNAS 62:733; Coleman & Renninger math Biosci 38:123). For the case $p_{ij}=p_x$ for $i\neq j$ and $p_{ii}=p_s$ for all i (simulating adaptation), oscillatory solutions to a step in e occur when:

(2) $[\xi-\eta_\ell+1/(1-\alpha_s)]^2-4\xi(1-\eta_\ell)/(1-\alpha_s)<0$

where $\xi=\tau_x/\tau_s$; $\eta_\ell=(\ell N-1)\alpha_x/(1-\alpha_s)$; $\ell=0$ or 1 (inside ellipse of figure below). For $\alpha_s<0$ ("normal" adaptation case) oscillations are damped in region 1; singular (growing indefinitely) in 2; overdamped solutions occur in 3 and 4; and non-oscillatory singular ones in 5 and 6. With step-function excitations, sustained oscillations do not occur except on the boundary between 1 and 2.

A similar picture holds in a physiologically more realistic 2-cell computer model which eliminates negative "frequencies" ($f\geq 0$). A "reverberatory" circuit ($\alpha_x>0$) and a reciprocal inhibition circuit ($\alpha_x<0$) were examined. In both cases stable sustained oscillations occur in region 2, and for $\alpha_x<0$, in 5 as well. It is of physiological interest that the range of parameters for stable oscillations is restricted, especially for $\alpha_x>0$. With a ceiling on f ($f\leq f_{max}$), the range of stable oscillation for $\alpha_x>0$ includes region 5, although firing frequency saturates during the bursts.

In all cases except the f_{max} constraint, oscillation frequency is independent of excitation, in contrast to most real networks. For 2 cells with unequal PSP areas, the diagram below is still useful taking $\alpha_x=\sqrt{\alpha_{12}\alpha_{21}}$. Parallel results have been obtained with still more physiologically faithful models. Comparisons with real nets will be presented. These results exemplify the quantitative constraints which must be met before an emergent hypothesis for rhythmic bursting in a network is tenable. Stabilizing influences of special cellular properties on oscillatory behavior will be discussed. Supported by NIH NS13138 and 15314.



137A.4 MODULATION AND GENERATION OF SPIKES IN THE PERIPHERAL BRANCHES OF A MOTOR AXON. P.J.Stephens and H.L.Atwood. Dept. of Zoology, Univ. of Toronto, Toronto, Ontario M5S 1A1, Canada.

In the limb of the crab Pachygrapsus the stretcher muscle is innervated by branches from 3 motor axons; the excitor (E), the specific inhibitor (SI) and the common inhibitor (CI). Preparations were made from autotomised limbs so that the 3 motor axons could be stimulated individually or in combination. At normal temperatures a single stimulus shock applied to the E axon evoked a single excitatory junctional potential (ejp) in the stretcher muscle fibers. However, above a critical temperature single E axon shocks produced 2 successive ejp's. Further temperature increases resulted in a progressive increase in the number of ejp's recorded from stretcher fibers following a single stimulus. Experiments using animals acclimated to different temperatures demonstrated that the threshold for repetitive firing is dependent upon the animal's thermal history.

When single axon shocks elicited repetitive ejp's in the stretcher muscle fibers, each ejp was associated with an E axon spike. Latency measurements and extracellular E axon recordings from 2 locations showed that spikes produced after the initial action potential are generated at the periphery.

If the SI axon was stimulated at the same time as the E axon all peripherally generated E spikes were abolished, with the result that only one (orthodromic) E spike and one ejp were recorded. Moreover, in preparations exhibiting prolonged ejp discharges following E axon shock, stimulation of the SI axon shortly after the E axon shock caused the abolition of only a portion of the secondary E response. These results suggest that activity in the SI axon can modulate or curtail the peripherally generated E axon spikes and the concomitant ejp's. Since our results were obtained from autotomised limbs we suggest that SI modulation of E axon activity must take place in the peripheral axon branches, possibly at the axo-axonal synaptic terminals. Further evidence for this was obtained from bath applications of GABA and picrotoxin at concentrations of 5×10^{-5}M. GABA is considered to be a crustacean inhibitory synaptic transmitter (Otsuka, et al, Proc. Natn. Acad. Sci. 56, 1966) and abolished the repetitive firing following E axon shocks. In contrast, picrotoxin is an antagonist to the action of GABA (Takeuchi and Takeuchi, J. Physiol. 205, 1969) and not only abolished all ijp activity following SI axon spikes, but also prevented SI modulation of peripherally generated E axon spikes.

137A.5 EVIDENCE FOR ELECTROTONIC COUPLING BETWEEN CA3 PYRAMIDAL CELLS OF RAT HIPPOCAMPUS: DYE-COUPLING AND SIMULTANEOUS INTRACELLULAR RECORDINGS. Brian A. MacVicar and F. Edward Dudek, Dept. Zool., Univ. Toronto, Toronto, Ontario M5S 1A1.

Hippocampal pyramidal cells are well-known for their susceptibility to seizure. Electrotonic coupling between pyramidal cells could mediate the synchronization and spread of epileptiform discharges. We have used two independent strategies to test the hypothesis that some CA3 hippocampal pyramidal cells are electrotonically coupled.

Lucifer yellow (LY) was injected intracellularly to determine if CA3 pyramidal cells are dye-coupled. LY has been shown to cross gap junctions in numerous other systems. Intracellular LY injections (10-17 min, 8 nA hyperpolarizing pulses) were continuously monitored and immediately terminated if the impalement was lost. In 10 out of 20 injections, two or more cells were stained when only one was injected. LY is most likely crossing through gap junctions into other dye-coupled cells since (a) in 7 extracellular ejections of LY, there was no evidence of uptake, (b) the cells were not disrupted by iontophoretic injection, and (c) no extracellular LY was present.

In a second series of experiments we have used simultaneous intracellular impalements of CA3 neurons to demonstrate electrotonic interactions directly. Recordings were obtained with two microelectrodes positioned as close as possible in the cell body layer. Coupling ratios were estimated using reciprocal current pulses. The simultaneous recordings revealed two situations. (A) There was perfect synchrony between recordings and coupling ratio was 1:1. In this case the two electrodes were evidently in the same cell. (B) Weak bidirectional coupling was observed between recordings and action potentials in one evoked fast prepotentials in the other. We interpreted these latter cases to be recordings from two electrotonically-coupled cells and not simultaneous impalements of soma and dendrite of the same cell since: (a) in several cases after the electrodes were in the same cell (case A) one electrode was advanced a few microns, another impalement was obtained and weak coupling was observed; and (b) in one successful case, Ni injection through one electrode and HRP through the other electrode showed two stained neurons and consequently the recordings were obtained from two cells.

Therefore, dye-coupling after LY injections and simultaneous recordings from hippocampal pyramidal cells have provided evidence for electrotonic coupling, which may be the basis for synchrony and spread of seizure. Furthermore, many fast prepotentials may be electrotonic coupling potentials rather than dendritic spikes.

137A.6 INTRACELLULAR POTENTIALS FROM FROG SARTORIUS MUSCLE FIBERS, T. M. Mikiten. Department of Physiology, University of Texas Health Science Center, San Antonio, Texas 78284.

Frog sartorius muscle fibers were stimulated with intracellular glass microelectrodes filled with either KCl or K acetate, using constant current pulses 10-300msec long. A recording electrode 10-500μM away detected responses to the stimuli. Hyperpolarizing pulses elicited repetitive responses that were not altered by TTX or by removing Na^+ from the medium. The apparent conduction velocity of the responses was 10^{-3} to 10^{-2} meters/sec. Raising the extracellular K^+ concentration to 150mM or replacement of Cl^- by methylsulfate did not block the responses. The repetitive responses could be halted by relocating the stimulating electrode to a different location along the long axis of the fiber. The response returned when the electrode was replaced. For these reasons, it seems possible that the responses arise from intracellular sites, especially the internal membrane system of the fiber. Special thanks to Robert Woodward for his technical assistance.

137A.7 ELECTROPHYSIOLOGICAL STUDIES ON RECURRENT INHIBITION IN THE HIPPOCAMPAL DENTATE GYRUS. R.S. Sloviter and J.D. Connor. Dept. of Pharmacology, Penn State Univ., Col. of Med., Hershey, PA 17033

Recurrent inhibition in the dentate gyrus of the urethane-anesthetized rat was studied using extracellular recording techniques. Fourteen repetitively firing (RF) cells in 14 rats exhibited high discharge frequency (450-700 Hz) for long durations (up to 200 msec) in response to activation of the perforant path, a physiological input to the dentate gyrus. RF cell bursts were dependent on stimulus frequency. At 1 Hz, RF cell discharges were not synchronized with the stimulus pulse. At or above 3 Hz the RF cell discharges followed the stimulus closely (8-10 msec). In other rats, granule cells (G-cells) were recorded that fired spontaneously in bursts of 2 or 3 spikes. During a series of triplet bursts from a G-cell, a RF unit (700 Hz) recorded simultaneously apparently converted the triplets to singlets. When the G-cell discharged in singlets, the RF cell did not discharge. These recordings presumably represent frequency dependent discharges of dentate basket cells which have been assumed to mediate recurrent inhibition in the dentate gyrus. Since these cells are rarely encountered, experiments were designed to determine the extent to which the G-cell evoked potential might serve as a model for studying the influence of inhibitory interneurons on G-cells. Stimulation of the perforant path evokes a field potential which reflects EPSPs in G-cell dendrites. Superimposed on this potential is a "population spike" which represents action potentials generated simultaneously in many G-cells. The amplitude of the spike is proportional to the number of G-cells firing (Lømo, 1971). At low frequencies (≤0.1 Hz), the population spike is relatively large. At 1 Hz, the spike amplitude is small, but at 2-4 Hz the spike amplitude increases again. The decrease in spike amplitude from 0.1 to 1.0 Hz is blocked by bicuculline (i.v. or ivt.). The twin pulse paradigm (Andersen et al., 1966) was also used to examine recurrent inhibition. At low frequencies (≤0.1 Hz), the second population spike of two evoked potentials (40 msec apart) is larger than the first, indicating potentiation of the test pulse by the conditioning pulse. At higher frequencies (>2 Hz), the first spike grows larger and the second is small or absent. This inhibition of the test spike represents frequency dependent recurrent inhibition of G-cells and is blocked by bicuculline or picrotoxin but not strychnine. As stimulus frequency is increased, or after administration of bicuculline, recurrent inhibition is abolished and epileptiform activity (large amplitude, repetitive spiking of granule cells) is observed. These observations are consistent with the view that loss of GABA-mediated recurrent inhibition results in uncontrolled epileptiform activity.

137A.8 REACTION-DIFFUSION MODELS FOR CALCIUM FLUXES IN NERVOUS TISSUE. A. F. Lawrence*, S. M. Bawin* and W. R. Adey (SPON: E. Schwartz) Research Service, VA Hospital, Loma Linda, CA 92357

Data from recent experiments involving the efflux of $^{45}Ca^{++}$ from the brains of live cats and from synaptosomes extracted from rat brains indicate that the steady-state kinetics of calcium exchange between cell membrane and extracellular pools may exhibit more complex phenomena than the usual simple (multi-) exponential decay of amounts of labeled atoms in various tissue pools. Evidence for periodic oscillations has been observed in the efflux of $^{45}Ca^{++}$ from both preparations. These oscillatory states may be induced by stimulation with weak electromagnetic fields generated externally to the preparation. A reaction-diffusion model based on a two-stage calcium binding mechanism (which has been observed in several proteins) may be used to fit the data. Explicit parabolic partial differential equations describe the reaction diffusion process, and hyperbolic-partial differential equations describe the propagation of the field. Coupling between the reaction-diffusion process and the induced field is shown to cause a shift in the steady-state solutions of the modeling equations between field-absent and field-present conditions. Oscillatory states in the numerical solutions are shown to parallel the experimental observations. Similar coupling effects between Ca^{++}, Na^+, K^+ and H^+ fluxes and electromagnetic fields may provide a mechanism for the cooperative action of neurons. 138.1 GLUCOCORTICOIDS INDUCE EXPRESSION OF THE ADRENERGIC PHENOTYPE IN A RAT SYMPATHETIC GANGLION. I.B. Black, M.C. Bohn, E.M. Bloom and M. Goldstein Division of Developmental Neurology, Cornell Univ. Med. Coll.,New York, N.Y. 10021 and Dept. Psychiatry, New York Univ. Med. Ctr., New York, N.Y. 10016.

The effect of glucocorticoid treatment on expression of the adrenergic phenotype in rat superior cervical ganglion (SCG) was monitored immunocytochemically. The adrenergic phenotype was defined as the presence of immunoreactivity to PNMT (phenylethanolamine-N-methyltransferase). In normal postnatal rats, adrenergic cells were never observed in the SCG. However, numerous PNMT positive cells appeared following treatment with dexamethasone (DXM) on days 0-6 or corticosterone pellets on days 0-3. PNMT was localized to elements resembling SIF cells; they were small cells of variable diameter, scattered or in groups, often associated with blood vessels. In contrast, PNMT was never observed in principal ganglion cells. Unilateral ganglion decentralization did not prevent the appearance of the adrenergic phenotype after glucocorticoid treatment, indicating that preganglionic innervation was not necessary for PNMT appearance. Moreover, DXM (10^{-7}M) directly affected the SCG since the steroid elicited PNMT appearance in ganglia cultured for 4 days.

This discrete population of steroid-responsive cells was also present in the embryonic SCG. Treatment of pregnant rats with DXM (4mg/Kg daily for 4-5 days) evoked the appearance of PNMT in embryonic ganglia at 18.5 and 20.5 days of gestation. However, no PNMT positive cells were observed in sympathetic ganglia in 14.5 or 16.5 day old embryos from DXM treated mothers.

Since we observed that cessation of steroid therapy resulted in the disappearance of PNMT, postnatal rats were re-exposed to DXM to help define the fate of these cells. We employed 4 treatment groups: 1) saline days 0-6 and 24-30; 2) saline days 0-6 and DXM 24-30; 3) DXM days 0-6 and saline 24-30; 4) DXM days 0-6 and 24-30. In 30 day ganglia, PNMT appeared only in rats exposed to DXM on days 0-6 and 24-30. These results suggest that after initial DXM treatment, cells which can re-express PNMT persist into adulthood. Consequently, DXM withdrawal results in loss of PNMT, but not death of these cells. More generally, we conclude that glucocorticoids can influence the expression of the adrenergic phenotype in extra-adrenal tissue during a critical period extending from late gestation to early postnatal life.

138.2 INFLUENCE OF GLUCOCORTICOSTEROIDS ON THE CHOICE OF TRANSMITTER TYPE OF SUPERIOR CERVICAL GANGLION NEURONS. I. S. McLennan*, I. A. Hendry*, C. E. Hill* (SPON: W. D. Chapple). Dept. of Pharmacol., John Curtin School of Med. Res., Aust. Natl, Univ., Canberra, A.C.T. 2601, Australia.

When intact immature superior cervical ganglia (SCG) are cultured, the neurons switch from an adrenergic to a cholinergic phenotype. This switching of phenotype is caused by a factor released by the non-neuronal cells (Patterson, A. Rev. Neurosci. 1, 1, 1978). If, however, physiological concentrations of glucocorticosteroids are included in the medium then the neurons are maintained in an adrenergic phenotype, as indicated by high levels of tyrosine hydroxylase (TH) and low levels of choline acetyltransferase (CAT) (McLennan et al., Nature 283, 206, 1980).

The mechanism by which glucocorticosteroids influence transmitter choice was studied by examining whether the glucocorticosteroid agonist dexamethasone (DEX) could irreversibly prevent the switching of phenotype. SCG from 2 day old rat pups were cultured in medium containing DEX (10^{-6}M) for various periods and then cultured for a further 14 days in medium lacking steroid. The ability of these ganglia to synthesize CAT was reduced after a 4 day, and abolished after a 7 day, culture in DEX. The loss of ability to switch phenotype parallels a similar age dependent change occurring in vivo. When SCG were cultured in the absence of steroid for 7 days, so as to make some of the neurons cholinergic and then subsequently cultured in DEX for 14 days, there was no significant elevation of TH or decrease of CAT in these ganglia, relative to ganglia cultured in the absence of steroid for 21 days. Thus DEX does not selectively destroy cholinergic neurons and is not acting as an adrenergic inducer. We therefore suggest that glucocorticosteroids influences transmitter type of the SCG in vitro by fixing the neurons in the phenotype being expressed at the time of exposure to the steroid.

138.3 HORMONAL CONTROL OF NEUROTRANSMITTER CHOICE IN CULTURED SYMPATHETIC NEURONS. K. Fukada. Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115.

Individual sympathetic neurons dissociated from superior cervical ganglia (SCG) of newborn rats have the capacity to become either cholinergic or adrenergic, depending on the culture environment (Patterson,P.H., Ann. Rev. Neurosci., 1:1, 1978). A factor produced by certain types of non-neuronal cells can influence this transmitter decision without affecting neuronal survival or growth. However, hormones in the sera used in the culture media have remained an uncontrolled variable in these studies. Recently, McLennan et al. (Nature, 283:206, 1980) have shown that glucocorticoids modulate transmitter choice of neonatal SCG in organ culture, suggesting a role for hormones in this aspect of neuronal development.

I have examined the effects of a variety of hormones on the development of sympathetic neurons after devising a serum-free medium for cardiac myocytes and fibroblasts (heart cells) according to Sato and coworkers (Bottenstein, J. et al., Methods in Enzymol. 58:94, 1979). Serum-free media supplemented with various hormones were incubated on heart cells, and the conditioned media (CM) from these cultures were tested for the ability to cause induction of neuronal acetylcholine (ACh) synthesis. Among the various hormones tested, epidermal growth factor (EGF) and glucocorticoids had large and antagonistic effects on the cholinergic induction : EGF stimulated the ACh induction more than 100-fold, while glucocorticoids decreased this stimulatory effect of EGF 10-20 fold. Thus the transmitter choice of SCG neurons can be controlled by certain hormones. However, it was not clear whether these hormones acted directly on the neurons or indirectly, via the heart cells, in causing cholinergic induction. Therefore, the effect of direct addition of EGF or glucocorticoids to neuronal cultures together with serum-free CM (without EGF or glucocorticoids) was tested. Since little effect on the transmitter choice was seen in such experiments, it was concluded that these hormones acted on the heart cells, controlling the ability of heart cells to produce effective CM.

These effects of EGF and glucocorticoids were relatively specific. The 24 hr incubation with these hormones for obtaining CM did not change the total DNA or protein content of the heart cells, or the amount of protein synthesized from ^{3}H-leucine.

These results suggest a further level of subtlety in the control of neurotransmitter choice in sympathetic neurons : specific hormones act on non-neuronal cells to selectively alter the production or liberation of a factor (or factors) that induces cholinergic development and reduces adrenergic development (supported by the M.D.A. and a NINCDS grant to P.H.Patterson).

138.4 ELEVATION OF MATERNAL GLUCOCORTICOID HORMONES ALTERS NEUROTRANSMITTER PHENOTYPIC EXPRESSION IN PRESUMPTIVE EMBRYONIC NEUROBLASTS. G.M. Jonakait, M.C. Bohn, M. Goldstein and I.B. Black. Div. of Developmental Neurology, Cornell Univ. Medical College, New York, N.Y. 10021 and Dept. of Psychiatry, NYU Medical Center, New York, N.Y. 10016.

We have been working with a population of presumptive neuroblasts, located in embryonic rat gut, which transiently expresses noradrenergic phenotypic characters. Immunoreactivity to tyrosine hydroxylase (T-OH) and dopamine-β-hydroxylase (DBH) as well as endogenous catecholamine (CA) fluorescence appear simultaneously in this population at gestational day 11.5 (E 11.5). Cells expressing these noradrenergic characters increase in number over the next 24 hrs, but by E 13.5 they have lost these noradrenergic traits. To characterize this population pharmacologically, pregnant rats were treated with reserpine (10 mg/kg, i.p.) on E 11.5, and embryonic guts were examined with both formaldehyde-induced CA fluorescence and immunohistochemistry 2 days later. Reserpine administration resulted in the persistence of both CA fluorescence and immunoreactivity to T-OH and DBH in embryonic gut cells. Since reserpine is known to elevate plasma glucocorticoids, we investigated the effects of these hormones on persistence of noradrenergic characters. Maternal hydrocortisone acetate administration (given as pellets implanted s.c. on E 11.0) reproduced the effect of reserpine on gut cells. In other experiments mothers were pretreated with dexamethasone (1 mg/kg) to inhibit the stress-induced rise of maternal plasma glucocorticoid hormones. This treatment, beginning one day before reserpine administration, prevented reserpine's effect of prolonging CA fluorescence in gut cells. In addition, pretreatment of mothers with mitotane (75 mg/kg, s.c., twice daily beginning E 5.5), a drug toxic to the adrenal cortex, inhibited the reserpine-induced persistence of CA fluorescence. Since 1) hydrocortisone mimicked reserpine; 2) inhibition of a stress-induced rise of plasma glucocorticoids blocked the action of reserpine; and 3) mitotane inhibited reserpine's effects, we conclude that the action of reserpine in prolonging expression of noradrenergic traits is mediated by the release of maternal glucocorticoid hormones.

138.5 DISSOCIATED CELL CULTURE OF SIF CELLS: HORMONE-DEPENDENCE AND NGF ACTION. A. J. Doupe, P. H. Patterson, and S. C. Landis. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Small intensely fluorescent (SIF) cells constitute a minority cell population in many sympathetic ganglia, where they may act as interneurons. Like the sympathetic principal neurons that surround them, SIF cells are neural crest-derived, but it is unclear how they differentiate into a separate population. The number of SIF cells in a ganglion is influenced by glucocorticoid hormones: after hydrocortisone treatment both in vivo or in explant cultures, rat superior cervical ganglia (SCG) contain many more SIF cells than untreated controls (Eränkö, O. et al., Histochem. J. 4:49, 1972). The mechanism of this effect is unknown; increased survival, mitosis, or recruitment from another population of cells have all been suggested.

The use of dissociated cell cultures of SIF cells may help in the resolution of these questions. We have been able to obtain such cultures of SIF cells from newborn rat SCG by growth in 5 μM dexamethasone, with antimitotic agents, and without nerve growth factor (NGF). These cultures are virtually free of principal neurons and non-neuronal cells. The properties of the SIF cells include (1) small size (10-20 μm in diameter), (2) intense formaldehyde-induced fluorescence, (3) large granular vesicles of several types (100 nm diameter, characteristic of Type I SIF cells, and 300 nm diameter, characteristic of Type II SIF and adrenal medullary cells), (4) the capacity to generate action potentials, and (5) the synthesis and storage of dopamine, norepinephrine, and epinephrine (as judged by the incorporation of (^{3}H)-tyrosine and by HPLC analysis of endogenous amines). The characteristic fluorescence and ultrastructure develop over the first ten days in culture, by which time the cell number is stable and more than 90% of the cells are intensely fluorescent.

Adrenal medullary cells, although not NGF-dependent, can respond to NGF by neurite outgrowth (Unsicker, K. et al., PNAS 75:3498, 1978), and injection of NGF into rat embryos causes the medullary cells to be replaced by nerve cells (Aloe, L. et al., PNAS 76:1246, 1979). SIF cells in culture are also capable of responding to NGF by outgrowth of neuron-like processes, even after they have developed intense catecholamine fluorescence. Some also lose their intense fluorescence and acquire a neuronal ultrastructure.

These observations raise the possibility that there are cells in the SCG which have the potential to become either neurons or SIF cells, and that glucocorticoids and NGF can influence this choice. Also, the cultures may prove useful for the study of the function of SIF cells in the SCG. (Supported by the NINCDS, the Rita Allen Fndn., and the Ins. Med. Sci. Schol. Fund)

138.6 THE EXPRESSION OF AN ADRENERGIC PHENOTYPE IN FETAL ADRENAL MEDULLARY CELLS IS NOT INDUCED BY GLUCOCORTICOIDS. M. Brodsky,* G. Teitelman, D.H. Park, M. New, T.H. Joh and D.J. Reis, Laboratory of Neurobiology, Dept. of Neurology, and Dept. of Pediatric Endocrinology, Cornell Univ. Med. College, New York, NY 10021.

During embryogenesis of the rat, the enzymes tyrosine hydroxylase (TH) and dopamine-β-hydroxylase (DBH), which synthesize norepinephrine, first appear in cells of the developing adrenal medulla at day 16 (E16). It is not until E18 that phenylethanolamine-N-methyltransferase (PNMT), the enzyme synthesizing epinephrine, first appears (Teitelman et al., PNAS 76:509, 1979). We sought to determine whether the expression and/or subsequent increase of adrenal PNMT depends upon glucocorticoids secreted by the developing adrenal cortex.

At E16, when PNMT activity is nil, corticosterone (CS) is present in the adrenal (4.8 ng/adr). At E18, when PNMT activity is first detected (21.9±1.42 pmol/adr/h), CS levels have increased 100-fold to 500 ng/adr. To determine whether the appearance of PNMT is induced by the surge in CS biosynthesis, adrenals removed at E16 (16+0) were cultured without ACTH. Under such conditions, adrenal CS concentrations were similar on 16+0 and 16+2. However, PNMT activity appeared on E16+2 (5.33±0.43 pmol/adr/h) and increased to 22.09±2.39 by E16+5 where it remained until E16+9. CS was undetectable in the media added to the cultures. To determine whether CS modulates PNMT activity in vitro, adrenals removed at E16 were cultured 2-9 days with or without 10^{-5} M dexamethasone. Although dexamethasone did not change the time at which PNMT appeared, it increased PNMT activity three-fold. Immunochemical titration with a specific antibody to PNMT demonstrated that the increase in enzyme activity was entirely due to an increased accumulation of enzyme protein. In contrast to PNMT, TH activity, which increased from 0.42±0.06 nm/adr/h at E16+2 to 0.73±0.02 nm/adr/h on E16+5, was not modified by the addition of dexamethasone. We conclude that while a high level of glucocorticoids is not required for the initial expression of PNMT, the amount of enzyme protein present in fetal adrenal medullary cells is regulated by CS. Factors other than GC are required for the differentiation of adrenal medullary cells into those that synthesize epinephrine.

(Supported by NIH grant HL 18974)

139.1 CORRELATION BETWEEN CELL BIRTHDATES AND SYNAPTIC CONNECTIVITY IN A NEURONAL ARRAY. M. Flaster and F. Macagno. Dept. of Biol. Sciences, Columbia University, New York, N.Y. 10027

The order in which cells of a developing neuronal array are generated may play a role in their subsequent formation of correct synaptic contacts. For example, orderly ingrowth of axons, coordinated with the sequential or relative availability of target neurons in the array, would result in a particular connectivity pattern. The order of generation of targets could be responsible for their sequential availability, or the age of the targets might determine their relative affinity for the incoming fibers.

In the visual system of adult Daphnia magna the position and connectivity of the 176 photoreceptors and the 110 laminar target neurons are invariant. The normal order of optic fiber ingrowth into the embryonic lamina is also stereotyped and invariant, with axons that project to lateral laminar targets arriving first and axons that project to dorsomedial targets arriving last. In the present study we find that there is a correlation between the order of cell generation in the lamina and the order of optic fiber ingrowth and subsequent formation of synaptic connections.

Embryos were micro-injected with ^{3}H-thymidine at specified developmental times and were subsequently fixed at maturity. They were then sectioned serially at 1 micron and processed for autoradiography. Computer-assisted 3-dimensional reconstruction and grain counting were used to follow the progress of all 110 laminar cells through their final round of DNA synthesis. The presumptive lamina completes its final cycle of cell replication in less than 10 hours at 22°, extending from about 29 to 39 hours of development (total development time is about 60 hours at this temperature). S-phase for individual cells is less than 3 hours in duration. We found that final mitoses (birthdates) proceed in an orderly manner such that cells most laterally situated in the lamina have the earliest birthdates, while dorso-medial cells are born last. This birthdate pattern closely parallels the pattern of fiber ingrowth from the eye into the lamina. EM serial reconstruction of control embryos fixed at injection time demonstrate that birthdates for cells of a particular location precede fiber contact by at least an hour. The time period following final S and prior to axonal contact and initiation of laminar cell morphological differentiation appears to be about the same throughout the lamina regardless of cell position. How the apparent clock-like coordination between cell cycle withdrawal by target cells and the contacting of these cells by photoreceptor axons is achieved is not known. The developmental significance of the order of this set of events remains to be established.

139.3 REINNERVATION OF TRANSPLANTED SYMPATHETIC GANGLIA. Dale Purves, Wesley Thompson and Joseph W. Yip. Department of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO. 63110.

Sympathetic ganglion cells are innervated preferentially by preganglionic axons arising from different levels of the thoracic spinal cord (see Purves and Lichtman, 1978, for a review). In the present study we have asked whether the basis of this phenomenon is a property of ganglion cells by transplanting different sympathetic ganglia to a common site.

Fifth thoracic or superior cervical sympathetic ganglia from donor guinea-pigs were transplanted to the bed of an excised superior cervical ganglion in host animals. In this way the same set of preganglionic axons (the cervical sympathetic trunk) was confronted with ganglion cells from different levels of the sympathetic chain. After 3-5 months the reinnervated transplants were examined by recording intracellularly from individual ganglion cells while stimulating thoracic ventral roots in vitro.

Transplanted thoracic and cervical ganglion cells were reinnervated to about the same extent by the preganglionic axons of the host's cervical sympathetic trunk. Thus, the mean amplitude of postsynaptic potentials, the estimated number of inputs, and the number of spinal segments providing innervation to each neuron were similar. Neurons in transplanted fifth thoracic ganglia, however, were reinnervated more frequently, and more strongly, by axons arising from more caudal thoracic segments than were neurons in transplanted superior cervical ganglia. Stimulation of axons arising from the fourth thoracic spinal segment (T4), for example, elicited postsynaptic potentials that were, on average, twice as large in transplanted fifth thoracic ganglion cells as in transplanted superior cervical ganglion cells; conversely, T1 axons reinnervated neurons in the superior cervical ganglion about 2-3 times more effectively than they reinnervated fifth thoracic ganglion cells. This difference in the reinnervation of the fifth thoracic and the superior cervical ganglion is in the same direction as (although less pronounced than) the normal difference in the segmental innervation of these ganglia.

We conclude that preganglionic axons can distinguish (or be distinguished by) ganglia derived from different levels of the sympathetic chain. Our findings are consistent with the view that some property of ganglion cells biases the innervation they receive.

139.4 SYNAPTIC COMPETITION AND SPROUTING DURING REINNERVATION OF FROG SYMPATHETIC GANGLIA. Daniel H. Feldman* (SPON: C.G. Reiness). Dept. of Physiol., Univ. California, San Francisco, CA 94143

In frog lumbar sympathetic ganglia, B cells and C cells can be distinguished by the propagation rate of antidromic spikes elicited in the postganglionic nerve trunk. The two types of ganglion cells are selectively innervated by separate populations of preganglionic axons; B fibers innervate B cells, and enter the sympathetic trunk at levels anterior to the sixth segmental ganglion, while C fibers innervate C cells and enter the trunk at the seventh and eighth segmental levels. Thus, fast excitatory synaptic inputs to B cell or C cell populations may be driven separately by stimulating the appropriate preganglionic nerve roots. This simple anatomical arrangement of selective inputs to two cell populations allows examination of the specificity of reinnervation of ganglia using intracellular recording techniques.

I reported that after surgical interruption of both B and C fibers, both groups of fibers eventually restore synaptic contact with their appropriate ganglion cell targets. Inappropriate synapses (B fiber → C cell) were formed during early reinnervation, but most of these were eliminated shortly after appropriate innervation had returned to most C cells (Feldman, '79, Neurosci. Abst. 5:625). Does the disappearance of inappropriate synapses depend on a competitive interaction with returning appropriate synapses, or would inappropriate synapses be eliminated even in the absence of a preferred synaptic input? To distinguish between these possibilities I employed a lesion designed to selectively delay the return of C fibers, thus providing a prolonged period of reinnervation by regenerating B fibers alone. In ganglia examined 6-10 weeks after lesion, 65% of C cells still were inappropriately innervated by B fibers. When C fibers were allowed to return, the frequency of inappropriate synapses was reduced to less than 10% by this time. Thus, inappropriate synapses are retained in the absence of preferred synaptic input, and selective elimination of these synapses appears to be due to competition with appropriate inputs.

In another study I cut only the preganglionic B fibers, thereby denervating only B cells. 1½-5 weeks after lesion, the intact C fibers had sprouted and formed synapses with 47% of the B cells. When the B fibers returned they formed synapses only with B cells, and the C fiber sprouts could no longer be detected physiologically. Thus, anomalous (C fiber → B cell) connections are induced by partial denervation, and these connections are eliminated when appropriate synaptic inputs return. Supported by NIH Grant #NS10792.

139.5 Synaptic Selectivity: A New Concept

S. Roper, W. Proctor, and B. Taylor*. Depts. of Anat. and Phsyiol Univ. Colo. Health Sciences Center, Denver, Colo. 80262.

A number of laboratories, including ours, have shown that parasympathetic neurons in the cardiac ganglion of the frog are capable of establishing and maintaining synaptic connections with inappropriate, or "foreign", cholinergic inputs. For example, preganglionic vagal axons can sprout and reinnervate ganglion cells after partial vagotomy (Nature, 259, 317, 261, 148, 1976). In addition, intrinsic synapses, which normally do not occur, develop between denervated ganglion cells (Nature, 268, 456, 1977). Furthermore, even spinal motoneurons can innervate denervated ganglion cells (PNAS, 76, 4695, 1979). Although an inappropriate nerve supply will establish synaptic contact with denervated parasympathetic cardiac ganglion cells, when the original axons (i.e. vagal preganglionic fibers) regenerate, they reinnervate the neurons and eliminate the foreign synaptic innervation. This has been interpreted as selective reinnervation insofar as there is a preferential reinnervation of the target by appropriate axons rather than by inappropriate ones.

An important feature is common to all the above examples of inappropriate synaptic reinnervation in the cardiac ganglion. Namely, inappropriate nerve terminals establish synaptic contact only on the axons of the target neurons. This is in contrast with reinnervation by the original, vagal, nerve terminals, where synaptic contact is restored both to the soma as well as the axon. The inability of foreign inputs to reinnervate the soma appears to reveal fundamental regional differences in the postsynaptic targets.

If this is a general property of nervous tissue repair, it leads to a concept of synaptic territoriality, in which certain territories on a denervated target cell (e.g. the axon, in the case of cardiac ganglion cells) can accept synaptic contact from a variety of sources, including inappropriate ones, whereas other regions (e.g. the soma, in the case of ganglion cells) are more selective and form synapses only with appropriate axons. Although the mechanisms whereby foreign inputs are excluded from one synaptic territory and not the other(s) are not known, the concept of synaptic territoriality may suggest promising experimental approaches to the study of neuronal plasticity.

139.6 TARGET REGULATION OF SYNAPTIC DENSITY IN THE REGENERATED OPTIC PROJECTION TO A HALVED OPTIC TECTUM IN GOLDFISH. M. Murray, S. C. Sharma and M. A. Edwards. Dept. Anatomy, The Medical College of Pennsylvania, Philadelphia, PA and NY Medical College.

When a crushed optic nerve regenerates into a tectum whose caudal portion has been ablated, the retinal axons establish a compressed retinotopic projection upon the remaining half tectum within a few months (Gaze and Sharma, 1965). This projection to a reduced target should be accompanied by a substantial increase in synaptic density if each retinal axon makes its normal number of contacts but synaptic density should remain normal if the number of contacts is regulated by the postsynaptic structures. We examined synaptic density in the stratum fibrosum et griseum superficialis (SFGS, the major tectal target for retinal axons) in: a) control tecta; b) tecta 3-9 months after contralateral optic nerve crush; and c) tecta 6-9 months after optic nerve crush and contralateral caudal tectal ablation. Synaptic types, size and density were estimated by morphometric analysis of electron micrographs supplemented by HRP, RAG and degeneration studies. Counts of optic nerve terminals stained by orthograde HRP method indicated that at least 40% of SFGS terminals are retinal in origin. Early stages of regeneration into intact tectum are characterized by an increase in SFGS thickness, largely accounted for by the massive influx of an excess number of regenerating axon collaterals. By 4 months p.o. both SFGS thickness and axon numbers have decreased toward normal levels. Despite the larger number of retinal axons, synaptic density is subnormal and only approaches normal values by 4 months p.o. The increase in SFGS thickness in the reinnervated half-tectum however, persists and this is associated with a persistance of a large number of regenerating axons. Synaptic density nevertheless remains close to control values in the half tectum preparation. These results support the conclusion that synaptic number is regulated by the postsynaptic target rather than by the axon and that competition for limited *accomodation (e.g. postsynaptic sites or trophic factors)* is one characteristic of the compression phenomenon.

140.1 TESTICULAR CONTROL OF THE FREQUENCY OF GONADOTROPIN RELEASING HORMONE SECRETION IN THE RHESUS MONKEY. T.M. Plant* (SPON: M.J. Kelly) Department of Physiology, University of Pittsburgh School of Medicine, Pittsburgh, Pa. 15261.

The intermittent secretion of the gonadotropic hormones is considered to be occasioned by, and therefore to reflect, a corresponding pulsatile pattern of gonadotropin releasing hormone (GnRH) discharge by the hypothalamus. Thus, in intact adult male rhesus monkeys GnRH appears to be released with a frequency of approximately 1 pulse every 2-3 h (Plant, 1980). In order to study the role of the testis in determining this discontinuous pattern of hypophysiotropic stimulation, 4 adult male rhesus monkeys (8.5-10.2 kg BW) were fitted with indwelling cardiac catheters and housed in remote sampling cages which permitted continuous access to the venous circulation without restraint of the animals. Sequential blood samples were taken via the catheter every 10 min for 8-12 h, between 0700 and 2100 h, one to 4 days before and 1, 2, 4 and 8 days after bilateral orchidectomy. Plasma luteinizing hormone (LH) concentrations were determined by a previously validated RIA (Karsch et al., 1973). The pulsatile release of LH prior to orchidectomy occurred, as previously described, with a frequency of 1 pulse every 2 to 4 h. Two days after castration, however, the frequency of LH release had increased dramatically to approximately 1 pulse per h and by the 4th postcastration day frequencies as high as 1 pulse every 0.5 h were observed in some cases. Subsequent sc implantation of testosterone (T) containing Silastic capsules, which produced plasma T concentrations in the upper physiological range, resulted in a progressive reduction in the high frequency of pulsatile LH secretion characteristic of the open-loop situation: 24 h after initiation of T replacement the frequency of LH discharge had declined from approximately 1 pulse every 40 min to approximately 1 pulse every 70 min and after 96 h of steroid treatment, frequencies (1 pulse every 2 h) comparable to the intact situation obtained.

These findings suggest that, in the rhesus monkey, the testis decelerate the hypothalamic mechanism responsible for the timing of pulsatile GnRH release, and that this gonadal influence on the pattern of hypophysiotropic stimulation may be mediated by testicular testosterone secretion.

140.2 BROMOCRYPTINE AND APOMORPHINE INCREASE 3H-ESTRADIOL UPTAKE BY SPECIFIC BRAIN AREAS AND PITUITARY IN THE RAT. W.G. Hope* and D.E. Woolley*. (SPON: V. Vijayan). Dept. of Animal Physiology, Univ. of Calif., Davis, CA 95616.

It is well known that catecholamines (CA) and estradiol (E_2) interact to regulate gonadotropin and prolactin secretion. For example, depletion of norepinephrine (NE) inhibited luteinizing hormone (LH) release in proestrous rats (Kalra and McCann, 1973), and dopamine (DA) infusion into the third ventricle evoked LH release more readily on diestrus-2 and proestrus than on other days of the cycle (Schneider and McCann, 1970). A possible neuroanatomical substrate for interaction of CA and E_2 has been suggested by the identification of estrocatecholaminergic neurons, which contain both E_2 receptors and a CA, in the basal hypothalamus and other brain areas (Stumpf and Grant, 1975). The purpose of the present study was to determine whether or not the interactions of CA and E_2 might be mediated via modulatory effects of CA on E_2 uptake by brain and pituitary. To do this Long-Evans rats were studied 3 days after ovariectomy. All rats received 3H-E_2 (1 µg/kg) iv. In addition, one group received 200 µg/kg diethylstilbestrol (DES) iv a few minutes before 3H-E_2 to help quantify the DES-blockable (receptor-mediated) uptake of 3H-E_2. Another group received bromocryptine (5 mg/kg) ip 1 hour before the 3H-E_2 and a final group received the bromocryptine plus DES. All animals were sacrificed 1 hour after 3H-E_2 administration. Bromocryptine pretreatment significantly increased receptor-bound 3H-E_2 levels in the nuclear fractions from pituitary, basal hypothalamus (BH) and septum. Binding was increased 30-70% in these areas. 3H-E_2 binding was also increased in anterior hypothalamus (AH), dorsal hypothalamus (DH), amygdala (AM) and cortex, but not significantly. In order to determine whether the effects of bromocryptine were mediated by its DA agonist properties, the experiment was repeated except that apomorphine, an established DA agonist, was substituted for bromocryptine. Apomorphine was injected ip in a dose of 1 mg/kg 15 min before, at the same time as, and 30 min after 3H-E_2 injection. Receptor-mediated nuclear binding of 3H-E_2 was significantly increased in the pituitary, AH, BH, DH and AM, though not in the septum or cortex. These findings suggest that CA neurotransmitters, perhaps DA especially, may influence the effect of E_2 on the brain and pituitary by increasing the uptake and/or binding of E_2. Further work is required to determine if the effects of these drugs are mediated primarily by increasing E_2 entry into cells, by increasing E_2 binding to its receptor, or by some other action. (Supported by NIH grant HD-12385-01.)

140.3 SEROTONIN-ACTIVE DRUGS MODIFY TEMPORAL PATTERNS OF PREOVULATORY LUTEINIZING HORMONE SECRETION IN RATS. R. F. Walker* (SPON: J.A. Winer). Dept. Anatomy & Sanders-Brown Center for Aging Research, Univ. Kentucky Med. Sch., Lexington, Ky. 40536

This study was designed to determine the influence of serotonergic neurotransmission on the dynamics of preovulatory LH secretion. Young female rats (Long-Evans) showing regular 4 day estrous cycles were housed in pairs in a 14:10 (lights on 0500h; off 1900h) photoperiod. Cyproheptadine (CP), methysergide (MS) (serotonin receptor antagonists) or quipazine (Q) (serotonin receptor agonist) was injected during the afternoon or evening of proestrus. Serial blood samples were collected from the tail vein of unanesthetized animals for determination of LH content following drug treatment. Serum LH concentrations peak in controls at approximately 1800h during the preovulatory "surge" under the photic conditions of the animal facility. When CP (7mg/kg) or MS (3mg/kg) were administered as a single injection (ip) at 1600h, the LH surge and ovulation were blocked. Continued daily injection of these drugs sustained the ovulatory blockade and caused vaginal smears to remain cornified. Since CP and MS have opposite secondary effects on dopamine receptors, the drug effects were probably due to blockade of serotonin receptors. If the first injections of CP or MS were given at 1700h, the LH surge was initiated but it terminated prematurely. Conversely, the LH surge was initiated early by an injection (sc) of Q at 1530h. When lights in the animal room were left on beyond 1900h on the evening of proestrus, serum LH levels remained high and serotonin turnover increased in the hypothalamus, compared with controls in the standard photoperiod. The stimulatory effect of extra light exposure on LH levels could be mimicked by an injection of Q at 1930h, ½ hour after lights were turned off. Serum LH values in Q treated rats were at surge values at 2000h while saline injected controls showed nearly basal levels at this time. Q injections given at 1530h or 1930h on diestrus 2, neither initiated nor sustained LH secretion. These data suggest that the temporal pattern of LH secretion during its preovulatory surge is determined, at least in part, by a period of serotonergic neurotransmission. Since Q was ineffective if given on diestrus, the response to this serotonin receptor agonist may be estrogen dependent, further suggesting that serotonergic neurotransmission may be a component of the positive feedback effect of estrogen on preovulatory LH secretion. (Supported by NIH AG05068)

140.4 A SEX-RELATED DIFFERENCE IN THE EARLY RESPONSES OF CENTRAL CATECHOLAMINERGIC AND LHRH NEURONS TO CASTRATION. L.V. DePaolo*, S.M. McCann and A. Negro-Vilar. Dept. of Physiology, Univ. Texas Health Sci. Ctr., Dallas, Tx 75235.

It is well known that acute pituitary gonadotropin responses to castration differ between male and female rats. While plasma FSH levels increase 4-8h after orchidectomy(ORDX) or ovariectomy (OVX), initial increments in LH occur 8-12h after ORDX, but are delayed for several days following OVX. Therefore, the present experiments were conducted to determine if alterations in turnover (T/O)rates of dopamine(DA) and norepinephrine(NE) as well as LHRH concentrations occur shortly after ORDX or OVX and if so, whether the observed changes may explain the diverse LH responses. Four-day cycling female rats were used on diestrus day 1. Animals were castrated(CAST) or sham operated at 0800h under ketamine anesthesia. Catecholamine(CA) T/O rates were estimated 3 and 8h after castration by injecting α-methyl-p-tyrosine (α-MPT, 190 mg/kg) through a chronic atrial cannula and measuring CA levels in rats decapitated 45 and 90 min after injection. Steady-state CA levels and LHRH concentrations in tissue and LH, FSH and prolactin levels in plasma were measured in separate groups of rats not receiving α-MPT. DA and NE contents were determined by radioenzymatic assay and LHRH contents by RIA in tissue punches of medial preoptic area(MPOA), suprachiasmatic nucleus(SCH), dorsal anterior hypothalamic area(DAHA), arcuate nucleus(ARC) and median eminence(ME). Significant increases ($p<.001$) in DA T/O rates occurred in the ARC 3 and 8h after ORDX when compared to T/O rates of this amine measured in sham rats. LHRH concentrations also were statistically higher($p<.005$) in the ARC of CAST rats at both time intervals after ORDX. These changes in ARC DA T/O rates occurred even though plasma prolactin levels did not differ between sham and CAST rats at either 3 or 8h after surgery. Similarly, the T/O rate of DA in the ME was faster($p<.05$) 3h after ORDX. Whereas ME LHRH concentrations were higher 3 and 8h after ORDX, the increased levels were significant($p<.005$) only at 8h. The T/O rates of NE in the DAHA(3h) and SCH(8h) of CAST male rats were elevated ($p<.001$ and $p<.05$, respectively) compared to sham rats. Contrastingly, CA T/O rates were generally unaffected or decreased following removal of the ovaries with the exception of an increased T/O of DA($p<.01$) in the ME 3h after OVX. Most importantly, no alterations in DA T/O rates or LHRH levels were observed in the ARC at any time after OVX. Likewise, no significant changes in LHRH levels were seen in any of the other areas studied at either 3 or 8h post-OVX. These studies reveal an important sex difference in the response of dopaminergic neuronal elements in the ARC to ORDX which may be related to the acute increases in ARC and ME LHRH levels and pituitary LH release in male rats after ORDX. (Supported by NIH grants HD05776 and HD09988).

140.5 IONTOPHORESIS OF MORPHINE INTO THE ARCUATE NUCLEUS: EFFECTS ON DOPAMINE CONCENTRATIONS IN HYPOPHYSIAL PORTAL PLASMA AND ON SERUM PROLACTIN CONCENTRATIONS. J.T. Haskins, G.A. Gudelsky, J.C. Porter, and R.L. Moss, Depts. of Physiology and Ob-Gyn, Univ. of Texas Southwestern Med. Sch., Dallas, TX 75235.

It is established that morphine and several opioid peptides stimulate the secretion of prolactin. Moreover, it has been suggested that this effect results from a suppression of dopamine release from tuberoinfundibular neurons into hypophysial portal blood, thereby removing the tonic inhibitory control of prolactin secretion. In the present investigation we have addressed the issue of whether morphine, instilled by iontophoresis in minute quantities into the arcuate nucleus of the hypothalamus, can inhibit the release of dopamine into hypophysial portal blood and stimulate the release of prolactin. Pituitary stalk blood was collected from pentobarbital-anesthetized diestrous rats for 3 consecutive and contiguous 30-min periods. During the second collection period, anodal current was used to iontophorese morphine (50 mM) or NaCl (150 mM) bilaterally into the arcuate nuclei. Iontophoresis of morphine at 1 μA for 10 min followed by 2 μA for 20 min resulted in no significant reduction in the concentration of dopamine in pituitary stalk plasma; however, when an iontophoretic current of 2 μA was used for 10 min followed by 5 μA for 20 min, there was a 60% decrease in the concentration of dopamine in stalk plasma. During the 30-min collection period following iontophoresis of morphine at this current, dopamine concentrations in stalk plasma were reduced 70%. After morphine application at a still higher current (2 and 10 μA), dopamine concentrations in stalk plasma were reduced 83% when compared to control values. Iontophoresis of NaCl at a current and polarity similar to that used with morphine had no significant effect on stalk plasma concentrations of dopamine. When rats were pretreated with the opiate antagonist, naloxone (5 mg/kg, ip), iontophoresis of morphine (2 and 5 μA) into the arcuate nuclei was no longer effective in reducing dopamine concentrations in pituitary stalk plasma. In still another group of animals, morphine was applied (2 and 5 μA) to the arcuate nuclei, and blood samples were taken from jugular cannulae before, during, and after iontophoresis. During and after iontophoresis, serum prolactin concentrations were 2 to 3 times greater than those seen during the pre-iontophoretic period. In view of these results, it seems reasonable to conclude that morphine can inhibit the release of dopamine and stimulate the release of prolactin by acting on nerve cells within the arcuate nucleus.

140.6 PROLACTIN AUGMENTATION OF THE K^+-INDUCED RELEASE OF ENDOGENOUS DOPAMINE AND NOREPINEPHRINE FROM SUPERFUSED MEDIAL BASAL HYPOTHALAMIC FRAGMENTS. M.M. Foreman and J.C. Porter, Depts. of Ob-Gyn and Physiology, Cecil H. and Ida Green Ctr. for Reprod. Biol. Sci., Univ. of Texas Southwestern Med. Sch., Dallas, TX 75235.

It has been demonstrated that the administration of prolactin can within 16-24 hr result in an increase in the turnover of dopamine (DA) within the median eminence (Hökfelt and Fuxe, Neuroendocrinology 9:100, 1972; Gudelsky et al., Neuroendocrinology 22:206, 1976) and in the concentration of DA in hypophysial portal blood (Gudelsky and Porter, Endocrinology 106:526, 1980). However, Clemens et al. (Brain Res 25:371, 1971) and Yamada (Neuroendocrinology 18:263, 1975) have observed an alteration in the electrical activity of hypothalamic neurons within minutes following the intravenous or iontophoretic administration of prolactin, respectively. Perkins and Westfall (Neuroscience 3:59, 1978) have found that prolactin can amplify the electrically induced release of tritium from hypothalamic fragments preloaded with [^{3}H]DA. The present investigation was undertaken to ascertain the effects of prolactin on K^+-induced release of endogenous catecholamines from superfused medial basal hypothalamic (MBH) fragments. DA and norepinephrine (NE) were quantified by a radioenzymatic assay procedure (Ben-Jonathan and Porter, Endocrinology 98:1497, 1976).

MBH fragments from adult male rats were placed in 120 μl chambers (3 MBH/chamber) and superfused at a rate of 70 μl/min at 37°C with a modified Krebs-Ringer bicarbonate solution (118 mM NaCl, 5.0 mM KCl, 1.15 mM $MgSO_4$, 1.15 mM NaH_2PO_4, 2.5 mM $CaCl_2$, 25 mM $NaHCO_3$, 11.1 mM glucose, 10 μM L-tyrosine, and 0.1% bovine serum albumin), which had been adjusted to pH 7.4 and equilibrated with 95% O_2/5% CO_2. After a 1-hr stabilization period, the fragments were superfused for 20 min with a Krebs-Ringer bicarbonate solution similar to that described above but which had been adjusted to 30 mM KCl and 93 mM NaCl. The addition of rat prolactin (50-5000 ng/ml) to the buffer containing 30 mM KCl was found to amplify significantly the K^+-induced release of both DA and NE in a concentration-dependent manner. The stimulatory effects of prolactin (200 ng/ml) on K^+-induced release of DA and NE were prevented by the addition of anti-rat prolactin gamma globulin (0.5 mg/ml) to the superfusion solution. The results of these experiments are supportive of the view that prolactin amplifies the acute release of DA and NE from the hypothalamus. The augmentation of catecholamine release by prolactin may be one mechanism by which prolactin influences hypothalamic neurosecretion.

141.1 SUBSTRATES OF A CEREBRAL ACTIVITY CODE PRECEDING SPEECH. D.H. York, T.W. Jensen and J.G. Rosenfeld. Dept. of Physiology, School of Medicine, University of Missouri, Columbia, MO 65212.

Previous studies in this laboratory have defined specific activity recorded from the scalp preceding speech which is related to the content of the speech production. The present study extends the initial findings and characterizes ten utterances of similar vocal tract configuration with variations in vowel consonant sequencing. Fifteen individuals consisting of right handed females with a mean age of 23.5 years who were either speech pathology or medical students served as subjects. A scalp electrode was placed over the midline interaural position, C_Z (10-20 International System) and referenced to linked ear lobes. A ground was placed on the right forearm. A differential recording of the EEG amplified 10^6 through a bandpass of 1-500 H_Z was recorded on one channel of a multichannel tape recorder. A second channel recorded a square wave coincident with the onset of voicing, sensed by a microphone placed in front of the mouth. A third and fourth channel were used to record EMG from various facial musclature including obicularis oris, obicularis oculi and masseter muscles. The subject sat in a reclined position with head supported at the neck in a semi-darkened room and maintained visual fixation on a white spot 1.0 meter distant. The subject was instructed to produce an utterance with normal inflection and tone at approximately 1/3 sec for 30 repetitions, following which a rest period was interposed before an additional voicing trial. When 100 repetitions of a word had been obtained a rest period followed, before a new word was attempted. Four or five words were voiced per session. Analysis of the data was undertaken by backward averaging the EEG activity using the voice onset trigger as reference. Sample periods of 200 msec, from 216-590 msec preceding voicing were analyzed by entering averaged waveforms into a microprocessor. Each peak was identified with a latency value such that all positive and negative going waves with a pulse width of 1.0 msec were identified. A second program then compared waveforms for 10 subjects and clustered peaks of identical latency (±1.5 msec) to find periods of common activity.

A temporal activity pattern of 28-44 peaks was defined for each utterance. The pattern for each word was unique, but consistent across subjects and significantly different from peaks generated randomly. Words of similar temporal production 'apple' versus 'apper' had portions of their activity pattern identical over the period 375-525 msec preceding voicing. However, marked differences were apparent in the period 216-300 msec, suggesting that the activity is temporally coded.

141.2 INFLUENCE OF TEMPORAL LOBE LESIONS ON RADIO-TELEMETERED ELECTRICAL ACTIVITY OF AMYGDALA TO SOCIAL AND VISUAL STIMULI IN PRIMATES. A. Kling, K. Sternberger*, V.W. Soo*, T. Willis* and M. Imran*. Departments of Psychiatry and Bioengineering, CMDNJ-Rutgers Medical School, Piscataway, N.J. 08854

Utilizing a chronic electrode in the amygdaloid nucleus electrical activity was recorded from 4 M. mulatta and 1 C. aethiops by radio telemetry during: 1) free-moving behavior, and 2) while restrained in a primate chair and viewing projected slides of varying subject matter. Three subjects were subsequently subjected to bilateral ablations of the temporal pole (TP) and two with lesions of the entire temporal neocortex (TL) and after complete recovery, the same conditions repeated. In each case, the depth electrode and radio-telemetry device was not disturbed by the superimposition of the neocortical lesions.

Following the ablation, all subjects showed varying degrees of tameness and hyperorality and in group setting marked decrements in social interactions. For all TP subjects, a marked reduction in amygdaloid electrical activity in all frequency bands (by Fourier analysis) occurred during all behavioral events. For the two subjects with TL lesions, one was similar to the TP subjects but in the other during solitary behavior showed a marked increase in amygdala activity when compared to its pre-operative recordings.

Analysis of electrical activity to viewing visual stimuli indicated a post-operative reduction in responses to the slides for the TP subjects while the reverse was true for the two TL subjects, namely an increase in the number of slides responded to as well as in the power spectrum.

These results suggest that neocortical inputs to the amygdala from TP are largely facilitating while inputs from the middle and posterior portions of temporal neocortex appear to be also inhibitory, especially with regard to processing of visual stimuli. The behavioral changes observed after temporal neocortical lesions in different social environmental settings may thus be related to alterations of amygdaloid function and processing of visual information.

141.3 AUDITORY BRAINSTEM RESPONSES IN AUTISTIC AND CONTROL CHILDREN. R.M. Edwards, P. Tanguay, J. Schwafel, R. Norman, N. Squires, and J. Buchwald. Depts. of Neuroscience and Psychiatry and Physiology, Brain Research Institute and Mental Retardation Research Center, U.C.L.A., Los Angeles, Calif. 90024.

Early infantile autism is characterized by a severe impairment in the cognition and use of language, although the hearing in these children has been described as normal. We have studied one aspect of language acquisition, the reception and transmission of sound, as a possible source of this language impairment, using an objective measure of function in the auditory brainstem pathway, the auditory brainstem responses (ABRs).

Seventeen autistic children, diagnosed using DSM-III criteria, and 17 age and sex matched children with no known disabilities participated in this study. ABRs to monaurally presented click stimuli of three intensities (45, 60, and 75 dB above normal hearing threshold) and three rates (20, 50, and 100/sec) were recorded from a vertex electrode referenced to the mastoid ipsilateral to the ear stimulated. The latencies from stimulus onset to the 5 vertex positive waves were measured and the central tranmission times for waves I to III, III to V, and I to V were calculated. The data were tested for significant group differences in wave latencies and transmission times between and within the two groups.

The latency and transmission time data were first inspected for outlying values (values ± 4 SD from the control means). Two of the autistic subjects, previously reported to have normal hearing, had a marked prolongation of wave I bilaterally. Their latencies at high intensity stimulation were similar to those for low intensities, consistent with a peripheral hearing loss. Their data were not included in subsequent analyses. Eleven of the remaining fifteen autistics had one or more outlying values which were generally longer than the normal means. None of the controls had outlying data.

Significant group differences were demonstrated in the central tranmission times under certain parametric conditions. The autistic subjects had longer III-V and I-V transmission times, but generally shorter I-III transmission times. While these trends were present in all the parametric data, they became significant with low stimulus intensity and fast rate.

ABRs, thus, indicate differences in the transmission of auditory information in autistic children compared to controls. Peripheral hearing impairments in two autistic children, previously thought to have normal hearing, were demonstrated; and prolonged transmission times of some auditory stimuli were found for the group as a whole.

141.4 COHERENCE SPECTRAL STUDIES ON THE EEG ACTIVITY OF THE AMYGDALA, LIMBIC STRIATUM AND CEREBRAL CORTEX INDUCED BY REPEATED DOSES OF THE AMPHETAMINES. R. J. Morgan, Colorado State Univ., Fort Collins, CO 80521; C. C. Turbes, G. T. Schneider* and J. M. Simard*, Creighton School of Medicine, Omaha, NE 68178.

Recordings are made from cats with chronic electrode implants using hardwire and telemetry techniques. Analog data is collected with an FM tape recorder from the cerebral cortex, septal nuclei, basal-lateral nucleus of the amygdala and the limbic striatum of the brain.

Data are analyzed using a Varian V-72 minicomputer. The discrete time data is transformed using a Fast Fourier Transform (FFT) algorithm. Auto and cross spectral studies show that the first administration of d- and l-amphetamines shows a marked decrease in power at all frequencies investigated. This is most apparent at cortical levels.

With repeated daily administration of d- and l-amphetamine there is an increase in power in the 12 to 16 Hz and the 32 to 50 Hz activity, which never reaches the preamphetamine levels. There is a shift of the 40 Hz rhythm toward 48 Hz. These changes are associated with abnormal behavior.

Coherence functions between two brain areas consider the phase locking of rhythmic activity in terms of power at a given frequency. Coherence spectral estimates made on the EEG activity between the sigmoid gyrus and basolateral amygdala following the first amphetamines decreases the per cent coherence in the 5 to 10 Hz, 12 to 16 Hz and the 32 to 50 Hz activity. In the second and third treatments with the amphetamines there is an increase in the per cent coherence in the 5 to 10 Hz, 12 to 16 Hz, 32 to 50 Hz and the 70 to 100 Hz activity. There is also an increase in per cent coherence between these same brain regions after the second and third doses of d- and l-amphetamine at 180 Hz to 300 Hz. In the 180 Hz to 300 Hz activity, the per cent coherence ranged from 18% to 30% before the amphetamines. During the second and third treatments of d- and l-amphetamines, per cent coherence ranged between 54% and 67% at 180 Hz to 300 Hz. This is during periods of very abnormal non-stereotyped motor and hallucinatory behavior.

141.5 BEHAVIORAL CORRELATES OF SPIKE-WAVE DISCHARGE IN PETIT MAL EPILEPSY. M. M. Orren* and A.F. Mirsky (SPON: A. Siegel). Lab. of Neuropsychology, Boston Univ. Sch. of Med., Boston, MA 02118.

Seven patients with generalized spike-wave discharges in the EEG and clinical absences were tested on a variety of behavioral tasks in order to ascertain their functional capabilities during seizures. All patients or their parents gave their informed consent before participating in this study. Performance on simple motor, stimulus-response and discriminative tasks were monitored simultaneously with six to ten channels of EEG activity recorded from bilaterally placed parasagittal scalp electrodes. Task stimuli included spatially discrete and diffuse visual stimuli, pure tones and, in a few cases, shock to the median nerve. The response required was the same for all tasks. During some of the testing sessions, eye position was also recorded on videotape.

The data of individual patients were considered separately, by task, except where similarity of findings warranted pooling of results. Only seizures with a clear-cut electrographic spike-and-wave or wave-and-spike onset were included. The analysis focused on changes in task responding during successive pre-seizure and seizure segments, defined from the polygraphic record.

The patients varied considerably in their ability to perform a simple motor task during spike-wave activity. Complete arrest of responding, as well as nearly perfect performance were observed, depending on the patient. All patients, however, were significantly impaired during spike-wave discharge when the task involved stimulus-contingent responding, regardless of the modality tested and information content of the stimulus. The degree of impairment and its time course in relation to the spike-wave burst did depend on stimulus modality. Patients were more responsive to auditory and somatosensory than to visual stimuli. Analysis of the videotapes and comparisons of performance to diffuse versus discrete visual stimuli indicated that seizure-related eye movements were not responsible for the relatively poor levels of responding on visual tasks.

The results presented here suggest the complexity and idiosyncratic nature of the petit mal absence attack. During paroxysmal discharge differential, rather than uniform disruption of functional systems is often observed.

141.6 COMPARISON OF DEPTH PROFILES OF SPINDLES AND SPIKE AND WAVE DISCHARGES IN GENERALIZED PENICILLIN EPILEPSY OF THE CAT . M.Avoli*, G. Kostopoulos, P. Gloor and A. Pellegrini*. Dept.Neurology & Neurosurgery, McGill University, MNI, Montréal, Canada, H3A 2B4.

Recent work in our Laboratory has suggested that spike and wave discharges in generalized penicillin epilepsy are generated by the same thalamocortical volleys which normally induce spindles. The cortical response to such thalamocortical volleys appears to assume a spike and wave form when there is a mild increase in cortical excitability.In order to test this hypothesis we compared the potential gradients through the cortical layers of barbiturate spindles and of spikes of spike and wave discharges observed in this model. We used 2 techniques: (a) comparison of epicortical EEG with sequential microelectrode recordings from increasing depths at steps of 200 µm(22 animals) and (b) simultaneous recordings at 8 different depths through a thin film multicontact electrode probe (distances between contacts: 300 µm: Prohaska et al, EEG Journal 1977, vol.42, p.421-422) (12 animals). Data obtained by both techniques were analyzed by visual inspection as well as by computer assisted averaging triggered from peaks of spindles or spikes of the epicortical EEG. The methodological advantages and limitations of the two techniques are complementary. They yielded similar results. Depth profiles of both spindles and spikes of spike and wave discharges showed a polarity reversal within the superficial cortical layers (for spindles, mean: 255 µm, range: 100 to 700 µm; and for spikes, mean: 310 µm, range: 100 to 900 µm) and maximum amplitude at about 0.8 to 1 mm from the cortical surface. The surface negativity mirrored by positivity in the depth was most prominent in spindles while the opposite held for the main phase of the spikes. Exact mirror images were not always observed for spikes, especially when they consisted of more than 2 phases.

142.1 ONTOGENY OF OPIATE RECEPTORS: DIFFERENCES BETWEEN HIGH AND LOW AFFINITY BINDING SITES. An-Zhong Zhang and Gavril W. Pasternak, George C. Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, New York, N.Y. 10021

Previous reports of the ontongeny of opiate receptor binding examined total binding without addressing possible receptor subpopulations. We now report differences in the development of high and low affinity opiate binding in rat brain. Saturation studies over wide concentration ranges, performed simultaneously on young and adult rat brain membranes, were analyzed by Scatchard analysis and expressed as percent of adult levels. While the appearance of total ^{3}H-D-ala^{2}-met^{5}-enkephalinamide binding was quite similar to previous reports, major differences between high and low affinity binding were found. Low affinity binding was relatively constant from day 2 through day 18, ranging from 55% to 62% of adult levels. By contrast, high affinity binding increased dramatically from day 2 (16%) to day 18 (68%; $p<0.002$). Significant differences between levels of high and low affinity binding in 2 day old rats found with a variety of ^{3}H-ligands (morphine, 22% vs 72%; ethylketocyclazocine 26% vs 77%; naltrexone, 27% vs 62%; and dihydromorphine, 23% vs 60%) disappeared by 14 days of age. Morphine's analgesic potency increased almost 2-fold from day 2 (ED_{50}: 56mg/kg) to day 7 (ED_{50}: 30mg/kg) and 40-fold to day 14 (ED_{50}: 1.4mg/kg). The correlation between log ED_{50} and levels of high affinity binding was very good ($r=0.98$). Similarly, β-endorphin (1μg,icv) or D-ala^{2}-met^{5}-enkephalinamide (15 μg, icv) was analgesic in all 14 day old rats tested but in none of the 7 day old animals ($p<0.001$; $p<0.006$, respectively). Unlike analgesia, morphine's depression of respiratory rates were more pronounced in 2 day old rats (ED_{50}: 2.5 mg/kg) than in 14 day old rats (ED_{50}: 9.3 mg/kg). Although the complexity of development precludes definitive conclusions, the apparent association of analgesia with high affinity binding and respiratory effects with low affinity binding is supported by very similar conclusions using the irreversible narcotic antagonist naloxazone (Pasternak et al Science 208 514, 1980). The similar development of high affinity mu, kappa and delta agonist and antagonist binding suggests that they may represent the same site, as previously proposed (Pasternak, Society for Neuroscience, Abstracts, 1980, this volume).

142.2 OPIATE AND DIGITALIS RECEPTOR ASSAYS DISTINGUISH BETWEEN NEUROEXCITANT AND INACTIVE ORGANOCHLORINE INSECTICIDES AND BETWEEN ANESTHETICS AND CONVULSANTS. F. S. LaBella. Dept. of Pharmacol. and Ther., Fac. of Med., Univ. of Manitoba, Winnipeg, Manitoba R3E 0W3.

Unitary theories of general anesthesia do not account for the inactivity or convulsant activity of close structural or isomeric analogs of neurodepressants. Other evidence suggests the existence of specific receptor sites mediating the actions of hydrophobic compounds, both of the neuroexcitant and neurodepressant types. To our knowledge, there does not exist a simple, isolated system that can differentiate between these two types of agents. We found that the specific binding of 3H-naloxone to rat brain tissue in vitro was inhibited in a concentration dependent manner by the excitant organochlorinated insecticides (OCI), by ether (E) and octanol (OCT), and by the convulsant Indoklon (IND), CF3-CH2-OCH2-CF3, and its anesthetic isomer, Isoindoklon (ISO), (CF3)2-CHOCH3. Inhibition of opiate receptor binding was closely related to lipophilicity of the compound, irrespective of its pharmacological action. However, in the presence of 100 mM NaCl the inhibition of naloxone binding by E, OCT, and ISO was greatly potentiated, whereas that by OCI and IND was attenuated. 100 mM KCl was equally effective as NaCl on the action of anesthetics, but the effect of the excitant drugs was, in contrast to NaCl, unaffected by KCl. Specific binding of 3H-ouabain in the absence of Na, was depressed by anesthetics and enhanced by neuroexcitants. In the presence of NaCl, which by itself inhibits ouabain binding to brain, both anesthetics and excitants enhanced ouabain binding. DDE, a non-insecticidal analog of DDT, and the dimethyl derivative of the cyclodiene OCI, lindane, were inactive in the receptor assays. These observations point to a unique isolated system which responds consistently to anesthetic agents as a class and, in a different way, to neuroexcitant compounds. The system appears to act as a reliable in vitro predictor of neuroactivity of hydrophobic chemical compounds. These findings also delineate brain receptors and/or associated membrane moieties as possible specific sites of action of both neuroexcitants and neurodepressants. Furthermore, the critical site of action of both classes of agents may be at the same or closely adjacent functional membrane components. (Supported by the MRC of Canada, the Manitoba Heart Foundation and the Sellers Foundation. The author is an MRC Career Investigator).

142.3 MORPHINE AND OPIATE PEPTIDES: DIFFERENTIAL ACTIONS ON CALCIUM ACTION POTENTIALS. M.A. Werz and R.L. Macdonald. Neurosciences Program and Department of Neurology, University of Michigan, Ann Arbor, MI 48109.

Opiates have been found to depress the release of transmitter from dorsal root ganglion (DRG) neurons (Macdonald and Nelson, et al: Sci 199: 1449, 1978; Mudge, et al: PNAS 76: 526, 1979). Since transmitter release is calcium-dependent, we have studied the effects of opiate compounds on the duration of calcium-dependent action potentials of mouse DRGs grown in primary dissociated cell culture. Furthermore, since recent studies have suggested the existence of multiple opiate receptors and differential physiological functions for morphine and the enkephalins, we have investigated the dose-dependent actions of morphine, leucine-enkephalin (L-Enk) and methionine-enkephalin (M-Enk).

Spinal cords and attached DRG's, from 12.5-14 day old fetal mice, were mechanically dissociated into single cell suspension and grown in culture for three to six weeks prior to electrophysiological study. Action potentials in DRGs have both sodium and calcium components. The calcium component was increased by recording in Tris buffered saline containing the potassium conductance blockers tetraethylammonium (17mM) and 3-aminopyridine (5mM). DRGs were differentiated from spinal cord cells by morphological characteristics. Action potentials were elicited at regular intervals while opiate agonists, naloxone plus opiate agonists, or control buffer were applied by superfusion.

Dose-dependent effects of morphine were observed, with low doses (2.0 μM) decreasing 34% and higher doses (20 μM) increasing (54%) the duration of calcium action potentials. In contrast, L-Enk prolonged calcium action potentials from .6 to 20 μM. Preliminary data with M-Enk suggest that it prolongs at low doses but shortens at higher doses. Both effects, prolongation and shortening of calcium action potentials, were reversed by superfusion with either control buffer or naloxone plus agonist.

Low doses of morphine shortened the duration of calcium action potentials, consistent with depression of transmitter release by opiates. However, high doses of morphine and low doses of enkephalin prolonged the calcium action potential, consistent with a convulsant action (Heyer and Macdonald: Neurology 30: 375, 1980; see abstract Macdonald and Werz). Thus, we have observed dual opiate effects, either prolongation or shortening of calcium action potentials, dependent upon opiate agonist and dose. These data are consistent with neurochemical and behavioral studies suggesting the existence of multiple opiate receptors. Supported by NIH grant NS 15225 and RCDA NS 00408 (R.L.M.).

142.4 CLASSIFICATION OF OPIATES AND OPIOID PEPTIDES ACCORDING TO THEIR AFFINITIES, AGONIST AND ANTAGONIST ACTIVITIES TO MORPHINE AND ENKEPHALIN RECEPTORS. K.-J. Chang*, E. Hazum*, P. Cuatrecasas* (SPON: A.T. Dren) Dept. of Mol. Biol., Wellcome Research Laboratories, RTP, NC 27709.

The binding of many opiates and enkephalins to enkephalin (δ) and morphine (μ) receptors was compared by using three different binding assays; a) ^{125}I-[D-Ala^{2}, D-Leu^{5}]enkephalin, and ^{125}I-[D-Ala^{2}, N-Me-Phe^{4}, Met(O)^{5}ol]enkephalin and b) [^{3}H]ethylketocyclazocine to brain membranes, and c) [^{3}H]diprenorphine and [^{3}H]naloxone to neuroblastoma cell and brain membranes, respectively. According to their relative binding potencies and the effects of Na^{+} and GTP on the binding to these two receptors, opiates and enkephalins can be classified into 7 classes: (1) morphine-type μ agonists; (2) enkephalin-type δ agonists; (3) mixed agonists-antagonists; (4) putative κ agonists; (5) putative σ agonists; (6) nalorphine-type antagonists; and (7) opiate antagonists. Studies with [^{3}H]ethylketocyclazocine do not reveal a specific κ receptor distinct from those already described that bind morphine and enkephalins. The benzomorphan analogs, ketocyclazocine and ethylketocyclazocine (putative κ agonists), and N-allylnormetazocine (putative σ agonist) bind to morphine (μ) and enkephalin (δ) receptors with similarly high affinity. The potency of putative κ agonists, measured by competition of binding of the ^{3}H-labeled antagonist, is greatly reduced by the presence of Na^{+} and GTP, the "Na^{+} and GTP ratios" are similar to those of morphine and enkephalins. However, Na^{+} and GTP greatly reduce the potency of binding of putative σ agonists to enkephalin receptors but only slightly reduce the binding affinity to morphine receptors. These data suggest that putative κ agonists have agonist activity toward both receptors, whereas putative σ agonists behave as agonists for enkephalin receptors while having antagonist activity for morphine receptors. Mixed agonists-antagonists also show smaller difference in affinity to both receptors. These findings may have important implications for understanding the differences in the pharmacological effects of these drugs. A model is hypothesized to explain the complex central pharmacological effects of opiates and opioid peptides.

142.5 CONVULSANT ACTIONS OF OPIATES ON MAMMALIAN NEURONS IN PRIMARY DISSOCIATED CELL CULTURE. R.L. Macdonald and M.A. Werz. Dept. of Neurology and Neurosciences Program, Univ. of Michigan, Ann Arbor, MI 48109.

Opiates have been demonstrated to have convulsant as well as analgesic actions. While specific opiate-induced depression of transmitter release from nociceptive afferents may underlie analgesic effects, the convulsant mechanisms of action remain uncertain. Recent studies have shown that neuronal calcium conductance may be of importance in production of paroxysmal depolarizing shifts (PDS) (Wong and Prince, Science 204:1228, 1979), the intracellular event underlying interictal spikes in the EEG of patients with epilepsy. We have shown that convulsants such as bicuculline and penicillin prolonged calcium-dependent action potentials (Heyer and Macdonald, Neurology 30:375, 1980) of spinal cord (SC) and dorsal root ganglion (DRG) neurons in primary dissociated cell (PDC) culture. Furthermore, we have demonstrated that leucine-enkephalin (L-ENK) and high concentrations of morphine (20 μM) prolonged calcium action potentials while morphine at low concentrations (.6 to 20 μM) shortened calcium action potentials (see abstract, Werz and Macdonald) of neurons in PDC culture. Thus L-ENK and morphine might be expected to be convulsant at concentrations that prolonged calcium action potentials, and we have investigated opiate actions on neuronal activity of mouse spinal cord neurons in PDC culture.

Spinal cords and dorsal root ganglia were mechanically dissociated, plated as a single cell suspension and grown for four to six weeks prior to electrophysiological study. Spontaneous activity was recorded from SC neurons in phosphate buffered saline at 35-37°C.

Morphine had dose-dependent actions on spontaneous activity in SC neurons. Low concentrations (2 μM) had little effect on spontaneous activity but high concentrations (20-50 μM) produced high amplitude paroxysmal depolarizations (paroxysmal depolarizing events (PDE)), an in vitro equivalent of PDS. The PDEs were abolished by naloxone (50 μM). The opiate peptide L-ENK (20 μM) also produced PDEs.

Thus, we have demonstrated that opiates have dose-dependent and naloxone reversible convulsant actions on mouse SC neurons in PDC culture at concentrations that prolong calcium action potentials. Since these opposing opiate actions on calcium conductance are dependent upon opiate agonist and dose (see abstract, Werz and Macdonald), it is likely that their convulsant and analgesic actions are mediated by pharmacologically distinct receptors. Supported by NIH grant NS 15225 and RCDA NS 00408 (R.L.M.).

142.6 COMPARATIVE STUDIES OF [^{3}H]-5-HYDROXYTRYPTAMINE BINDING IN MEMBRANE PREPARATIONS OF RAT BRAIN AND RAT GUT. J. A. Heltzel and W. H. Vogel, Dept. Pharmacology, Thomas Jefferson University, Philadelphia, PA. 19107.

The specific binding of [^{3}H]-5-hydroxytryptamine (5HT) was measured in crude homogenates of whole rat brain minus cerebellum using a modification of the method outlined by Bennett and Snyder (1976). Homogenates of rat gut were prepared from strips of longitudinal intestinal muscle with attached myenteric plexus, as described by Creese and Snyder (1975). For brain and gut binding studies, the preparation consisted of a washed 50,000 x G pellet, using a tissue concentration of 40 mg/ml 50 mM TRIS·HCl containing 5 mM $CaCl_2$, pH 7.4.

In rat brain, 5HT binding met the following criteria: ligand saturability, tissue linearity, reversibility, rapid equilibration, and temperature dependence. Specific 5HT binding was evaluated using 10 μM unlabelled 5HT as a blank for nonspecific binding. Scatchard analysis in rat brain yielded an equilibrium dissociation constant (K_D) of 2.1 nM and the apparent number of binding sites (B_{max}) was 17.4 pmol/gram wet weight.

In rat gut, however, there were notable differences. Saturation of ligand binding could not be demonstrated up to a concentration of 40 nM [^{3}H]-5HT. The binding equilibrium was approached gradually, reaching completion by two hours. Once equilibrium was reached, the binding was slowly dissociable. Increasing tissue concentrations produced enhanced 5HT binding, but the relation was not strictly linear. Specific 5HT binding was measured using 0.5 μM unlabelled 5HT as the nonspecific binding blank. Under these conditions, Scatchard analysis in rat gut gave values for K_D = 4.0 nM and B_{max} = 13.6 pmol/gram wet weight.

Displacement of 5HT binding employed the serotonin agonists, tryptamine (TA) and 5-methoxytryptamine (5MT), and the serotonin antagonists, methysergide (MS) and N,N-diethyltryptamine (DET). Preliminary data suggest that the rank order of displacing potencies shows good agreement between gut and brain, although TA, MS, and DET are two orders of magnitude more potent in brain.

	IC_{50} Brain	IC_{50} Gut
TA	3×10^{-6} M	8×10^{-4} M
5MT	2×10^{-7} M	4×10^{-7} M
MS	3×10^{-7} M	2×10^{-5} M
DET	4×10^{-6} M	$> 1 \times 10^{-4}$ M

147.1 ORGANIZATION OF VISUOSPATIAL FUNCTIONS IN HUMAN NON-DOMINANT CORTEX: EVIDENCE FROM ELECTRICAL STIMULATION. G. Ojemann, I Fried*+, C. Mateer*, R. Wohns* and P. Fedio*#. Dept. Neurol. Surg., Univ. of Washington, Seattle, WA 98195.

Cortical localization of several visuospatial functions was assessed with the electrical stimulation mapping technique at 5-9 sites in the right, nondominant hemisphere of 10 patients undergoing craniotomies under local anesthesia for treatment of medically intractible epilepsy. Visuospatial functions measured include perception and memory for faces and angles, and emotional labeling of faces.

Perception of faces or angles was measured in all cases. Repetitive errors were evoked in 4 of 69 sampled sites, in 4 patients. These sites were at the parieto-occipital junction, except for one in inferior premotor frontal cortex. Post-distractional short-term memory for angles was measured in 5 cases; for faces in 2. Significant errors occured at 12 of 36 sites sampled for angle memory and 6 of 12 samples for face memory, at least one site in each patient. All but 2 of these sites are in posterior superior temporal gyrus or adjacent supra-marginal gyrus. With two exceptions, only stimulation during either input, or storage, or output phase of memory altered performance at a given site; sites where performance on one phase of the memory test was altered in different patients cluster together. When memory for both faces and angles was measured in the same patient, sites where this was altered overlap. Emotional labeling of face was measured at 56 sites in 8 patients. Significant alterations were evoked at 6 sites in 4 patients, all these sites are in posterior middle temporal gyrus. Facial recognition was intact at these sites: the stimulation effect was an alteration in the label usually used by that patient for the emotion portrayed by that face, but without any consistent emotional bias in the type of alteration. In each individual patient, changes in these different spatial functions were evoked from different cortical sites. No site showed evoked changes in more than one function, although changes in the same function (memory) occured at the same site with different spatial inputs (faces vs. angles). There is discrete localization of these visuospatial functions in the non-dominant hemisphere. That localization is at least as discrete, and perhaps with even less individual variability than is seen for language in dominant hemisphere.

147.2 PATTERN REPRODUCTION AND POSTERIOR PARIETAL LESIONS IN THE MONKEY. Henry V. Soper, Edward H. Yeterian*, and William A. Wilson, Jr. Department of Psychology, University of Connecticut, Storrs, Connecticut 06268.

The integrity of the posterior parietal cortex is generally thought to be essential for normal processing of spatial information, but the deficits which have been observed may not reflect a simple inability to determine spatial relationships between objects. If, as in the human Balint's syndrome, parietal monkeys fixate on a focus, neglecting all peripheral information, there may be no deficit in appreciating spatial information per se. The present study was designed to determine if the posterior parietal cortex is involved in the ability to appreciate spatial relationships between objects, or if it is more likely that animals with this area removed tend to fixate more on a focus, possibly neglecting information away from the focus.

Six monkeys (Macaca mulatta) were presented with a 5 X 5 matrix of possible reward locations, one or two correct locations being illuminated during the cue presentation interval. Responding to a location illuminated it, and correct responses reproduced the cue pattern. The animals, initially experimentally naive, were tested until each had reached an asymptote in performance. Then they were divided into three equal groups. The animals in the posterior parietal group received lesions of the inferior parietal lobule, dorsal prestriate cortex, and the precuneal gyrus. One control group received lesions of the inferotemporal cortex, whereas the other received no lesions. The animals were tested for 100 sessions with no delay between the cue and response presentations. Then for 100 sessions a 2-sec delay was interposed, followed by 40 sessions with a 4-sec delay.

There was no difference between the groups on the 0-sec delay task, but introducing a 2-sec delay impaired the performance of the control groups much more than of the parietal one ($F's_{(2,3)}$ 13.1, 23.2, p's .05, .025 for the first and second 20-session blocks respectively). When the 4-sec delay was imposed the parietal performance was essentially unchanged, while the performance level of the other animals declined.

The results clearly demonstrate no impairment in processing spatial information per se following the removal of the posterior parietal cortex. These results do suggest that the parietal animals tend to fixate more on the focus of attention -- the reward locations -- than normal. The visual fixation appears to reflect that found in Balint's syndrome in humans with similar damage.

147.3 CUTANEOUS DELAYED RESPONDING AND OTHER BEHAVIORS AFTER PREFRONTAL CORTICAL ABLATIONS IN CATS. R.B. Glassman, D.E. Cook*, and H.N. Glassman*. Dept. Psychol., Lake Forest College, Lake Forest, IL 60045.

Frontal damage causes deficits in delayed responding and other behaviors in various testing situations, usually involving visual stimuli. We report similar deficits in four frontally damaged cats trained to discriminate cutaneous cues.

The blindfolded cat, remaining on a small pedestal, was trained for food reward to stand on its hindlegs (up-response) when stroked on the upper lateral surface of either forelimb and to reach down below the pedestal surface with its mouth (down-response) when tapped in the same place (Physiol. Behav., 1977). Cats were then trained to delay discriminative responses for five seconds, while blocked by plates moved into position above the head and below the chin.

The following behaviors were seen after bilateral ablation of gyrus proreus: 1. Deficit in nondelay performance for 1-4 sessions; 2. During the same sessions, reluctance to complete up-responses to the learned cue, but performance of the same responses briskly and reliably to tactile stimuli to the head eliciting pursuit; 3. Early postoperative disorientation - stepping off pedestal and pacing, turning on pedestal, striking reflexly at the tactile cue, frequent meowing, remaining in up-response position with forepaws on top restraining plate; 4. After recovery from 1-3, deficit in delayed responding (near random level), associated with failure to maintain preparatory position during delay, gradually recovering to near normal over ten sessions. Two of the cats received ablation in stages; after the first, deficits were symmetrical and milder than after bilateral loss. Deficits were not usually seen in cutaneous, auditory, or visual orientation-localization, in movement, or in food motivation; however there was early postoperative reluctance to perform in a food retrieval test of forelimb motor control. Late postoperative nondelay testing with stimuli applied for the first time to the hindleg, revealed transfer as excellent as in normal cats.

Most of the findings fit the interpretation that proreal damage caused neither a sensory nor motor deficit, but a deficit in learned sensory-motor associations. Regional knowledge of response properties of single neurons helps to explain somesthetic or motor deficits seen after localized cortical damage. It is much more difficult to theorize about the microscopic neural phenomena that underlie the sensory-motor behavioral "connections" that were disturbed in the present experiment.

147.4 SOMATOSENSORY INVOLVEMENT IN VISUAL NEGLECT. Robert Sinclair*, Simon Horenstein, and Arthur Toga*. Departments of Neurology and Psychology, Saint Louis University, Saint Louis, Missouri 63104.

Ablation of somatosensory areas II (SII) in the cat did not produce modification of a visually dependent learned task. As previously reported, ablation of auditory cortex in posterior ectosylvian gyrus (Ep) modified preference to double simultaneous visual stimulation (DSS) without affecting lateral preference to unilateral stimulation. Clinical cases of sensory neglect are usually trimodal. Somesthetic stimulation elicits visual orienting responses, and in the major sensory areas association fibers reciprocally connect all known subdivisions. This suggests that lesions of somatosensory cortex might also produce visual neglect.

A common corticocortical projection point (Vss) between auditory Ep and visual cortex exists in mid suprasylvian gyrus. SII does not demonstrate a similar connection with visual cortex. It does project to somatosensory area I (SI) as well as to part of auditory area I (AI), and has thalamic connections similar to the visual system. A third auditory area which is described in the upper and anterior portions of the ectosylvian gyrus (SIIA) exhibits overlap of auditory and somatosensory evoked responses.

The organization of the somatosensory system exhibits many similarities to the auditory and visual systems with the exception of visual-auditory projections to Vss. The purpose of the present study was to determine whether damage to SII results in visual neglect. This might indicate the degree of significance of lesions of Vss in causing sensory neglect.

Three cats were appetitively conditioned in a specially designed "Y" maze (Toga, A.W. et al., Psychological Reports, 40:1071-4, 1977) equipped for multiple modalities of stimulation. On unilateral stimulation animals were required to move into the sole lighted arm of the maze and on DSS to move into either of two in order to obtain food reward delivered from an identical feeding cups at the end of each. Each animal established its own lateralization pattern to DSS. Response to unilateral stimulation was usually appropriate to the side stimulated. After training, subpial resection of SII in the anterior ectosylvian gyrus was performed and animals tested from the 1st to 10th postoperative days. After intracardiac saline-formalin perfusion, brains were removed for anatomic study. Lesions imposed no apparent postural bias. There was no statistically significant effect on visually dependent discrimination.

Results suggest visual-auditory projections to Vss represent a unique relationship between these primary sensory areas. While Vss lesions may produce somesthetic neglect, subcortical connections alone may be responsible for the somesthetic involvement in trimodal neglect following parietal lobe damage in human cases.

147.5 ENVIRONMENTAL CONSTRAINTS ON THE MOTOR ABILITIES OF DENEOCORTICATE RATS. I.Q.Whishaw, A.J.Nonneman and B. Kolb. Department of Psychology, University of Lethbridge, Lethbridge, Alberta, Canada, T1K 3M4.

The motor abilities of deneocorticate (all neocortex removed) rats have been subjected to careful analysis in a number of recent studies. Prominent among the rat's chronic disabilities are: 1. Lack of forepaw inhibition during swimming, 2. Inability to chain together long sequences of grooming behavior, and 4. Reduced exploratory activity in an open field.

In the present study we reexamined the motor abilities of deneocorticate rats, and in addition, we varied the environmental condition under which the tests and observations were made. Performance varied markedly with test conditions.

In swimming tests deneocorticates swam ineffectively and showed no forepaw inhibition in warm water (37.5°C), but swam more vigorously than control rats and also showed forepaw inhibition in cold water (18°C).

Deneocorticates failed to sit up and manipulate food when given large (4 gm) pieces of food, but they ate small pieces of food in the normal way. Unlike controls, however, they had difficulty holding on to, and chewing, small food pellets.

When the grooming of deneocorticate rats was scored when they were wet and in a novel environment they were profoundly impaired. When grooming was scored when the rats were dry and in their home cage, grooming sequences approximated those of normal rats. However, deneocorticates still neglected the caudal part of their body more than control rats.

When activity tests were given in a lighted open field, deneocorticate rats were less active than control rats. When the tests were given in the dark they were more active than control rats and left the walls of the open field more than control rats.

Environmental conditions also placed constraints on many other behaviors including drinking water, eye blinking, righting responses, and motor activity in activity wheels.

The results show that the motor behavior of deneocorticate rats is more subject to environmental variation than is true for normal rats. This suggests that a general function of the neocortex is to release an animal from environmental constraints, and give it more control of its motor activity in widely divergent environmental conditions.

147.6 RELATIONSHIP BETWEEN BEHAVIORAL CORRELATES OF UNIT ACTIVITY IN THE ANTEROMEDIAL CORTEX AND THALAMUS IN THE RAT. T. L. Martin and H. M. Sinnamon, Laboratory of Neuropsychology, Wesleyan University, Middletown, CT 06457.

Previous work in this laboratory (Kanki et al, Neurosci. Abst. 5:276, 1979) had identified a population of neurons in the anteromedial cortex of the unrestrained rat which possibly code rewarding and aversive motivational properties of various stimuli by decreases and increases in activity, respectively. The activity of these cells decreased during rewarding brain stimulation, drinking saccharin, and sniffing-exploration; activity increased during withdrawal from various objects and often after removal of a drinking tube. The purposes of this study were first, to further describe this class of cells by testing them with wider range of aversive stimuli, and second, to determine whether the thalamus also showed this biphasic pattern.

Water deprived rats were presented with various stimuli: drinking tubes containing .1% saccharin, 50% condensed sweetened milk, 10% quinine or nothing; scent-marked Petri dishes; a conspecific of opposite sex; tactile probing of face and body; a startling click; a black-white grid moving in the visual fields; an aversive odor; aversive prodding by means of a metal rod; and repetitive bright flashes from an overhead strobe. Unit activity was recorded differentially through a pair of 25 µm stainless steel wires lowered in a bundle of four wires by means of a chronically implanted microdrive.

So far, 34 thalamic recording sites in and around the dorsomedial (DM) nucleus have been tested. Within the medial part of DM activity in 13 sites was correlated with head movements (n=9), visual stimulation (n=1), orienting (n=1), or tactile stimulation of the snout (n=1); activity in one site had no observable relation to behavior. Of the 9 sites tested in the lateral DM, increases in activity were associated with head movement (n=5), locomotion (n=1), or forepaw movement (n=1); two sites had no detectable correlate with behavior. The activity of 8 sites in the nucleus parafasicularis (PF), was correlated with tactile stimulation of the vibrissae (n=4), sniffing (n=1), movement of the forepaw (n=1), or head movement (n=1); the activity of one unit could not be related to behavior. Two cells within the anterior thalamic complex demonstrated increases in unit activity during the presentation of aversive stimuli, while another was sensitive to the animal's place within the testing chamber. One site in the posteromedial nucleus was associated with mouth movements. These preliminary results suggest that the DM is less likely to be involved in the coding of motivational properties that it is with the processing of head movement information.

147.7 Unilateral Thalamic Damage and Motor Behavior of Rhesus Monkeys R. K. Deuel and T. W. Anderson.* Departments of Pediatrics and Neurology, Washington University School of Medicine, St. Louis, MO 63110.

In primates, bilateral destruction of thalamic nuclei, notably medialis dorsalis (nMD), has been reported to cause behavioral deficits that are known to follow removal of specific frontal cortical grey sectors. To test whether unilateral nMD lesions result in hemineglect and other behavioral symptoms that follow unilateral frontal cortical damage, we implanted yttrium-90 pellets unilaterally in five mature (4.0-5.3 K) naive rhesus monkeys, using Olszewski's stereotoxic atlas as a guide.

On standardized, scored neurological exams given at intervals from 20 - 1,184 days postoperatively, preference for the hand ipsilateral to the lesion (I hand) was found, with impaired dexterity of the hand contralateral to the lesion (C hand). These deficits were stable over at least two years, and even worsened in two animals. Mild somatosensory, but no visual field, deficits were found. Postoperative learning of a contingent arm and hand response by the C limb was normal, whereas there was severe impairment in learning a motor response with C fingers.

Histological verification of the lesion revealed destruction of nMD in all animals, with marked additional nuclear destruction that varied among animals. The internal capsule was invaded in two animals.

Unilateral nMD lesions result in deficits in fine motor learning and performance, but not visual field deficits. Spontaneous recovery, such as occurs after frontal cortical lesions, was not observed. Rather, motor deficits were unchanged even after prolonged training of the affected limb.

147.8 IMPAIRED HEAT STRESS-INDUCED SALIVA SECRETION IN VMH LESIONED RATS. F. W. Flynn*, L.A. Evey* and J.C. Mitchell. Dept. of Psychology, Kansas State University, Manhattan, Ks. 66502.

A previous study demonstrated that ventromedial hypothalamic (VMH) lesions reduce basal saliva secretion in rats (Flynn et al., Physio. Behav., 1980, 24, 451-455). The present study examined the salivary response of "static" VMH and control rats to heat stress. Saliva secretion of five control and five VMH rats was observed at four different ambient temperature settings: 26° (room temperature), 31°, 36°, and 41°C. Rats were exposed to a temperature setting for 30 min and then saliva secretion was measured. Salivation was measured by inserting a preweighed cotton swab into the rat's mouth and holding it there for 1 min. The swab was then reweighed to determine the amount, by weight, of saliva secreted. Rats were adapted to this procedure prior to the heat stress tests. Body temperature was measured rectally following 30 min exposure to a temperature setting.

Rats with lesions of the VMH displayed less saliva secretion and lower body temperature than controls. VMH rats required both a higher ambient temperature and a higher body temperature than controls for saliva secretion to increase significantly.

While VMH lesioned rats appeared to have no gross impairment of a heat loss mechanism, the lesions did alter the initiation and amount of saliva secreted. These changes in saliva secretion indicate that the lesions interfere with autonomic control of the salivary glands.

There is conflicting literature on temperature regulation by VMH rats. Our observation of hypothermia is consistent with Han (Am. J. Physiol., 1968, 215, 1343) but conflicts with Mayer and Greenberg (Am. J. Physiol., 1953, 173, 523) who reported hyperthermia in VMH rats at room temperature. However, Mayer and Greenberg reported that when exposed to 40°C, VMH rats had lower body temperature than controls. The reason for the conflicting reports of temperature regulation by VMH rats is not immediately apparent.

147.9 HIPPOCAMPAL SUPERSTITION: A CASE OF CA-MEDIATED STEREOTYPY. L. D. Devenport, J. A. Devenport* and F. A. Holloway. Dept. Psychiat. & Behav. Sci., U. Okla. Health Sci. Ctr., Oklahoma City, OK 73190.

Rats are quite resistant to the development of superstitious behavior, but this resistance is lost after bilateral lesions of the hippocampus are made (Devenport, Science 205:721, 1979). Subsequent analysis has revealed that although adventitious response-reinforcer conjunctions definitely contribute to the response topographies observed (Devenport, Behav. Neur. Biol., in press), hippocampal superstition is primarily a condition of relative behavioral invariance which is exacerbated by the non-contingent delivery of reinforcers (Devenport & Holloway, J. Comp. Physiol. Psychol, in press).

Perhaps the hippocampus opposes the action of dopaminergic (DA) systems involved in the production of behavioral stereotypy. The shift toward DA dominance following hippocampal lesions would be further potentiated by noncontingent reinforcement (Fouriezos et al., J. Comp. Physiol. Psychol. 92:661, 1978). This possibility was tested in two ways.

In one, sham- and hippocampal-lesioned rats were maintained in clear plastic cages where activity was automatically monitored. Stereotypy (0-6 scale) was rated "blindly" across days of free-feeding, total deprivation, and daily refeeding (an amount sufficient to maintain body weights at 80%). Groups did not differ significantly during free-feeding, but deprivation, and most especially, scheduled refeeding strongly boosted the activity and stereotypy scores for hippocampals. Shams showed only slight increases. When stable, stereotypy scores taken 1 hr. before refeeding were about 3.3 for hippocampals, 0.5 for shams. Administration of haloperidol (0.1 mg/kg, s.c.) to hippocampals reversed their activity and stereotypy to the sham level. Administration of d-amphetamine (2 mg/kg, i.p.) to shams was sufficient, in combination with the refeeding regimen, to elevate their respective scores to undrugged hippocampal levels.

In the second experiment, hippocampals and shams were tested in operant chambers under an interval schedule of pellet delivery. Some were trained to lever press, others received pellets noncontingently. Noncontingently-maintained hippocampals developed robust superstitious behavior but other groups did not. Haloperidol administered to hippocampals eliminated all evidence of superstition but affected contingently-maintained performance only moderately. D-amphetamine had opposite symmetrical effects in shams.

Our evidence suggests that the hippocampus opposes catecholamine-mediated stereotypy, superstition being a particular instance.

147.10 EFFECTS OF SEPTAL AND HIPPOCAMPAL LESIONS ON PERFORMANCE OF A SHOCK ESCAPE TASK. Sarah E. De Rossett* and William G. Drew*. (SPON: Ralph E. Miller). Behav. Neurophys. Lab., Dept. of Psych., Univ. of Ky. Col. of Med., Lexington, Ky. 40536

In an attempt to distinguish between the behavioral effects of septal and hippocampal lesions, young adult male Long-Evans hooded rats were given either septal or hippocampal lesions, allowed to recover, and then tested twenty days post-operative on performance of a shock escape task previously shown to be sensitive to the effects of septal, but not hippocampal, lesioning. Individual animals were placed in standard operant conditioning chambers and 90 sec later, a 1.5 mA scrambled footshock was delivered to the cage floor. Shock was terminated when the animal pressed one of two bars present within the chamber. Daily sessions consisted of ten trials. Behavioral measures included: (1) total number of bar presses made during the session, (2) number of times shock onset occurred while the animal had the bar depressed, (3) total amount of time during the session in which the bar was depressed, and (4) the latency with which the animal terminated the shock. Testing was conducted for five days, after which the animals were tested on the reversal of the task (i.e. the other bar present within the chamber functioned to terminate shock). Subsequent to behavioral testing, all animals were sacrificed and lesion sizes were determined.

Repeated measures analysis of variance revealed that septal, hippocampal, and sham-operated controls all learned to terminate the shock during both phases of testing, increasing their efficiency in doing so over sessions. No significant treatment effect was seen. The total number of bar presses made during each session did not differ between any of the groups during either phase of testing. The number of times the animal had the bar depressed when shock onset occurred increased across the five days of initial testing, while remaining relatively constant during the reversal. No significant differences existed between the groups, however, during either phase. Total bar time increased across days for all the groups during the first phase of testing, remaining relatively unchanged during the reversal. No significant differences existed between any of the groups during either phase. Thus, none of these measures differentiated the groups.

The fact that animals with hippocampal lesions perform this task comparably to controls corroborates previous unpublished findings. The demonstration that septal animals improve their performance across sessions, however, stands in marked contrast to previous work by Gotsick et al. (Phys. Behav. 6:199, 1971). These data suggest that strain and age differences, post-operative recovery time, as well as contextual cues may be responsible for the discrepancy.

147.11 FUNCTIONAL MAPPING OF HYPOTHALAMIC PATHWAYS ELICITING AGGRESSION AND ESCAPE BEHAVIOR IN THE CAT: A RADIOAUTOGRAPHIC STUDY. S. Fuchs, A. Siegel, and H. Edinger. Depts. of Physiology and Neurosciences, College of Medicine & Dentistry of N.J.--N.J. Medical School, Newark, New Jersey, 07103.

This study was designed to identify the efferent pathways associated with quiet biting attack, affective defense, and escape behavior in the cat. Behavioral responses noted above were elicited from the hypothalamus subsequent to electrical stimulation utilizing moveable electrodes which were advanced through guide tubes anchored to the skull. Under anesthesia, the electrode was removed and replaced with a Hamilton syringe which was lowered to the exact position previously occupied by the electrode. An injection of 0.2 µl ^{3}H-leucine was then placed into the site of the electrode tip. Following survival times of 1-4 days, animals were sacrificed and the brain tissue prepared for autoradiography.

Following injections placed into the anterior lateral hypothalamus and associated with quiet biting attack, labeled axons and terminals were traced to the dorsal septum, diagonal band, preoptic area, supramammillary region, ventral tegmental area, midline thalamus, and lateral habenular nucleus. Labeled axons arising from affective display sites situated in the ventromedial nucleus were traced principally in a rostral direction and terminated in greatest quantities in the bed nucleus of the stria terminalis and medial preoptic area. Fiber pathways associated with affective display and which project as far caudally as the midbrain central gray and ventral tegmentum appear to arise from the borderline region of anterior medial hypothalamus and preoptic area. Fibers associated with flight behavior seem to arise from the dorsomedial hypothalamus and have widespread projections to the substantia innominata, preoptic area, diagonal band, medial amygdaloid nucleus, supramammillary region, central gray and central and ventral tegmental fields. Additional studies currently under investigation utilizing ^{14}C-2-deoxyglucose tracing method have appeared to replicate the findings reported above. For example, stimulation of affective display points in the ventromedial nucleus results in subsequent activation of the anterior medial hypothalamus, medial preoptic area, bed nucleus of stria terminalis, but not of any structures caudal to the site of stimulation.

147.12 **EFFECTS OF STRIA TERMINALIS AND AMYGDALOID LESIONS ON SEX AND AGGRESSION OF MALE GOLDEN HAMSTERS.** **Mike S. Perkins*, Mary N. Perkins and B.N. Bunnell. Department of Psychology, University of Georgia, Athens, GA 30602**

Since corticomedial amygdaloid (CMA) and stria terminalis (ST) lesions produce ejaculatory deficits in rats, the effects of such lesions were examined in hamsters. Adult male hamsters were given 4 Preop sexual satiation tests. Hormonally treated ovariectomized lures were introduced to males adapted to an arena. Two pairings with submissive male hamsters were given in which test and stimulus animals had access to their home cages and a neutral area. Bilateral radiofrequncy lesions were placed in the ST, amygdaloid-hippocampal area (AHA) or both the CMA and AHA (CMA-AHA). Electrodes were lowered into the brain for sham operations (Sham) but current was not applied. Two social tests were conducted between Postop satiation tests given on days 3 and 10. Relative to the last 2 Preop tests, Sham and ST lesions failed to affect ejaculation frequency (EF). Increases in EF following

Group	n	Mean Ejaculation Frequency				Aggres. Resp.	
		Preop 3 & 4	Postop 1 & 2	Preop High	Postop High	Preop	Postop
Sham	5	11.4	11.8	14.6	13.6	47	26
ST	5	12.9	13.1	15.8	15.0	41	0
AHA	3	12.2	17.0	14.0	20.7	45	26
CMA-AHA	4	14.1	17.1	15.0	19.8	44	7

amygdaloid (AMYG) damage (AHA plus CMA-AHA groups) were especially pronounced during one of the two Postop tests despite substantial declines in female receptivity with increased EF. Comparison of Preop and Postop tests having highest EF dramatically illustrates increased EF following AMYG damage. Despite changes in EF, there were decrements in achieving individual ejaculations. Ejaculatory latencies increased during the middle of tests after AHA lesions and during the middle and later components following CMA-AHA lesions. Intromissions with thrusting (tI) typically occur toward the end of tests, but the percentage of ejaculatory series having tI increased markedly after AMYG damage (Preop=11%, Postop=49%). All groups showed Postop reductions in mean aggressive responses but decreases were similar in Sham and AHA lesion groups. ST lesions abolished aggression whereas CMA-AHA lesions caused a substantial decline. In summary, AMYG damage either facilitated or attenuated mating depending on the behavioral measure. ST lesions did not affect copulation but abolished aggression. Affects of AMYG damage on aggression depended on lesion placement. Finally, the AMYG and ST may have different roles in controlling sexual behavior of rats and hamsters.

147.13 EFFECTS OF ELECTROLYTIC AND KAINIC ACID SEPTAL LESIONS ON HYPERREACTIVITY AND PENTOBARBITAL NARCOSIS. S.M.Simasko*, P.W.Kalivas* and A.Horita*(SPON:R.M.Quock). Dept. of Pharmacology and Dept. of Psychiatry and Behavioral Science, School of Medicine, University of Washington, Seattle,WA 98195.

Electrolytic septal lesions have been shown to cause a hyperreactivity syndrome (Albert and Richmond,Physiol.Behav. 15:339-347,1975) and a prolongation of pentobarbital narcosis (Harvey,et.al.,J.Pharmacol.Exp.Ther.144:24-36,1964).Electrolytic lesions destroy both cell bodies and passing fiber tracts thus preventing identification of the cells responsible for the resulting effects.Kainic acid has been shown to selectively destroy neurons receiving glutaminergic input while preserving the majority of passing fibers (Herndon and Coyle, Science 198:71-72,1977). To determine wether the effects of electrolytic septal lesions are caused by cell body or fiber tract destruction we have investigated the effects of kainic acid induced septal lesions. Male S.D. rats (280-330) were given kainic acid lesions (0.5µg/1µl/20min.) or radiofrequency electrolytic lesions (10 mamps/30sec) of the septum. Two control groups received intraseptal saline (1µl/20min) or bilateral intraventricular kainic acid (0.25µg/0.5µl/10min/hemisphere). All lesions were histologically verified after the experiment. All rats were tested 3 days prior to surgery for hyperreactivity (a standard test of poking,tapping,etc. with reactivity of response rated by an observer blind to the treatment of animal),and on days 3,7,and 10 post surgery. Animals with electrolytic and kainic acid septal lesions were significantly more reactive than both control groups on day 3 post-surgery. Hyperreactivity decreased to control levels by day 10. Following the last hyperreactivity test the rats were given I.P. injections of 45 mg/kg pentobarbital. Loss of righting reflex and narcosis duration were measured. Time to loss of righting reflex took greater than 5 minutes in 67% of animals receiving intraseptal kainic acid while less than 30% of the control and electrolytic lesioned animals required more than 5 minutes. Narcosis duration was greater than 150 minutes in 100% of electrolytic lesioned animals. In contrast, narcosis duration was less than 150 minutes in all other treatment groups. These results suggest that septal lesion hyperreactivity is mediated by neurons originating in the septum. Prolongation of pentobarbital narcosis by electrolytic lesions require destruction of non-kainic acid sensitive neurons or involves fiber tracts passing through the septum.

147.14 FUNCTIONAL CORRELATES OF THE AMYGDALA AND ASSOCIATED STRUCTURES IN THE RAT BRAIN: A ^{14}C-2-DEOXYGLUCOSE ANALYSIS. Robert E. Watson, Jr., Allan Siegel, Henry Edinger, Jennifer J. Poulakos,* Raymond Troiano* and Saul Weiner*. Depts. of Physiology and Neuroscience, N.J. Medical School, Newark, N.J. 07103.

In an attempt to further characterize the nature of the functional organization of the amygdala, patterns of uptake of ^{14}C-2-deoxyglucose (2DG) were assessed following electrical stimulation of various sites within the amygdala and associated structures in the rat. The experimental paradigm consisted of electrical brain stimulation delivered continously for periods of 30 sec on and 30 sec off for 45 minutes following injection of 2DG. Brains were removed and processed for autoradiography.

It was noted that a specificity existed regarding nuclei, which when stimulated, resulted in metabolic activation of the hypothalamus. Amygdaloid and related structures producing such activation included the medial, basomedial and cortical nuclei and the medial entorhinal cortex and bed nucleus of the stria terminalis. These nuclei differentially activated regions of the hypothalamus. Stimulation of the basomedial amygdaloid nucleus resulted in an activation pattern restricted more to the lateral hypothalamus while stimulation of the cortical and medial amygdaloid nuclei activated medial hypothalamus. Stimulation of the bed nucleus of the stria terminalis resulted in a more homogeneous distribution of label over both lateral and medial hypothalamic areas.

The overall patterns of subcortical activation following stimulation of these structures were similar. In these instances, label was noted in the stria terminalis, the bed nucleus of the stria terminalis, medial aspect of nucleus accumbens, lateral aspect of the lateral septal nucleus and substantia innominata. All amygdaloid nuclei were labeled over at least a portion of their rostro-caudal extent.

In contrast, stimulation of the lateral, basolateral, central and anterior amygdaloid groups as well as pyriform or lateral entorhinal cortices did not result in demonstrable metabolic activation of any area of hypothalamus. Stimulation of those amygdaloid nuclei which did not produce hypothalamic activation generally resulted in labeling of the substantia innominata and bed nucleus of the stria terminalis, with the exception of the anterior amygdaloid area which failed to label the bed nucleus.

Two important conclusions resulting from this work include: 1) electrical stimulation of only the medial, basomedial and cortical amygdaloid nuclei result in metabolic activation of the hypothalamus, and 2) a prevalent activation of nucleus accumbens and substantia innominata was noted following electrical stimulation of most amygdaloid nuclei. (Supported by NIH Grant NS 07941-11.)

147.15 ACUTE HYPERKINESIA AND GASTRIC ULCERATION INDUCED BY HYPOTHALAMIC LESIONS: EFFECTS OF DRUGS AFFECTING CATECHOLAMINE SYSTEMS. J.N. Nobrega and N.I. Wiener. Psychology Department, York University, Downsview, Ontario, M3J 1P3, Canada.

Hypothalamic lesions can induce a number of autonomic and behavioral effects in the first 24 hr post-surgery, including pronounced motor hyperactivity and stomach ulceration. Two series of experiments were conducted to investigate the possible involvement of norepinephrine and dopamine systems in the acute gastric and motor effects of hypothalamic lesions. Rats received anodal electrolytic lesions (1 mA/ 30 sec) in the medial hypothalamus followed 1 1/2 hr later by s.c. injections of drug or vehicle solutions. Total motility scores (stabilimeter counts) were recorded at 6 and 24 hr after the lesion. Stomachs were examined for ulcers 24 hr after the brain lesion.

In the first series of experiments, chlorpromazine (3, 10, 30 mg/kg) and haloperidol (1, 4.5, 9 mg/kg) significantly attenuated lesion-induced hyperactivity. Clozapine (3, 12, 18 mg/kg), phentolamine (3, 12, 36 mg/kg) and propranolol (3, 12, 36 mg/kg) had less pronounced effects on lesion-induced hyperactivity. Chlorpromazine and haloperidol significantly reduced lesion-induced ulceration. Phentolamine aggravated lesion-induced ulceration, while clozapine and propranolol had inconsistent effects across the doses tested. The combination of phentolamine + propranolol (12 mg/kg of each) induced a several-fold increase in the number and total length of lesion-induced ulceration.

In a second series of experiments, post-lesion injections of amphetamine (2, 6, 12 mg/kg) and apomorphine (1, 5, 15 mg/kg) induced qualitative changes in lesion-induced hyperactivity (from rearing and running to gnawing and biting) but did not result in higher stabilimeter scores at 6 or 24 hr post lesion. Isoproterenol (10, 15, 30 mg/kg) attenuated lesion-induced hyperactivity and pargyline (100 mg/kg) potentiated the hyperactivity after the first 6 hr. Amphetamine, apomorphine, isoproterenol and pargyline all caused significant reductions in the number and total length of lesion-induced gastric ulcers.

These results suggest that increased dopaminergic activity, perhaps due to increased DA turnover in terminals of lesioned pathways, may play an important role in lesion-induced hyperkinesia. On the other hand, decreases in central and/or peripheral noradrenergic activity may be a prominent factor in gastric ulceration induced by hypothalamic lesions.

147.16 AFFERENTS TO THE MESENCEPHALIC TEGMENTUM IN THE RAT. R. Waltzer*, P. Saxton, J. Siegel, T. Masino*, and N. Forrest*. Inst. for Neuroscience and Behavior, Univ. of Delaware, Newark, DE 19711.

The bulbar brainstem is a locus of both ascending and descending inhibitory influences. Previous experiments (Neurosci. Abst. 3, 213, 1977; Neurosci. Abst. 5, 204, 1979) in rat and cat injecting horseradish peroxidase (HRP) into the gigantocellular tegmental field (FTG) of the medulla have shown a consistent diffuse projection from the rostral mesencephalic reticular formation (MRF). In an effort to anatomically explore the influences converging upon the MRF injections of HRP were made in the mesencephalic tegmentum dorsal to the rostral tip of the red nucleus.

The use of tetramethylbenzidene (TMB) as a chromagen in these experiments made it possible to limit the amount of HRP injected to 0.02µl and therefore localize the injection to the target area. Despite the small injections labelled cells were seen from the rostral foretip of frontal cortex to the solitary nucleus of the caudal medulla, showing widespread afferent projections converging upon the MRF. By the HRP technique not only areas with robust projections but diffuse pathways from a few isolated cells were seen, revealing two patterns of afferent projections upon the MRF.

Cells projecting to the MRF were found bilaterally throughout the bulbar and pontine RF as well as contralaterally in the MRF. The ipsilateral neocortex displays two patterns of projections; one which is robust from the frontal cortex, and one which is diffuse from the cortex overlying the diencephalon and mesencephalon. In the thalamus, the centromedian nucleus was seen to project robustly to the MRF. Isolated labelled cells were also seen in structures known to be synchronogenic, i.e. the ipsilateral preoptic-basal forebrain area, dorsal raphe, and contralateral solitary nucleus. In addition, labelling was found in regions which serve to relay sensory information. These structures include the ipsilateral medial and lateral geniculates and the superior colliculus; the contralateral dorsal and ventral nuclei of the lateral lemniscus and the principal sensory and spinal trigeminal nuclei; and the bilateral parabrachial and vestibular nuclei.

The pathways found in this study from structures affecting the level of arousal or relaying sensory input provide further anatomical information about sources of influence upon the MRF. Moreover, these diffuse projections from synchrogenic structures suggest an anatomical pathway for inhibitory control of arousal.

147.17 AN ANALYSIS OF OPEN FIELD HYPERACTIVITY FOLLOWING ELECTROLYTIC MEDIAN RAPHE LESIONS IN THE RAT. D. Wirtshafter, K. E. Asin and E. W. Kent. Dept. Psychology, Univ. Ill. at Chicago Circle, Chicago, IL 60680.

A number of authors have reported that electrolytic lesions of the median raphe nucleus (MR) produce dramatic hyperactivity. In the current study, therefore, we examined in detail the behavior of MR lesioned rats in two open field situations.

In a standard open field, MR lesioned animals entered many more squares over a 5 min period than did sham operated controls. Measurment of the amount of time spent locomoting demonstrated, however, that this hyperactivity resulted entirely from MR lesioned animals spending a greater amount of time moving. Actual rate of motion (i.e. number of squares entered/time spent moving) was almost identical in MR lesioned and control rats. Whereas control animals frequently stopped to investigate parts of the field, MR lesioned animals rarely did so. Frequency of rearing was similar in the two groups, demonstrating that this behavior is controlled by different mechanisms than locomotion. Statistical analysis of the patterning of movement showed that MR lesioned animals moved about the field in a significantly more stereotyped fashion than did controls. This observation may be related to the stereotyped behaviors shown by MR lesioned rats in a variety of other situtations including tests of spontaneous alternation and 8-arm radial maze performance.

In our second experiment the open field was divided into two halves, in one of which a number of objects were placed. Both control, and to a significantly lesser extent, MR lesioned rats showed a preferance for the 'interesting' side of the field. Both control and MR lesioned animals spent more time per square in the 'interesting' than in the 'uninteresting' side, but this effect was significantly smaller in MR lesioned animals. Number of squares entered per unit time by MR lesioned animals in the 'interesting' side was about equvalent to that of controls in the 'uninteresting' side.These results demonstrate that the activity of MR lesioned animals is less sensitive to environmental complexity than is that of controls'and suggests the possibility that the hyperactivity of MR lesioned animals may result, at least in part, from their paying less attention to environmental stimuli than do controls.

Evidence for an attentional defecit was also obtained in a study of simultaneous discrimination learning. MR lesioned rats showed normal acquisition of a black/white discrimination, in agreement with our previous findings, but were severely impaired on the acquisition of a light grey/dark grey discrimination. It is possible that an attentional defecit may be able to account for many of the behavioral effects of damage to the MR and related limbic structures such as the hippocampus and septum.

147.18 ACTIVITY OF SINGLE NEURONS IN THE BASAL FOREBRAIN DURING SOCIALLY MOTIVATED APPROACH AND OTHER LOCOMOTION. J. W. Mink, D. B. Adams, and H. M. Sinnamon. Dept. of Psychology, Wesleyan Univ., Middletown, CT 06457

The purpose of this study was to search for a correlation between the socially mediated approach behavior of a male rat and the neural activity of the basal forebrain. The basal forebrain is considered here to include the medial and lateral preoptic areas, the bed nucleus of the stria terminalis, the lateral septum, the nuclei of the diagonal band, and nucleus accumbens.

Neural activity was recorded differentially through pairs of 25 micrometer stainless steel electrodes, implanted chronically. Stimulation electrodes were implanted ipsilateral to the recording electrode in the medial forebrain bundle (MFB) and lateral midbrain central gray (CG) to allow anatomical and electrophysiological identification of behaviorally tested neurons. Activity of neurons was measured during several standardized conditions: 1) during behavioral immobility; 2) while the water-deprived male rat ran in a running wheel to approach a water reward; 3) during running in the opposite direction so that the male subject approached an estrus female rat; 4) during exposure to olfactory, tactile, visual, and auditory stimulation; 5) during escape from the experimenter's grasp; 6) during single pulse stimulation to the MFB and CG.

So far, 40 neurons have been recorded in six animals. The recorded cells fall into 10 behaviorally defined categories. A total of 19 cells were found to be maximally active during drinking (N=5), approach to the female (N=2), orienting behavior (N=3), locomotor activity (N=4), escape from the experimenter (N=2), tactile stimulation (N=1), or when the rat was located in a specific place in the testing apparatus. Twenty-one cells were classified as uncorrelated fast (N=6), uncorrelated slow (N=8), or uncorrelated phasic (N=7). Responses to MFB or CG stimulation were found in six behaviorally tested cells and in five other cells that could not be sufficiently isolated for behavioral testing. Preliminary findings support the suggestion that the basal forebrain is involved in socially motivated approach.

147.19 ANODAL HYPERPOLARIZATION BLOCK TECHNIQUE PROVIDES EVIDENCE FOR ROSTRO-CAUDAL CONDUCTION OF REWARD RELATED SIGNALS IN THE MEDIAL FOREBRAIN BUNDLE. Peter Shizgal, Catherine Bielajew, and Ivan Kiss. Dept. Psychol., Concordia U., Montreal, Quebec.

Recent experiments (Shizgal et al., J.c.p.P., 1980, 94, 227.) suggest that longitudinally oriented, reward related fibers link the lateral hypothalamus (LH) and ventral tegmental area (VTA). This inference is based on a behaviorally derived measure of collision effects obtained with concurrent, two electrode stimulation. Although the collision technique provides measures of anatomical linkage and conduction velocity, it cannot determine the behaviorally relevant direction of conduction in the directly stimulated pathway. The present experiment was designed to obtain such information.

Subjects were male rats that showed evidence of collision during concurrent, unilateral self-stimulation of the LH and VTA. To test for the behaviorally relevant direction of conduction, we gathered four sets of strength-duration curves per rat using the following anode-cathode combinations: 1) skull screw anode, LH cathode; 2) VTA anode, LH cathode; 3) skull screw anode, VTA cathode; and 4) LH anode, VTA cathode. A constant behavioral output, self-stimulation paradigm was used throughout.

The results from the first two subjects suggest that reward related action potentials in directly stimulated MFB neurons propagated rostro-caudally. Strength-duration curves for the two VTA cathode conditions were parallel. In contrast, the curve for condition 2 converged on the curve for condition 1 as pulse duration was increased. This would be expected if the VTA anode in condition 2 produced a hyperpolarization block between the synaptic terminals and the point of current exist at the LH cathode. At short pulse duration, the block should decay before the action potentials triggered by the LH cathode arrive at the VTA. At longer pulse durations, current should continue to enter through the VTA electrode as the action potentials arrive and hence, some conduction failures should occur.

With the LH cathode, the direction of current flow appeared to have a large effect on substrate excitability. At the shortest pulse duration (100 μsec), the current threshold using the VTA anode was only about 60% of the threshold for the skull screw anode condition. Thus, the blocking effect at the longer pulse durations was manifested in a convergence of the initially lower strength-duration curve for condition 2 with the curve for condition 1.

The LH-VTA conduction time estimates from the collision test were consistent with the pulse durations at which the putative block reached maximum strength.

147.20 THE CONTRIBUTION OF NIGRAL EFFERENTS TO SUBSTANTIA NIGRA SELF-STIMULATION. R.M. Clavier, C.R. Gerfen, and D.H. Henkelman*. Dept. of Anatomy, U. of British Columbia, Vancouver, B.C. V6T 1W5

The substantia nigra (SN) has repeatedly been used as a locus to elicit intracranial self-stimulation (ICSS). However, the neural elements critical to SN ICSS have not been identified. The suggestion that SN ICSS results from stimulation of the A-9 dopaminergic (DA) cell group located in the substantia nigra pars compacta (Corbett and Wise, 1980) is not supported by findings that SN ICSS persists following generalized lesions of DA systems with 6-hydroxydopamine (6-OHDA) (Clavier and Fibiger, 1977, Cooper, et al., 1978). The latter two studies did not rule out DA involvement in SN ICSS since the facilitation of the behavior by d-amphetamine (1.0 mg/kg) was reversed after the lesions. In the present study 6-OHDA (5 ug in 2.5 ul 0.9% saline with 0.3 mg/ml ascorbic acid) was injected via a combined electrode-cannula into the SN ICSS site to limit the lesion to the A-9 DA cell group. 15 rats in the present study were shown to have had complete A-9 lesions as revealed by catecholamine (CA) histofluorescence. The A-10 DA cell group ipsilateral to the lesion was spared in all 15 animals. The nucleus accumbens and medial caudate nucleus showed normal CA fluorescence while the lateral two-thirds of the caudate was devoid of CA fluorescence. All 15 animals recovered to prelesion SN ICSS rates by 10 days after the lesion and most recovered to over 80% of prelesion rates within 3-4 days. Of the 10 rats that showed prelesion potentiation of SN ICSS with 1.0 and 0.5 mg/kg d-amphetamine, 5 animals showed the same degree of facilitation to the drug after A-9 destruction. However, the other 5 animals responded to 1.0 mg/kg d-amphetamine with a significant (85%) reduction of SN ICSS bar pressing. 0.5 mg/kg amphetamine administration did not significantly alter these animals' ICSS rates. A possible anatomical correlation is suggested in that the latter 5 electrode placements were caudal to the former 5 sites.

Since the above data suggest that SN ICSS persists in the absence of A-9 DA neurons the possible contributions of non-DA SN efferents to nigral ICSS was investigated. Electrolytic lesions of the following areas that receive non-DA SN efferents were ineffective in altering the behavior: the parafascicular thalamic nucleus (bilateral), the paralamellar mediodorsal thalamic nucleus (bilateral), the ventromedial thalamic nucleus, the superior colliculus, the central grey, and the pedunculopontine nucleus. Interestingly,lesions that involved the midbrain reticular formation led to a persistent (21 days) and significant (80%)reduction of SN ICSS (N=4). Contralateral lesions involving the same region had no effect on the behavior. We are currently investigating this area and its relationship to SN ICSS.

147.21 EXCITABILITY CHARACTERISTICS OF THE SUBSTRATES FOR FRONTAL CORTEX AND LATERAL HYPOTHALAMIC SELF-STIMULATION. S. Schenk*, P. Shizgal, and C. Bielajew*. (SPON: J. Stewart). Concordia University, Dept. of Psychology, Montreal, Quebec, Canada.

The present experiment was designed to compare the excitability characteristics of the substrate(s) supporting frontal cortex (FC) and lateral hypothalamic (LH) self-stimulation. This is part of a long-term mapping project aimed at characterizing the pathways underlying the rewarding effects of electrical brain stimulation. These pathways may then be identified using electrophysiological recording techniques.

Male Charles River rats, weighing 300-400 grams were stereotaxically implanted with two monopolar stimulating electrodes aimed at the LH and FC. Following recovery from surgery, rats were trained to self-stimulate at both electrode placements; depression of a lever produced a 500 msec. train of cathodal, rectangular pulses, .1 msec. in duration. Stabilization consisted of delivering trains of pulses and varying the number of pulses per train in a descending series. The number threshold (NT) was defined as the number of pulses that supported a one-half maximal rate of responding.

The refractory period test consisted of a series of NT determinations. In the first and last determinations, trains of equally spaced single pulses were used; trains of pulse pairs were delivered in the remaining NT determinations. Both the first pulse (the C-pulse) and the second pulse (the T-pulse) of each pair were delivered to the same electrode. The interval between the pulses (the C-T interval) was varied from 0.15 to 15.0 msec. A T-pulse effectiveness ratio was computed for each C-T interval. This was determined by comparing the paired pulse NT with that for single pulse stimulation.

At the short C-T intervals (<.6 msec) the value of the T-pulse effectiveness was at a minimum at both electrode placements. However, at the LH placement, there was a gradual increase in effectiveness between 0.6 msec and 1.2 msec., when a leveling off in effectiveness was observed. In contrast, the T-pulse effectiveness at the FC placement was minimal for as long as 1.6 msec.; asymptotic levels were not reached until a C-T interval of 5.0 msec.

These data suggest that either (1) different neurons with different excitability cycles are being stimulated by FC and LH stimulation; or (2) different parts of the same fibers are being stimulated by FC and LH stimulation. We are currently applying the collision technique (Shizgal et al., JcpP, 1980, in press) in an attempt to distinguish between these two possibilities.

147.22 RESPONDING IS AN IMPORTANT FACTOR IN BRAIN-STIMULATION REWARD. A.Ettenberg, A. Laferrière*,P.M. Milner* and N. White. Dept. of Psychology, McGill University, Montreal,Qué.,Canada,H3A 1B1.

A major tenet of reinforcement theory is that when two responses lead to the same reinforcement, an animal will choose the least effortful response. There is, however, a growing literature the results of which are particularly difficult to reconcile with the concept of "least-effort". In a variety of situations, animals prefer food or water reinforcers when they are self-administered (earned) as opposed to when they are provided ad lib (free). A problem exists however, concerning the notion of response-independent or noncontingent reinforcement. With natural reinforcers, for example, animals must perform a consummatory response and therefore such reinforcement cannot truly be considered noncontingent. The use of rewarding brain-stimulation (BSR), on the other hand, can overcome this difficulty since it can be applied without the subjects having to perform a consummatory, or any other contingent response. While a few experiments have been done which touch on this question of free vs. earned reinforcement, they are methodologically weak. A properly conducted study would provide important insights into the theoretical notions of reinforcement as well as its neural substrates. The present experiments, therefore, investigated this phenomenon using two novel experimental paradigms.

In one set of experiments, male albino rats were trained to lever-press for 0.5 sec trains of 60Hz sine wave lateral hypothalamic stimulation. Stimulation consisted of 90 sec periods after which the BSR-lever was retracted and experimenter-administered or imposed stimulation (EAS) was presented at the same rate and current parameters as during the self-stimulation. The rats could demonstrate a preference for self-administered BSR by pressing a reset lever located on the opposite wall of the test chamber. This action terminated the EAS and reinstated the BSR-lever for an additional 90 sec. The results show that rats prefer to respond for BSR than to have the same stimulation imposed by the experimenter. This was true even when a signal preceded each train of EAS or when subjects had a great deal of previous EAS experience. In another experiment, conditioned taste preferences were observed following novel-taste/self-stimulation pairings but not following various novel-taste/EAS pairings. Together these data suggest a response mechanism involvement in the rewarding nature of intracranial stimulation. The importance of this finding for distinguishing between drug-induced reward and performance deficits in self-stimulation behaviors is discussed.

147.23 PROTOCOL TIMING AND DATA ACQUISITION BY MICROCOMPUTER. Rodney B. Murray* and Ronald J. Tallarida* (SPON: E.B. Geller). Dept. of Pharmacology, Temple Univ. School of Medicine, Philadelphia, PA 19140.

This paper describes a technique that may improve the accuracy of data collection in behavioral and pharmacologic testing. This technique could be used when a precise injection and observation schedule must be geared to the kinetics of one or more drugs, such as in the time-dependent method for studying drug-receptor affinity (Tallarida, et al., JPET 206:38, 1978). For example, it would not be unusual to design a pharmacologic experiment that employs 4 groups of 5 animals each. If each animal was to be tested for two different responses during a control period and 5 times after drug administration, 240 separate tasks would have to be performed. These programs were designed to minimize the required time and the confusion during such an experiment.

The authors' programs were written in BASIC with the exception of a short machine language subroutine used to generate tones to prompt the user. The programs were run on an inexpensive microcomputer (TRS-80 Level II with 16K RAM). The entire microcomputer with video monitor, tape recorder, and small amplifier/speaker unit were mounted on a portable typewriter table. The operator is instructed with the use of prompts on the video display to enter the parameters of the particular experimental protocol. Prompting messages on the video display and audible tones alert the operator to perform the proper task at the correct time. The tones generated by the computer vary in pitch and in number according to the selected protocol. In addition, the operator may enter data directly into the computer for processing and/or storage on magnetic tape.

This technique is currently being used in our in vivo study of narcotic agonists and antagonists. Program listings are available from the authors.

147.24 SEIZURES EVOKED BY ELECTRICAL STIMULATION OF SUBCORTICAL STRUCTURES IN COLLARED LIZARDS. R. A. Sugerman* (SPON: R. I. Peters). Dept. Biol. Sci., Wichita State Univ., Wichita, KS 67208.

In mammals chemical and electrical stimulation are often used to evoke seizures. Chemicals like strychnine and penicillin have been found to readily evoke seizures in turtles, snakes, and lizards. The use of electrical stimulation of the brain in reptiles for evoking seizures is a technique which has not often been utilized. Volanschi and Servit (Exp. Neurol., 24:137-146, 1969) in a brief statement reported that diffuse electrical stimulation evoked seizures. The following study was conducted to determine the current threshold levels which are required to evoke seizures from the lizard's brain and eye and compare the optimal stimulation parameters for lizards and mammals.

The animals were anesthetized using either hypothermia or Nembutal (20 mg/Kg) and monopolar insect pin electrodes were implanted into the fore- and midbrain in arrays of 1 to 7 electrodes or as a single electrode in a movable apparatus. Constant current stimulation was provided using biphasic square wave pulse pairs of a 2 msec duration, a frequency of 5 or 50 Hz, and current between 0.1 and 1600 μA for the brain; and up to 10 mA in the vitreous body. Stimulation sites were marked using the Prussian blue technique. The brains were fixed in formalin, embedded in paraffin, and serially sectioned in the frontal plane.

Electrical stimulation of the brain in collared lizards evoked seizures from subcortical structures of the fore- and midbrain at current thresholds between 15 to 1600 μA. Areas in or near the ventral diencephalon had the lowest thresholds while much higher thresholds were localized in the anterior forebrain and midbrain. Thresholds for evoking seizures from sites in or near the amygdaloid complex are higher than sites in the hypothalamus. In mammals, the amygdala has a lower threshold for evoked seizures than the hypothalamus. The stimulation parameters for evoking seizures in lizards and mammals are essentially the same for the CNS. At considerably higher thresholds seizures could be evoked from direct stimulation of the eye.

148.1 PLASTICITY OF THE TECTOFUGAL PATHWAY DURING VISUAL CONDITIONING. J. Wall, J.M. Wild, J. Broyles*, C.M. Gibbs* and D.H. Cohen. Dept. of Neurobiology & Behavior, SUNY, Stony Brook, N.Y. 11794.

Visually conditioned heart rate change in the pigeon has been developed as a vertebrate model system for cellular studies of associative learning. In delineating the relevant neural pathways we showed that the ascending visual pathways transmit the conditioned stimulus information. Described here is an initial evaluation of neuronal activity along these pathways during conditioning, including (a) the retinal ganglion cells and (b) the thalamic and telencephalic neurons of one involved pathway, the tectofugal system.

Upon isolating the activity of a single neuron in a behaviorally naive animal, 10 6-sec pulses of whole field illumination were given. Presented next were 40 such lights followed by .5-sec foot-shocks (conditioning), 40 unpaired lights and shocks (sensitization) or 40 additional lights alone (habituation). The small unconditioned cardioacceleration to the light was enhanced by conditioning and attenuated by non-associative procedures.

Retinal output was assessed by recording from single optic tract fibers. We previously showed that with whole field illumination almost all such cells discharge at light onset, cease discharging during sustained illumination, and discharge at light termination. A large number of response parameters were statistically evaluated over training and none changed; maintained activity was also unchanged. We thus conclude that retinal output remains invariant during associative and non-associative training.

To analyze the tectofugal pathway we began at its telencephalic target, ectostriatum, since negative results would suggest the pathways's sub-telencephalic relays are also unaffected. Most ectostriatal cells respond to whole field illumination, distributing into various response classes. At least two such classes show enhancement of light-evoked responses during conditioning and attenuation or no change during non-associative treatment.

Given this, we undertook analysis of the thalamic relay, nucleus rotundus, to pursue the most peripheral site of change. All rotundal cells responded to whole field illumination and showed significant enhancement of their light-evoked responses over conditioning; during non-associative procedures responses either remained unchanged or attenuated. Maintained discharge was unchanged in both rotundus and ectostriatum.

The tectofugal pathway thus undergoes training-induced modification. Germane in this regard is that the tectofugal neurons of this study also generally responded to the foot-shock, unlike the retinal ganglion cells. Study of the optic tectum must now be initiated to identify the most peripheral sites of such change along the tectofugal pathway. (Supported by NSF grant BNS7919166 and NIH grant PO1 NS14620.)

148.2 PLASTICITY OF THE THALAMOFUGAL PATHWAY DURING VISUAL CONDITIONING C.M. Gibbs* and D.H. Cohen, Dept. of Neurobiology & Behavior, SUNY, Stony Brook, N.Y, 11794.

Visually conditioned heart rate change in the pigeon has been developed as a vertebrate model system for cellular studies of associative learning, and as part of this development we showed that the ascending visual pathways transmit the conditioned stimulus information. Another report at this meeting (Wall et al.) describes our initial analysis of these pathways during conditioning, and it was found that the retinal ganglion cell discharge does not change but that neuronal discharge in both the thalamic and telencephalic components of the tectofugal system is modified.

To evaluate the generality of these findings we initiated study of another of the involved visual pathways, the thalamofugal system. We began with the principal optic n. (OPT), the avian homologue of the lateral geniculate, since this provided an opportunity to examine a retinorecipient cell group. OPT consists of various subnuclei; in these preliminary experiments we sampled cells primarily in the n. dorsolateralis anterior, pars lateralis.

Upon isolating the activity of a single neuron in a behaviorally naive animal, 10 6-sec pulses of whole field illumination were given. Presented next were 40 such lights followed by .5-sec foot-shocks (conditioning) or 40 unpaired lights and shocks (sensitization). The small unconditioned cardioacceleration to the light was enhanced by conditioning and attenuated with unpaired stimuli.

Approximately 90% of the OPT neurons responded at short latency to whole field illumination with a range of 26-55 msec. (The latency range of retinal ganglion cell responses is 19-54 msec.) Several response classes were formulated on the basis of the short latency responses, including units with increased discharge, decreased discharge, or biphasic responses. Discharge patterns after the initial response were complex and are not yet fully analyzed.

With respect to the short latency responses, these changed over conditioning in > 80% of the units, generally augmenting. In contrast, non-associative training resulted in either no change or, more commonly, response attentuation. Maintained activity of OPT neurons did not change, and approximately 90% responded to the foot-shock, generally at latencies > 150 msec.

These findings extend the tectofugal results and indicate that at least two of the pathways implicated in transmitting the conditioned stimulus information show associative change. They further suggest that such change may occur at retinothalamic synapses. (Supported by NSF grant BNS7919166 and NIH grant PO1 NS14620.)

148.3 NEURONAL ACTIVITY IN THE AUDITORY SYSTEM DURING DIFFERENTIAL CONDITIONING IN RABBITS. K. Foster*, E. Orona*, R. Lambert* and M. Gabriel. (SPON: W. Riffee). Dept. Psychol., Univ. Texas, Austin, TX 78712.

Past studies (e.g., Gabriel, Miller, and Saltwick, 1977) have demonstrated that neurons in cingulate cortex of rabbits develop discriminative activity to the auditory stimuli used for differential behavioral conditioning. The discriminative activity developed at an early stage of conditioning, prior to the development of discriminative behavior. However, neurons in the reciprocally connected anteroventral nucleus of the thalamus developed discriminative activity in a late stage of training, after the advent of significant behavioral discrimination. The present study represents a preliminary report of research directed towards establishing whether early and late developing discriminative activity occurs in the cortical and thalamic components of the auditory projection system.

The results indicated that auditory system neurons manifested both early and late developing discrimination. However, the early developing effects occurred primarily within structures of the secondary projection pathway (dorsal and medial divisions of the medial geniculate nucleus of the thalamus, and the secondary auditory cortex), whereas late developing discrimination occurred within the classical projection pathway (ventral division of the medial geniculate nucleus and the primary auditory cortex; chi square, df = 1, = 6.07, $P < .05$). Unlike the effects seen in the cingulate cortical-anteroventral thalamic system, no differences in the development of neuronal discrimination were observed between the cortical and thalamic components of the auditory pathways.

Reversal of the CS-UCS contingencies, so that the original CS+ became the CS- and the original CS- became the CS+, led to an immediate reversal (during the first session of reversal training) of discriminative neuronal activity in both primary and secondary auditory structures (chi square, df = 1, = 5.26, $P < .05$). (In contrast, cingulate cortical and anteroventral thalamic neurons manifested activity appropriate to the original task during the first three sessions of reversal training.) These data suggest distinctive functional contributions of the auditory and the cingulate cortical-anteroventral thalamic systems to behavioral conditioning. (Supported by NIMH Grants 26276 and 31351 to M.G.)

148.4 MODIFICATION OF AUDITORY CORTEX SINGLE UNIT ACTIVITY DURING PUPILLARY CONDITIONING. W. Hopkins* and N. M. Weinberger. Dept. Psychobiology, Univ. of Calif., Irvine, CA 92717.

Previously, differential plasticity has been found in morphologically distinct subdivisions of the medial geniculate body during pupillary conditioning; magnocellular neurons (MGm) develop discharge plasticity in contrast to ventralis cells (MGv) which are not plastic (Ryugo & Weinberger, Beh. Biol., 1978, 22, 275). The present study investigated primary auditory cortex which receives convergent input from MGm and MGv. Single unit activity was recorded during acquisition of the classically-conditioned pupillary dilation response in chronically-prepared cats under neuromuscular paralysis and artificial respiration (Oleson et al., Beh. Biol., 1972, 7, 829). Subjects were trained with tone or white noise signalled pawshock. A sensitization phase, consisting of non-paired presentation of these stimuli, preceded pairing and controlled for nonassociative factors. Data were obtained from one neuron in a single training session during which the pupillary conditioned response was generally established. Subjects were routinely involved in several training sessions at weekly intervals.

When compared with the sensitization phase, the evoked activity of 17 of 32 neurons (53%) was significantly altered during conditioning. Background rate was changed significantly in 11 neurons (32%). Furthermore, background, but not evoked, activity developed a change in sign (usually decrease to increase) from sensitization to conditioning. Evoked and background activity changes often varied independently for a given neuron, as previously reported (Kitzes et al., Exp. Neurol., 1978, 62, 678; Perkins & Disterhoft, Neurosci. Abst., 1979, 5, 218).

Recent studies of single unit activity in MGm and MGv during pupillary conditioning have revealed no discharge plasticity in MGv but plasticity in virtually 100% of MGm neurons (Weinberger, DuPont Symp., June 1979, Wilmington). Furthermore, MGm neurons show an increase in either evoked or background activity but not both. The present findings indicate that many auditory cortical neurons are altered during the conditioning procedure. Further, they do not merely reflect the dynamics of either MGm or MGv cells during conditioning, but rather exhibit effects which could be due to the combined influence of both of these thalamic sources of input.

148.5 ASSOCIATIVE CHANGE IN NEURONS OF INTERMEDIATE AND DEEP LAYERS OF SUPERIOR COLLICULUS OF BEHAVING RAT DURING DIFFERENTIAL APPETITIVE CONDITIONING. D. Birt and M. E. Olds. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

We have previously shown that neurons in a region near the caudal tip of rat medial geniculate show associative short latency response changes during a differential appetitive conditioning and reversal paradigm in which different frequency tones are used as the conditioned stimuli. The horseradish peroxidase technique has been used to identify afferents to this region so that other portions of the neural circuitry involved in these associative changes may be identified and studied. This technique shows that one source of afferent input to this region is the intermediate and deep layers of the ipsilateral superior colliculus (SC). In the present experiment multiple unit auditory evoked responses were recorded from electrodes chronically implanted in deep and intermediate layers of SC of behaving rats during a similar conditioning paradigm.

Most units responded phasically to a wide range of auditory frequencies and were also responsive to somatosensory stimuli, particularly those applied to the contralateral face and anterior portion of the body. The majority of units showed a selective increase in response to the tone frequency paired with pellet presentation during conditioning. These increases started as early as the period 14-28 ms after stimulus onset and persisted throughout the interval between tone onset and pellet presentation. The early latency unit response changes were only very loosely correlated in magnitude and latency with learned movements of the head and body toward the pellet dispenser, while longer latency unit changes were highly correlated with movements of the head and body. These results support a role of the intermediate and deep layers of SC in the neural circuitry which evaluates and responds to the behavioral significance of sensory stimuli.

(Supported by NSF BNS 77-22289)

148.6 NEURONAL RESPONSES RELATED TO VISUAL RECOGNITION. E.T. Rolls, W. Caan,* D. Perrett,* and F.A.W. Wilson.* Dept. of Exp. Psychology, Oxford Univ., Oxford, England.

To analyse the neural basis of long-term memory of visual stimuli, recordings were made from single neurons in monkeys performing a visual recognition task of the type impaired in anterograde amnesia in man. Each visual stimulus was shown usually only twice per day, once as novel, and after 0-17 other intervening items in the recognition task, on a second trial as familiar, when the monkey could lick to obtain fruit juice if he recognized the stimulus correctly. Close to the fornix in the region where it descends through the far anterior thalamus into the septal region, a population of neurons was found which responded to the visual stimuli only when they were familiar. The neurons responded with latencies of 130-190 ms to the familiar stimuli compared with latencies of 400-500 ms for the lick responses made by the monkey. These neurons could fail to respond if the monkey licked incorrectly to a novel stimulus, and were not phasically activated during ad lib licking, so that their responses were not due to the lick responses made by the monkey in the recognition task. Further, in a different, visual discrimination, task a number of these neurons were found to respond both to the familiar rewarded visual stimulus to which the monkey always licked, and to the familiar aversive visual stimulus to which he did not lick. This not only shows that the responses of these neurons are independent of the monkey's lick responses, but also shows that in an association memory task these neurons respond on the basis of recognition memory, providing firm evidence for a dissociation of these types of memory, and their neural encoding. In further experiments it was shown 1) that the responses of individual recognition-related neurons became smaller as the number of intervening stimuli and the retention interval increased, 2) that these neurons differed in the number of intervening stimuli over which recognition-related responses could occur, 3) that if a stimulus was shown twice, this could enhance the magnitude of the recognition-related response on a later trial, and enable these neurons to respond to a stimulus over even 140 intervening stimuli, and 4) that these neurons responded selectively to familiar visual stimuli even when the monkey was not performing a task.

148.7 CORRELATES OF HIPPOCAMPAL UNITS IN RATS PERFORMING A WORKING MEMORY TASK. S.J. Mitchell and D.S. Olton. Dept. of Psychology, The Johns Hopkins Univ., Baltimore, MD 21218

Rats were trained to solve a spatial working memory task on an elevated 3-arm radial maze, the arms of which could be raised like drawbridges. At the beginning of each trial, one of the arms was lowered; the rat ran to the end of it and drank some milk there. When the rat returned to the center of the maze, he was confined there while milk was placed at the end of some other arm. The arm with milk, and the arm previously visited were then lowered. The correct response for the rat was to go to the arm with milk and avoid the arm already chosen. Because the arm lowered at the beginning of each trial changed from trial to trial, the only way the rat could determine which arm ought to be chosen when two arms were presented was to remember which arm had been chosen earlier in that trial. Rats with bilateral fimbria-fornix lesions are unable to solve this task.

Following training, each rat had a pair of blunt cut insulated wires implanted in one hippocampus (HPC) and a device for holding a microelectrode assembly implanted above a hole in the skull over the other HPC. Screws in the frontal bone and the interparietal bone served as the indifferent electrode and the ground, respectively, for the rat. A microelectrode assembly was screwed into the holding device prior to a recording session. With the rat in the center of the maze, the microelectrode was lowered to HPC. The signal was led through field effect transistors attached firmly to the rat's implant and then through standard amplifiers to the audio channel of a videorecorder. When a cell was isolated, the rat's behavior during the spatial memory task and during a free period was filmed on the video channel of the videorecorder and the activity of the cell recorded simultaneously on the audio channel. After the cell's activity was recorded, slow waves were recorded from the microelectrode and compared to slow waves from the other HPC electrodes to determine the placement of the microelectrode.

The mean rate of activity of each unit was determined for each location on the maze and each period of the memory task. Units had correlates to particular locations, and to locations combined with behaviors thought to be associated with the memory components of the task.

148.8 HIPPOCAMPAL UNIT ACTIVITY RELATED TO SENSORY, MOTOR AND EEG EVENTS DURING ODOR DISCRIMINATION LEARNING. J. Phillips*, H. Eichenbaum, & M. Kuperstein*, Dept. Biol., Wellesley Coll., Wellesley, MA 02181 & Dept. Psychol. & Brain Sci., M.I.T., Cambridge, MA 02139.

Recent analyses of the behavioral correlates of hippocampal neuronal activity emphasize either unit responses to sensory and motor events during learning (Olds et al., J. Neurophysiol. 35: 202, 1972; Thompson et al., Amer. Psychol. 31:209, 1976), or unit activity patterns related to unlearned behaviors and EEG (Ranck, Exper. Neurol. 4:461, 1973). In an initial attempt to relate these findings, an odor discrimination task previously used to describe synchronization of sniffing cycle and hippocampal rhythmic slow activity (RSA; Neurosci. Abstr. 5:900, 1979) was applied to an analysis of hippocampal unit activity.

Sniffing, RSA and dentate single unit activity were recorded in rats performing 400 trials on a go, no-go, water-rewarded discrimination of 4 S+ and 4 S- odors presented individually. In post hoc analyses, unit activity was correlated with trial periods: 1) approach to the stimulus port, associated with high amplitude RSA, 2) stimulus sampling, associated with synchronized sniffing and low-amplitude RSA, and 3) reward consumption associated with the absence of RSA.

Nearly every unit fired maximally at a preferred phase of RSA, and altered its firing rate reliably during trials. Most units increased firing abruptly at the onset of stimulus sampling, had greater responses to S+ than S- stimuli, and some responded differentially to odor quality. Other units fired maximally during the reward period; some during reward consumption only; others after non-reward only. Other units fired in bursts in phase with RSA and were most active during approach and after non-reward, and were minimally active during drinking; at the onset of stimulus sampling, a long burst was succeeded by groups of 1-3 action potentials in phase with RSA and sniffing cycle.

These results are consistent with observations of Olds and Thompson who also found that units in the hippocampus are differentially responsive to stimuli of learned significance. In addition, the behavioral correlates of many units observed in this situation are similar to those described in freely behaving rats by Ranck. This training paradigm combines useful aspects of different strategies in the study of neuronal-behavioral correlates.

148.9 RATE-DEPENDENT SHIFTS IN HIPPOCAMPAL SLOW WAVES DURING CLASSICAL CONDITIONING. S.D. Berry and R.F. Thompson, Dept. of Psychology, Miami Univ., Oxford, OH 45056 and Dept. of Psychobiology, Univ. of California, Irvine, CA 92717

Learning-dependent changes in hippocampal slow wave activity were assessed in 16 New Zealand White rabbits during classical conditioning of the nictitating membrane (NM) response. The conditioning paradigm consisted of a tone conditioned stimulus (CS, 350 msec, 85 dB, 1 Khz) and corneal air puff unconditioned stimulus (US, 210g/cm^2, 100 msec duration) The US was given 250 msec after CS onset. Subjects were given 13 blocks of training trials per day, each block consisting of 8 paired (CS-US) trials and 1 test (CS alone) trial. The intertrial interval averaged 60 sec. Training for each subject continued until it had reached a criterion of 8 conditioned responses (CRs) in 9 consecutive trials, or for a maximum of 4 sessions. A CR was defined as NM extension of more than 0.5 mm prior to US onset or (on test trials) within 500 msec of CS onset.

Hippocampal slow waves were recorded on magnetic tape from a multiple unit electrode located in the CA1 pyramidal cell layer of the dorsal hippocampus. Two-minute samples were recorded prior to the start of training and at the end of the testing session in which criterion was reached. Slow waves were analyzed on a PDP-12 computer that calculated frequency histograms based on the period between successive positive-going zero crossings. The values in the histogram were transformed into a frequency index, consisting of the ratio of high (8-22 Hz) to low (2-8 Hz) frequency waves. This index, when computed from a baseline slow wave sample, was previously reported to predict rabbit NM conditioning rate (r=.72; Berry, S.D. and Thompson, R.F., Science, 200:1298, 1978).

In this paper, we report that, although the post-criterion frequency index was not significantly related to the rate of conditioning (r= -.013), the shift in slow wave index from pre-training to post-criterion was highly correlated with the number of trials taken to reach criterion (r= -.86, $p < .01$). Faster-learning subjects displayed more high frequency activity after training than before, reflected by an increase in frequency index. Slower-learning animals shifted in the opposite direction, displaying relatively more low frequency activity after training. An additional 4 subjects, given a control treatment (explicitly unpaired tones and air puffs), showed no consistent shift across 2 days of testing.

These data indicate that hippocampal slow waves in the rabbit display frequency changes across training that are more related to the rate of NM conditioning than to training per se.

148.10 EFFECTS OF SEPTAL LESIONS ON SENSORY EVOKED POTENTIALS IN THE DENTATE GYRUS OF THE CHRONIC RAT. M.O. West, J.H. Robinson* and S.A. Deadwyler*. Dept. Physiol. & Pharmacol., Bowman Gray Sch. Med., Winston-Salem, NC 27103

Averaged evoked potentials (AEPs) were recorded from the perforant path synaptic zone of the dentate gyrus of rats conditioned to respond in the presence of a tone stimulus on an operant stimulus discrimination paradigm. As previously reported (West et al. Fed. Proc. 39(3): 1753, 1980), the N_1 negative component (20-30 ms latency, 20-30 ms duration) of the AEP was mediated by the perforant path projection from entorhinal cortex; N_1 varied inversely with the conditioned status of the animal and therefore appeared to be related to stimulus novelty. The N_2 negative component (70-80 ms latency, 50-80 ms duration) was recorded in the synaptic zones of perforant path and commissural/associational projections to the dentate gyrus, exhibiting maximum amplitude in the inner molecular layer; N_2 may therefore have resulted from the activation of intrahippocampal circuits. N_2, in contrast to N_1, was never observed in unconditioned normal animals and varied directly with the conditioned status of the animal; N_2 reached maximum amplitude during well-established stimulus discrimination performance but was attenuated or absent during extinction of the conditioned behavior. The N_1 component of AEPs recorded from animals sustaining lesions of the medial septal nucleus did not differ from N_1 in normal animals during any stage of conditioning. However, in contrast to normal animals, a prominent N_2 component was consistently observed in unconditioned septal animals; AEPs obtained from unconditioned septal animals thus resembled AEPs from conditioned normal animals (i.e., both N_1 and N_2 components were present). A further difference between AEPs from normal vs. septal animals was observed during extinction of the conditioned behavior: whereas the N_2 component of the AEP was attenuated or nonexistent in normal animals during extinction, a prominent N_2 component was recorded from septal animals during behavioral extinction (no deficits were observed in the behavior of septal animals in either acquisition or extinction of the conditioned behavior). These results suggest that activation of septal input to the hippocampus by a sensory stimulus serves to suppress activity in intrahippocampal circuits until the stimulus acquires behavioral significance.

148.11 HABITUATION OF HUMAN LIMBIC SENSORY RESPONSES. Charles L. Wilson, Michael Wang*, Thomas L. Babb, Eric Halgren and Paul H. Crandall. Brain Res. Inst., Reed Neurological Res. Cntr., and Dept. of Surg. (Neurol.), Sch. Med., UCLA, Los Angeles, CA 90024.

Investigators concerned with sensory processing in the animal limbic system have found that a high proportion of units in the amygdala and hippocampal formation: 1) are responsive to simple sensory stimuli, 2) are polysensory, and 3) display rapid habituation with repeated presentation of stimuli (Brown and Buchwald, Exper. Neurol., 40: 608-631, 1970; Lidsky et al., Exper. Neurol., 44: 130-134, 1974; Vinogradova, In: Isaacson and Pribram (Eds.), The Hippocampus, Vol. II, pp. 3-70, 1975). Limbic units recorded in patients with chronically implanted 40 μM platinum fine wires for localization of temporal lobe seizure foci, were tested with simple auditory and visual stimuli. Out of over 500 single and multiple units recorded from electrode placements verified by X-ray localization as being within amygdala, hippocampus, or entorhinal cortex, the 11% responding to diffuse flash or binaural click stimuli presented at a rate of 0.5 Hz were analyzed to determine whether they showed response decrements indicative of habituation. Habituation of neural responsiveness was assessed by measuring changes in amplitude of excitatory or inhibitory components of PSTH's evoked by initial vs. later portions of a train of sensory stimuli. Of the 60 units responsive to sensory stimulation, 95% responded to photic stimuli, 12% to auditory stimuli, and 7% were bimodally responsive. Out of 158 amygdala units, just three were responsive and only one showed habituation. Of 154 hippocampal units tested, 20 were responsive, 40% of these showing response decrement during stimulus presentation, while 44 out of 210 entorhinal cortex units were responsive with 35% of these showing habituation. Thus human limbic units differ from those of lower mammals in that a smaller proportion are influenced by sensory stimuli, but a substantial number of those which do respond show habituation. With response latencies ranging between 27 and 225 msec, habituation occurred in only 2 of 11 units having latencies equal or less 30 msec, while over 50% of 29 units with latency between 31 and 100 msec showed habituation. Further aspects of response decrements to sensory response will be related to the functional significance of phylogenetic changes in hippocampal formation and amygdala.

148.12 CINGULATE CORTICAL AND ANTERIOR THALAMIC CORRELATES OF REVERSAL LEARNING IN RABBITS. Michael Gabriel, Edward Orona*, and Kent Foster*. Dept. Psychol., Univ. Texas, Austin, TX 78712.

Multiple-unit activity of the cingulate cortex and the anteroventral (AV) nucleus of the thalamus in rabbits was examined during reversal training following differential conditioning of a locomotory (wheel rotation) avoidance response. The positive and negative conditional stimuli (CS+ and CS-) were pure tones (1 kHz and 8 kHz) and the unconditional stimulus (UCS) was a footshock (1.5 ma.) delivered through the grid floor of the wheel.

During the first session of reversal training, neuronal activity appropriate to the original task (i.e., a greater neuronal response to the CS- than to the CS+) occurred in the deep laminae (V & VI) of cingulate cortex. Activity in the superficial laminae (I-IV) manifested the original discrimination in certain records, and the reverse discrimination in others. These effects diminished and ceased during subsequent sessions. However, the short-latency (25-msec.) deep laminar discrimination appropriate to original learning, persisted throughout training to the reversal criterion. Activity of the AV nucleus underwent a gradual transition, in parallel with behavioral reversal learning, from activity appropriate to the original task to that appropriate to the reversal task. Extra footshocks presented following the attainment of behavioral criterion educed the neuronal discrimination appropriate to the original task in the deep laminae, and they educed discrimination appropriate to the reversal task in the superficial laminae.

These results considered together with the data of original learning lead us to propose that the encoding of the associative significance of the CSs during original learning occurs in the deep laminae of cingulate cortex, but continuing operation of the code during performance of the well-learned behavior, and any recoding that may be called for such as reversal of the code, are processes which occur at the level of the AV nucleus. While recoding occurs in the AV nucleus the deep laminae manifest persistent retention of the activity appropriate to the original task. The persistent original code may interfere with the attainment of behavioral reversal. Finally the present results and other findings (Gabriel, M., Miller, J. D., Saltwick, S. E. Physiol. Psychol., 4: 124, 1967) suggested that the superficial laminae are sites of convergent input from the AV nucleus and from the primary auditory system. However, the influences from these regions are manifested in superficial laminae only under conditions fostering high arousal. (Supported by NIMH Grants 26276 and 31351 to M.G.)

148.13 ACQUISITION OF NEURONAL ACTIVITY OF THE PREFRONTAL CORTEX AND THE MEDIODORSAL THALAMUS DURING DISCRIMINATIVE CONDITIONING. Edward Orona*, Kent Foster*, Richard W. Lambert*, and Michael Gabriel. (SPON: D. Albrecht). Dept. Psych., Univ. Texas, Austin, TX 78712.

Multiple-unit activity was recorded in the prefrontal cortex (PFC) and the reciprocally interconnected mediodorsal thalamic nucleus (MD) during discriminative conditioning of a locomotory (wheel rotation) avoidance response. The conditional stimuli were pure tones (1 kHz and 8 kHz) and the unconditional stimulus (UCS) was a footshock (1.5 ma.) delivered through the grid floor of the wheel. Rabbits received daily sessions of differential conditioning, in which the CS+ (followed in 5 sec by UCS onset) and the CS- (never paired with shock) were presented in a random sequence. Assessments of neuronal discriminative activity were made for specific behaviorally-defined stages of conditioning, so to compare directly these regions to a previously studied limbic corticothalamic system (the cingulate cortex and anteroventral thalamus; Gabriel, M., Miller, J.D., & Saltwick, S.E., J. Comp. Physiol. Psychol., 91: 423, 1977). The earliest discrimination in PFC appeared during the first session of conditioning, prior to behavioral discrimination. The magnitude of the effect was greatest then and during the session of first significant behavioral discrimination. When the stringent criterion of discriminative performance was met, the magnitude of PFC discrimination was reduced relative to the prior stages. In contrast, the MD demonstrated its largest discriminative effects at the criterial stage.

This sequential pattern of discriminative effects bears a striking similarity to the previous findings obtained in the cingulate cortex and anteroventral thalamus. However, the present data indicated a difference between the two systems: the proportion (.63) of records in PFC which manifested discriminative activity in the first session of conditioning exceeded significantly that proportion (.33) of the cingulate records. Also a greater proportion (.64) of the MD records manifested neuronal discrimination in the early (precriterial) sessions of conditioning, relative to the proportion (.33) of anteroventral thalamic records manifesting early discrimination. Thus the PFC-MD system may develop discriminative neuronal activity more rapidly during the course of training than the cingulate cortical-anteroventral thalamic system. These findings suggest the PFC and MD may be part of a rapid "working memory" system, involved in the initial-most encoding of associative significance of cues during behavioral learning. (Supported by NIMH Grants 26276 and 3151 to M. G.)

148.14 MULTIPLE UNIT ACTIVITY OF THE ABDUCENS NERVE IN THE ANESTHETIZED AND PARALYZED RABBIT. N. E. Berthier* and J. W. Moore. Dept. of Psychology, University of Mass., Amherst, Ma. 01003.

The unconditioned nictitating membrane response (NMR) of rabbit to stimulation of the paraorbital region of the face was investigated using electrophysiological recording from neurons of the abducens (6th cranial) nerve. Rabbits were anesthetized with chloralose and urethane, paralyzed with gallamine, and artificially respirated. Tungsten or glass microelectrodes were inserted into the 6th nerve using a ventral approach. Electrical stimulation (1.5 mA, 5ms duration) to the area surrounding the ipsilateral eye evoked a response of 5 ms latency. The latency of the motor volley suggests that this reflex is di- or trisynaptic. The number of activated units increased as a function of stimulus intensity and duration. Increases in stimulus duration but not intensity increased the duration of the efferent volley. Repetitive stimulation at intervals of .3 to 30 s produced consistent habituation, i.e., fewer activated units and reduced duration of the response volley.

Auditory stimuli and tactile stimulation of the paraorbital region are typically employed as conditioned and unconditioned stimuli, respectively, in the unanesthetized-unparalyzed rabbit NMR preparation. In the present study, action potentials from the 6th nerve were evoked by tactile stimulation of the ipsilateral paraorbital region and by an intense auditory stimulus ($>$ 100 dB SPL). These findings indicate that the neural elements mediating the unconditioned NMR remain intact in the acute anesthetized preparation. Neurophysiological investigation of the mechanisms of classical NMR conditioning in this preparation are indicated.

149.1 Response of Cutaneous Receptors to a Pruritic Stimulus. R. P. Tuckett* (Spon: P. R. Burgess). Department of Physiology, University of Utah, Med. Ctr., Salt Lake City, Utah 84108

The purpose of this study was to apply a potent itch-producing substance, cowhage (Mucuna pruriens), to cutaneous receptors and, by a process of elimination, determine which might be involved in signaling the sensation of itch to the central nervous system.

All types of myelinated fiber receptors have been sampled in cat (type I, type II, G_1 hair, intermediate hair, G_2 hair, F_1 field, intermediate field, F_2 field, D-mechanoreceptor, and delta nociceptor). None showed any response to application of cowhage. Whole-nerve recordings from small cutaneous nerves, in which individual delta fibers potentials could be distinguished, showed no change in activity after application of cowhage to the entire receptive field of the nerve.

Most unmyelinated-fiber receptor populations have also been sampled. Six C-mechanoreceptors, four thermal cooling receptors and one thermal warming receptor did not respond. A subcutaneous receptor was also unresponsive.

Twenty polymodal nociceptors were tested with cowhage and all but four responded. Polymodals can be activated by noxious mechanical and thermal (heat) stimuli. While firm rubbing of the skin and heating the skin (to what are noxious levels in humans, 46-52°C) produced a vigorous discharge from most polymodal receptors I studied, these stimuli do not produce itching sensations in normal human subjects. Hence, the nervous system must have a mechanism to differentiate among the variety of modalities to which polymodal receptors respond. (Supported by Grant NS15102 from USPHS).

149.2 NEUROTENSIN CELL BODIES IN SUBSTANTIA GELATINOSA. V. Seybold and R. Elde. Dept. of Anatomy, Univ. of Minnesota Medical School, Minneapolis, MN 55455.

The immunohistochemical localization of neurotensin immunoreactive (N-IR) terminals in substantia gelatinosa (SG) of the rat spinal cord has been confirmed by several laboratories. By combining the peroxidase-antiperoxidase (PAP) procedure of immunohistochemistry and thick sections (50-100 µm),it has been possible to describe two kinds of N-IR cell bodies within SG which may give rise to the terminals within the same region.

Six, 300 gm, male albino rats were used in these studies. Under anesthesia, PE-10 tubing was inserted in the cisterna magna and directed 9 cm down the subarachnoid space of the spinal cord to the lumbar enlargement. Colchicine (25 µg in 10 µl) was injected through the tubing, and the tubing was withdrawn. Two days later, the animals were sacrificed by vascular perfusion with 4% paraformaldehyde. 50 -100 µm frozen sections were cut in a transverse plane or a longitudinal plane along a radial axis through one dorsal horn. Free floating sections were processed for neurotensin immunoreactivity using the PAP procedure. The neurotensin antiserum used in this study does not cross-react immunohistochemically with other peptides localized in SG to date.

In transverse sections, two bands of N-IR fibers and cell bodies are observed in cross-section: one at the outer border and one at the inner border of SG. Cell bodies were 5 µm in diameter in this plane and 15-20 µm in length in the longitudinal plane. In the longitudinal plane, primary dendrites emanate from the rostral and caudal aspects of the cells, but the two bands of cells differed in arborizations of their dendrites. The secondary dendrites of N-IR cells in the inner band began branching closer to the cell body and tertiary dendrites had a greater medial and lateral extension in comparison to N-IR cells in the outer band. Interestingly, N-IR axons were not observed in these sections.

Based on comparisons of dendritic arborizations, the N-IR cells in outer SG are similar to the islet cell and the N-IR cells in inner SG are similar to the II-III border cell described by Gobel (J. Comp. Neur. 180:395, 1978).

149.3 NISSL, WEIL AND GOLGI ANALYSIS OF THE PERIAQUEDUCTAL GREY IN RAT, CAT AND MONKEY. Ingrid A. Abols* and Patrick W. Mantyh* (Spon: J. deGroot) Dept. of Anatomy, Univ. of Cal., San Francisco, Ca.94143

In a comprehensive analysis of the periaqueductal grey (PAG), Nissl and Weil stained sections through the midbrain were examined in 10 rat, 6 cat, 3 macaque and 9 squirrel monkey cases. In addition, Golgi material was obtained in 5 rat, 2 cat, 5 macaque and 3 squirrel monkey cases, by processing 3 mm blocks according to Golgi Cox or Golgi Kopsch methods.

Nissl and Weil stained material did not reveal any cyto- or myelo- architectural borders within the PAG, except for an apparent cell poor region immediately surrounding the cerebral aqueduct. No significant difference in cell size or shape was found within various regions of the PAG in any of the animals examined.

Golgi impregnated material revealed the PAG to be composed of a heterogeneous group of cells which do not appear to be regionally segregated according to size, shape or dendritic arborization. Most cells observed had extensive dendritic arborizations in the coronal plane with lesser, but still extensive arborizations in the sagittal plane. The cell somas ranged in size from 10-30um and had shapes ranging from small spherical to large pyramidal. Also noticeable in the Golgi sections was a dense plexus composed of both neuronal processes and glia in the border immediately surrounding the aqueduct. The lateral border, or annulus, of the PAG, formed chiefly by the mesencephalic root of V seen in Nissl or Weil material, is not readily seen in Golgi impregnated material. The stratum profundum of the superior colliculus and the adjacent ventrolateral tegmentum appeared similar in cytoarchitecture to the PAG. Both PAG neurons and neurons from these surrounding areas have dendritic arbors that interdigitate with each other without respect to borders defined by Nissl cytoarchitecture or more apparent myeloarchitecture features. Some PAG cell dendrites extended beyond the stratum profundum into the stratum intermedium of the superior colliculus. No striking differences in the organization of the PAG or its constituent cell morphology was observed between rat, cat, macaque or squirrel monkey.

The PAG in the animals examined appears to be composed of a population of cells with a wide range of soma size and shape that have extensive dendritic arbors, which often extend into adjacent parts of the tectum or tegmentum. Therefore cytoarchitectural and connectivity (Mantyh, Neurosci. Abstr. '80) features of the PAG do not reveal apparent anatomical correlates to the variety of functional subdivisions suggested by immunohistochemical and physiological studies. (Supported by H.J. Ralston NS-11614 and W.R. Mehler NASA task 199-05-02-07).

149.4 EFFECT OF LESIONS OF NUCLEUS RETICULARIS GIGANTOCELLULARIS ON MORPHINE- AND STIMULATION-PRODUCED ANALGESIAS IN THE RAT PERIAQUEDUCTAL GRAY. J.S. Mohrland, D.Q. McManus* and G.F. Gebhart, Dept. of Pharmacology, Univ. of Iowa, Iowa City, IA 52242

Focal brain stimulation (FBS) and microinjection of morphine into the periaqueductal gray (PAG) region of the mesencephalon results in a profound analgesia. That analgesia has been shown to involve an inhibitory spinopetal pathway. The lack of a substantial anatomical projection from the PAG to the spinal cord implicates more caudal brainstem nuclei in this descending system. Nucleus reticularis gigantocellularis (NGC) of the medullary reticular formation is known to be involved in transmitting nociceptive information, and recent evidence suggests it is also involved in PAG-induced analgesias. In the present study NGC lesions were used to evaluate the role of this nucleus in analgesias produced by PAG morphine and FBS.

Cannula/electrode assemblies were constructed to allow for stimulation and morphine microinjection at essentially the same PAG locus. At least one week following stereotaxic implantation of the assemblies into the PAG of rats; the analgetic efficacy of morphine (5µg base in 0.5µl artificial CSF) and FBS (40-120µA of 64 Hz, 0.5 msec biphasic pulse pairs for 5 min) was evaluated using standard hot plate and tail-flick tests. Electrolytic lesions were then made bilaterally into NGC; approximately two weeks later the analgetic efficacy of the PAG manipulations (vide supra) was again evaluated.

Control (pre-morphine) hot plate and tail-flick reaction times were not altered by NGC lesions. The lesions also failed to alter the increase in reaction times produced by FBS (both tests) and by morphine on the hot plate test. NGC lesions did, however, significantly attenuate the analgesia produced by PAG morphine administration as measured by the tail-flick test, an effect not observed in sham-treated animals. These results further implicate NGC in analgesia resulting from microinjection of morphine into PAG. They also suggest a separation of analgesia produced by FBS from that by morphine microinjection.

149.5 AN ANALYSIS OF REGIONAL SUBDIVISIONS AND NEURONAL POPULATIONS IN THE RODENT PERIAQUEDUCTAL GRAY. A. J. Beitz. Dept. of Anatomy, Univ. of South Carolina, Sch. of Med., Columbia, S.C. 29208.

Nuclear volume, neuronal and glial numbers, neuronal and glial density, neuronal shape and neuronal orientation were studied in the rat periaqueductal gray (PAG). A statistical analysis of the data obtained from measurements of neuronal lengths, widths and areas indicated that the neuronal population of the PAG is heterogeneous and cannot be divided into subpopulations based on cell size. The cells which comprise this midbrain region are extremely small in size. The mean area of the total cell population is 80.28μm^2 while the mean length and width are 13.77μm and 6.86μm, respectively. The nuclear volume occupied by the PAG as calculated from cross-sectional areas of the nucleus was 8.16 x 10^{-3} cm^3. The average neuronal density calculated from a series of coronal sections is 1.65 x $10^7/cm^3$ while the glial cell density is 6.44 x $10^7/cm^3$. The neuronal cell density was found to gradually increase from caudal to rostral portions of the central gray. In an attempt to accurately delineate the nuclear subdivisions which comprise this region, the PAG was divided into 19 regions on a purely subjective basis using the criteria of cell size, shape and orientation and cellular packing density. Data concerning the length, width, area and orientation of the individual neurons which comprised each region was entered into a computer and the regions were then statistically compared utilizing both a cluster analysis system and box plots. The results of this computer analysis indicated that the PAG can be divided into four nuclear divisions: (1) A dorsal division in which the cells display no particular orientational preference; (2) a dorsolateral division in which the majority of cells are oriented at a 30-70^o angle with respect to the cerebral aqueduct; (3) a ventrolateral division in which the majority of cells are oriented at 110-150^o angle with respect to the aqueduct; and (4) a medial division composed of small cells that surround the aqueduct, the majority of which maintain an orientation parallel to the aqueduct. The medial division contains the smallest neurons found within the PAG while the ventrolateral subdivision is characterized by the presence of large cells. These results support the existence of medial and dorsal subdivisions within the rodent PAG as originally described by Hamilton (1973) in the cat and, in addition, provide new evidence that dorsolateral and ventrolateral subdivisions are also present in the PAG.

Supported by NSF Grant BNS 7906486.

149.6 A GOLGI ANALYSIS OF THE RODENT PERIAQUEDUCTAL GRAY. S.M. Prichard and A.J. Beitz. Dept. of Anatomy, Univ. of South Carolina, Sch. of Med., Columbia, S.C. 29208

The neurons of the midbrain periaqueductal gray (PAG) of the rat were studied with several variants of the Golgi technique. Three general classes of cells have been identified in the PAG: (1) fusiform cells; (2) triangular cells, and (3) stellate cells. The fusiform cell type can be divided into two major subclasses: a small bipolar neuron which is the most prominent cell type encountered in the PAG being present in all four subdivisions, and a large fusiform cell which is most prominent in the ventrolateral subdivision of the PAG. The small bipolar neurons are characterized by an orientation which parallels the transverse or oblique plane of section and their distal dendrites often display prominent dendritic excrescences. Many of the small bipolar cells of the dorsal and dorsolateral subdivisions direct their axons toward the overlying inferior and superior colliculi. The small bipolar neurons and the large fusiform neurons of the ventrolateral subdivision, however, project the majority of their axons into the neighboring reticular formation. The triangular cells are a major constituent of the dorsolateral subdivision. These cells typically give rise to 3 or 4 primary dendrites which branch several times to form an ellipsoidal dendritic territory. The dendrites of these cells are highlighted by the presence of numerous dendritic spines, especially along their distal extremities. The final neuronal class, the stellate cells, also can be divided into two basic varieties: (1) an ovoid shaped large multipolar neuron (LMN), and (2) a spherically shaped smaller multipolar neuron (SMN). The ovoid shaped LMN's are characterized by a prominent elongated cell body which gives rise to 5 or 6 primary dendrites which branch only once or twice to form an ellipsoidal dendritic arborization. The spherical LMN's are characterized by a round cell perikaryon from which 4 or 5 primary dendrites originate. Moreover, these cells are most commonly found in the dorsal and dorsolateral subdivisions. The results of this study indicate that the rodent PAG is comprised of five basic neuronal types as identified in Golgi impregnated material. Moreover, this study supports the existence of four subdivisions within the PAG of the rat as defined in Nissl preparations (Beitz, 1980). The morphological variations defined above may underlie the functional heterogeneity of this region.

Supported by NSF Grant BNS 7906486.

149.7 RAPHE STIMULATION INDUCES PRIMARY AFFERENT DEPOLARIZATION OF BOTH LOW-THRESHOLD MECHANOSENSITIVE AND NOCICEPTIVE TRIGEMINAL AFFERENTS. James W. Hu and Barry J. Sessle. Faculty of Dentistry, University of Toronto, Canada M5G 1G6.

The nucleus raphe magnus (NRM) and periaqueductal gray (PAG) have been implicated in endogenous opiate-related mechanisms of suppression of nociceptive transmission. In the trigeminal (V) system, we previously reported that PAG and NRM conditioning stimulation inhibits reflex and single brainstem neurone responses to noxious oral-facial stimuli; we noted however that the responses of low-threshold mechanosensitive neurones also can be suppressed. Since these findings suggest that raphe influences may not be selective for nociceptive transmission, and since it has been suggested that the raphe influences may act presynaptically, we wished to determine if conditioning stimulation of PAG and NRM could presynaptically influence V afferents that were functionally identified as being either low-threshold mechanosensitive afferents or nociceptive (tooth pulp;cutaneous) afferents. The effect of stimulation in histologically verified sites in PAG and NRM was tested in anaesthetized or decerebrated cats on the antidromic excitability of single V primary afferents recorded in the V ganglion. The afferents were antidromically excited from V brainstem nuclei oralis or caudalis, and an increase in antidromic excitability was used as the measure of primary afferent depolarization (PAD) which is generally considered to reflect presynaptic inhibition. Facial nociceptive afferents responded to cutaneous noxious mechanical stimuli and some also were excited by noxious radiant heat. They could be antidromically excited from V nucleus caudalis, and had mean conduction velocities of 0.84±0.18 m/sec (n=20; C fibres) and 5.16±3.66 m/sec (n=5; A delta nociceptive fibres). The low-threshold mechanosensitive afferents in contrast responded only to non-noxious tactile stimulation of very restricted mechanoreceptive fields, could be antidromically excited from oralis or caudalis and had conduction velocities of 41.4±13.6 m/sec (n=48). The pulp afferents also could be antidromically excited from either oralis or caudalis, and had conduction velocities of 36.4±14.7 m/sec (n=10). NRM or PAG conditioning produced PAD in all 4 pulp afferents tested, in agreement with our earlier findings (Nature, 1978). PAD also occurred in 5 of 8 facial nociceptive afferents. However, PAD could also be produced in the same animals in 41 of 42 low-threshold mechanosensitive afferents. These findings suggest that PAG and NRM may exert a presynaptic regulation on V somatosensory relays but that the effect is not selective for nociceptive transmission.

Supported by NIH grant DE04786.

149.8 RAPHE, RETICULAR AND PERIAQUEDUCTAL INFLUENCES ON SENSORY RESPONSES OF DORSAL HORN NEURONS IN THE CAT. Bruce Gray * and Jonathan O. Dostrovsky, (SPON: J. Duffin), Department of Physiology. Univ. of Toronto, Toronto, Canada, M5S 1A8.

Previous work indicates that electrical stimulation of the periaqueductal gray (PAG) or nucleus raphe magnus (NRM) produces analgesia and blocks the nociceptive responses of spinal dorsal horn neurons. It is generally accepted that the PAG-NRM decending system(s) controls the transmission of nociceptive information at the spinal level. However recent results indicate that the inhibitory effects of the descending systems may not be limited to nociceptive neurons and furthermore that the effective regions in the brainstem do not appear to be limited only to the PAG and NRM but that adjacent reticular formation regions can also be quite effective. Thus it was decided to compare the effects of electrical stimulation of the PAG, NRM and nucleus gigantocellularis (NGC) on both nociceptive and non-nociceptive neurons.

Experiments were performed on chloralose anesthetized adult cats. Single unit recordings were obtained from the lumbar spinal cord using carbon fiber microelectrodes. Bi-polar stimulating electrodes were stereotaxically implanted in the PAG, NRM and NGC and the stimulation sites subsequently verified histologically. A total of 44 neurons were studied. These were identified according to standard criteria as low threshold mechanoreceptive (non nociceptive), wide dynamic range, and high threshold mechanoreceptive by a careful sensory examination. To test for inhibitory effects from the brainstem the neurons were excited at just suprathreshold levels by electrical skin stimulation or by a mechanical transducer which delivered tactile impulses. The brainstem conditioning stimuli were delivered 130 ms. prior to the peripheral stimulus and consisted of a 100 ms. 500Hz train of 0.1 ms. pulses. 90% of the cells tested could be inhibited by stimulation of either PAG, NRM, or NGC at currents below the maximum used (400 μA). In any given cat the thresholds for NRM and NGC were similar. PAG threshold currents were, on average, higher than NRM or NGC currents but, as with the latter sites, were similar for the different cell classes. Surprisingly no consistent differences in threshold currents were required for inhibition of the 3 different types of neurons.

Supported by MRC of Canada.

149.9 MARGINAL ZONE PROJECTION TO NUCLEUS SUBMEDIUS IN THE MEDIAL THALAMUS OF THE CAT: A POSSIBLE PAIN CENTER. A.D. Craig, Jr. and H. Burton. Depts. of Anatomy-Neurobiology and Physiology-Biophysics, Washington Univ. Sch. Med., St. Louis, MO 63110

Previous studies of spinothalamic projections have disclosed terminations in medial thalamus mainly in the central lateral nucleus (CL), and more sparsely in the central medial (CeM) and parafascicular (Pf) nuclei. However, with the use of the anterograde transport of horseradish peroxidase (HRP) apparent terminal labeling can be observed in several additional loci (Craig & Burton ('79) Soc. Neurosci. Abst. 5:705). In medial thalamus, diffuse and/or isolated labeling occurs in the paraventricular, parataenial, paracentral, mediodorsal, ventromedial, and reuniens nuclei. A relatively compact and dense field of label occurs in the submedius nucleus (Sm), which lies just ventrolateral to CeM; this projection has been confirmed autoradiographically. The spinal zone of Sm is ca. 800 µm long; the cervical zone appears to be caudal to the lumbar zone. The portion of Sm caudal to the spinal zone, extending ca. 1mm, is labeled following anterograde transport from the medullary dorsal horn (n. caudalis). Labeling homologous to these results has also been observed in the Sm of the monkey following spinal HRP injections.

Small HRP injections (35-100 nl, 50% solution in 0.8% poly-L-ornithine) in and around Sm have been made in the cat. Analysis of retrogradely labeled spinal and medullary cells indicates that the projection to Sm arises from lamina I cells, probably exclusively. Spinothalamic terminations in surrounding nuclei appear to arise overwhelmingly from laminae VII-VIII cells, in accordance with the results of previous retrograde studies (e.g. Carstens & Trevino ('78) JCN 182:151; Willis, et al. ('79) JCN 188:543). The retrograde results support the somatotopography described above, as well as the proportionately larger projection from n. caudalis. Labeled spinal marginal zone cells are consistently located at the dorsolateral apex of the dorsal horn, while medullary cells occur in clusters but are more evenly distributed mediolaterally in lamina I.

These results indicate that a discrete and compact spino- and trigemino-thalamic projection to Sm arises from the marginal zone. Recordings obtained from Sm neurons suggest that these cells respond vigorously to noxious thermal and mechanical stimuli, which is consistent with previous physiological results indicating that many spinothalamic lamina I cells are nociceptive-specific. This suggests that Sm may be functionally specific for pain.

149.10 CONTRASTING FUNCTIONS OF VENTROBASAL AND MEDIAL-INTRALAMINAR THALAMIC NEURONS IN THE AWAKE SQUIRREL MONKEY. K. L. Casey and T. J. Morrow. Depts. of Physiology and Neurology, Univ. Mich. Med. Sch., Ann Arbor, MI 48109.

Previous studies indicate that ventrobasal (VB) thalamic neurons encode discriminative features of somatic stimuli, but the role of spinothalamic input to the medial and intralaminar (M-IL) thalamus remains unclear. Accordingly, we are comparing the responses of VB and M-IL neurons to natural stimuli and to electrical stimulation in the spinal lemniscus (SL) of awake, partially restrained squirrel monkeys. A chronic microelectrode system (Morrow, T. J., Brain Res. Bull. 5:91-93, 1980) is used in conjunction with stimulating electrodes implanted bilaterally in the SL at midbrain levels. Single pulse stimulation of the SL and natural somatic, auditory and visual stimuli are used to test unit responses.

Each of fifty-eight VB units had irregular resting discharge frequencies ranging from 5 to 15 Hz and showed little or no variation with the monkey's level of alertness. Thirteen units recorded from the ventral posterolateral nucleus were reliably driven by SL stimuli below 20 Hz and had latencies ranging from 0.8 to 2.0 ms. All these cells had small contralateral receptive fields and were excited by light tactile stimuli or hair movement; none were affected by noxious mechanical or thermal stimuli. The remaining VB units either lacked an apparent sensory or motor correlate or discharged in relation to specific limb movements.

In contrast, the discharge of 97 M-IL units ranged from 1 to 40 Hz and varied considerably in rate and pattern with the monkey's behavioral state. The resting and evoked activity of some units was markedly attenuated or completely eliminated during induction of second stage anesthesia with halothane. Sleep or drowsiness was associated with a slow bursting spontaneous discharge. The 9 units securely driven by SL stimuli (latencies: 3.5 to 15 ms) and 10 units not responding to SL pulses all gave brief burst responses to brisk but innocuous taps or deep stimuli delivered to any limb. Responsiveness declined with repeated innocuous stimuli. Noxious somatic or sudden non-somatic stimuli which elicited behavioral alerting and movement evoked maximum unit responses. The activity of these neurons did not correlate with ocular or somatic movement. Other M-IL units showed marked changes in excitability and stimulus specificity associated with changes in behavioral orientation and attention.

These results suggest that, in contrast with the discriminative function of VB neurons, the activity of M-IL neurons encodes some aspect of the arousal function of somatic and other sensory events.

149.11 EVALUATION OF ELECTROCUTANEOUS PAIN: (1) COMPARISON OF OPERANT REACTIONS OF HUMANS AND MONKEYS AND (2) MAGNITUDE ESTIMATION AND VERBAL DESCRIPTION BY THE HUMAN SUBJECTS. C.J. Vierck, Jr., O. Franzen* and B.Y. Cooper. Dept. of Neuroscience, University of Florida, Gainesville, FL, 32610.

The purpose of the study is to evaluate by means of human psychophysical methods the intensive and affective aspects of AC and square wave electrical shocks used in monkey experiments. By using operant reaction measures for human and monkey subjects and also various direct psychophysical techniques of estimating the intensive and affective aspects of the same stimuli the present study relates the animal data to the human domain. The stimuli applied to the lateral calf of the leg consist of short trains (38-50 msec) at a rate of 4 Hz. The train repetition rate was chosen in order to minimize a very pronounced adaptation that was found to occur with continuous stimulation.

The psychophysical functions are best described by a two-limbed function and they show a high correlation with the verbal sensory descriptors.

Human and monkey subjects yielded similar monotonic functions relating force and latency of shock-escape to stimulation intensity in the pain range. These results permit a more accurate estimation of the alteration of pain reactions produced in experimental animals by CNS intervention.

Supported by grant NS 07261 from NINCDS.

149.12 A COMPARISON OF OPERANT AND REFLEXIVE MEASURES OF MORPHINE ANALGESIA. B. Y. Cooper and C. J. Vierck, Jr. Dept. of Neuroscience, University of Florida, Gainesville, Florida, 32610.

The behavior of monkeys (macaca speciosa) in a shock escape task was examined. Measures were taken during the receipt of shock and during intertrial periods. In this manner we assessed both pain responsiveness and anticipation. Measures of escape vigor (bar pull force and latency), intertrial activity (vocalization, movement and bar pulls) and pain-induced reflexes were made. By using an ascending and descending pattern of shock stimuli, we were able to examine pain-induced analgesia mechanisms as well. We found that bar pull escape latencies and forces were strongly related to shock intensity, while pain-induced reflexes and intertrial measures showed only a weak relationship.

The effects of morphine on pain (.5, 1, 2 and 3 mg/kg) were clearly refected in all measures. These measures indicated large differences in individual responses to pain and susceptability to morphine analgesia. Treatment with PCPA or disulfiram showed a preferential blocking of morphine analgesia on the reflex measure. The disparities found between operant and reflexive pain measures are under further study.

149.13 ELECTROANALGESIA-INDUCED LATENCY SHIFT IN PULP-DRIVEN AFFERENT UNITS OF CAT TOOTH. Patrick J. Reynolds, Ann Kloka*, Richard B. Tacke* and R. Wayne Fields. School of Dentistry, University of Oregon Health Sciences Center, Portland, Oregon 97201.

In a previously reported study (Reynolds et al., Abstr. Soc. Neurosci. 5:615, 1979) of afferent unit activity from cat tooth pulp during administration of electroanalgesia (EA) current, a phenomenon of unknown origin and significance was observed. The unit discharge latency following rectangular pulse (0.1 msec) electrical test stimulation was seen to increase in some, but not all, units following administration of EA current. The phenomenon was transient and variable in most aspects, with these few common features: it was observed only as an increased latency (slowed conduction) from the pre-EA control value; it was observed only when threshold was elevated from pre-EA control; it occurred sometimes during, but most often after, a given EA administration protocol; it was always of a much briefer duration than the corresponding EA-induced threshold elevation for any unit.

The magnitude of the shift ranged from about 50% to over 400% in cases that were documented. Its transient nature made it difficult to document in some cases, where it appeared more as a "jitter" in latency, shifting between higher and lower values at alternate 1 second test intervals. In retrospect it cannot be ruled out as having occurred at a lesser magnitude (a few percent) in the 4 of 18 units where it was not apparent, since the time base resolution was not fine enough to detect such small change.

One explanation for the phenomenon is spread of stimulating current to an alternate, slower conducting, intrapulpal branch of the observed afferent unit (Matthews and Holland, Brain Res. 98:354-358, 1975). An often observed monotonic decrease in latency toward control over a 60-120 sec. period would argue against this hypothesis.

An alternative explanation would be a hyperpolarization-induced decrease in conduction velocity in the intrapulpal segment of the afferent unit. The potential occurence of large latency shifts should be considered carefully in the reporting of conduction blockade in peripheral nerve fibers.

An analysis of radiographs of several of the teeth from this study is underway to detect a possible relationship between EA dose and magnitude of latency shift. No other systematic quantitative correlate of the phenomenon is yet apparent.
(Supported by NIH Grant DE 04281)

149.14 ANALGESIA FOLLOWING MICROINJECTION OF CYCLIC NUCLEOTIDES AT SITES IN THE CAUDAL BRAIN STEM. R. A. Levy, B. D. Goldstein, M. M. Elyjiw* and H. K. Proudfit. Dept. of Pharmacology, Univ. of Illinois College of Medicine, Chicago, IL 60680.

Cyclic nucleotides cause analgesia following intracerebroventricular injection in rodents (Cohn et al., Science 199:319, 1978). Since cyclic nucleotides are believed to act as second messengers at noradrenergic and cholinergic synapses, it is possible that this effect reflects an action at such synapses located in pain modulating pathways. The nucleus raphe magnus (RM) of the caudal brain stem,which controls nociceptive threshold via its descending projections to the spinal cord, appears to be modulated by inhibitory noradrenergic and excitatory cholinergic inputs. We have tested the involvement of cyclic nucleotides in this modulation by determining their capacity to alter nociceptive threshold following microinjection at sites within the RM.

The dibutyryl derivatives of cyclic guanosine and adenosine 3':5'-monophosphate (db cGMP and db cAMP) were injected, in 0.5 µl saline, at caudal brain stem sites with a 28 gauge cannula inserted through a chronically implanted guide sheath. Nociceptive threshold was assessed prior to and following injection of 20 µg db cGMP or 10 µg db cAMP using the tail flick, paw pinch, and hot plate tests.

Injection of db cGMP at midline sites, near or within the RM, caused no significant alteration in nociceptive threshold in any of the three tests. This suggests that endogenous cGMP does not play a role in either NE-mediated inhibition or ACh-mediated excitation of RM neurones. However, injection of db cGMP at sites located about 0.5 mm lateral to the midline, within the nucleus gigantocellularis (GC), caused a marked analgesia in all three tests. Since cGMP has been implicated as a second messenger for cholinergic transmission, the analgesia produced by injection of db cGMP at GC sites suggests such a role for endogenous cGMP at cholinergic synapses associated with pain modulatory pathways in the lateral/caudal brain stem.

Microinjection of db cAMP at sites within the RM caused a marked increase in nociceptive threshold in all three tests. This effect may reflect a facilitation of the cholinergic excitatory input to the RM by an enhancement of ACh release, analogous to the action of cAMP at the neuromuscular junction (Standaert et al., JPET 199:553, 1976). This analgesic effect of db cAMP also suggests that endogenous cAMP is not a second messenger at the inhibitory noradrenergic synapse onto the RM, as it is at noradrenergic synapses at other CNS sites; if cAMP played such a role then microinjection of db cAMP would be expected to inhibit the RM, thereby producing hyperalgesia instead of the observed analgesia. (Supported by GM 25998-01A1).

149.15 NEUROPHARMACOLOGICAL INVESTIGATION OF TRIGEMINAL NEURALGIA G.H. Fromm, A.S. Chattha*, C.F. Terrence*, and J.D. Glass. Dept. of Neurology, Univ. of Pittsburgh, Pittsburgh, PA 15261.

We have previously found that drugs effective in relieving trigeminal neuralgia (carbamazepine, baclofen, phenytoin) facilitate inhibitory mechanisms as well as depressing excitatory mechanisms in the spinal trigeminal nucleus of cats. The facilitation of inhibitory mechanisms seemed to be at least as important as the depression of excitatory mechanisms, and suggested that a failure of inhibitory mechanisms may play a significant role in the pathogenesis of trigeminal neuralgia.

We have now investigated the effect of carbamazepine on various types of neurons in both the nucleus oralis and the nucleus caudalis of the trigeminal complex. Neurons were classified as relay neurons if they responded to stimulation of the trigeminal lemniscus with an unvarying short latency and followed repetitive stimulation at 200 Hz. Neurons were classified as type A interneurons if they responded transsynaptically to stimulation of the trigeminal lemniscus, and as type B interneurons if they did not respond to stimulation of the trigeminal lemniscus. We studied the effect of carbamazepine on excitatory synaptic transmission by observing its effect on the neuron's response to maxillary nerve stimulation. We studied carbamazepine's effect on inhibitory mechanisms by investigating its effect on the segmental inhibition produced by delivering a conditioning stimulus to the maxillary nerve prior to the test stimulus.

The administration of 5-20 mg/kg carbamazepine depressed the response to maxillary nerve stimulation of all the neurons studied in both nucleus oralis and nucleus caudalis. Carbamazepine also markedly facilitated the segmental inhibition of all the B interneurons in nucleus oralis. This facilitation was considerably greater than the depression of excitation. The segmental inhibition of relay neurons and of A interneurons in nucleus oralis was usually decreased by low doses of carbamazepine (5 mg/kg) and increased by high doses of carbamazepine (20 mg/kg). The segmental inhibition of all neurons in nucleus caudalis was also decreased by low and increased by high doses of carbamazepine.

The most striking effect of carbamazepine in these experiments was its facilitation of the segmental inhibition of B interneurons in nucleus oralis. This segmental inhibition appears to be presynaptic, mediated by primary afferent depolarization, and it represents a negative feedback type of inhibition. Facilitation of this negative feedback mechanism could very effectively decrease the response of the trigeminal nucleus to abnormally increased firing of the trigeminal nerve, and so prevent the paroxysms of tic douloureux without affecting the response to normal levels of activity.

149.16 EEG CHANGES INDUCED BY SYSTEMATIC ADMINISTRATION OF MORPHINE IN THE RAT.[+] J. D. Bronzino, W. Forbes, M. Kelly*, C. Cordova*, N. Oley and P. J. Morgane. Trinity College, Hartford, CT 06106

In a study of the effects of morphine on the electrographic activity of the brain, power spectral and amplitude analysis techniques have been applied to quantify EEG parameters not readily discernible by visual observation. Recent evidence Rieger et al., Pharmakopsychiat. 12: 94-101, 1979) suggests that the development of EEG amplitude histograms may be an important method that can be used to distinguish and quantify alterations in the EEG. In addition, we (Bronzino et al., Proceedings of IEEE-GEMB, 1980) have demonstrated that several indices namely the standard amplitude, skewness and kurtosis are sensitive and reliable measures of these amplitude histograms. In the present studies, this technique was used to quantify the EEG effects brought about by systematic injection of morphine. Adult Sprague-Dawley rats (n=10) were implanted with chronic indwelling bipolar recording electrodes in the frontal and parietal cortices. After a considerable recovery period, systematic injections of morphine (5mg/kg, 15mg/kg and 30mg/kg) as well as a control injection of Ringer's solution were given a week apart. Power spectral analysis and amplitude analysis techniques were then utilized to quantify the impact of these pharmacological manipulations upon the cortical EEG of the rat.

In agreement with the work of others (Khazan, N., In: Methods in Narcotics Research, pp. 173-209, 1975; Steinfels, G. F. et al., Neuropharmacology 19: 69-74, 1980; Yeung, J. C. et al., Neuropharmacology 17: 525-532, 1978) we have found that morphine produced a dose-dependent behavioral antinociception and sedation associated with EEG slowing and synchronization. However, the availability of compressed spectra arrays and the development of amplitude histograms have enabled us to better visualize the transition from desynchronization through spindling to a continuously synchronized EEG pattern. In addition, the measures of skewness and kurtosis follow the transition process and provide a finer resolution than visual inspection. The impact of systematic morphine injection upon these EEG measures are presently being utilized to compare and evaluate the effect of direct cerebral injection of morphine to the region of the nucleus tractus solitarius - area postrema upon cortical EEG.

149.17 BENACTYZINE-INDUCED REVERSAL OF PHYSOSTIGMINE AND COLD-WATER ANALGESIA, J.A. ROMANO* J.M. KING. USA Biomedical Laboratory, Aberdeen Proving Ground, MD 21010 (SPON: L. OATMAN).

The cholinergic system has been implicated in the production of morphine analgesia. Physostigmine potentiates the antinociceptive effects of morphine whereas atropine and hemicholinium attenuate morphine analgesia on the tail flick test (Ann. N.Y. Acad. Sci., 1976, 281, 262). The attenuation of morphine effects was shown to involve central muscarinic pathways (Psychopharm., 1977, 52, 7). Physostigmine but not neostigmine is a potent analgesic in its own right and its effects are blocked by anticholinergic compounds (JPET, 1969, 169, 17).

The evidence for opiate involvement in stress produced analgesia is threefold: (1) administration of endorphin produces analgesia (2) hypophysectomy blocks antinociception of restraint stress, suggesting a role for pituitary endorphin, and (3) cross-tolerance also occurs between endorphin and morphine administration (Life Sci., 1977, 20, 1259).

The role of the cholinergic system in stress- and anticholinesterase produced analgesia was explored using three behavioral measures of pain: tail flick (TF), jump flinch (JF), and hot plate (HP). HP temperature was calibrated at 56.4°C and TF intensity at 69.1°C. One baseline measure was taken on JF and HP, three on TF. Benactyzine HCl (Ben), a drug which has known central anticholinergic properties, was used in each test (1.8 mg/kg, i.p.) to block either physostigmine salicylate (.65 mg/kg, i.p.) (Physo) or cold water analgesia (3.5 min at 2°C).

	HP(sec)		JF(mA)		TF(sec)	
	Pre	Post	Pre	Post	Pre	Post
Physo	13.5±2.4	17.0±1.8	.52±.06	.78±.07	7.8±1.7	21.0±3.2
Physo+ Ben	12.6±1.6	15.7±2.0	.56±.06	.57±.05	7.1± .9	6.6± .8
CWS	14.1±1.8	19.1±1.5	.60±.09	.80±.25	4.6± .3	11.4±1.3
CWS+Ben	14.2±2.5	18.2±2.5	.65±.04	.48±.02	4.5± .4	6.2± .6
Ben HCl	14.1±1.5	10.7±1.6	.53±.07	.63±.07	6.6± .4	6.4± .7
Control	13.3±1.2	14.4±1.6	.45±.06	.57±.06	7.2±1.0	6.3± .5

Ben was given 4 min before either the administration of physo or CWS. Analysis of variance indicated that Ben blocked the analgesia produced by either Physo or CWS on both TF ($p < .01$ and .02, respectively) and JF ($p's < .01$), but not on HP. These data are in agreement with those of Yaksh (Brain Res., 1979, 160, 180) that spinally mediated reflexes may be dependent upon non-endorphin-supra-spinal descending neurotransmitter systems.

149.18 ENHANCEMENT OF PHYSOSTIGMINE ANALGESIA BY MORPHINE: DEPENDENCE ON DOSE AND TEST SYSTEM. J.M. King and J.A. Romano*. USA Biomedical Laboratory, Aberdeen Proving Ground, MD 21010.

Physostigmine produces analgesia and potentiates the analgetic effect of morphine in the tail flick test (L. Harris, Fed. Proc., 1970, 29, 28). This enhancement has not been found using shock threshold measures (H. Herken, et al., Arch. Exp. Path. Pharm., 1957, 230, 313), and elevated central acetylcholine antagonizes morphine analgesia on the hot plate test (L. Botticelli, et al., Comm. Psychopharm., 1977, 1, 519). Different drug sensitivities have been found for tail flick and hot plate (T. Yaksh, Brain Res., 1979, 160, 180). Thus, the nature of the physostigmine-morphine interaction may be influenced by the analgesia measure employed. For the tail flick, animals received 3 predrug and 3 postdrug trials; with the hot plate 1 trial of each type was run. Stimulus intensities were 69.1°C for tail flick and 56.4°C for hot plate. Tail flick difference scores were analyzed using ANOVA's; hot plate data were analyzed using ANOCOVA procedures. For tail flick and hot plate, animals received simultaneous morphine SO4 (0, 1, 2, or 4 mg/kg) and physostigmine salicylate (0, .32, or .65 mg/kg). In both tail flick and hot plate procedures 9 animals received each of the 12 drug combinations. All drugs were given IP in a volume of 1 cc/kg. Drug effects were measured 30 minutes following injection. Tail flick latencies were recorded automatically. Foot thumps and paw licks were used as criterion responses in the hot plate test. Mean predrug latencies were 5.4 seconds for tail flick and 11.4 seconds for hot plate. In the tail flick, physostigmine and morphine yielded significant analgesia, and were additive in combination.

DRUG DOSES		Tail Flick latency change (sec)				Hot Plate corrected latency (sec)			
MORPHINE(mg/kg)		0	1.0	2.0	4.0	0	1.0	2.0	4.0
PHYSO-	0	-0.9	0.7	0.7	2.8	11.0	11.6	13.1	13.5
STIGMINE	0.32	7.1	5.7	10.0	11.7	11.8	12.0	16.2	16.5
(mg/kg)	0.65	9.2	11.4	10.1	12.1	20.5	17.8	22.4	13.4

In the hot plate, 2 & 4 mg/kg morphine were additive with .32 mg/kg physostigmine, as were 2 mg/kg morphine and .65 mg/kg physostigmine; however, 4 mg/kg morphine antagonized the analgesia produced by .65 mg/kg physostigmine. Thus, the degree and type of physostigmine-morphine interaction is determined by (a) the doses of each drug, and (b) the test system employed to measure analgesia. This latter determinant may reflect a difference in the level of mediation for tail flick and hot plate responses within the nervous system.

149.19 DIFFERENTIAL ROLES FOR ACTH AND VASOPRESSIN IN PAIN MODULATION OF BRATTLEBORO AND NORMAL RATS. M.M. Wallace, R.J. Bodnar, D. Badillo-Martinez*, J. Kordower*, T. Puleo*, G. Nilaver and E.A. Zimmerman. Dept. of Psychology, Queens College, Flushing, NY 11367 and Dept. of Neurology, Columbia University, College of Physicians and Surgeons, NY, NY 10032, USA.

Acute exposure to severe environmental stressors produces anti-nociceptive responses which adapt with repeated presentation. While certain stressors utilize endogenous opioid pathways, others, such as cold-water swims (CWS), appear to act independently and are mediated, in part, by the hypothalamo-hypophyseal axis. Hypophysectomy and destruction of the medial-basal hypothalamus diminish its analgesic effects in normal rats. Brattleboro rats genetically deficient in vasopressin and impaired in adrenocorticotrophic hormone (ACTH) release, also display attenuated analgesic responses to CWS, yet show normal analgesic reactivity to morphine. To analyze the role of vasopressin and ACTH in anti-nociceptive responses, the present study assessed whether central punctate administration of these peptides altered basal pain threshold responses as well as analgesic responsivity to stress in Brattleboro and normal rats. Flinch-jump pain thresholds were measured in cannulated rats 30, 60 and 90 min following intraventricular injections of 5 ul of either arginine vasopressin (AVP: 5 ug), ACTH (0.5 ug) or a vehicle control according to a Latin Square design. Relative to the vehicle control, pain thresholds were elevated by AVP in Brattleboro rats and lowered in normal animals across the entire test sequence. A smaller effect was observed following ACTH: pain thresholds were elevated 30 and 90 min afterwards in the Brattleboro and lowered 90 min afterwards in the normal animals. The same doses of AVP, ACTH or vehicle were then administered 30 min before CWS and 60 min prior to pain threshold tests. Preliminary data show that CWS analgesia dramatically increased in Brattleboros following ACTH and to a lesser degree by AVP. Peptide supplements failed to affect CWS analgesia in the normals. These data suggest an integral role for these peptides in modulation of nociceptive reactivity in Brattleboro rats. (Supported by NIH Grant NS 1449, NYSHRC Grant 1518 and NIH GRSG 5-S05-PR-07064.)

149.20 INTERACTION BETWEEN ANALGESIA AND CENTRAL BLOOD PRESSURE REGULATION. B. Delbarre, D. Casset-Senon*, G. Delbarre. Lab. Chir. Exp., Fac. Méd., 37032 TOURS CEDEX, FRANCE.

Recently, ZAMIR et al. (Brain Res., 160, 170-173, 1979) found changes in pain sensitivity in renal hypertensive rats. IGARASHI et al. (Neurosci. Lett., 12, 189-193, 1979) found a convergence of sensory input from tooth pulp, optic chiasma, sciatic nerve onto locus coeruleus neurons which are known also to play an important role in the central blood pressure (BP) regulation. All these facts suggest an interaction between brain circuits involved in central blood pressure regulation and pain perception.

To test this hypothesis, we have studied the action of drugs known for their analgesic effects on BP. In unanaesthetized cats, intraventricular injections of met-enkephalin (20 µg/kg), morphine (20 µg/kg), substance P (1 µg/kg) and Db.c.AMP (75 µg/kg) increase significantly BP, while naloxone (10 µg/kg) induces a long lasting fall of BP. In spontaneous hypertensive rats (SHR), naloxone (5 mg/kg S.C.) decreases significantly BP, two and three hours after administration. At the same dose, this drug decreases significantly the nociceptive threshold two hours after administration in SHR but not in Wistar Kyoto rats.

All these facts suggest that neurotransmitters involved in central blood pressure regulation may be related to those mediating pain.

149.21 RAPHE AND RETICULAR FORMATION NEURONS: CONTRASTING RESPONSES CORRELATED WITH THERMAL PAIN AND BEHAVIOR IN CATS. S. F. Eisenhart, Jr. and K. L. Casey. Neurosciences Program and Depts. of Physiology and Neurology, Univ. Mich., Ann Arbor, MI 48109.

There is evidence that the caudal reticular formation mediates both the activation and suppression of pain behavior. Some neurons in nucleus reticularis gigantocellularis (NGC) and nucleus reticularis magnocellularis (NMC) may mediate the activation of pain mechanisms; in contrast, nucleus raphe magnus (NRM) neurons have been most consistently implicated in pain suppression mechanisms. We are testing this hypothesis by recording the activity of single neurons from the caudal brainstem of awake, behaving cats.

Cats are trained to eat while partially restrained so that thermal pulses (7 sec duration, 20°C/sec rise time, 38 to 55°C) can be delivered to the shaved outer thighs. Hindlimb movements, interruption of eating, and vocalizations terminate the thermal stimulus and show a marked increase in frequency following thermal pulses above 52°C. These behaviors are significantly reduced if stimuli are delivered coincident with eating, thus providing an opportunity to correlate modulation of behavioral responses with changes in unit activity.

The NRM cells identified thus far show increases in discharge which are correlated with stimuli eliciting escape responses. For example, a cell with a resting discharge of 3.2 Hz discharged at 9.5 Hz following a 55°C pulse which did not elicit escape, but discharged at 26 Hz when the same stimulus elicited escape. The NRM cells show markedly increased activity 1 to 2 sec before an escape response; they do not discharge in relation to movements independent of the stimulus. Neurons in NGC and NMC recorded thus far have distinctly different response properties; in general, their activity is best correlated with motor behavior which is not necessarily related to the thermal stimulus or to escape behavior. However, some cells in the medial NGC have shown decreased activity only during noxious thermal pulses eliciting escape.

These results support the hypothesis that neurons in the medial caudal brainstem reticular formation mediate or modulate behavioral responses specifically elicited by noxious stimuli.

Supported by NIH Grants NS12581, NS12015, and NIMH Training Grant MH14279.

149.22 ALTERATIONS IN NOCICEPTIVE THRESHOLD AND MORPHINE-INDUCED ANALGESIA FOLLOWING THE SELECTIVE DEPLETION OF SPINAL CORD MONOAMINES. H. K. Proudfit and T. L. Yaksh. Dept. Pharmacology, Univ. of Ill. Coll. Med., Chicago, IL 60680 and Mayo Fdn., Rochester, MN 55901.

These studies examined the proposal that serotonergic and noradrenergic neurons with axonal projections to the spinal cord are components of a neuronal system which modulates nociceptive threshold and mediates the antinociceptive actions of opiate drugs. This hypothesis was tested by examining the capacity of morphine to induce analgesia following the selective destruction of axon terminals in the caudal segments of the spinal cord which contain serotonin (5-HT) and norepinephrine (NE). Selective destruction of spinal monoamine terminals was achieved using specific neurotoxins injected directly into the spinal cord subarachnoid space near the lumbar enlargement. Thus, 5-HT, NE or both amines were depleted by injecting 5,6-dihydroxytryptamine (5,6-DHT), 6-hydroxydopamine (6-OHDA) and both neurotoxins, respectively. Both nociceptive threshold and morphine dose-response curves were determined between 7 and 21 days following intrathecal injection of neurotoxins. Spinal cord content of both 5-HT and NE determined 35 days after injections was found to be depressed to 10% of control values. The most prominent effect observed following depletion of spinal cord 5-HT was a pronounced, but transient, decrease in nociceptive threshold (hyperalgesia) which was evident on both the tail flick and hot plate tests. Depletion of spinal cord NE had identical effects. Although the spinal cord 5-HT and NE content remained depressed throughout the course of the study, the hyperalgesia exhibited recovery by 14 days. Despite alterations in nociceptive threshold following depletion of spinal cord 5-HT there was no alteration in the capacity of morphine to induce analgesia using either the tail flick or hot plate tests. The reduction of spinal cord NE produced a modest attenuation of morphine-induced analgesia. However, this effect was evident only when analgesia was assessed using the hot plate test, but not the tail flick test.

These studies support the following conclusions: (1) tonically active descending serotonergic and noradrenergic neurons regulate the transmission of nociceptive information at the level of the spinal cord; (2) descending serotonergic neurons do not appear to contribute measurably to the mediation of analgesia produced by the systemic administration of opiates; and (3) descending noradrenergic neurons appear to mediate some of the antinociceptive actions of opiates. (Supported by USPHS NS 12649 and NS 14629).

149.23 ANALGESIC TOLERANCE IS FACILITATED BY ANALGESIC TESTING. C. Advokat. Dept. Pharmacol., Univ. Ill. Med. Sch., Chicago, IL 60680.

Classical theories of opiate tolerance have emphasized the pharmacological mechanisms responsible for this phenomenon. Recent evidence, however, has shown that psychological, e.g. enrivonmental, variables play a significant role in tolerance development (Siegel, JCPP, 89:498-506, 1975). The present studies demonstrate a profound effect of the assessment environment on tolerance to opiate analgesia as measured by the spinal nociceptive tail flick reflex.

Naive, male albino rats were made tolerant by subcutaneous implantation of pellets containing 75 mg of morphine. In the first study, one group received morphine pellets while a second group received placebo implants. One half of the animals in each of these two groups was tested on the tail flick at 3, 24 and 48 hrs after the implant. At 3 hrs the Morphine group was significantly more analgesic than the Placebo group, however, by 48 hrs post implant these groups did not differ. At this time a 7.5 mg/kg subcutaneous injection of morphine produced significantly more analgesia in the Placebo group than in the Morphine group, further indicating that the Morphine group had become tolerant. In contrast, the remaining half of the Morphine group, which had not previously been tested, was still significantly more analgesic than its corresponding Placebo group at 48 hrs post implant. Furthermore, in response to the acute morphine injection these latter two groups were equally analgesic, indicating that the previously untested Morphine group was not tolerant.

In a second experiment, three groups of animals received morphine pellets. One group was tested 3, 6, 12, 24 and 48 hrs after the implant. A second group received only one test, at 48 hrs, in the same environment in which it had been housed and made tolerant. The third group also received only one test, at 48 hrs, but this occurred in a novel, unfamilar environment. These three groups differed significantly among themselves. The first group, which had received several successive tests, was significantly less analgesic than the other two groups, which received only a single test. Furthermore, these differences were maintained after an acute injection of 7.5 mg/kg of morphine.

These studies demonstrate profound modulation of analgesic tolerance to opiates by the context associated with the drug. The fact that such modulation can be obtained with a spinal reflex suggests that the mechanisms might be amenable to more detailed neuronal investigation. Such analyses could not only provide insight into processes underlying behavioral tolerance but to other forms of behavioral plasticity, e.g. learning, as well. (Supported by USPHS NS 12649).

149.24 EFFECTS OF INTRATHECALLY ADMINISTERED AMINE ANTAGONISTS ON NOCICEPTIVE THRESHOLD AND MORPHINE-INDUCED ANALGESIA. Donna L. Hammond and Herbert K. Proudfit, Mayo Fdn., Rochester, MN 55901 and Univ. of Ill. at the Med. Ctr., Chicago, IL 60612.

Indirect evidence has suggested that activation of serotonergic and/or noradrenergic bulbospinal pathways may mediate the production of analgesia by opiates. In addition, these projections may tonically inhibit responsiveness to noxious stimuli. Therefore, the present study examined the capacity of the amine antagonists, phentolamine (PTA) and methysergide (MSG) to decrease nociceptive threshold and attenuate morphine-induced analgesia when injected into the spinal cord subarachnoid space.

Male rats weighing 400-425 g were each implanted with an intrathecal catheter (PE-10) which extended 7.5 cm caudal from the atlanto-occipital junction. Seven days later, nociceptive threshold was measured using both the tail flick (TF) and hot plate (HP) tests. Each animal then received either 3.0 or 7.5 mg/kg morphine sulfate s.c.). Thirty minutes later the elevation of nociceptive threshold produced by morphine was assessed. Immediately following this assessment of analgesia, either 30 µg MSG maleate, 30 µg PTA HCl or saline was injected intrathecally in 15 µl of saline. Nociceptive threshold was then re-assessed 5, 15 and 30 min later. Comparison to the alterations in morphine-induced analgesia produced by intrathecally administered MSG or PTA with those produced by saline using a two-way ANOVA revealed that MSG failed to antagonize the analgesia induced by either 3.0 or 7.5 mg/kg morphine using either the TF or HP tests. In contrast, PTA produced a significant attenuation of the analgesia induced by 3.0 mg/kg morphine when assessed using the HP test. However, this antagonism was surmountable and was not evident following 7.5 mg/kg of morphine. No antagonism of the analgesia assessed using the TF test was produced by PTA. Both MSG and PTA decreased nociceptive threshold when injected intrathecally in separate groups of rats pretreated 30 min earlier with saline (s.c.).

The ability of either MSG or PTA to produce hyperalgesia when injected intrathecally supports the suggestion that bulbospinal aminergic neurons tonically inhibit the transmission of nociceptive information. However, these data do not support the participation of bulbospinal serotonergic projections in mediating morphine-induced analgesia. Some support is offered for the suggestion that noradrenergic projections to the spinal cord participate to some extent in mediating morphine-induced analgesia, although this may be dependent on the analgesiometric test used. Finally, these data agree with similar studies performed in rats with chronic depletion of spinal cord amine content.

149.25 HYPOALGESIA INDUCED BY THE LOCAL INJECTION OF PHENTOLAMINE IN THE NUCLEUS RAPHE MAGNUS: REVERSAL BY THE INTRATHECAL INJECTION OF PHENTOLAMINE. J. Sagen* and H.K. Proudfit (SPON: E.G. Anderson). Dept. of Pharmacol., Univ. of Ill. Coll. Med., Chicago, IL 60680.

Numerous studies have demonstrated that activation of neurons in the n. raphe magnus (NRM) produces hypoalgesia. Noradrenergic (NA) projections to the NRM appear to be inhibitory since iontophoretically applied norepinephrine inhibits these neurons. In addition, blocking the NA input by the local injection of NA antagonists into the NRM produces hypoalgesia which may result from disinhibition of NRM neurons. These data suggest that brain stem NA systems function to enhance the sensitivity to noxious stimuli. However, bulbospinal NA systems appear to decrease pain sensitivity, since the injection of norepinephrine into the spinal cord subarachnoid space produces hypoalgesia (Yaksh et al., JPET, 208:466, 1979) and the NA antagonist phentolamine (PTA) produces hyperalgesia (Hammond and Proudfit, Neurosci. Abstr., 1980). Thus, NA systems in the brain stem appear to augment pain transmission while spinal NA system appear to have the opposite action.

The present studies provide evidence for an interaction between these two NA systems. More specifically, hypoalgesia induced by the local injection of PTA in the NRM can be antagonized by the injection of PTA into the spinal cord subarachnoid space. Male rats weighing 400-425 g were chronically implanted with both a guide sheath aimed at the NRM and an intrathecal catheter (PE-10 tubing) which extended to the lumbar spinal segments. Following recovery from surgery, nociceptive threshold was assessed using the tail flick test, and PTA (10 µg in 0.5 µl of saline, pH 6.9) was microinjected into the NRM through an injection cannula inserted through the guide sheath. Animals exhibiting significant hypoalgesia by 20 min received either an intrathecal injection of PTA (30 µg in 15 µl of saline and flushed with 10 µl of saline, pH 6.9) or saline (25 µl, pH 6.9) or a subcutaneous injection of naloxone (0.4 mg/kg). Nociceptive threshold was again determined at 5, 15 and 30 min after the intrathecal injection. Intrathecal injection of PTA, but not saline reversed the hypoalgesia induced by PTA injection into the NRM. Furthermore, this hypoalgesia was not altered by systemically-administered naloxone.

These data suggest that disinhibition of raphe-spinal NRM neurons by PTA induces hypoalgesia which is mediated, at least in part, by subsequent activation of spinally-projecting NA neurons. The failure of naloxone to alter the hypoalgesia produced by microinjection of PTA in the NRM does not support the participation of enkephalinergic neurons in this action. (Supported by USPHS Grant NS 12649).

149.26 A NEW QUANTITATIVE TEST FOR ANALGESIA IN RATS. P. Warren*. (SPON: C. Kellogg). Reflex Modulation Laboratory, University of Rochester, Rochester, New York 14627.

A new quantitative test for analgesia based on the startle response is described. Brief noxious shocks (approx. 1.0 mA, 20 msec.) and tones (110 dB, 10 KHZ, 20 msec.) reliably produce startle responses in rats. In the present experiment morphine (10 mg/kg, ip.) significantly reduced the amplitude of the startle response to shock, but had no significant effect upon the response to tone. This morphine induced inhibition of the response to shock was antagonized significantly by naloxone (10 mg/kg, ip.).

When the shock stimulus is presented 1 sec. before the tone, the response to the tone is reduced. This inhibition of the response to tone was not affected significantly by morphine or naloxone. When tone precedes shock by 1 sec., the amplitude of the response to shock is unaffected. Neither morphine nor naloxone affected this apparent lack of inhibition of tone upon the response to subsequent shock.

149.27 ELECTROCONVULSIVE SHOCK-INDUCED ANALGESIA: ANTAGONISM BY NALOXONE AND EFFECTS OF HYPOPHYSECTOMY. E. H. Chudler,* J. W. Lewis, J. T. Cannon, & J. C. Liebeskind. Dept. Psychol., UCLA, Los Angeles, CA 90024.

A variety of experimental manipulations have been shown to reduce reactivity to painful stimuli, presumably through activation of one or more endogenous pain-inhibitory mechanisms. Holaday and colleagues reported an array of opiate-like effects following electroconvulsive shock (ECS), including analgesia. Naloxone's antagonism of ECS-induced analgesia suggested the involvement of endorphins (Holaday et al., 1978). The source of those endorphins responsible for ECS-induced analgesia is unknown. That pituitary endorphins are involved in stress-induced analgesia is suggested by findings that hypophysectomy reduces this form of analgesia (Amir & Amit, 1979; Bodnar et al., 1978). Therefore, in this study we sought to determine whether ECS-induced analgesia was similarly affected by hypophysectomy.

Male albino rats subjected to hypophysectomy (n=12), sham surgery (n=12), or no surgery (n=12) were used. Each group was divided into saline or naloxone pretreated subgroups. Animals were tested on the hot-plate (51.5°C) for baseline paw-lick latencies, then injected with either naloxone (3 mg/kg) or saline. Rats were again tested 13.5 min later on the hot-plate to assess drug effects. Finally, all subjects received transauricular ECS delivered through stainless steel clips (140 volts, 60 Hz, 2 sec) and were retested on the hot-plate at 6 min intervals for up to 30 min.

ECS significantly increased paw-lick latencies in all groups. In sham and unoperated controls, this effect was markedly diminished by naloxone pretreatment ($p<.05$). In hypophysectomized rats, the analgesic response was considerably longer in duration. Naloxone, appeared to reduce the magnitude of this analgesic effect in some hypophysectomized rats, although the effect was not statistically reliable. Naloxone itself had no effect on paw-lick latencies.

Our findings serve to reinforce the importance of the opioid peptides in ECS-induced analgesia. That endorphins of CNS origin may be responsible for these effects was suggested by the potent analgesic response observed in the hypophysectomized rats. The failure of naloxone to alter reliably the analgesic response in these animals, however, makes it seem likely that another, non-opioid mechanism was called into play. These findings do not preclude the possibility that pituitary endorphins serve an important role in ECS-induced analgesia in intact rats. (Supported by NIH grant NS07628. JWL was supported by MHTP grant NH15345)

149.28 SPINAL ANALGESIA AND HYPERALGESIA IN THE MOUSE. Janice L. K. Hylden , Cathy J. Cleary and George L. Wilcox. Dept. of Pharmacology, University of Minnesota, Minneapolis, MN 55455.

The spinal injection technique recently introduced by Hylden and Wilcox (Fed. Proc. 1980) was used to investigate the analgesic or hyperalgesic actions of various substances in the spinal cord of the mouse. A small incision is made in the skin of the back and a 30 ga. needle is inserted between two caudal lumbar vertebrae. The material is injected in a volume of 5 µl. Calibration experiments were performed by monitoring subdural distribution of methylene blue dye or [^{3}H]-morphine base. Not more than 5% of the injected material reached supraspinal structures. We observed tail flick and hot plate latencies, straub tail, and the occurrence of a characteristic behavioral response (after substance P and capsaicin). The following drugs were administered: morphine sulfate (MS), clonidine HCl (CLON), substance P (SP) and capsaicin (CAP).

MS was found to produce dose related, spinally mediated straub tail (ED50 0.5 µg, 0.25-1.0) and tail flick analgesia (ED50 0.85 µg, 0.35-2.0). Naloxone (2 mg/kg, s.c.) reversed these effects. CLON was 40 times as potent as MS in the tail flick assay (ED50 0.02 µg). SP elicited a characteristic biting and scratching response. The incidence, intensity and duration of this response were dose related (ED50 40 ng). Spinal MS did not inhibit this reaction (up to 20 µg). Thirty minutes following SP at 0.5 µg, mice showed tail flick analgesia. CAP evoked a biting and scratching response similar to that of substance P but of longer duration (2-3 min). These mice subsequently showed prolonged tail flick analgesia (>2 wks).

MS and CLON may exert an important part of their analgesic action at the spinal level. We believe our observations of SP's actions to be the first behavioral data consistent with the hypothesis that SP acts as a nociceptive neurotransmitter. That spinal MS does not inhibit the action of exogenous SP supports the contention that MS is not an antagonist for the SP receptor but exerts its antinociceptive action presynaptically. That analgesia follows SP administration by 30 minutes indicates that SP activates endogenous antinociceptive systems. The role of CAP as a SP releaser and depletor is supported by our observation of the biting and scratching response and subsequent analgesia. (Supported by NIDA Grant DA 01933 and U.S.P.H.S. Grant DA 00289.)

150.1 SOMATOTOPY OF PRESYNAPTIC CUTANEOUS NEUROPIL IN CAT DORSAL HORN. P. B. Brown and H. R. Koerber, Dept. of Physiology, West Virginia University Medical Center, Morgantown, WV 26506.

The projections of hindlimb cutaneous nerves to cat dorsal horn in segments L_2-Ca_1 were examined using transganglionic transport of horseradish peroxidase. Dorsal view maps were used to analyze the locations of terminal arbors in laminae III-IV. Nerves studied included three branches of the posterior femoral cutaneous nerve, medial and lateral branches of the sural nerve, the saphenous nerve, medial and lateral branches of the plantar nerve, and the lateral femoral cutaneous nerve. In order to compare the innervation and projection fields of pairs of nerves, two different nerves were loaded on opposite sides in the same cat.

Proximal preaxial nerves projected to segments rostral to L_6 and L_7, usually with a narrow band of terminals in lateral L_6 and L_7, skirting the representation of foot and toes which takes up the medial two thirds of laminae III-IV in these segments. Proximal postaxial nerves projected to segments caudal to L_6 and L_7, usually with a narrow band in lateral laminae III-IV in these segments. Nerves with both preaxial and postaxial components projected both rostral and caudal to L_6 and L_7. No somatotopically inappropriate projections were seen.

The degree of overlap or separation of projection fields of pairs of nerves was correlated with the degree of overlap or separation of their innervation fields on the leg, within 1-3 cm proximodistally and 2-4 cm circumferentially. The greater overlap circumferentially is consistent with the fact that within a given segment there are many dorsal horn cells with receptive fields overlapping both preaxial and postaxial skin. Thus, although there is a high degree of resolution in the organization of the terminal neuropil along the proximodistal skin axis at a given anteroposterior level, there is less resolution around the circumference of the leg. On the other hand, nerves with different circumferential locations of their innervation fields appear to project to different anteroposterior positions in the dorsal horn, as a consequence of the anteroposterior axis reflecting the dermatomal trajectory.

These results are consistent with the concept that the cells in laminae III-IV assemble their receptive fields largely by direct contact between their dendrites and cutaneous axon terminals, and that their receptive field locations, shapes and sizes are determined largely by the portions of the somatotopically organized presynaptic neuropil penetrated by their dendrites.

150.2 INHIBITORY AND WIDESPREAD CONVERGENCE OF SOMATIC AND VISCERAL INPUTS ONTO THORACIC SPINAL NEURONS IN THE CAT. Roger Thies and Robert D. Foreman, Dept. of Physiology and Biophysics, Univ. of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

We have studied with extracellular microelectrodes the discharges of single neurons in the T_2 and T_3 segments of the left spinal cord in chloralose-anesthetized cats. Of 33 neurons studied, 16 were identified as projecting to higher centers by antidromic activation from the ventral lateral quadrant at the spino-medullary junction, and eight were identified as spinoreticular by antidromic activation from the nucleus gigantocellularis. Of the nine remaining cells, four were excited and one was inhibited orthodromically by such stimuli. For visceral stimuli electrical shocks were applied to left or right sympathetic chains (at the stellate ganglion), to vagal branches from the heart, and to the central cut ends of cervical vagi. Twenty-four neurons had excitatory receptive fields in response to pinching skin or skin and muscle of the left upper foreleg and flank, similarly to spinothalamic neurons.

Eight of the nine neurons of interest here were inhibited by somatic stimuli; the ninth was excited by stimuli to all four limbs. Four of these were antidromically activated from the ipsilateral brain stem, and none were activated contralaterally. Their somatic fields showed inhibition in response to light touch or joint bending or firm pressure or pinching of one or more limbs, with contrasting excitatory fields from other limbs. Stimulation of left or right sympathetic chains inhibited two neurons, excited four, had no effect on four, and for one neuron excited from the left and inhibited from the right. These effects correlated with somatic stimulation overlying the visceral input. In addition, vagal stimuli had no effect on six neurons but inhibited three, a descending effect that we have reported previously (Thies & Foreman, Fed. Proc. 39:840, 1980).

These results show that some spinoreticular neurons in the upper thoracic cord have input from much of the body surface and viscera. This preprocessing of widespread information by some relay neurons may give higher centers an integrated view of sensory input, in comparison to the majority of neurons with restricted fields.

150.3 ULTRASTRUCTURE OF DORSAL ROOT AFFERENTS TO THE VENTRAL HORN IN THE CAT. M.S. Beattie, J.C. Bresnahan and F. Liuzzi*. Depts. of Surg. and Anat., The Ohio State University, Coll. Med., Columbus, Ohio, 43210.

Details of the terminal patterns and synaptic organization of primary afferent input to laminae VII-IX have been difficult to obtain with degeneration methods. The ultrastructure of these terminations has only recently been described in the monkey using electron microscopic autoradiography (Ralston and Ralston, '79). We have employed the anterograde transport of horseradish peroxidase (HRP) after application to the central ends of cut dorsal rootlets to provide a more complete picture of the light and electron microscopic morphology of this system in the cat lumbosacral cord. The distribution of primary afferent axons to the ventral horn appears to be restricted to the region close to the entry zone. A medial projection travels through the intermediomedial zone and descends along the medial border of lamina VIII arborizing in the medial motor nuclei. In mid-lumbosacral enlargement where lateral motor nuclei are present, an additional but more diffuse bundle of axons descends through mid-lamina VII and arborizes among the cells in lateral lamina IX. Light microscopic observations suggest that synaptic terminations are most numerous around the cell bodies in lamina IX, but are also present in laminae VII and VIII.

Electron microscopic observations confirm the presence of labeled synaptic terminals on cell bodies in lamina IX. Some of these terminals are associated with subsurface cisternae. Contacts with dendrites and dendritic spines are also present. All terminals have round and oval vesicles. A prominent feature is the presence of axo-axonic contacts between primary afferents and axon terminals containing pleomorphic clear vesicles. (Supported by N.I.H. Grants NS-10165 and NS-14457).

150.4 THE SYNAPTIC ORGANIZATION OF THE DEEP DORSAL HORN OF THE MACAQUE MONKEY. H.J. Ralston III and D.D. Ralston*. Dept. of Anatomy, Univ. of California, School of Medicine, San Francisco, CA 94143.

A quantitative electron microscopic study of the deep dorsal horn (Rexed's laminae IV, V and VI) has been carried out in normal animals and in those having dorsal root afferents labeled by degeneration following dorsal rhizotomy, or by autoradiography following injection of H^3 leucine into dorsal root ganglia. In all three lamina, synaptic profiles with round vesicles (R) constituted from 30 to 40% of the total synaptic population; profiles with pleomorphic and flat vesicles (F) made up about 60% of all synapses; central profiles (C), which are large dilatations along the course of certain axons, and which contain round vesicles and make multiple contacts with postsynaptic structures, comprise from 2 to 6% of all synapses. Profiles with large granular vesicles (LGV's) are uncommon in all 3 laminae. The vast majority of synaptic contacts are axon-dendritic; axosomatic synapses are about 1 to 2% of the total (most being formed by F profiles); and 1 to 2% are axoaxonal, mostly being F to C contacts. Presynaptic dendrites appear to be uncommon in the dorsal horn.

18 hours after dorsal rhizotomy, early degenerative changes occur in many C terminals and a few of the R's. These early changes are principally the accumulation of filaments and a clumping of synaptic vesicles. Within the next few days post-rhizotomy, most of the C's and about 10% of the R's undergo degeneration. In addition ot the filamentous degeneration found at 18 hours, many C and R profiles exhibit lucent alterations, with a loss of vesicles and other organelles, and no filamentous changes. Such lucent alterations are particularly evident in V and VI. By 5 days post-rhizotomy, many of the degenerating C's have been cleared from IV and V, but are still common in VI. Degenerating R's remain in all laminae through the first week. The majority of axoaxonal contacts present are upon degenerating synapses. Autoradiography results in the labeling of most C's and some R profiles, as well as numerous axons.

It is concluded that the primary afferent axons make up most of the C's and 10-15% of the R's. The different types of synaptic degeneration suggests different classes of afferent fibers. Most of the axoaxonal contacts are upon dorsal root axons. (Supported by NS-11614 from NIH.)

150.5 STRUCTURAL DIVERSITY OF PRIMATE MARGINAL (LAMINA I) NEURONS IN THE LUMBOSACRAL SPINAL CORD: A GOLGI STUDY. J.A. Beal, Department of Anatomy, Louisiana State Univ. Med. Ctr., Shreveport, LA 71130

To facilitate their examination, marginal neurons from adult Macaque monkies were divided into four groups on the basis of major structural differences in conformation, distribution and specialization of dendritic arbors. Group I consists of neurons with large diameter dendritic trunks which taper gradually and have few spines. This is a heterogeneous group of neurons of varying shapes which can be further subdivided into several subgroups on the basis of cell size (large-small) and other structural features. Group II is composed of large to medium size neurons and characterized by spiny dendrites. The cells are primarily elongated along the longitudinal axis and have a fusiform or pyramidal shape. Variations in dendritic conformation and distribution of spines here generates several subgroupings. Group III is composed of small to medium size neurons which have slender aspiny dendrites. Group III is composed of 2 subgroups, one characterized by dendrites confined to lamina I and the other characterized by tortuous interstitial dendritic branches which ramify in Lissauer's fasciculus and the lateral funiculus. Group IV consists of small spiny neurons which are fusiform to pyramidal in shape. These cells give rise to delicate, longitudinal spiny dendrites and are prevalent in the deeper regions of lamina I.

In summary, the present study demonstrates that the marginal neurons in the lumbosacral cord of the primate exhibit greater morphological variation than has been previously reported. There is enough structural variation within the subgroups to predict several functionally distinct cell types. Studies involving intracellular staining and recording of marginal neurons will have to consider and account for these structural variations.

150.6 EFFECTS OF TEMPERATURE ON RESPONSES OF SPINOCERVICAL UNITS TO LOW-INTENSITY CUTANEOUS STIMULI. G. W. King, T. J. Ebner, J. R. Bloedel. Depts. of Neurosurg. and Physiol., Univ. of Minnesota, Minneapolis, MN 55455.

The effects of thermal stimuli on the encoding of cutaneous information by spinocervical cells were studied in cats anesthetized with alpha chloralose. Forty-three units in the lower lumbar enlargement were identified as spinocervical neurons by demonstrating that they were antidromically activated from the ipsilateral lower cervical cord but not from the cervical cord rostral to the C-1 roots. A probe was placed on the most sensitive part of the cutaneous receptive field to produce small sinusoidal deflections of fur and/or toes at frequencies of 0.5-50 Hz. and amplitudes up to 0.5 mm. Cycle histograms characterizing the responses were compared with and without the application of radiant heat (skin temperature 35 to 60°C.) on and off the receptive field. Units typically responded with short bursts near the peak of the sinusoidal stimulus and usually followed inputs up to 15 Hz. The responses were initiated at a precise phase of the input at each input cycle. Heating of the skin within the receptive field usually produced an increase in the background noise (band pass equal to 50 Hz.) and the occurrence of a first order harmonic or doublet at low input frequencies even in the absence of a change in the fundamental response. Heating of skin areas outside the receptive field usually reduced the amplitude of the response with a decrease in the background noise and an increase in the degree of phase locking. Transient rebound excitation lasting 2-5 min. appeared when the heat was discontinued. The effect of heating was dependent upon input frequency. At stimulus frequencies of 10 Hz. or higher, heating resulted in a greater modulation of unitary activity with an associated increase in the signal-to-noise ratio. At input frequencies below 7.5 Hz., heating generally increased the background noise and decreased the signal-to-noise ratio. These experiments show that high intensity thermal stimuli produce specific changes in the way spinocervical neurons encode low intensity peripheral stimuli. Selective effects on the first harmonic of the response were noted independent of changes in the amplitude of the fundamental. Furthermore, heating increased the upper range of frequencies at which the spinocervical neurons could be modulated while decreasing the signal-to-noise ratio at lower input frequencies. This suggests that the frequency response characteristics of the spinocervical system shifts when noxious thermal stimuli are applied to the extremity. Supported by NIH Grant No. 5 RO1-NS 13002.

150.7 LOCALIZATION OF THE LAST ORDER INTERNEURON IN THE PATHWAY PRODUCING PRESYNAPTIC DEPOLARIZATION OF Ia FIBER TERMINALS IN THE LUMBO-SACRAL SPINAL CORD OF THE CAT. P. Rudomin, S. Dueñas* I.Jiménez*and E. Jankowska* Department of Physiol. & Biophys., Centro de Investigación del IPN, México and Department of Physiol. Goteborg University, Sweden.

The relatively long latency (2.5 to 4 msec) of the primary afferent depolarization (PAD) has indicated that polysynaptic pathways are involved in its generation. In addition, studies on the activation patterns of spinal interneurons suggest that those mediating the PAD of group I fibers may be located in the intermediate nucleus (Eccles et al, J. Physiol. 1962, 161:237). To have more information on the presumed location of the PAD-mediating interneurons we studied the effects of intra-spinal (IS) stimulation on the excitability of individual Ia fibers ending either in the intermediate or in the motor nucleus. In the cat anesthetized with pentobarbital we observed that 1) The excitability of group Ia fiber terminals was increased by IS stimulation. The lowest threshold regions (<2μA) producing the shortest latency effects (0.6 - 0.8 msec) were located in the region where group I fibers terminate, that is, within the intermediate and motor nuclei. 2) The excitability increase produced by IS stimulation could be obtained with intensities below the threshold of the afferent fiber whose excitability was being measured. 3) IS stimulation failed to increase the excitability of rubro-spinal and vestibulo-spinal fibers ending close to group I fibers in the intermediate and motor nuclei, respectively. 4) Stimulation of cutaneous afferents reduced the PAD of group Ia fibers produced by group I flexor muscle afferents, but did not affect the excitability increase produced by IS stimulation. 5) The excitability increase of group I fiber terminals produced either by sensory nerve or by IS conditioning stimulation was depressed (but not abolished) by picrotoxin or bicuculline. These results suggest that: 1) IS stimulation activates neuronal elements, presumably interneurons, which are able to depolarize group I fiber terminals but not nearby descending fibers. 2) This rather specific action results, at least in part, from direct activation of the last interneuron in the PAD pathway, located close to the terminals of the target afferent fibers. 3) The inhibition that cutaneous volleys produce on the PAD of group Ia afferent fibers is probably not exerted on the last interneuron in the PAD pathway. This suggests that the shortest possible pathway for the PAD of Ia fibers is trisynaptic.

150.8 ALPHA-CHLORALOSE SUPPRESSION OF SINGLE NEURON ACTIVITY IN THE DORSAL HORN OF THE SPINAL CORD. J.G. Collins, E. Homma* and L.M. Kitahata. Dept. of Anesthesiology, Yale University School of Medicine, New Haven, Ct. 06510.

It has recently been reported that the presence of an anesthetic agent can profoundly alter the functioning of neurons within the central nervous system (Collins and Roppolo 1980)[1]. Alpha-chloralose is widely used as an anesthetic agent in neurophysiological research, often because of the belief that it causes minimal suppression of neuronal activity. This study was undertaken in order to determine what effect an anesthetic dose of alpha-chloralose would have upon activity of single cells in the dorsal horn of the spinal cord in the absence of descending supraspinal influences.

We examined the effects of recrystallized alpha-chloralose on activity of neurons in the dorsal horn of decerebrate, spinal cord transected (L-1) cats which were paralyzed with gallamine triethiodide. The animals (2.2-4.8 kg) had been surgically prepared (tracheal, carotid artery and jugular vein cannulation and lumbar laminectomy, L-7, L-4) under halothane, nitrous oxide-oxygen anesthesia, but at least 3 hours passed between the end of anesthetic administration and the start of drug studies. Physiological parameters were monitored and maintained within normal limits. Tungsten microelectrodes were used to record extracellular single unit activity from low threshold, wide dynamic range, and proprioceptive neurons in the dorsal horn at the L-5, L-6 level. Light brushing was used to activate low threshold neurons. Noxious radiant heat (51°C) was used to activate wide dynamic range neurons. Spontaneous activity of proprioceptive neurons was recorded, in addition to the spontaneous activity of low threshold or wide dynamic range neurons. We report that a low anesthetic dose of alpha-chloralose (50 mg/kg I.V., dissolved in propylene glycol), caused a profound reduction, although not a complete elimination, of activity in neurons recorded from the dorsal horn of the spinal cord. Transection of the spinal cord eliminated the possibility that the effect was mediated by supraspinal mechanisms. Although extrapolation from this preparation to all parts of the central nervous system is not possible, the results of this study, in combination with recent reports (e.g. Haimann et al. 1978)[2] strongly suggest that the presence of alpha-chloralose in a neurophysiological preparation may cause significant changes in neuronal activity and thus influence the possible interpretation of the resultant data. 150.9 SEGMENTAL- AND BRAINSTEM-EVOKED DORSAL ROOT POTENTIALS (DRP) SELECTIVELY AFFECTS SPONTANEOUS ANTIDROMIC ACTIVITY. Barry D. Goldstein and Edmund G. Anderson. Dept. of Pharmacology, Univ. of Ill. Med. Ctr., Chicago, IL 60612.

Spontaneous antidromic action potentials observed in afferent nerves, called the dorsal root discharge (DRD), appears to be a normally occurring phenomenon associated with primary afferent depolarization (PAD), but is pharmacologically distinct from the process involved in generating evoked-DRPs (Repkin et al., Brain Res. 117:147, 1976; Kammerling and Anderson, Neurosci. Abst. 3: 502, 1977). Seventy percent of the afferent fibers exhibiting DRD have conduction velocities (CV) corresponding to group II fibers (40-72 m/sec), while the remaining 30% have group I conduction velocities (72-120 m/sec). Examination of multiple unit recordings have shown that synchrony of the DRD occurs during the segmentally-evoked DRPs (seg-DRP). Since seg-DRPs occur in group I fibers and brainstem-evoked DRPs (bs-DRP) occur in group II fibers (see Schmidt, Ergeb. de Physiol. 63:20, 1971), it was important to determine whether the DRD in afferents identified by conduction velocity was selectively influenced by stimulation at these two sites.

Dorsal laminectomies were performed on unanesthetized spinal and decerebrate cats. L7 and S1 dorsal roots were isolated and cut distally. Single unit DRD activity was obtained by carefully splitting the dorsal roots into filaments. The conduction velocities of fibers displaying DRD were determined from the latency between two pairs of recording electrodes. Once the unit was identified, group I threshold seg-DRPs were evoked via stimulation of the S1 dorsal root and bs-DRPs were evoked using an electrode stereotaxically placed in the brainstem.

In eight spinal cats, 30 single units were obtained with spontaneous DRD. Twenty-four units had CVs in the group II range and six had CVs in the group I range. Of the 24 group II fibers, only 17% discharged in synchrony with the seg-DRP as shown by post-stimulus time histograms. However, 67% of the group I fibers responded in synchrony with the seg-DRP. In five anemically decerebrate cats, 20 single units with spontaneous DRD were observed with 14 units having CVs in the group II range and six in the group I range. In these animals, both bs- and seg-DRPs were evoked. Seventy percent of the group II fibers responded in synchrony to the bs-DRP while none of the group I fibers responded. Conversely, 29% of the group II fibers and 100% of the group I fibers fired in synchrony to the seg-DRP.

These data show that PAD in group I fibers selectively affects group I DRD while PAD in group II fibers selectively affects group II DRD with modest cross-activation in the other fiber groups. (Supported by PHS NS-14985).

150.10 THE FUNCTIONAL ANATOMY OF THE COERULEO-SPINAL PATHWAY. R. T. Stevens†, C. J. Hodge, A. V. Apkarian†, G. D. Vogelsang†, H. J. Wisnicki* and O. Brown* (SPON: S. G. Nord) Dept. of Neurosurgery, Upstate Medical Center, Syracuse, NY 13210.

Retrograde and antegrade transport studies have demonstrated projections, which are primarily ipsilateral, from the noradrenaline (NA) containing cells of the locus coeruleus (LC) to the spinal cord. Essentially all spinal catecholamines are contained in the terminals of the coeruleo-spinal and other bulbospinal pathways. Our previous studies have shown that the modulating effects of LC on spinal sensory units is functionally bilateral. This study was done to correlate anatomic and physiologic data demonstrating the location of the functional crossover of coeruleo-spinal and descending noradrenergic pathways.

Anatomic determination of the location and density of noradrenaline (NA) containing terminals in the dorsal horn was done using a glyoxylic acid histofluorescence method and confirmed by quantitative determinations using high pressure liquid chromatography. For these studies, various spinal cord lesions were made two weeks prior to the sacrifice. Physiologic studies entailed the determination of the effects of ipsilateral and contralateral stimulation of LC on lumbar dorsal horn unit responses to skin stimulation. For the physiologic experiments various acute spinal cord lesions were made. The cord lesions for the physiologic and anatomic studies were identical.

Midthoracic cord section resulted in complete loss of dorsal horn terminal fluorescence below the level of the lesion and abolished any effects that LC stimulation had on dorsal horn cell responses. After low thoracic hemisection significant amounts of equally distributed catecholamine (CA) fluorescence were found below the level of the lesion on both sides of the cord. Low thoracic hemisection had no effect on the inhibition of dorsal horn cell responses caused by either ipsilateral or contralateral LC stimulation. The addition of a midline sagittal section to the hemisection caused loss of CA fluorescent terminals only ipsilateral to the hemisection along the rostro-caudal extent of the sagittal section. Similarly only those cells in dorsal horn ipsilateral to the hemisection and within the rostro-caudal limits of the sagittal section were uneffected by LC stimulation.

These results suggest that the descending noradrenergic coeruleo-spinal pathway gains access to both sides of the spinal cord via both suprasegmental and local segmental crossover.

150.11 **NEURAL ORGANIZATION OF SACRAL SPINAL CORD IN CATS.** **B. Dubrovsky and P. Pacheco*. Neurophysiology Laboratory, Allan Memorial Institute, McGill University, Montreal, P.Q.**

The caudal end of the spinal cord; 2nd, 3rd sacral and caudal segments, is involved in reflex control of midline structures, notorious among which, in many quadrupedal mammals is the tail. Intactness of sensory and motor nerve fibers in the pudendal nerve (2nd and 3rd sacral divisions) is a necessary condition for maintenance of the tonic activity observed in the EMG of the external sphincter muscle of both anum and urethra. The caudal end of the spinal cord also mediates neural activity associated with sexual behavior. Further, tail and neck movements are integrated to various extents with the main girdes of the back of different species and have a balancing or cantilever function. In our studies the spinal cord was sectioned between the 1st and 2nd cervical level while the animals were under ether anesthesia. Monosynaptic connections described by Lloyd and Wilson (J. Gen. Physiol. 42, 1219) with direct dorsal root electrical stimulation in S3 were obtained only by stimulation of nerve trunks innervating tail musculature. Pudendal nerve stimulation as well as of the nerve of the levator ani muscle, only elicited polysynaptic reflexes recorded from proximal sections of S2 and S3 ventral roots. Neither with maximal stimulation, monitored by recording afferent volleys from corresponding dorsal roots, nor with tetanic priming stimulation was it possible to observe monosynaptic responses. The absence of monosynaptic responses to pudendal nerve stimulation suggests that spindle receptor organs in both external ani and urethral sphincter muscles subserve only the tonic component of the stretch reflex. Analogous phenomena, the existence of the tonic, but not phasic component of the stretch reflex was also noted by us in extraocular muscles of the cat (Barbas and Dubrovsky, Neurosc. Absts. 5, pp. 689).

The amplitude of polysynaptic potentials recorded in L7 and S1 ventral roots to maximal electrical sural nerve stimulation were significantly affected by cervix and perivaginal skin stimulation. The head piece of an otoscope was positioned in the vaginal cavity. Through the openings of the piece a glass rod could be directly applied to the cervix thus eliminating spurious sources (vaginal, cutaneous) of activation. Pressure on the cervix decreased ventral root potentials by 25-30% of control values. This effect could not be maintained, however, throughout the duration of the stimulation. After 4-5 sec. potentials returned to control levels. In contrast, perivaginal skin tapping decreased the amplitude of ventral root potentials by as much as 90% of the control amplitude. Moreover, this effect outlasted the effect of the tapping by as much as 5-10 sec.

150.12 THE STRUCTURAL ORGANIZATION OF SPLANCHNIC NEURONS IN POSTERIOR SPINAL SENSORY GANGLIA OF THE CAT STUDIED BY A MODIFIED HORSERADISH PEROXIDASE (HRP) REACTION USING THE CRYOSTAT. David C. Kuo*, George M. Krauthamer and Dwayne S. Yamasaki*. Anatomy Dept., Rutgers Medical School, Piscataway, N.J. 08854

The organization of visceral sensory neurons in the posterior spinal ganglion has not been investigated. This organization is elucidated in the present study by HRP technique. Retrograde transport of HRP from the central cut end of the major splanchnic nerve was used to label splanchnic sensory neurons in thoracic spinal ganglia. In addition, the conventional HRP reaction was modified using the cryostat to ensure proper orientation and sequence of tissue sections.

With the animal lying on its right side, a left laparotomy was performed. The left major splanchnic nerve was identified and dissected free from surrounding tissue. The nerve was cut. A small sheet of plastic was placed under the central nerve stump, which was exposed to HRP crystals for 60 min. Animals survived for two to five days.

In our initial experiments, left posterior spinal ganglia were cut into 50-75 μm sections using the freezing microtome. Sections were reacted free floating with tetramethyl benziding (TMB). Round to oval HRP labeled neurons of splanchnic origin were identified in spinal ganglia from T3 to T13 with the majority of cells concentrated between T5 and T11. In other experiments, in order to ensure proper orientation and sequence of tissue sections, the HRP reaction was modified using the cryostat. Serial cryostat sections (20-30 μm) cut at -20°C were plated immediately onto glass slides pretreated with chrome-alum. Sections were heat dried at 65°C for 45 to 60 min. and then incubated with TMB. Sensory ganglia were reconstructed by photomicroscopy and camera lucida drawings. Useful data for this study came from eight animals.

Our results showed that HRP labeled visceral neurons were distributed throughout the entire ganglion. Labeled cells measured between 20 and 80 μm. Clustering of visceral cell bodies was seen but there was no discernible pattern of localization. Visceral sensory organization is thus similar to somatic representations within posterior spinal ganglia. We speculate that cell clusters of visceral origin may represent functional segregation or, perhaps, specific innervation of individual viscera.

150.13 ACCUMULATION OF TOTAL CALCIUM IN EXPERIMENTAL SPINAL CORD TRAUMA R. D. Happel*, K. P. Smith*, J. M. Powers*, J. D. Balentine*, N. L. Banik and E. L. Hogan, J. Byrd*. Depts. of Neurology and Div. of Neuropathology, Med. Univ. of South Carolina, Charleston, S.C. 29403.

An increase in tissue calcium may be involved in the pathogenesis of experimental spinal cord trauma. Recent EM studies demonstrated intracellular Ca^{2+} deposits in the lesion shortly after injury. (Balentine and Spector, Ann. Neurol:2,520, 1977). In order to examine further the cellular effects of trauma, we have quantitatively measured the time course of Ca^{2+} accumulation in the traumatic lesion. Spinal cord trauma was produced in rats by dropping a 10 gm weight from 30 cm on exposed dura-invested spinal cord. Lumbar sections of traumatized spinal cord and internal controls from non-traumatized cervical cord were excised and analyzed for Ca^{2+}. Spinal cord sections (9mm length) were lyophilized to dry weight and 50 ± 2mg dry weight tissue was digested in 0.5 ml HNO_3 (8 hrs. at 37°C). Following appropriate dilution with 1% $LaCl_3$ in 0.1 N HCl, the samples were centrifuged (15,000 xg, 10 min.) and total Ca^{2+} was determined in the supernatant using atomic absorption apectroscopy. Ca^{2+}-levels in the lesioned area were significantly elevated over control values within 45 minutes post-trauma ($p < .005$), with maximal increase at 8 hrs. (1147 ± 7 µg Ca^{2+}/gm dry wt. tissue). This value which represents a 4.1 fold increase in Ca^{2+} showed no evidence of decreasing after 72 hours post-trauma. Using Paired-t analysis the mean deviation between cervical control and lumbar lesion Ca^{2+} levels was 465.5± 120.7 (df=8) µg Ca^{2+}/gm dry weight tissue. In the same animal model, Banik et al. (abs. Soc. Neurosci. 9:396, 1979) found an increased proteinase activity which was inhibited by EDTA. The increase of tissue calcium in the lesion suggests that Ca^{2+} activation of neutral proteinase may be a mediator of the traumatic cell necrosis. (Supported by NIH-NINCDS Grant No. NS 11066).

150.14 CALIBRATION OF SPIKE AMPLITUDE PROFILES OF CELLS IN CAT SPINAL CORD LAMINAE I-VI: A PRELIMINARY TO EXTRACELLULAR CHARACTERIZATION OF CELL TYPES. H. R. Koerber and P. B. Brown (SPON: R. Millecchia), Dept. of Physiology, West Virginia University Medical Center, Morgantown, WV 26506.

The correlation of physiological properties of neurons with their anatomical properties, such as cell location, size, and dendritic geometry, is best accomplished by a combination of extracellular recording to characterize the cell's response properties and intracellular penetration to inject a dye to visualize the cell after histological processing. Unfortunately the yield is low using such a technique. For studies which require recording from large numbers of cells in the same animal, such as dorsal horn mapping experiments in which the somatotopy or right and left dorsal horn must be compared after unilateral partial deafferentation, extracellular recording is the method of choice, provided that some statements can be made about such anatomical attributes of the cells as their laminar, anteroposterior, and mediolateral locations, and cell size.

A beginning toward these objectives has been realized using a "smart electrode" program on the LM-SQUARE computer to control the stepping microdrive carrying the microelectrode, and an action potential wave form detector to follow the transformations of a single unit's wave form as a function of electrode depth. The smart electrode system can follow such transformations, even in the presence of other wave forms which are also changing with electrode position. A plot of the peak-to-peak amplitude of a unit's spike wave form, the amplitude profile, is used to determine the depth at which the recorded unit lies, the distance of the unit from the electrode track, and the relative size of the element generating the spike.

Calibration experiments reveal a close agreement of the depth of the recorded cell (indicated by a small electrolytic lesion at the depth of maximum amplitude) in a number of different tracks at different distances and in different directions from the unit. In addition, the distance of the cell from the electrode track has been demonstrated to be related to the slope of the amplitude profile, in triangulation experiments. Also, the relative cell size distributions, calculated from the peak amplitudes and the distances of units from electrode tracks, are correlated with the observed distributions of cell sizes in histological reconstructions.

The calibration functions thus obtained have been used to enhance the smart electrode system so that it can search for and select for cells lying within a specified recording radius of the electrode track and to select for relatively large or small cells.

150.15 TACTILE DISCRIMINATION FOLLOWING THORACIC CORD LESIONS IN CAT. G. P. Frommer. Dept. Psychol., Indiana U., Bloomington, IN 47405

The effect of lesions in thoracic cord of cats was tested on discriminations between touches on the left and right side, between rostrally and caudally directed strokes, or between large diam. (5 or 3.8 cm) and small diam. (.6 cm) discs. The cat had to turn its head toward food cups to its left or right, depending on which stimulus from a pair was manually delivered to its thigh. All but one cat preoperatively mastered the side of touch task to a criterion of > 90% correct on two of three consecutive days. All but three mastered one of the other tasks as well. Pain reactivity was tested with pin pricks and strong pinches. Orienting to hair movement was tested while the cat was eating. The lesions, made with the aid of a dissecting microscope, were aimed at (a) dorsal columns (DC) (N=2); (b) dorsal lateral columns (DLC) (N=2); (c) DC+DLC (N=2); or (d) ventral cord sparing DC (N=2) or DC+DLC (N=3). Animals are still being tested, so anatomical verification is not yet available.

DLC lesions permitted immediate recovery to preoperative levels of performance. After lesions in DC, cats took 46 and 122 days to recover mastery of the stroke direction and size discriminations, respectively. Lesions of DC+DLC prevented relearning within the allotted time. Performance on the simplest task (side of touch) remained at chance for 34 days. Above the level of the lesion this task was mastered within 25 days. When pin pricks below the level of the lesion replaced touch stimuli, one cat remained at or near chance for 43 days, while the other began performing consistently above chance after 33 days. Reactivity to painful stimuli was grossly normal postoperatively in all cats with lesions in the dorsal cord. Lesions in the ventral cord permitted learning or slow relearning of the side of touch task (2 cats) and the stroke direction task (2 cats). This lesion prevented recovery of the size discrimination (1 cat), which was the most difficult task to learn preoperatively. Cats with ventral lesions showed little if any reaction to painful stimuli below the level of the lesion, but they oriented reliably and consistently to hair movements.

150.16 A METHOD FOR CONTINUOUS AND CONTROLLED DRUG DELIVERY TO THE TRANSECTED SPINAL CORD. J. C. de la Torre and N. Hayashi*. Dept. of Neurosurgery, Univ. Miami Sch. of Med., Miami, Fl 33101.

A technique has been developed to deliver drugs or fluids to experimentally transected spinal cord using an osmotic minipump connected to a catheter system.

Long-Evans hooded rats undergo laminectomy and transection of the spinal cord at T_{10} and after bleeding is controlled, a graft is inserted between the transected cord stumps.

The minipump is loaded with the drug or fluid and a 1.5 cm PE-60 tubing is loosely fitted to it while its distal end is connected to a "flared" PE-10 tubing. The latter tubing is shaped by heating to resemble the Greek letter "omega" or a "horseshoe" at its end so that the "arched" section of the tubing fits above, but does not touch, the transected cord tissue. The two ends or "legs" of this horseshoe-shaped tubing are anchored with 4-0 sutures to the muscles just lateral to the spinal cord. A syringe with a 30 gauge needle is connected to the end of the PE-10 tubing and the entire catheter is filled with the same solution contained in the minipump.

After the catheter system has been filled, the proximal end of the PE-60 tubing is connected to the flow moderator of the minipump. With a fine-tip ophthalmic cautery, a 1 mm puncture is made in the middle of the arched PE-10 tubing above the cord. A moist, pressed, gelfoam pledget is placed on the dorsal spinal cord to cover the transected ends while drugs or fluids from the punctured catheter above, drip on the gelfoam at a rate of 1 µl/hr. After surgery, the muscles and skin are closed in layers and the minipump is placed in a subcutaneous pouch. The minipump may be reloaded after 1 week.

Post-mortem studies on 9 rats show that minipump-catheter delivery of 10% Evans-Blue fluorescent dye to the transected cord area for 1-2 weeks, is taken up by the spinal cord tissue throughout its cephalo-caudal length as evidenced by fluorescent staining of blood vessels and tissue.

The method appears reliable for the continuous and rate controlled flow of drugs, fluids and dye markers to the spinal cord tissue and may be of value in CNS regeneration studies.

150.17 A RELIABLE E-M FIXATION PROCEDURE FOR THE ADULT RAT FUNICULI GRACILI.

P.K. Hill, J.C. de la Torre and S.B. Thompson*. Anatomy Dept. EVMS, Norfolk, VA. 23510 and Neurological Surgery Dept., U. Miami School of Med., Miami, Fla. 33101

To develop an adequate fixation of adult rat dorsal funiculi for ultrastructural study, experiments utilizing 5 female Sprague-Dawley rats (250-300 gm.) involved cannulation of the ascending aorta via the left ventricle. Five minutes before cannulation of the heart, the abdominal aorta immediately before its bifurcation is ligated and 8 cc. of 1% sodium nitrite-heparin is injected into the inferior vena cava (I.V.C.). The Harvard apparatus compact pump #975 delivers 600 cc. of 4% glutaraldehyde - 6% paraformaldehyde in 0.1M sodium cacodylate buffer containing 0.2% $CaCl_2$ (pH 7.4, r.t.) at 24 cc./min. for the first 3 min. and then 33 cc./min. for completion of prefixation. A small incision in the I.V.C. serves as a fluid release. The spinal cord is removed immediately and microscopic dissection of the right and left L-1 dorsal columns prepared (+4°C). The tissue is washed overnite in cold cacodylate buffer and post-fixed in a 1% osmium tetroxide (OsO_4) solution buffered in a 2% aqueous stock solution of OsO_4 that is diluted immediately before use. Dehydration involves 2 changes in cold 50% ethanol (EtOH) for 5 min. each, 1 change each in cold 70%, 80% and 95% EtOH, 2 changes for 10 min. each in cold 100% EtOH and 2 changes of propylene oxide (P.O.) for 15 min. each. The tissue is first infiltrated in a 1:1 mixture of P.O.: epon for 1 hr. at 37°C and then placed in pure epon for 1 hr. in a desiccator and embedded in flat molds with a fresh change of epon under vacuum at 5 lb./in.^{2} overnite at +60°C. One µm sections are prepared with glass knives and stained in aqueous 0.5% methylene blue-azure blue in 0.05% sodium borate. The fasciculi gracili are located medially and dorsally in the right and left L-1 dorsal columns and trimmed down for ultra-thin sectioning. Silver-toned sections prepared with the Dupont diamond knife are stained with a saturated ethanolic uranyl-acetate solution for 20 min. and 2.0% lead citrate for 3 min. Ultrastructural examination is done with the Philips 301 electron microscope. The results indicate consistently that unmyelinated, small-medium sized myelinated fibers, glia and blood vessels are well preserved. Some medium-sized myelinated fibers and large myelinated fibers show slight separation of lamellae. To remedy that problem, pressures that would potentially distort the entire tissue would have to be used. When comparing preservation of unmyelinated and myelinated fibers of the dorsal funiculus with those of the ventral gray matter, it is reassuring to know that the adequacy of fixation is similar inspite of a two-fold greater blood supply to the ventral gray matter.

150.18 SPONTANEOUS ACTIVITY GENERATED IN SCIATIC NEUROMAS, A (^{14}C)2-DEOXYGLUCOSE UPTAKE STUDY IN THE RAT.

S. David* and A.J. Aguayo. The Neurosciences Unit, Montreal General Hospital and McGill University, Montreal, Canada.

Electrophysiological studies after sciatic nerve section in the rat have demonstrated that spontaneous activity is generated at the site of nerve section; the peak of this activity occurring between 5-15 days after injury (Brain Res. 159:406-410, 1978). In the present study we have examined the effects of such electrical discharges on spinal cord activity utilizing the (^{14}C)2-deoxyglucose (2DG) technique.

Both sciatic nerves were transected above the knee in 200-300 gm. Sprague-Dawley rats. The cut end of the nerves was ligated and capped with a polyethylene tube to prevent regeneration. Thirteen days after nerve section animals were anesthetized with sodium pentobarbital and the neuroma on one side was exposed and bathed in 2% Xylocaine. Animals were then injected with 2DG (15µCi/100 gm.), sacrificed 45 minutes later and segments of the lumbar spinal cord prepared for 2DG autoradiography and histology. The autoradiographs were scanned with a Zeiss Axiomat microscope and T.V. densitometer along with a PDP 11 computer. Results of the microdensitometric analysis indicate an increase in 2DG uptake at the L_4-L_5 levels of the spinal cord particularly in laminae I to V and IX on the side of the neuroma not blocked with Xylocaine.

Since there was a reduction in 2DG uptake on the side of the spinal cord ipsilateral to the nerves treated with local anaesthetic, the increase in autoradiographic density seen on the untreated side is considered to be largely due to the spontaneous ongoing activity generated at the site of the neuroma. These findings support the view that similar activity from injured nerves might be responsible for the sensory symptoms observed in patients with post-traumatic neuromas (Nature 248:740-743, 1974).

(Supported by the MRC of Canada).

150.19 DISTRIBUTION, DENSITY, AND SIZE OF MUSCLE RECEPTORS IN CAT TAIL.

M.D. Goldfinger and Y. Fukami, Dept. of Physiology & Biophysics, Washington University, St. Louis, Missouri, 63110.

In nembutal anesthetized adult cats, dorsolateral tail muscles on both sides were exposed to 1 or 2.5% OsO4 in 0.1M cacodylate buffer for 20-40 minutes, washed in Ringer, divided into segments, and stored in glycerol. Under a dissecting microscope, darkly stained myelinated nerve fibers were easily recognized and traced to their termination (or terminal branches) on extrafusal muscle fibers as well as in muscle spindles and tendon organs (GTO). The size and distribution of muscle receptor capsules (ie. visible capsule space) along the tendon and entire muscle length were determined for each side of each caudal segment (starting with #4 or #5). Data were obtained for three tails.

For an entire tail side, the number of receptors and muscle mass per segment decreased caudally. The average numbers of receptors per segment were: 7 spindles (5-8) and 6 GTOs (5-6). The average total numbers of receptors per side were: 63 (56-71) spindles and 53 (43-58) GTOs. An average of 25% of ipsilateral spindle capsules were 'tandem'; there were 7 tandems (avg.) per side. The average ipsilateral receptor densities were: 142 spindles/g-muscle (92-188); 121 GTO/g-muscle (79-166). Opposing side total receptor numbers were similar: the range of departure from right vs. left average was 3-12% for spindles and GTOs; for a given segment, the dissymmetry could be larger. Correcting for multi-GTO innervation by single axons, the average ipsilateral Ia/Ib afferent axon ratio was 1.3 (1.0-1.7).

Averaging the means of receptor capsule space size distributions for the three whole tail samples gave:

Spindles - Length: 900µm(360-1510), Center Width: 140µm(40-240);
GTO - Length: 870µm(350-1120), Center Width: 75µm(30-100).

Scatter plot regression analysis revealed significant correlation between spindle capsule space length and center width; for GTO capsules, this correlation obtained in 2 of 3 tails.

The average spindle position-expressed as percent extrafusal muscle length from tendon to capsule center-was 45% (avg. range: 2-99%). While spindle capsules were distributed uniformly over 75% of the muscle length from the tendon, there was a lower (avg. 53%) occurrence over that 25% muscle length closest to the origin. There was no correlation between spindle capsule space length or center width and capsule center position on the extrafusal muscle longitudinal axis.

GTO capsules received an average of 10 input muscle fibers (avg. range: 3-22). In 2 of 3 tails, the number of input muscle fibers was significantly correlated with capsule width.

150.20 MUSCLE SPINDLE DENSITY IN REGIONS WITH VARYING OXIDATIVE INDICES OF PIGEON FOREARM MUSCLES.

Alfred Maier. Department of Anatomy, University of Alabama, Birmingham, AL 35294.

Preferential location of muscle spindles in regions with high oxidative index (OI; sum of number of slow-twitch oxidative and fast-twitch oxidative-glycolytic fibers/total number of fibers x 100) has been noted first in rat hindlimb muscles (Yellin, Am. J. Anat., 125:31-46, '69), and since then has been reported for other species. From these findings the view arose that muscles with high OI have greater spindle densities than muscles with low OI. In the past, OI calculated from single histochemical series have been routinely used to characterize whole muscles and their associated spindle densities, but with few exceptions (e.g. cat soleus), muscles are not histochemically homogeneous. The present work took regional histochemical variation into account when considering relations of OI to spindle density in 13 muscles of the pigeon forearm. The muscles were grouped into wrist flexors, wrist extensors, flexors of digits, extensors of digits, pronators, supinator and anconeus. Three specimens of each kind of muscle were serially cross-sectioned. Each fifth section was mounted and stained by the van Gieson technique. At appropriate intervals, sections incubated for myofibrillar adenosine triphosphatase or succinic dehydrogenase were interposed to evaluate the histochemical profile at different points along the length of muscles. This allowed the partitioning of individual muscles into from 7 to 27 segments of different histochemical composition. Spindle density was calculated per mm^3 for each separate segment. The level of OI below which no spindles were found in a fascicle ranged from 50% (pronators) to 67% (supinator). Plots of spindle density against OI showed a positive correlation for each muscle. Means of populations of slopes representing concomitant increases in spindle density with increasingly greater units of OI were not significantly different ($p \leq 0.01$) among the seven muscle groups. However, correlation coefficients (r) varied within muscle groups, or even among specimens of the same kind of muscle. The lowest values of r were seen in flexors and extensors of the wrist, anconeus and supinator. The correlation held best for extensors of the digits. In these, r was significantly greater ($p \leq 0.01$) than in flexors and extensors of the wrist, anconeus and supinator. Nevertheless, in any muscle group there was a range of spindle density values for the same value of OI. Low densities for OI greater than 90% were as frequent as high densities for OI below 70%. It has been suggested (Botterman et al., Am. Zool., 18:135-152, '78) that the distribution of spindles is preferentially linked to readily recruited "oxidative" motor units. The scatter in density indicates that this presumed functional association can proceed without strict incremental allotments of spindles for increasingly greater values of OI.

150.21 MECHANORECEPTOR FATIGUE IN CAT TRIGEMINAL NEURONS.

Paul D. Shepard*, Kathy L. Howard* and David J. Barker. Dept. of Physiology, North Texas State University/Texas College of Osteopathic Medicine, Fort Worth, TX 76107.

In the course of investigating the effects of sympathetic efferent stimulation on facial mechanoreceptors in the cat, we observed that fatigue was prominent in most receptors. Fatigue is defined as a reduction in number of impulses to repeated presentations of the same mechanical stimulus. Fatigue differs from adaptation which is a reduction in number of impulses during a constant stimulus. Fatigue is reversible with rest periods of sufficient length. We also observed that phentolamine, a sympathetic noradrenergic antagonist produced a temporary reversal of the fatigue process. The present study was undertaken to (a) Examine the relationship between fatigue and various stimulus parameters (amplitude, duration, interstimulus interval); and (b) Further examine the reversal of fatigue by phentolamine.

Single units were recorded from the trigeminal ganglion of anesthetized (pentobarbital) cats. Facial cutaneous mechanoreceptors were stimulated with trapezoidal waveforms delivered by an axial displacement generator. The following stimulus parameters were included: (a) amplitude: 250, 500 and 1000 microns; (b) duration: 1, 5 and 10 sec; (c) interstimulus interval: 10, 20 and 40 sec. The following results were obtained: (1) Fatigue occurs to some extent in all mechanoreceptors, depending on the particular combination of stimulus parameters; (2) The magnitude of fatigue is greater among slowly adapting receptors (average of 50% decline in number of spikes over 10 trials of the same stimulus) than among rapidly adapting receptors (20% decline in spikes over 10 trials); (3) A 3 minute rest period is sufficient to reverse fatigue; that is, fatigue does not occur when the interval between stimuli is this long; (4) Generally, among slowly adapting receptors, the magnitude of fatigue varies directly with stimulus amplitude and duration, and varies inversely with interstimulus interval. However, the effects of interstimulus interval are different at different amplitudes and durations; (5) In about 50% of the slowly adapting receptors, IV injection of phentolamine (5 mg) resulted in periodic reversal of fatigue and/or an increase in spontaneous firing (during the interstimulus interval). The peak magnitude of this effect and duration coincided with the time to maximal response and duration of action of this drug. Our results suggest that fatigue can be a significant component of mechanoreceptor response profiles and may be a significant source of variability in studies of mechanoreceptor coding. The phentolamine data suggests that sympathetic efferents may alter viscoelastic properties of skin which may be important in mechanoreceptor fatigue.

151.1 HYPOPHYSECTOMY PREVENTS THE STRIATAL DOPAMINE RECEPTOR SUPERSENSITIVITY PRODUCED BY CHRONIC HALOPERIDOL TREATMENT. Lynn M. Ludmer* and Robert E. Hruska (SPON: Paul D. Thut). Neurotoxicology Section, NINCDS, NIH, Bethesda, MD 20205.

Chronic Haloperidol (HAL) treatment of adult male rats is well known to produce supersensitive dopamine (DA) receptors in the striatum. This phenomena has been proposed to result from a compensatory increase in DA receptor number. This supersensitivity is thought to be important in the clinical development of tardive dyskinesia, which results from chronic neuroleptic treatment. In the pituitary DA acts to inhibit prolactin secretion. Blockade of the DA receptors by HAL produces an increase in prolactin release, which is maintained during chronic HAL treatment. We have tested the effects of chronic HAL treatment on striatal DA receptors in rats after hypophysectomy (Hypox). Male rats were obtained from Taconic Farms on the day after Hypox. These rats were maintained on a drinking solution containing 5% dextrose and a balanced salt solution, and kept in the warmest part of the animal room (25°C). At the same time a group of weight matched non-operated control rats were obtained and housed in the same area. The experiment was initiated on the second day after Hypox. One-half of the control rats and one-half of the Hypox rats were injected daily, i.p., with 1 mg/kg HAL for 3 weeks. The remaining rats were injected with saline. Then treatment was discontinued for one week before sacrifice by decapitation. DA receptors were measured in the striata using [^{3}H]spiroperidol in our routine assay procedure (Eur. J. Pharmacol. 61: 397). In the control rats, HAL treatment produced the expected increase in the number of striatal DA receptors (28%), but did not change their affinity. Hypox, by itself, did not alter either the number or affinity of the DA receptors. However, Hypox did prevent the development of striatal DA receptor supersensitivity normally produced by chronic HAL treatment. It should be noted that during the 4 weeks of this experiment, the Hypox rats gained no weight or lost some, while the control rats gained an average of 130 g. Chronic HAL treatment did not appear to affect weight gain in either treatment group. This experiment suggests that the striatal DA receptor supersensitivity produced by chronic HAL administration is mediated through the pituitary or requires a pituitary cofactor. Further it is possible that the production of this supersensitivity depends on prolactin, since HAL increases prolactin levels in control rats, while there is no prolactin available in the Hypox rats. This may be of relevance in the mechanism of the development of tardive dyskinesia after chronic neuroleptic treatment, and may explain the reported higher incidence of tardive dyskinesia in females, who have higher circulating levels of prolactin.

151.2 THE STRIATAL DOPAMINE RECEPTOR SUPERSENSITIVITY PRODUCED BY ESTROGEN MAY BE MEDIATED THROUGH PROLACTIN. Robert E. Hruska, Lynn M. Ludmer* and Ellen K. Silbergeld. Neurotoxicology Section, NINCDS, NIH, Bethesda, MD 20205.

We have previously reported that estrogen treatment of rats results in an increase in the number of dopamine (DA) receptors in the striatum without a change in their affinity (Eur. J. Pharm. 61: 397). Behavioral experiments, such as stereotypy, also showed an increase in DA receptor sensitivity after estrogen treatment. The effect of estrogen on DA receptors has been extensively characterized. Only the β-diastereomer of estradiol is active. Other striatal receptors are not affected. DA uptake, a presynaptic function, remains unaffected by estrogen treatment. Estrogen in vitro does not affect DA receptors. In order to determine a possible mechanism of action of estrogen, we treated male rats, after hypophysectomy (Hypox) with 125 μg 17β-estradiol valerate in sesame oil, s.c., 6 days before measurements were made. Striatal DA receptors were measured using [^{3}H]spiroperidol in our routine assay procedure, and stereotypy was measured using apomorphine (4 mg/kg) (see above ref.). Hypox, by itself, did not alter the number or the affinity of the DA receptors; however, it did prevent the increase in DA receptor number normally produced by estrogen. Hypox also prevented the increase in apomorphine-induced stereotypy which occurs after estrogen treatment. This suggests that a pituitary secretion is involved in the increase in DA receptor sensitivity. Since estrogen directly increases prolactin secretion by the pituitary, prolactin may mediate the increase in DA receptor sensitivity. To test this hypothesis we implanted male rats, s.c., with Alzet mini-pumps which delivered 120 ng of ovine prolactin per hr for 7 days. The rats were then evaluated behaviorally and biochemically for striatal DA receptor sensitivity. Prolactin treatment significantly increased the number of striatal DA receptors (27%). The DA receptor affinity did not change. Similarly, prolactin administration enhanced stereotypy produced by either apomorphine (4 mg/kg) or by amphetamine (2.5 mg/kg). These results indicate that prolactin may influence striatal DA receptors, and that the effect of estrogen may be mediated through prolactin. Chorea of pregnancy or chorea associated with the use of oral contraceptives is thought to be related to a relative increase in striatal DA sensitivity. Estrogen has been suggested to be the agent which produces this form of chorea; however, our data suggests that further investigation of prolactin may be indicated.

151.3 6-HYDROXYDOPAMINE DIFFERENTIALLY AFFECTS PNMT ACTIVITY AND EPINEPHRINE CONTENT IN RAT HYPOTHALAMUS: EVIDENCE FOR COMPENSATORY ENHANCEMENT IN NEURONAL FUNCTION. Susan K. Burgess*, Lee E. Eiden, Richard E. Tessel* (SPON: Ronald T. Borchardt); U. of Kansas, Lawrence, KS, 66045, and Lab. Clin. Sci. NIMH, Bethesda, MD, 20205.

The observation that phenylethanolamine N-methyltransferase (PNMT) activity in the hypothalamus (HT) is unchanged 10 days after i.vent. 6-hydroxydopamine (6HD) has been interpreted as evidence that epinephrine (EPI) neurons are intact after 6HD treatment (Jonsson et al., Med. Biol. 54:421, 1976). However EPI content in HT is substantially depleted by 6HD (Tessel et al., Brain Res. 153:615, 1978) indicating that these neurons are subject to 6HD neurotoxicity. The mechanism for the discrepancy between enzyme activity and neurotransmitter content in EPI neurons has been explored. The EPI/PNMT disparity is not a general consequence of lesioning: surgical isolation of the HT resulted in equivalent decreases in EPI and PNMT in the medial basal HT. Whereas dopamine (DA) content was not significantly changed by either chemical or surgical lesions, norepinephrine (NE) and EPI contents were markedly depleted by both lesions. The apparent 6HD-resistance of DA and PNMT neurons is not due to a lack of 6HD affinity for their neuronal uptake systems. 6HD in vitro released endogenous EPI, DA, and NE from chopped HT with approximately equal potencies, indicating that 6HD was taken up by all three types of neurons.

PNMT activity was significantly lowered one day after 6HD injection (compared to sham or day 10), suggesting that a compensatory increase in enzyme activity has occurred by day 10. In addition, MAO inhibition with pargyline (50 mg/kg, 2½ h), which did not increase HT catecholamines in control rats, more than doubled the EPI and NE content of 6HD-treated rats (day 10). This suggests that, in EPI and NE neurons of the HT, catecholamine storage capacity is impaired and/or turnover rate is increased after 6HD. The percentage of endogenous EPI, NE, or DA released in the presence of pargyline, either by depolarization or by amphetamine, was the same in HT tissue obtained from 6HD-treated or control rats. This argues against either the selective destruction of intraneuronal storage vesicles, or the long-term impairment of the uptake system in undamaged neurons after 6HD.

These data suggest that EPI neurons more closely resemble NE than DA neurons in the HT, and are consistent with the hypothesis that a compensatory increase in EPI synthetic capacity of the residual EPI neurons accounts for the EPI/PNMT disparity after 6HD lesioning.

151.4 **AN EVALUATION OF THE BIOACTIVITY OF AN ENDOGENOUS INHIBITOR OF ^{3}H-DIAZEPAM BINDING.** **Leonard G. Davis, Helen McIntosh*, Dean Reker*, Luci Fikes* and Ron Cohen*. Missouri Institute of Psychiatry, Univ. of Missouri, 5400 Arsenal St., St. Louis, MO 63139.**

The isolation from bovine brain of a factor that is a competitive inhibitor of ^{3}H-diazepam binding (BBRC 92, 141, 1980) has supported the possibility that an endogenous diazepam-like compound exists. The present preliminary studies are concerned with the determination of the bio-active actions that this isolated factor might have in comparison to diazepam and placebo. The intraventricular injection, through chronically implanted cannula, of 5μl of either solution preceded the behavioral testing by thirty to sixty minutes. The test situations included motility, ataxia, EEG, suppression of hyperthermia, behavioral disinhibition (conflict) and retardation of pentylenetetrazole induced convulsions. In each situation, the material isolated from the brain has affects similar to those observed for diazepam. In particular, the endogenous material was able to relieve the shock-induced inhibition associated with the bar press in the conflict test. It was also possible to reduce the onset of convulsions with this brain extract. These observations support the concept of an endogenous diazepam-like substance. Studies are presently aimed at the purification and structural characterization of this putative-natural ligand for the benzodiazepine receptor.

151.5 CATECHOLAMINE AND CYCLIC NUCLEOTIDE CONCENTRATIONS IN THE CEREBELLUM OF PCD MUTANT MICE. B. D. Sawyer,* S. Hemrick-Luecke,* M. J. Schmidt, R. W. Fuller and B. Ghetti. The Lilly Research Laboratories, Indianapolis, IN 46285 and Indiana University Medical Center, Indianapolis, IN 46202

Purkinje cells in the cerebellum receive noradrenergic input from the locus coeruleus, and this input inhibits Purkinje cell firing possibly through an elevation of cyclic AMP. Unexpectedly, we observed that in vitro in the presence of norepinephrine, levels of cyclic AMP were dramatically increased in cerebellar slices prepared from mutant mice (pcd or nervous), animals in which Purkinje cells degenerate. The present experiments were done to determine if elevated levels of cyclic AMP were present and concentrations of norepinephrine were altered in the cerebellum of pcd mice in vivo. Determinations were made in animals ranging in age from 23-290 days. Mice were sacrificed by exposure to high level microwave radiation, and cyclic nucleotides were determined in the cerebellum by radioimmunoassay. Catecholamine concentrations were determined in the cerebella of mice which had been decapitated and the brains frozen shortly after death. HPLC and electrochemical detection were used to assay amines.

Cyclic AMP levels were similar in control and affected mice prior to 44 days of age, at which time cyclic AMP was 45 percent higher in pcd mice. Cyclic AMP remained elevated in affected animals at all times thereafter, with a peak elevation at 60 days of age. The concentration of cyclic GMP, on the other hand, was lower in pcd mice at all ages.

Norepinephrine levels were not significantly different in control and pcd mice at 23 days of age, but at all later ages concentrations of norepinephrine were markedly elevated in the cerebella of mutant mice. The greatest difference was observed in the oldest mice in which norepinephrine levels were 150 percent higher in affected animals. In contrast, the total content of cerebellar norepinephrine was not different in pcd and control mice. Apparently, the increased norepinephrine concentration is due to the reduction of cerebellar volume. These results indicate that despite the loss of a major post-synaptic target (Purkinje cells), the cerebellar noradrenergic input remains stable. The present studies illustrate that increases in cyclic AMP and norepinephrine in vivo are coincident with marked norepinephrine stimulated accumulations of cyclic AMP in vitro in the cerebella of pcd mutant mice.

151.6 AN ACID HYDROLYZABLE CONJUGATE OF DOPAMINE IN HUMAN VENTRICULAR FLUID. N.S. Sharpless, G.M. Tyce*, L.J. Thal*, J.M. Waltz*, K. Tabaddor*, and L.I. Wolfson*. Albert Einstein College of Medicine, Bronx, NY 10461, Mayo Clinic and Mayo Foundation, Rochester, MN 55901, and St. Barnabas Hospital, Bronx, NY 10457.

In earlier work (J. Neurochem. 34:210, 1980) a substantial amount of a conjugate of dopamine (DA) was found in lumbar CSF of 2 Parkinson patients being treated with Sinemet (a 10:1 mixture of L-DOPA and a peripheral decarboxylase inhibitor). We now confirm the presence of an acid hydrolyzable conjugate of DA in CSF from patients taking Sinemet and also present evidence for the presence of conjugated DA in ventricular CSF from patients never treated with L-DOPA. Free DA was removed from an aliquot (2 ml) of ventricular CSF by adsorption onto alumina. The alumina-treated CSF was acidified with $HClO_4$ and heated at 100°C for 45 min to hydrolyze the DA conjugate. Liberated DA was adsorbed onto alumina which was then washed and eluted with 0.5 M acetic acid. The eluates were freeze-dried, reconstituted in 0.1 ml, and aliquots (25 µl) were analyzed for DA by high-performance liquid chromatography with electrochemical detection (Column: µBondapak C_{18}, 4 mm x 30 cm; Solvent (1.0 ml/min): 0.07 M NaH_2PO_4(pH 4.8), 0.2 mM Na_2EDTA, 0.5 mM heptanesulfonate, 8% methanol). Recovery of DA added to CSF was 75%; recovery of DA liberated from DA-sulfate during hydrolysis was 71% from DA-3-sulfate and 79% from DA-4-sulfate. Although only trace amounts (58 pg/ml or less) of free DA were detected in ventricular fluids from 7 patients with movement disorders, all of the hydrolyzed fluids had a clearly defined peak with the same elution time (11 min) as authentic DA. With 6% methanol and 1 mM heptanesulfonate authentic DA and the CSF peak both eluted at 17 min; with 2 mM heptanesulfonate the peaks appeared at 23.5 min. Levels of conjugated DA in ventricular CSF from 3 Parkinson patients who had taken Sinemet ranged from 210-1508 pg/ml and correlated inversely with the time between the last dose of Sinemet and withdrawal of the fluid (23-65 h). The estimated half-life for disappearance of conjugated DA from ventricular CSF after cessation of L-DOPA was 15 h. Values for conjugated DA in ventricular CSF from 4 patients with movement disorders (cerebral palsy; multiple sclerosis) who had never taken L-DOPA ranged from 105-218 pg/ml. Ventricular fluid from one patient who had recently sustained a severe head injury had increased concentrations of both free (483 pg/ml) and conjugated (435 pg/ml) DA. The physiological significance of conjugated DA in human ventricular CSF is not yet known. Sulfation of the meta hydroxyl group of DA may compete with O-methylation for inactivation of released DA. Conjugated DA may also represent a convenient transport form for removal of DA from brain and CSF.

151.7 EFFECTS OF DRUGS ON DOPAMINE RELEASE AS ESTIMATED BY SIMULTANEOUS RADIOENZYMATIC ASSAY OF DOPAMINE AND 3,4-DIHYDROXYPHENYL ACETIC ACID. C.H. Cheng and G.F. Wooten. Depts. of Neurology & Pharmacology; Washington University School of Medicine; St. Louis, Missouri 63110.

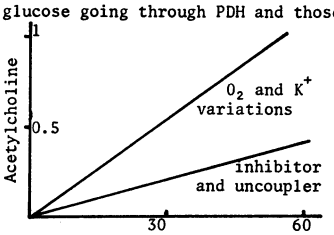
The formation of 3,4-dihydroxyphenyl acetic acid (DOPAC) in the striatum (CS) appears to occur primarily in terminals of dopaminergic neurons and may reflect metabolism of released dopamine (DA) which has been recaptured. Thus short-term changes in relative concentrations of DA and DOPAC may be a useful index of the rate of DA release. We have developed a highly sensitive and specific radioenzymatic assay for simultaneous estimation of DA and DOPAC. These compounds were enzymatically transmethylated on the meta-hydroxy groups in the presence of partially purified catechol-O-methyltransferase with S-[methyl-^{3}H] adenosyl-L-methionine serving as the methyl donor. The reaction products were isolated by organic solvent extraction, resin treatment, and thin layer chromatographic separation on silica gel plates. The method provides a sensitivity of 10 pg for DA and 100 pg for DOPAC. Cross-contamination between DA and DOPAC was less than 1%. Control rat brain levels of DA were 9.6 ± 0.3 µg/g wet weight in CS and 5.0 ± 0.3 µg/g in olfactory cortex-nucleus accumbens (OA); while control DOPAC levels were 1.2 ± 0.1 µg/g and 1.0 ± 0.2 µg/g in CS and OA respectively.

Treatment with haloperidol 1 mg/kg SC, a DA receptor antagonist, resulted in a 2.7-fold increase at 1 hour and a 3.1-fold increase at 2 hours of DOPAC in CS. DA levels were not affected. In contrast, administration of apomorphine 0.5 mg/kg SC, a dopamine agonist, resulted in a 50% reduction in striatal DOPAC 1 hour after drug administration while no changes were noted in striatal DA. However, neither DA nor DOPAC levels were changed in OA after apomorphine administration suggesting that mesolimbic dopaminergic neurons may not be subject to feedback control as is the case for nigrostriatal dopaminergic neurons. Injection of amphetamine 2.5 mg/kg SC, a drug which increases turnover of DA by enhancing release and blocking re-uptake, produced a small (20%) but significant increase in striatal DA 1 hour after administration; however, DOPAC levels were reduced by 61% and 49% at 30 minutes and 1 hour respectively after injection.

Thus simultaneous estimation of DA and DOPAC provides a useful index of DA release in most instances. But in the special case of drugs such as amphetamine which block DA re-uptake, estimation of DA and DOPAC levels may falsely suggest a reduction in the rate of release.

151.8 ACETYLCHOLINE SYNTHESIS AND $^{14}CO_2$ PRODUCTION FROM VARIOUSLY LABELLED GLUCOSES. H.J. Ksiezak* and G.E. Gibson, Dept. Neurology, Cornell Univ. Medical College, Burke Rehab. Center, White Plains, NY 10605

A variety of data suggest that there is a close link between oxidative metabolism and acetylcholine (ACh) synthesis. This is shown by a parallel inhibition of ACh synthesis and of $^{14}CO_2$ production from pyruvate or glucose by a variety of compounds (J.Neurochemistry 26, 1073). However, the molecular basis of this link is unknown. Furthermore, some compounds stimulate CO_2 production but inhibit ACh synthesis (e.g. dinitrophenol, DNP). We studied this relation further by comparing ACh synthesis from [U-^{14}C]glucose to $^{14}CO_2$ production from [3,4-^{14}C]glucose (a measure of pyruvate dehydrogenase reaction, PDH), [2-^{14}C]glucose (a measure of the tricarboxylic acid cycle, TCAC) and from [U-^{14}C]glucose (a measure of overall oxidative metabolism). We studied these variables in synaptosomes and in brain slices under several conditions which stimulate or inhibit oxidative metabolism: low O_2 content (<0.01%), low K^+ (5 mM) and high K^+ (35 mM) concentrations, with an inhibitor of electron transport (antimycin) and with an uncoupler of oxidative phosphorylation (DNP). Under all of these conditions we analyzed the relation of ACh synthesis to the decarboxylation of [3,4-^{14}C]glucose, [2-^{14}C]glucose, [U-^{14}C]-glucose and to the efflux of metabolites from the TCAC. The latter was calculated as the difference between the nanomoles of glucose going through PDH and those decarboxylated by the TCAC.



Efflux of metabolites from the tricarboxylic acid cycle

The highest correlation was between ACh synthesis and the efflux of metabolites from the TCAC (r=0.860) as compared to any of the other relations (r<0.741). When O_2 and K^+ variations data were grouped separately (see Figure), the correlation was much higher (r=0.986). For the rest of the data with the inhibitor or uncoupler the correlation coefficient was r=0.946. The lower slope with the inhibitor and uncoupler suggests that in these conditions the efflux is directed more into metabolites other than ACh. In summary, ACh synthesis is linearly related to the efflux of metabolites from the TCAC under a variety of conditions. The physiological control of this efflux and its implications to the control of ACh synthesis has not been determined.

151.9 PURIFICATION OF CHOLINE ACETYLTRANSFERASE FROM DROSOPHILA MELANOGASTER. J.R. Slemmon*, P.M. Salvaterra, and E. Roberts. Division of Neurosciences, City of Hope Research Inst., Duarte, CA 91010

The heads of Drosophila melanogaster are one of the richest known sources of choline acetyltransferase (ChAT) activity, with a specific activity approximately twice that of Torpedo electric organ and ten times that of Rat or Rabbit brain. We are continuing the work begun in this laboratory (Driskell et al., J. Neurochem. 30:1135, 1978) to purify and characterize this important neurotransmitter synthetic enzyme. The results of our current purification procedure are summarized below. Homogenization was carried out in low pH (5.1) sodium citrate buffer. The supernatant was precipitated with polyethylene glycol. The precipitate from 5 to 15% polyethylene glycol was resuspended in citrate phosphate buffer, pH 5.9, and chromatographed on DEAE-Bio Gel A. ChAT activity was eluted with a 0 to 0.3 M sodium chloride gradient. The pH of the pooled ChAT activity was adjusted to 5.1, and the sample was chromatographed on an Octyl Sepharose column. The column was washed with one volume of buffer (sodium citrate, pH 5.1) and the activity eluted with 10 mM citrate phosphate, pH 5.9. The pooled concentrated sample was added to a Green A-Agarose column so that the sample volume was entirely included in the column. The column was left to equilibrate for 30 min followed by a wash with 10 mM citrate phosphate, pH 5.9. ChAT activity was eluted with 20 mM sodium phosphate, pH 7.0, containing 0.5 mM Coenzyme A. Polyacrylamide gel electrophoresis in SDS showed two protein bands at 67,000 and 54,000 daltons.

ChAT Purification from 100 g Fly Heads

	Volume (ml)	Units (μmole/min)	Protein (mg)	Sp/Ac (units/mg prot)

151.10 SPECIFIC ENZYMATIC SYNTHESIS OF γ-GLUTAMYLHISTAMINE IN APLYSIA CNS IN VITRO. C. Stein* and D. Weinreich. Dept. of Pharm. & Exptl. Therap., Univ. MD, Sch. Med., Baltimore, MD 21201.

Much evidence supports a neurotransmitter role for histamine (HA) at identified synapses in Aplysia cerebral ganglia. A mechanism for inactivation of synaptically released HA would provide further evidence for such a role. To this end, we have examined the possibility that metabolism participates in terminating the action of neuronal HA. Previous studies of intact Aplysia CNS incubated with radiolabeled HA revealed formation of a single labeled product, γ-glutamylhistamine (GHA; Weinreich, D., J. Neurochem. 32:363, 1979).

In the present study, we have developed an in vitro enzyme assay to characterize the properties of the dipeptide-forming enzyme(s). Homogenates of ganglia were incubated in the presence of radiolabeled HA. The unique formation of GHA was detected by high voltage electrophoresis, and column and thin layer chromatography by comparison with standards. Formation of the peptidoamine was linear with tissue and time. In addition, neither anisomycin (5–500 μM) nor ribonuclease T_1 (10 mg/ml) had any effect on GHA synthesis. It seemed probable, therefore, that metabolism of HA was under enzymatic control.

The enzyme(s) mediating GHA synthesis demonstrated an absolute requirement for ATP which could not be replaced with AMP, ADP, GTP or c-AMP. Dithiothreitol and Mg^{++} ions were also essential for activity. The enzyme had a K_m and V_{max} for HA of 240 μM and 17 nmol/mg protein/hr, respectively, and a pH 8 optimum. A variety of imidazole compounds and HA analogs had no effect on synthesis of GHA. Glutamate was essential for product formation. Glutathione and glutamine, two major γ-glutamyl compounds in tissue, were not appreciably incorporated into peptide linkage with HA. Methionine sulfoximine, an inhibitor of glutathione and glutamine biosynthesis, had minimal effect on GHA formation, supporting the view that glutamate is a substrate rather than a precursor. Glutamine and methionine, active substrates for γ-glutamyl transfer by γ-glutamyl transpeptidase, did not affect GHA synthesis. Serine and borate, known inhibitors of γ-glutamyl transpeptidase, did not decrease formation of product.

Since GHA (up to 10^{-3} M) has no discernible neuronal effects, this enzyme(s) could participate in the inactivation of synaptically released HA.

151.11 BRAIN REGIONAL DISTRIBUTION OF GLUTAMATE-INSENSITIVE CYSTEINE SULFINATE DECARBOXYLASE ACTIVITY. Ronald M. Spears* and David L. Martin (SPON: A. T. Campagnoni), Department of Chemistry, University of Maryland, College Park, MD 20742.

Cysteine sulfinate decarboxylase (CSAD) catalyzes one step in the biosynthesis of taurine. During purification of the enzyme from hog brain, CSAD activity was resolved into two distinct components by chromatography on hydroxylapatite (referred to as Peaks I and II). When the hydroxylapatite column eluate was assayed for glutamate decarboxylase (GAD) activity, a single peak was observed which coincided with Peak II of CSAD activity. There was no detectable GAD activity in Peak I of CSAD. The value of K_m for cysteine sulfinate for Peak I of CSAD was 0.4 mM. The values of K_m for Peak II were 3.8 mM for cysteine sulfinate and 1.2 mM for glutamate. Kinetic studies with Peak II showed cysteine sulfinate and glutamate to be mutually competitive but glutamate did not inhibit CSAD activity in Peak I. These results suggested that CSAD activity in Peak II was due to GAD. Studies in other laboratories have shown that highly purified GAD also has CSAD activity. We have developed a procedure to measure the glutamate-insensitive CSAD activity (Peak I) in the presence of Peak II (GAD) activity. The decarboxylation of cysteine sulfinate was determined using 3.0 mM [^{35}S]cysteine sulfinate as substrate. The product, [^{35}S]hypotaurine, was separated from substrate on small Dowex 1-X8 columns (0.5 x 3 cm). To measure the glutamate-insensitive CSAD activity (Peak I) in the presence of GAD activity (Peak II), CSAD assays were carried out in the presence of 100 mM glutamate. Under assay conditions, 100 mM glutamate inhibited the decarboxylation of cysteine sulfinate by Peak II by more than 90%, but inhibited Peak I by less than 5%. To measure total cysteine sulfinate decarboxylation by the tissue, no glutamate was added. Glutamate-insensitive and total CSAD activity was measured in various regions of hog brains. The glutamate-insensitive CSAD activity was 35-45% of the total activity in all regions examined except the superior colliculus and the pons in which it was 20% and 60%, respectively. Highest levels of glutamate-insensitive CSAD were found in the caudate/putamen/globus pallidus and lowest values were found in the thalamus. Other brain regions examined were hippocampus, amygdala, inferior colliculus, lateral and medial geniculate bodies, and medulla.

Supported by Grant MH-29629 from United States Public Health Service.

151.12 A COMPARISON OF THE ION EXCHANGE RESIN AND THE SOLVENT EXTRACTION RADIOCHEMICAL METHODS FOR THE ASSAY OF MONOAMINE OXIDASE ACTIVITY. S.M. Anderson* (SPON: P. Lerner). NINCDS, NIH, Bethesda, MD 20205.

The commonly used radiochemical methods for the assay of monoamine oxidase activity (MAO) involve the incubation of the enzyme with the radioactive substrate for a fixed time period. After the reaction is stopped the aldehyde, acid and/or alcohol products are separated from the unchanged amine and quantitated by liquid scintillation counting. Two separation methods are in wide use. The products and the substrate may be separated by the use of negatively charged ion exchange resin columns or by the extraction of the product into an organic solvent. The present study compares the two assay methods in the measurement of MAO activity in crude tissue homogenates of mouse brain and liver. MAO activity was measured by the oxidation of three substrates: phenylethylamine (PEA), tyramine (TYR) and 5-hydroxytryptamine (5-HT). Activity measured by a variation of the solvent extraction method of Wurtman and Axelrod (Biochem. Pharmacol., 12:1439, 1963) was compared with activity measured by a variation of the ion exchange resin procedure of Donnelly and Murphy (Biochem. Pharmacol., 26:853, 1977). Toluene:ethyl acetate was found to be an efficient solvent for the extraction of all three substrates. Both Dowex-50 and Amberlite CG-50 were found suitable for the retention of the unchanged amines in the ion exchange method. Recovery of the metabolites from these two methods is equivalent. Inbred strain mean rank ordering of MAO activity in crude brain homogenates suggest that these two methods yield similar results (Pearson Product Moment correlation coefficients describing the relationship between these two procedures are 0.92, 093 and 0.83 for PEA, TYR AND 5-HT, respectively). Sample to blank ratios from the ion exchange method, however, are low. The ion exchange resins failed to retain 3-5% of the unchanged substrates when the columns are washed. Crude liver homogenates from mice contain 20% MAO-A and 80% MAO-B (determined by chlorgyline and deprenyl inhibition curves). When low levels of MAO activity are measured in mouse liver homogenates using 5-HT as the substrate, sample to blank ratios are unacceptable (<2). The solvent extraction procedure yields sample to blank ratios >5 even for low levels of activity as found in mouse liver with 5-HT as the substrate. In general, results of studies presenting data on MAO activity measured by the oxidation of PEA, TYR or 5-HT by either of these methods should be comparable. On the other hand, the solvent extraction method is superior if 5-HT is the substrate and low levels of activity are expected.

151.13 O-METHYL-CATECHOLAMINE METABOLITE ANALYSIS USING ^{3}H•DANSYL CHLORIDE. C. F. Saller* and I. J. Kopin. Laboratory of Clinical Science, NIMH, Bethesda, MD 20205

Dansyl chloride was introduced as a means of producing fluorescent derivatives of phenolic and amino compounds, but radiolabelled dansyl chloride has been used to extend the level of sensitivity in assaying such compounds. We have optimized the production and isolation of ^{3}H•dansyl chloride derivatives of O-methylated catecholamines in perchloric acid extracts of tissue to develop a sensitive and specific assay for these catecholamine metabolites. Samples of brain or other tissues are homogenized in 4 volumes 0.2 N $HClO_4$. After centrifugation, 36 µl of the supernatant is removed and added to 4 µl 0.2 N $HClO_4$ or 4 µl 0.2N $HClO_4$ containing 10 picomoles each of 3-methoxytyramine, normetanephrine, and metanephrine as internal standards. Next, 10 µl 1N NaOH and 20 µl 1 M Na_2CO_3 are added and the samples are incubated at 37°C for 30 min. to destroy catecholamines. Then, the samples are washed with 1 ml toluene to remove non-phenolic amines. The aqueous phase is frozen and the toluene decanted. After thawing, 10 µl 0.8 N HCl are added and the samples are divided into three 20 µl aliquots. Twenty µl 2.5 mM (1 µCi) dansyl chloride in acetone are added to each aliquot and this mixture is incubated at 37°C for 15 min. Five µl proline (150 mg/ml H_2O) are added and the incubation is continued for another 10 min. Benzene (80 µl) containing 25 µM of each dansyl derivative is added and the ^{3}H•dansyl derivatives are extracted by vortexing. Sixty µl of the benzene extract are applied to each channel of 19-channel silica TLC plates and the derivatives are separated using benzene : triethylamine (1:1). The fluorescent derivatives are located under uv light, the appropriate areas scraped into scintillation vials, and the tritium assayed by liquid scintillation spectrometry. Less than 2-4 picomoles of each metabolite can be assayed. Their levels in several tissues and brain areas and changes induced by drug administration will be presented.

151.14 GLUCOCORTICOID INDUCTION OF TRYPTOPHAN OXYGENASE: ATTENUATION BY DIETARY CARBOHYDRATES AND CARBOHYDRATE METABOLITES. A. Yuwiler and A. Altar*. Neurobiochemistry Lab., VA Med. Ctr Brentwood, Los Angeles, CA 90073.

Tryptophan oxygenase (TPO) is a glucocorticoid-inducible liver enzyme which appears to regulate the amount of dietary tryptophan catabolism and nicotinic acid anabolism in the rat. The glucocorticoid-induced increase in TPO synthesis has been associated with an increase in both *in vitro* and *in vivo* tryptophan degradation within the kynurenine pathway. TPO induction can be blocked by pretreatment with glucose, but the attenuation may involve a metabolite of glucose such as NADPH and/or NADH. The present experiments determined the extent to which glucose or other intermediates of carbohydrate metabolism which regenerate liver HADH and NADPH attenuate the induction of TPO by short- or long-acting glucocorticoids.

Continuous *in vivo* TPO activity in male rats was estimated from the rate of production of 14-CO_2 after the intragastric administration of 14-C-2-tryptophan. Hydrocortisone-21-sodium succinate (Solucortef) or Triamcinolone acetonide were injected to respectively elevate hepatic TPO activity on an acute (4 hr) or chronic (24 hr) basis. Glucose, fructose, glycerol, or pyruvic acid were intragastrically intubated in doses ranging from 2 to 16 mMoles in attempts to reverse either the acute or chronic TPO inductions.

Solucortef produced a dose-related elevation of TPO over the range of 0, 25, and 50 mg/kg while the 50 mg/kg dose produced an inverted U-shaped induction of TPO over time which was maximal 3-4 hours post-injection. 16 mMoles of any carbohydrate intermediate completely abolished the TPO induction by Solucortef when given one-half hour before 14-C-tryptophan. Lower doses of these compounds were capable of somewhat less attenuation of TPO induction. Both fructose and glycerol, the only intermediates tested following Triamcinolone pretreatment, were capable of blocking chronic TPO induction. The present findings are consistent with the notion that dietary constituents that are capable of regenerating hepatic NADH and/or NADPH are capable of blocking glucocorticoid-induced elevations of TPO.

151.15 ABNORMALITIES IN ENDOGENOUS PHOSPHORYLATION IN A HEREDITARY MODEL OF EPILEPSY. J.M. Tuchek,* D.D. Johnson, S.L. Polvi*and R.D. Crawford.* Dept. of Pharmacology, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0

The relationship between high seizure susceptibility and endogenous protein phosphorylation was investigated by comparing the *in vitro* phosphorylation of brain proteins from carrier and epileptic fowl. The high seizure susceptibility in epileptic fowl is due to an autosomal recessive mutation. Homozygotes (epilpetics) undergo spontaneous seizures and also convulse in response to stroboscopic stimulation or hyperthermia whereas heterozygotes (carriers) do not develop seizures.

The incorporation of ^{32}P from radiolabelled ATP into brain proteins from epileptics and nonepileptic fowl was studied by incubating 100 µg protein in 100 µl of 50 mM Tris-HCl buffer pH 7.4 containing 10 mM $MgCl_2$, 10 mM $CaCl_2$ and approximately 5 µM [α^{32}P] ATP at 35°C for 20 seconds. The reactions were terminated by the addition of 50 µl of a stop solution consisting of 5% SDS, 5% sucrose, 3 mM EDTA, 30% mercaptoethanol and 30 mM Tris-HCl pH 7.5. The proteins were then subjected to SDS polyacrylamide gel electrophoresis, stained with coomassie blue, dried and placed in contact with x-ray film for a period of time ranging from 24-72 hours.

No differences were observed in the SDS-polyacrylamide brain protein profiles of carriers and epileptics. However, three major electrophoretic bands in the epileptics showed significantly less net incorporation of ^{32}P than did the corresponding bands from non-epileptic fowl. These proteins had approximate molecular weights of 72, 60 and 16 x 10^3. Although these proteins were present in all the brain areas studied, the abnormal phosphorylation was evident only in the proteins from the cerebral hemispheres and the optic lobes. Subfractionation of the homogenates revealed that the low molecular weight protein was associated with the myelin fraction whereas the two higher molecular weight bands were present in the 100,000 x g supernatant fraction.

To our knowledge, this is the first reported abnormality in endogenous brain protein phosphorylation that is associated with an observable neurological syndrome. The finding of abnormalities in brain protein phosphorylation associated with high seizure susceptibility may provide a valuable model for studies on the cause of epilepsy as well as providing some insight into the role that phosphorylation of neuronal proteins has in normal brain function.

Supported by the MRC of Canada Grant No. MT-5893.

151.16 ACUTE EFFECTS OF KAINIC ACID ON ENERGY STATE IN THE STRIATUM OF THE MOUSE. Konrad C. Retz and Joseph T. Coyle, Dept. of Pharmacol. and Expt. Therapeut., Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

The proximate mechanism of neuronal degeneration caused by intra-striatal injection of kainic acid (KA) may be an irreparable alteration in the energy state of affected neurons due to continuous depolarization. To test this hypothesis, striatal energy metabolism was measured in the mouse. KA (1.64 nmoles in 0.3 1 saline) was stereotaxically injected into the left striatum of ether-anesthesized adult male mice using the coordinates 0.6 mm A, 2.0 mm L and 3.4 mm V to the bregma. At 48 hr after treatment, the specific activities of choline acetyltransferase and glutamic acid decarboxylase in the striatum were reduced by 51 ± 7% and 50 ± 7% respectively, whereas specific activity of tyrosine hydroxylase was increased by 145 ± 22% of contralateral (n = 7-8). Histologic examination of Nissl-stained sections through the forebrain revealed a sphere of neuronal degeneration of 2.7 mm in diameter in the head of the striatum. Except for neuronal degeneration in the deep layers of the overlying frontal cortex, structures outside the striatum including the pyriform cortex and dentate gyrus of the hippocampus were unaffected. Thus, KA causes a pattern of selective neuronal degeneration in the mouse striatum similar to that described in the rat.

Striatal parameters of energy metabolism were measured in mice sacrificed by focused microwave irradiation (1300 V; 2450 MHz; 0.95 sec) at 0.5, 1 and 2 hr after the 1.64 nM KA injection. In control striatum, the values in umoles/g were: phosphocreatine 3.4 ± 0.2,ATP - 2.2 ± 0.1, ADP 0.42 ± 0.04, AMP 0.12 ± 0.01, total adenosine nucleoside phosphates (Ad-P) - 2.8 ± 0.1, glucose 1.3 ± 0.1 and lactate 1.8 ± 0.2 with an energy charge of 0.89 ± 0.01. The content of ATP and phosphocreatine was significantly decreased at all time points but was lowest at 2 hr with a 23 ± 4% decrement in ATP and a 30 ± 5% fall in phosphocreatine in the lesioned striata relative to the contralateral (n = 8). ADP content was not significantly altered whereas AMP was increased by 70 ± 28% and the Ad-P pool was decreased by 20 ± 4% resulting in an energy charge depression from 0.87 ± 0.01 in the contralateral to 0.79 ± 0.02 in the lesioned striatum ($p < 0.005$; n = 8). An increase in glycolytic activity was evidenced by a 44 ± 8% increase in lactate levels in the lesioned striatum accompanied by a 58 ± 7% decrease in glucose content as compared to the contralateral striatum (n = 7). These findings demonstrate that the acute neurotoxic affects of kainic acid are associated with a significant alteration in the energy state of the lesioned brain area.

151.17 EPILEPTOGENIC EFFECT OF KAINIC ACID ON HIPPOCAMPAL SLICES MAINTAINED IN VITRO. E. Lothman and J. Ferrendelli. Div. of Clin. Neuropharm. and Dept. Neurology, Wash. Univ. Med. Sch., St. Louis, MO 63110.

We have previously shown that intravenous kainic acid (KA), a rigid analogue of glutamate, is a potent and selective activator of seizures in limbic structures (Neurology 30:386, 1980). To investigate possible mechanisms for this epileptogenic action of KA, we have studied the effects of this drug in vitro.

Slices of guinea pig hippocampus (400 µm) were prepared and maintained according to standard techniques and constantly perfused with an oxygenated, physiological buffer with an ionic composition similar to brain ECF (127 mM NaCl, 2 mM KCl, 1.5 mM $MgSO_4$, 1.5 mM $CaCl_2$, 26 mM $NaHCO_3$, 1.1 mM KH_2PO_4, 10 mM glucose, pH 7.4). Extracellular recordings were led from CA_3 and CA_1, and stimulation of mossy fibers and Schaffer collaterals provided a measure of the efficiency of orthodromic excitatory connections.

KA produced several changes in the spontaneous activity of hippocampal slices. From 0.01 to 0.1 µM KA the discharges of single units increased. Between 0.1 to 1 µM this increased activity became synchronized into discrete epileptiform bursts (interictal spikes-IIS), similar to those produced by penicillin. Up to 1 µM, IIS had a regular rate proportional to the concentration of KA, but they disappeared with higher concentrations. IIS were synchronized in CA_3 and CA_1 with intact slices, and transections between these two areas blocked IIS in CA_1 but not in CA_3. Both potentials evoked in CA_3 by mossy fiber stimulation and potentials evoked in CA_1 by Schaffer collateral stimulation were augmented and prolonged with afterdischarges over certain concentration ranges of KA, beginning at a level subthreshold for IIS (0.01 µM) and ranging to 1 µM (CA_3) and 10 µM (CA_1). Above these levels the potentials were suppressed or reversed in polarity.

We conclude that, since KA produces epileptiform activity in hippocampal slices in the presence of physiological ion concentrations and selectively induces seizures in limbic centers in vivo, this system is a useful model to study mechanisms of epilepsy, especially temporal lobe seizures. Based on the changes in evoked potentials and results obtained in other systems, we suggest that epileptogenic amounts of KA enhance excitatory glutamatergic connections while higher concentrations tonically and excessively depolarize neurons. Our data also imply that within the hippocampus epileptic discharges arise at discrete loci with secondary spread to other areas.

151.18 TOPICAL PENICILLIN REDUCES GABA-MEDIATED INHIBITION IN FELINE CEREBELLAR CORTEX IN VIVO. J. Davenport. VA Medical Center, Departments of Neurology and Physiology, University of Missouri, Columbia 65201

A current working hypothesis for the epileptogenic effects of penicillin (PCN) ascribes induced cellular hyperactivity to the reduction of synaptic inhibition mediated by GABA. Evidence from many simple synaptic systems supports the hypothesis, but such an effect has been at times difficult to demonstrate in more complex mammalian tissues.

Experiments were conducted with intact, anesthetized cats, using standard stimulation and recording techniques in the cerebellar vermal cortex. Glass micropipette electrodes recorded extracellular field potentials at several levels in the molecular and Purkinje layers, evoked by stimulation of nearby cortical surface and of Purkinje axons in subcortical white matter.

Topical application of 133 mM Na-PCN to the cortical surface reduced both the slow positive field potential following surface stimulation attributed to GABA-mediated basket cell IPSP currents, and the surface-evoked inhibition of antidromic Purkinje activation. Considerable variability of these effects was seen among several experiments.

In the absence of intracellular recordings from Purkinje and basket cells, these data are presumptive evidence of a local blockade by PCN of GABA-mediated postsynaptic inhibition in feline cerebellar cortex.

151.19 **SUBSTANCE P DEGRADATION AND THE DEVELOPMENT OF STABLE ANALOGS.** **C.M. Lee*, M.R. Hanley, B.E.B. Sandberg* and L.L. Iversen*. MRC Neurochemical Pharmacology Unit, University of Cambridge, England.**

Substance P (SP) is degraded rapidly by neural tissues. In view of its possible role as a neurotransmitter, attempts were made to identify the enzymatic cleavage sites involved in its inactivation. A SP-degrading enzyme preparation was highly purified from a membrane fraction of human diencephalon. Enzyme activity was monitored by measuring the rate of disappearance of added SP with radioimmunoassay.

By a combination of high performance liquid chromatography and amino acid analysis, the break-down products were identified and the enzyme preparation was shown to cleave SP between Gln^6-Phe^7, Phe^7-Phe^8 and Phe^8-Gly^9 with an endopeptidase action. A similar cleavage pattern was also demonstrated in membrane fractions prepared from rat brain. This information was used in the design of stable analogs of SP. Stabilization against enzymatic digestion was tested by incubation with the purified enzyme preparation and with washed rat brain slices. Biological activities were routinely tested on guinea pig ileum, isolated rat parotid gland fragments, rat vas deferens and rat salivation in vivo. Several analogs have been synthesized which are stable towards enzymatic digestion and have prolonged biological activities both in vitro and in vivo.

151.20 STIMULATION DEPLETES SEROTONIN AND NORADRENALINE FROM VESICLES OF PINEAL SYMPATHETIC NERVES. G. Jaim-Etcheverry and L. M. Zieher*. Instituto de Biología Celular, Fac. de Medicina, Buenos Aires, Argentina.

The sympathetic fibers innervating the pineal gland of the rat contain serotonin in addition to the neurotransmitter noradrenaline. Previous cytochemical studies at the ultrastructural level have shown that both amines are stored in the cores of the vesicles that are characteristic of those nerves. Indirect biochemical and pharmacological evidence suggests the possible coexistence of both amines in these nerve vesicles. Thus, it is conceivable that serotonin might be released together with noradrenaline from pineal nerves by stimulation.

To study this possibility, the preganglionic nerves to the superior cervical ganglia of rats were bilaterally stimulated with square wave pulses (25 Hz, 1 msec, 20 min) at supramaximal voltage. After stimulation or sham-stimulation, the pineals were processed with conventional techniques for electron microscopic observation and with cytochemical procedures for the ultrastructural demonstration of serotonin and of noradrenaline plus serotonin (Jaim-Etcheverry, G. and Zieher, L.M., J. Histochem. Cytochem. 16:162, 1968). Electrical stimulation markedly reduced the number of dense cores of nerve vesicles in conventionally processed pineals. Vesicular size and shape were modified by nerve stimulation. The cores reacting for serotonin that are normally present in these nerves, were almost absent after nerve stimulation. A similar observation was made in tissues processed with the technique showing noradrenaline and serotonin. These results indicate that both amines are depleted from their vesicular stores by nerve stimulation. The content of noradrenaline was reduced in stimulated pineals when compared with that of controls. Stimulation of the nerves for longer periods (60 min) at a frequency of 10 Hz, resulted in a similar reduction of cytochemically reactive cores. When the glands were incubated "in vitro" in the presence of 5-hydroxydopamine after stimulation, the vesicles incorporated the exogenous amine, showing that even after depletion by stimulation, they retain the capacity to store monoamines.

These findings support the assumption that several substances with presumed transmitter or modulatory functions might be released simultaneously by nerve stimulation from a given terminal. (Supported by grants from CONICET, SECYT and Secretaría de Salud Pública, Argentina).

151.21 SMALL GRANULAR VESICLES IN THE LOCUS COERULEUS MAY INDICATE DENDRITIC RELEASE OF NOREPINEPHRINE. L.Y. Koda, G. Aston-Jones, and F.E. Bloom. The Arthur V. Davis Center for Behav. Neurobiol., The Salk Institute, La Jolla, CA 92037.

Small granular vesicles (SGV's) appear to be a distinguishing characteristic of monoamine-containing structures. SGV's have been tentatively localized within dendrites of norepinephrine (NE)-containing neurons in the rat locus coeruleus (LC). This result may indicate that LC neurons release NE from their dendrites, and follows from previous evidence suggesting dendritic release of transmitter from DA-containing neurons in substantia nigra.

Male rats (150-250 g) were perfused with 150-200 ml of a cold 2% glyoxylic acid-0.5% paraformaldehyde solution. Razor blade sections from the rostral pons were trimmed to include the LC. Tissue blocks were fixed (30-45 minutes at 4°C) in potassium permanganate, then stained (in 1% uranyl acetate), dehydrated, embedded and sectioned. SGV's were observed in LC perikarya and neuropil. SGV's within perikarya were often clustered near the periphery of the soma, but were also seen individually within a group of agranular vesicles. In the neuropil, SGV's were found in large (1-2 μm), medium (0.5-1 μm) and fine (200-300 nm) processes. The large processes (tentatively identified as dendrites) contained mitochondria and few vesicles. The medium-sized profiles contained mitochondria and many vesicles, and accounted for about 2.5% of the total synaptic bouton population. Approximately 9% of these medium-sized SGV-containing profiles were in synaptic-like apposition to dendritic profiles. The fine processes, although rare, have not been observed to make synaptic-like appositions and presumably represent intervaricose segments of NE-containing axons. All SGV's within the LC were absent 4-6 hrs after a 10 mg/kg i.p. dose of reserpine, indicating that endogenous SGV's may reflect storage sites for NE within LC.

The presence of SGV's in LC dendrites does not in itself indicate dendritic release of NE; additional support for this notion is found in certain electrophysiological properties of LC neurons. The waveform typical of LC neuron spikes suggests that substantial dendritic depolarization follows antidromic or orthodromic soma impulse activity. In addition, there is pharmacological as well as electrophysiological evidence for recurrent collateral interaction among the NE-containing neurons within LC.

Further anatomical and electrophysiological studies are underway to test more definitively the possibility that SGV's in LC neuron dendrites reflect release sites of NE. (Supported by the B.W. Foundation of L.A. and AA 07273).

151.22 RELEASE OF NOREPINEPHRINE FROM HYPOTHALAMUS AND BRAINSTEM OF GENETICALLY OBESE MICE(obob). M.F. Callahan*and G.A. Oltmans. Dept. Pharmacol., Chicago Medical School, Chicago IL 60612.

Recent work suggests an abnormality in noradrenergic function in genetically obese(obob) mice. Mice with the obob mutation have significantly elevated levels of hypothalamic(HT) and brainstem norepinephrine(NE)(Lorden et al., 1976, Brain Res.; Feldman et al., 1979, Hormone Res.). Other studies indicate that the obob mouse is less sensitive than its lean littermates to depletion of HT NE by 6OHDA or reserpine(Lorden, 1979, J.Comp.Physiol.Psych.; Oltmans, 1980, Neuropharmacol.). In the current study, adrenergic function was further explored by examining the effects of K^+ and amphetamine(AMPH) upon NE release from chopped suspensions of HT and brainstem tissue of obob and lean mice.

Baseline NE release(15 min at 37°C) in unstimulated HT tissue was significantly higher in obob mice(3.22 +/- 0.99 ng/mg protein N=11) than in lean mice(2.22 +/- 0.60, N=12). When stimulated by 15 mM K^+, NE release increased more in lean than in obob tissue, producing nonsignificantly different amounts of total NE release for the two groups(lean=2.82 +/- 0.97; obob=3.27 +/- 0.81). At high K^+ concentrations(85 mM) obob HT tissue suspensions again released greater amounts than suspensions from lean tissue(obob= 6.18 +/- 0.86; lean=4.32 +/- 0.85). However, when the stimulated release was expressed as a change from baseline release, no significant differences between obob and lean mice were found in the amount of NE released at the higher K^+ concentrations.

AMPH stimulated release was similar to K^+ release. At low AMPH concentrations(10^{-8} to 10^{-7}M) HT NE release did not differ between lean and obob mice. At higher AMPH concentrations (10^{-4} M) HT tissue from obob mice released more NE than HT tissue from lean mice(4.32 +/- 0.72 vs. 2.60 +/- 0.69, $p < .05$). Again, when the stimulated release was expressed as a change from baseline, there were no differences between lean and obob mice.

Both K^+ and AMPH stimulated release from brainstem preparations paralleled the findings with HT tissue.

In summary, nonstimulated baseline release of NE is higher in obob than in lean mice. At low concentrations of either K^+ or AMPH these differences disappear. They then reappear when the concentrations of K^+ and AMPH are increased. Although NE release in obob mice is not different than in lean mice in all cases, the data at high K^+ and high AMPH concentrations are consistent with the possibility of abnormal NE activity in obob mice. (Supported in part by grant # 1 RO 1 NS15600 from NINCDS)

151.23 ADRENAL INFLUENCE ON NORADRENALINE RECEPTORS IN THE HIPPOCAMPUS. D.C.S. Roberts and F.E. Bloom. A.V. Davis Ctr. for Behav. Neurobiology, Salk Inst., La Jolla, CA 92037.

Bilateral 6-hydroxydopamine (6-OHDA) lesions of the dorsal noradrenergic bundle (DB) have been shown to increase ^{3}H-dihydroalprenolol (DHA) binding in the hippocampus. The effect of adrenalectomy on this increase in receptor binding was examined and a significant interaction between adrenalectomy and the 6-OHDA treatment was observed. Male 300g rats received bilateral stereotaxically placed infusions of 6-OHDA (4 μg/1μl) into the DB (A:+2.6, L:±1.1, D:+3.7 from stereotaxic zero; incisor bar, -4.2) followed 3 weeks later by either bilateral adrenalectomies or sham operations, and were sacrificed 1 week later. Binding of ^{3}H-DHA was determined in the presence and absence of 1 μM alprenolol. Scatchard analysis revealed the following values (from 4-7 replications):

	K_D (nM)	max binding ± S.E.M. (fmole/mg protein)
control	1.67	56.0 ± 4.3
DB-6OHDA	1.72	*79.4 ± 3.9
DB-6OHDA-adrenalectomy	1.51	†*94.4 ± 4.8
Adrenalectomy	1.38	61.7 ± 7.1

*$p < .05$ significantly different from control
†$p < .05$ significantly different from DB-6OHDA

No significant increase in receptor binding was observed after adrenalectomy. The 6OHDA treatment produced a 41% increase in maximum binding and the combined treatment produced a significantly greater increase (68%). Daily treatment with corticosterone (s.c., 1.0 mg/kg/12 hours) for one week following the adrenalectomy reduced the effect of the adrenalectomy. These data argue for a steroid involvement in the regulation of central noradrenergic receptors in the hippocampus.

Previous behavioral experiments have shown an apparent interaction between lesions to the dorsal noradrenergic bundle and adrenalectomy. Either treatment alone did not significantly affect the acquisition of shock avoidance behavior, whereas rats which received both treatments were markedly impaired in their ability to learn the appropriate response (Ogren and Fuxe, Neurosci. Letters, 5 (1977) 291). These observations together with the present data suggest that steroids may interact with central NA receptors to be an intregral part of the learning process in stress related situations. (Supported by Medical Research Council of Canada.)

152.1 IONTOPHORETIC APPLICATION OF ADRENERGIC AGONISTS POTENTIATES ANGULAR BUNDLE EVOKED FIELD POTENTIALS IN THE DENTATE GYRUS. C. Harley and R. Neuman. Dept. of Psychology and Basic Sciences Division, Memorial Univ. of Nfld., St. John's, Nfld. A1B 3X9.

An interest in norepinephrine (NE)'s putative involvement in forebrain plasticity led us to explore the effects of iontophoretically applied NE on evoked field potentials in the hilar region of the dentate gyrus.

Adult rats were first anesthetized with halothane in oxygen and then maintained on urethane 1.1 mg/kg supplemented as required. Seven barrel micropipettes were used for recording and drug applications. Solutions used included 4M NaCl for recording and current balance barrels; 0.1M NE; 0.5M tyramine; and 0.5% HRP with 0.05% adenosine in phosphate buffer, pH 6,8. Other putative neurotransmitters and a variety of adrenergic agonists and antagonists were also included in particular experiments.

The micropipette and a concentric stimulating electrode were located relative to bregma with the rat's skull adjusted to the horizontal plane. Co-ordinates for the micropipette were AP - 3.5 mm and ML ± 2 mm. Depth was determined by the shape and amplitude of the dentate field potential. Placements in the granular cell layer of the upper blade and in the infragranular layer of the dentate hilus were confirmed by HRP iontophoresis. Field potentials were evoked by constant current biphasic pulses delivered through a stimulating electrode angled at 20° in the AP plane (AP - 8.5 mm, ML ± 4.1 mm, DV - 3.75 mm). Stimulus frequency was varied between 0.2 and 0.1 Hz. Stimulus intensity was adjusted to produce a submaximal population spike. Evoked potentials were recorded via the center barrel of the micropipette, processed by computer and displayed on a chart recorder.

Application of NE and tyramine (80-100nA) for 2-4 min. resulted in increases in the population spike amplitude ranging from 20% to 400%. These increases outlasted the drug application by at least several minutes and often continued for as long as observations were made (20-40 min.). With this complex potential it was not always possible to evaluate EPSP changes but in some cases a clear enhancement was observed. Preliminary analyses with adrenergic agonists and antagonists suggest that beta receptors rather than alpha receptors are mediating the potentiation obtained.

These results imply that NE plays a modulatory role in gating throughput in the hippocampus. Further, the long time course of these effects suggests a possible role for NE in long term plasticity.

Supported by grants from MRC and NSERC of Canada.

152.2 Frequency specific effects of dopamine in the nucleus accumbens. J.F. DeFrance, R.W. Sikes, G. Palmer, and R.B. Chronister. Department of Neurobiology and Anatomy, University of Texas Medical School, Houston, TX and Department of Anatomy, University of South Alabama, Mobile, Ala.

Significant controversy has arisen in the past several years concerning the function of dopamine (DA) in the central nervous system. The purpose of the present is to show some attributes of DA function in the nucleus accumbens that add additional complexities to any model of DA function.

Electrophysiological observations were taken from rabbits, anesthetized with urethane. Stimulation micropippettes (1-5 meg ohm) were placed in the lateral margin of the ipsilateral fimbra (IFIM). Multi-barrel micropipettes were used for recording field potentials in the nucleus accumbens following IFIM stimulation, and for the iontophoresis of DA (10 mM-50 mM, pH 6.5). To test for the specificity of the DA effect, haloperidol (Haldol, 0.3-0.7 mg/kg) was injected intravenously.

To determine the potential for DA to stimulate adenyl cyclase activity, the nucleus accumbens was removed and homogenized in cold glycylglycine buffer (2 nM + 1 nM Mg SO_4) + 0.1 mM EGTA, pH 7.4). All assays were in duplicate.

DA had a differential effect which depended upon the frequency of IFIM stimulation. At 0.5 Hz, DA had a suppressive effect which was relatively slow to develop and slow to dissipate. In contrast to the suppressive effects at 0.5 Hz, DA has essentially no effect on responses at a stimulation frequency of 6.0 Hz. Haloperidol was able to reverse the suppressive effects of DA at 0.5 Hz. The data indicated that the suppressive effects are independent of modifying intrinsic inhibitory mechanisms.

Concentrations of 0.1 - 100μM DA were tested for the ability to elicit adenylate cyclase activation. Maximal enzyme activation (47%) was observed at a 100 μM concentration; the ED (50) value was 4.5 μM. Fluphenazine effectively blocked the DA activation of adenylate cyclase.

These results suggest that DA is capable of enhancing cyclic AMP activity in the nucleus accumbens and the resultant inhibition is expressed largely when incoming signals are arriving at relatively low frequencies.

152.3 EFFECT OF IONTOPHORETICALLY APPLIED DOPAMINE ON THE RESPONSE OF NUCLEUS ACCUMBENS NEURONS TO ELECTRICAL STIMULATION OF THE AMYGDALA. C. Y. Yim* and G. J. Mogenson. Dept. of Physiology, University of Western Ontario, London, Canada N6A 5C1.

The nucleus accumbens (NA) receives inputs from various limbic structures and in turn projects to the globus pallidus. It also receives strong dopaminergic (DA) projections from the ventral tegmental area (VTA). The NA has received considerable attention as a possible interface between the limbic and motor systems of the brain. The present study investigates the effect of DA on the response of NA neurons to amygdala (AMG) stimulation to test the possible role of DA in gating the transfer of signals from the limbic system to the motor system.

Extracellular single unit recordings were obtained from neurons in NA of urethane-anesthetized rats using glass micropipettes filled with 0.5 M sodium acetate. Recordings were obtained from the medial part of NA (1.1-1.5 mm lateral to the midline) shown to receive the heaviest DA projection from the VTA. Effects of electrical stimulation of the AMG (500 μA, 0.15 ms) was investigated. In some experiments, 7-barrel glass micropipettes were used for recording and iontophoretic application of DA or glutamate.

NA neurons were observed to have a slow discharge rate with bursts of 3-4 spikes. Electrical stimulation of AMG elicited in 64% (89/139) of the units tested a relatively short latency (mean = 9.5 ms) excitation followed by a prolonged period of inhibition. 17% (24/139) were inhibited only and 19% (26/139) did not respond. Iontophoretically applied DA at > 15 nA decreased the baseline firing rate (BFR) of all units tested. When DA was applied at 5-10 nA the excitatory response to stimulation of the AMG was either markedly attenuated or abolished in 28 of 32 units tested, even in the absence of a significant change in BFR. The prolonged inhibition that followed the original excitation remained unchanged. For neurons inhibited only by AMG stimulation, 4 out of 14 showed an enhanced inhibition when DA was applied.

These observations indicate that the AMG sends a strong excitatory projection to a large proportion of NA neurons. Dopamine appears to modulate this excitatory response. The mechanism of this modulatory effect is not known but it is of interest to note that there was no significant change in BFR and the inhibitory response that followed was not modified. It is also not known if the recorded units are output neurons from NA and if DA released from the VTA-NA projection would have the same effect. These possibilities are being investigated.

152.4 EVIDENCE THAT BENZODIAZEPINES AND NOREPINEPHRINE ACT THROUGH A COMMON MECHANISM TO FACILITATE PURKINJE CELL RESPONSES TO GABA. W. Smith*, B. D. Waterhouse, H. C. Moises, H. H. Yeh, H. M. Geller, and D. J. Woodward. (SPON: L. Grandison). Dept. of Cell Bio., Univ. of TX Health Sci. Ctr., Dallas, TX 95235; and CMDNJ-Rutgers Med. Sch., Dept. Pharmacology, Piscataway, NJ 08854

We have previously shown that microiontophoretically released flura zapam (FLU) and norepinephrine (NE) can potentiate Purkinje cell (PC) inhibition induced by iontophoresis of GABA. The hypothesis tested here was that both FLU and NE share a common mechanism to alter cerebellar neuronal responsiveness to GABA.

Extracellular single unit PC activity was recorded from halothane-anesthetized, naive FLU-tolerant and FLU-withdrawn albino rats using a multibarreled pipette. Responses to microiontophoretic pulses of GABA were examined before, during, and after NE (0.5 M) or FLU (0.1 M) iontophoresis. Peri-event histograms were used to quantitate effect of NE and FLU on spontaneous activity and GABA-induced inhibition. Doses of GABA sufficient to produce depression of PC activity in naive rats (5-40 nA) depressed firing rate in all 19 PC cells tested in tolerant animals. In 14 tolerant cells, responses to GABA were either unchanged (10 cells) or reduced (2 cells) during FLU (2-25 nA) iontophoresis, despite suppression of spontaneous firing. Similarly, in 8 of 12 cells, NE was ineffective in potentiating GABA actions despite causing depression of background discharge. Augmentation of GABA was observed with FLU (2 cells) or NE (4 cells); however, such facilitating effects were substantially weaker than similar actions demonstrated in naive rats. Tests in tolerant animals, 48 hr after withdrawl of FLU injections, showed potentiation of GABA inhibitory action by FLU and NE in 4 of 5 and 3 of 5 cells, respectively. In naive animals, interactions between FLU and GABA were examined during concurrent iontophoresis of sotalol. Gaba potentiation by NE was reversibly antagonized by sotalol in 2 of 3 cells; no antagonism of FLU potentiation by sotalol was observed in 3 other cells. In summary, the results presented here suggest that NE and FLU potentiate PC response to GABA via a common mechanism beyond the point of noradrenergic receptor activity. Moreover, results presented here represent the initial electrophysiological demonstration of tolerance to benzodiazepine actions in the CNS. (Supported by NIDA DA-02338 to D.J.W.; NIH 2F 32N5-056-99-03 to B.D.W.; NIH NS 15468 and NSF BNS 79-14003 to H.M.G., and the Biological Humanics Foundation.)

152.5 ONTOGENY OF NORADRENERGIC INPUT TO RAT CEREBELLUM: INTERACTIONS OF NOREPINEPHRINE WITH IMMATURE CEREBELLAR CIRCUITRY. Hermes H. Yeh, Hylan C. Moises, Barry D. Waterhouse and Donald J. Woodward. Dept. Cell Biology, Univ. Tx. Hlth. Sci. Ctr., Dallas, Tx. 75235

We have begun an initial series of experiments to characterize the course of functional development of the norepinephrine (NE)-containing fiber afferents to the cerebellum. Earlier work from our laboratory has demonstrated that chemosensitivity exists in Purkinje cells (PC) at birth, and that PC responses to parallel and climbing fiber synaptic inputs can be elicited by day 3. The present study was conducted to evaluate the interaction between iontophoretically applied NE and GABA, and between NE and climbing fiber synaptic input in the immature cerebellar circuitry.

Multibarrel micropipettes were used to apply drugs in halothane-anesthetized rat pups. Single-barrel recording electrodes attached to the multibarrel assembly were critical for obtaining stable recordings of PC unit responses while applying drugs. Three shocks (0.2 msec duration at 0.1/sec) were applied to the sensorimotor cortex through an array of 3 bipolar concentric electrodes to evoke climbing fiber responses. Poststimulus time or drug response histograms were computed before, during and after NE iontophoresis.

In 27 cells tested on selected days over the first 2 weeks of postnatal development, PC spontaneous discharge was consistently inhibited by NE and GABA iontophoresis. In 13 cells tested for NE interaction with evoked climbing fiber complex spikes, there occurred a preferential inhibition of spontaneous activity over complex spikes in all cases. Sweep-by-sweep analysis of oscilloscope tracings revealed that NE induced a bias toward complex spikes by converting inactivation spike and waves to groups of full-size action potentials. In many cases, single spikes with no evidence of inactivation waves were converted to distinct climbing fiber bursts during NE. These results were observed as early as day 6. In 7 of 9 cells, inhibitory responses to GABA were augmented during application of NE at levels subthreshold for inducing significant depressant effects on background discharge. This NE enhancement of GABA inhibition exists by day 5 when neither basket-stellate cell contacts nor glial cell investment of neuronal processes have fully matured.

In summary, evidence is provided here that NE can exert differential effects early in development by inhibiting spontaneous activity while promoting activity evoked by afferent climbing fiber inputs. Furthermore, the ability of NE to enhance GABA-induced inhibitions at day 5 suggests that PC postsynaptic receptivity as revealed by interactions between putative transmitters is programmed early into development and is not dependent on the emergence of adult synaptic function and circuitry. (Supported by NSF BNS77-01174 and the Biological Humanics Foundation)

152.6 MODIFICATION OF VISUAL RESPONSE PROPERTIES OF CEREBELLAR NEURONS BY NOREPINEPHRINE. Hylan C. Moises, Richard A. Burne and Donald J. Woodward. Dept. of Cell Biology, The University of Texas Health Science Center, Dallas, Texas 75235.

Previous studies from our laboratory have demonstrated in the rat that norepinephrine (NE), released iontophoretically or by electrical stimulation of the noradrenergic pathway from the locus coeruleus, can enhance the responses of cerebellar Purkinje (P) cells to both excitatory and inhibitory afferent input. To determine the functional significance of this noradrenergic action in cerebellar information processing, we characterized here the effects of local NE iontophoresis on the response properties of visually sensitive cells in the rat paraflocculus, a newly identified cerebellar visual cortical projection zone (Burne and Woodward, 1978, Neurosci. Abst. 4:64).

Extracellular recordings of single unit activity were obtained in unanesthetized, immobilized Long-Evans hooded rats, and perievent raster and histogram analyses were employed to determine neuronal response properties following the presentation of computer controlled visual stimuli. Noradrenergic effects on the response pattern of a cell to visual presentation were assessed by construction of raster and histogram records before, during and after iontophoresis of NE.

Presentation of visual stimuli elicited pure excitatory, inhibitory or mixed excitatory-inhibitory responses in 13 of 19 total neurons and in 9 of 14 identified paraflocular P cells. Responses of visually sensitive cells were elicited by flashed on-off stationary or moving bars of light (at 80-240°/sec velocities) and showed evidence for directional, velocity and positional sensitivities. NE was applied at levels which depressed background neuronal activity in 15 of 19 cells. In 11 of 13 visually responsive units tested with NE, stimulus-related excitation was increased above control levels (5 cells) or enhanced relative to the suppression in background firing (6 cells) such that signal to noise ratios were markedly increased. Moreover, during NE application marked excitatory or inhibitory responses were elicited in 4 of 5 P cells previously found unresponsive to presentations of visual stimuli during control periods.

In summary, the overall effect observed with NE application on visual units in the parafloculus was a sharpening of their response properties to stimulus presentation above the ongoing level of background activity. Our hypothesis is that one physiological expression of endogenous noradrenergic activity in cerebellar visual integration may be the refinement of the spatial-temporal response properties (i.e., receptive fields) of visually sensitive cells.

152.7 LOCUS COERULEUS STIMULATION POTENTIATES SOMATOSENSORY CORTICAL NEURONAL RESPONSES TO AFFERENT SYNAPTIC INPUTS. Barry D. Waterhouse, Hylan C. Moises and Donald J. Woodward. Dept. Cell Biology, Univ. Tx. Health Sci. Ctr., Dallas, Tx. 75235

Previously we reported that iontophoretically released norepinephrine (NE) facilitated somatosensory cortical neuronal responses to both excitatory and inhibitory afferent synaptic inputs and to direct application of the putative cerebrocortical transmitter agents, acetylcholine and GABA. In this study we examined whether endogenous NE released via electrical stimulation of the locus coeruleus (LC) could enhance somatosensory cortical neuronal responsiveness to afferent synaptic input.

Single glass micropipettes were used to record extracellular activity of neurons in the somatosensory cortex of halothane-anesthetized albino rats. Somatosensory afferent pathways were activated by suprathreshold mechanical stimulation (500 micron punctate deformation of glabrous skin at 0.5 Hz) of the contralateral forepaw. Post stimulus time histograms were used to quantitate the neuronal response before and at various time intervals after preconditioning stimulation of the LC.

All cortical neurons studied were spontaneously active and had one of the following responses to forepaw stimulation: 1) short latency excitation, 2) inhibition or 3) excitation followed by a period of inhibition. In 9 of 13 (69%) cells tested, synaptically evoked excitatory responses were potentiated (from 1.0 to 1.26 spikes/stimulus) when preceded by LC conditioning stimulation (3-6 shocks of 0.2-0.5 msec duration, 100-300 microamp at 100 Hz) which alone produced no change in cortical neuron spontaneous discharge. In a similar fashion, subthreshold LC stimulation increased by 46% the magnitude of stimulus bound inhibition or post-excitatory suppression of activity in 9 of 13 (69%) additional cells. This enhancement of cortical neuronal responsiveness resulting from LC activation was typically observed when conditioning preceded forepaw stimulation by 100-600 msec. Stimulation in areas outside of LC antagonized or had no effect on stimulus bound excitation and inhibition in 6 of 8 and 4 of 8 cases, respectively. These results suggest that increased activity in the coeruleus-cortical pathway may enhance the efficacy of conventional afferent input to somatosensory cortical neurons. Moreover, these data are consistent with the notion that a primary physiological function of the noradrenergic projection system may be to modulate the transmission of sensory information within the CNS.

152.8 SEROTONERGIC SUPPRESSION OF SOMATOSENSORY CORTICAL NEURONAL RESPONSES TO PUTATIVE NEUROTRANSMITTERS AND AFFERENT SYNAPTIC INPUTS. Donald J. Woodward, Barry D. Waterhouse and Hylan C. Moises. Dept. Cell Biology, Univ. Tx. Hlth. Sci. Ctr., Dallas, Tx. 75235.

The present study was conducted to investigate the action of serotonin (5HT) on transmission of information through somatosensory cortical neuronal circuits. Extracellular activity of cortical neurons was recorded from halothane-anesthetized albino rats using multibarrel micropipettes. Responses to microiontophoretic pulses (10 sec duration at 40 sec. intervals) of the putative cerebrocortical transmitters, acetylcholine (ACH), glutamate (GLUT) and gamma-aminobutyric acid (GABA), were examined before, during and after 5HT iontophoresis (3-20 nanoamps). Excitatory and inhibitory responses of single units to mechanical stimulation (500 micron punctate deformation of glabrous skin at 0.5 Hz.) of the contralateral forepaw were also examined before, during and after 5HT administration. Post-drug and post-stimulus time histograms were used to quantitate 5HT effects on spontaneous and drug or stimulus induced activity.

In 10 of 16 neurons, 5HT suppressed stimulus bound excitation more than background discharge such that signal to noise ratio was decreased approximately one third. Evoked spiking in 6 cells was depressed below control levels during 5HT application despite little change in background activity. Similarly, excitatory responses to ACH and GLUT were antagonized by iontophoretic 5HT in 6 of 10 and 4 of 5 neurons, respectively. In 7 of 7 cases, 5HT blocked stimulus bound inhibition while producing a concomitant, slight depression of background discharge. In a similar fashion, the magnitude of GABA-induced inhibition was effectively reduced relative to baseline firing rate during 5HT iontophoresis in 6 of 9 neurons. The response to GABA was completely blocked in 2 cells.

In summary, these results suggest that low levels of 5HT reduce the responsiveness of somatosensory cortical neurons to afferent synaptic inputs and putative transmitter agents. Parallel studies on norepinephrine (NE) in somatosensory cortex have demonstrated largely opposite actions, i.e. amplification of neuronal responses to synaptic inputs and to application of putative transmitter agents, despite a common effect of both 5HT and NE to suppress background firing. The data suggest that 5HT, along with other monoamines may modulate activity of other conventional transmitter systems as a means of regulating information transfer in the cerebral cortex.

152.9 EFFECTS OF 5-HT DENERVATION AND DEPLETION ON NEURONAL RESPONSIVENESS TO BIOGENIC AMINES IN CEREBRAL CORTEX: A MICROIONTOPHORETIC STUDY IN THE RAT. A. Ferron*, T.A. Reader and L. Descarries. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, Canada.

In adult rats under urethane anesthesia (1.25 g/kg, i.p.), a vast majority of spontaneously active neurons in the fronto-parietal cortex respond by prolonged depression of their firing rate to microiontophoretic applications (50-100 nA during 30 s.) of serotonin (5-HT), noradrenaline (NA) or dopamine (DA). To further investigate the role of 5-HT in cerebral cortex, the responses to these amines were examined after destruction of 5-HT afferents with 5,7-dihydroxytryptamine (5,7-DHT, 200 µg F.B., i-vt, 2 weeks earlier), or pharmacological depletion of 5-HT stores by pretreatment with p-chlorophenylalanine (PCPA, 400 mg/kg, i.p., q.d. for 2 or 14 d.). In 5,7-DHT deafferented cortex, depression of spontaneous firing rate by 5-HT was of longer duration (mean 14 min.) than in controls (mean 5 min.). Moreover, small ejection currents of 5-HT (2 nA) were sufficient to induce a prolonged depression. In contrast, responsiveness to NA and DA was markedly reduced in units which were supersensitive to 5-HT. In PCPA-pretreated rats, there was no change in the responsiveness to 5-HT despite a mean 90% depletion of cortical 5-HT content. However, as in denervated cortex, responsiveness to NA and DA was significantly decreased. In a third series of experiments, a selective 5-HT uptake blocker, fluoxetine (20 mg/Kg, i.p.), was administered in control and PCPA-pretreated rats to determine to which extent the suppression of 5-HT reuptake contributes in the denervation supersensitivity to 5-HT. Fluoxetine induced prolongation of the response to 5-HT but failed to enhance the sensitivity of cortical neurons to small currents of 5-HT.

These data indicate that, in cerebral cortex, 5-HT supersensitivity results primarily from the removal of 5-HT terminals and not from depletion of 5-HT content. Two components may be involved in the denervation supersensitivity to 5-HT: the suppression of reuptake (presynaptic component) could account for the prolonged duration of responses to 5-HT, whereas a modification of the 5-HT receptor on target cells (postsynaptic component) could be mainly responsible for the greater sensitivity to 5-HT. The decreased sensitivity to NA and DA following 5-HT deafferentation or depletion suggests that the responsiveness to NA and DA may be regulated by 5-HT release.

152.10 QUIPAZINE FACILITATION OF SPINAL MOTONEURON EXCITABILITY IN 5-7-DIHYDROXYTRYPTAMINE PRETREATED RATS. S.R. White and R.S. Neuman. Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland A1B 3V6.

The purported 5-HT agonist, quipazine (QPZ), has serotonin mimetic actions in the central nervous system which may result from activation of postsynaptic 5-HT receptors, blockade of presynaptic 5-HT reuptake, release of 5-HT or some combination of these mechanisms. To test these alternatives, the ability of iontophoretically applied QPZ to mimic 5-HT enhancement of motoneuron excitability was examined in the spinal cords of 5-7-dihydroxytryptamine (DHT) pretreated rats and control rats which received no pretreatment. Rats were anesthetized with urethane and prepared for spinal cord motoneuron unit recording combined with multibarrel microiontophoretic drug application as described previously (White & Neuman, Brain Res. 188, 1980, 119). Motoneuron activity was evoked by short uniform applications of glutamate cycled automatically. Following the establishment of stable responses to glutamate application, the effects of other drugs on the glutamate elicited activity were examined.

In control rats both QPZ (10-40nA, 30-120 sec) and another purported 5-HT agonist, MK-212 (10-40nA, 60-180 sec), facilitated glutamate elicited motoneuron activity, as did 5-HT (10-30nA, 30-60 sec). The facilitation produced by all three drugs was often, but not always, preceded by short periods of depression during current application. While the period of facilitation often lasted for several minutes for all three drugs, the delay to peak facilitation was greater for QPZ and MK-212 than for 5-HT. Metergoline, 0.1 mg/kg i.v., antagonized the facilitatory effects of 5-HT, QPZ, and MK-212, but not norepinephrine.

DHT pretreated rats received intracisternal injections of DHT (100-200 µg in 20 µL of a saline-ascorbic acid solution) 45 to 90 min. following injections of desmethylimipramine (25 mg/kg, i.p.). The effectiveness of this treatment for destroying spinal cord 5-HT terminals was assessed 2 to 5 days later by the application of the 5-HT releasing agent, p-chloramphetamine (PCA). In control rats, PCA (50-100nA, 30-60 sec) increased glutamate elicited motoneuron activity, while in DHT pretreated rats, PCA (60-100nA, 60-120 sec) produced only initial depression of motoneuron activity with no subsequent facilitation.

Although the PCA results indicated that 5-HT was not being released from nerve terminals in the vicinity of the motoneurons in the DHT-treated rats, QPZ (10-50nA, 60-120 sec) was still capable of facilitating glutamate elicited motoneuron activity. These results suggest that at least some of the serotonin mimetic actions of QPZ can be attributed to direct effects on postsynaptic 5-HT receptors.

152.11 MODIFICATIONS IN THE EXCITABILITY OF LOCUS COERULEUS SYNAPTIC TERMINALS BY ADRENERGIC AGENTS. S. Nakamura*, J.M. Tepper*, S.J. Young*, and P.M. Groves. (SPON: M. Dubin). Dept. Psychiatry, Univ. Calif., San Diego, La Jolla, CA 92093.

Many experimental studies have suggested the existence of presynaptic receptors on the terminals of catecholaminergic neurons which may participate in feedback regulation of transmitter release, synthesis and other processes. It is possible that presynaptic receptor activation alters the polarization of the terminal membrane in a way similar to the self-inhibitory effects proposed for catecholamines released within such cell groups (Groves et al., Prog. Neuropsychopharm., 3:315, 1979). To test this possibility, the excitability of locus coeruleus neurons was determined using direct electrical stimulation of their terminal fields following local administration of adrenergic agents. Experiments were performed on urethane anesthetized, curarized and artificially respired subjects. Antidromic responses of locus coeruleus neurons were recorded extracellularly following bipolar stimulation of frontal cortical terminals. The tip of a 32 gauge cannula was placed approximately 100 microns from the site of stimulation. Prior to drug infusion, stimulus current was varied in order to determine a current just sufficient to produce 100% antidromic invasion. Adrenergic agents were then infused for a duration of 5 minutes at a rate of 0.0625 microliters/minute and the threshold value redetermined at frequent intervals. Infusion of between 10^{-6} to 10^{-5} molar amphetamine produced a decrease in excitability in 20 experiments, an increase in 7 and no effect in 5 cases. Phentolamine over the same range of concentrations produced an increase in terminal excitability in 5 experiments and no effect in 5 others. Propranolol at these concentrations decreased terminal excitability in 8 experiments with no effect in 2 others. Control infusions of saline in 5 experiments did not alter terminal excitability. Spontaneous activity and action potential waveforms were unaffected by drug infusion. Antidromic latency appeared to covary with changes in terminal excitability. These results indicated that the excitability of noradrenergic terminals can be modified by adrenergic agonists and antagonists and suggest that activation of presynaptic receptors alters the electrical properties of the presynaptic membrane. (Supported in part by grant DA 01467 and Research Scientist Development Award DA 00056 from the National Institute on Drug Abuse to PMG.)

152.12 LOCUS COERULEUS MODULATES LATERAL GENICULATE NEURON EXCITABILITY VIA AN α-ADRENOCEPTOR. Michael A. Rogawski and George K. Aghajanian. Departments of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06510.

Microiontophoretic application of norepinephrine (NE) in the vicinity of dorsal lateral geniculate (LGN) neurons produces an increase in their spontaneous firing rate and facilitates their responsiveness to optic pathway stimulation. These effects appear to be mediated by an α-adrenoceptor (Brain Res. 182: 345-359; Exp. Neurol., in press). The LGN receives a dense noradrenergic innervation originating exclusively in the locus coeruleus (LC). In the present study, we compared the effects of LC stimulation and iontophoretically applied NE to provide evidence for a transmitter role of NE in the coeruleogeniculate pathway.

Electrical stimulation (1 msec pulses at 10 Hz, 0.3-0.8 mA, 10-60 sec trains) was delivered with coaxial electrodes in the vicinity of the ipsilateral LC of chloral hydrate anesthetised rats. Such stimulation invariably produced an increase in the spontaneous firing rate of LGN neurons. Iontophoresis of NE (5-10 nA) near the same neurons mimicked this effect. LGN neurons were not driven by single shocks to the LC nor was a field potential ever observed. As with iontophoretically applied NE, the effect of LC stimulation was delayed in onset (requiring 1-30 sec to attain a peak response) and sustained beyond the duration of the stimulus train (up to 20 sec). Optimal effects were obtained when the electrode tip was either within the LC or just anterior to the LC, presumably in the dorsal NE bundle. The activating effect of LC stimulation was transiently suppressed by systemic (100 µg/kg, i.v.) or iontophoretic (15-30 nA) administration of the α-adrenoceptor antagonist WB-4101.

When afferent excitation from the retina is eliminated by enucleation of the eyes, many LGN neurons cease firing spontaneously. Silent neurons in enucleated animals generally did not respond to iontophoretically applied NE although they were easily activated by the excitatory amino acid glutamate. However, low currents of NE (5-10 nA) markedly enhanced the responsiveness of these cells to glutamate, suggesting that NE acts in a neuromodulatory fashion to increase their excitability. Similarly, LC stimulation generally failed to excite silent cells in enucleated animals but was able to facilitate the response to glutamate. Both the facilitatory effects of NE iontophoresis and LC stimulation were antagonized by WB-4101. We conclude that activation of the coeruleogeniculate pathway and local application of NE are physiologically and pharmacologically similar in their modulation of LGN neurons excitability.

152.13 LOCUS COERULEUS NEURONS IN BEHAVIORALLY-INTACT RATS ALTER THEIR SENSORY-RESPONSE AND SPONTANEOUS DISCHARGE CHARACTERISTICS DURING THE SLEEP-WAKING CYCLE. G. Aston-Jones[1] and F.E. Bloom. A.V. Davis Ctr. for Behav. Neurobiol., Salk Inst., La Jolla, CA 92037 and [1]Div. of Biology, Calif. Inst. of Tech., Pasadena, CA.

We previously reported that norepinephrine-containing locus coeruleus (NE-LC) neurons in freely moving rats discharge as a function of sensory stimulation and stages of the sleep-waking cycle (S-WC) . These neurons characteristically responded to non-noxious environmental stimuli with a 15 to 20 msec latency excitation, usually followed by a more variable and longer duration inhibition. During the S-WC, spontaneous rates were highest during active waking (2.03 Hz), lower during slow-sleep (0.65 Hz) and very low in paradoxical sleep (PS) (0.02 Hz).

In our continuing studies on this system, we have found additional characteristic properties of NE-LC neuron discharge. 1) The magnitude of sensory response in NE-LC neurons varies during the S-WC: The greatest response is elicited by stimuli which awaken the animal from slow-sleep (SWS), a smaller response follows stimuli presented during waking (W), and an even smaller response is elicited by stimuli within SWS; NE-LC neurons appear to be unresponsive to such stimuli during uninterrupted PS. 2) Spontaneous rates during the S-WC are higher for neurons located on the edge of the nucleus than for non-edge cells; in addition, neurons in the ventrocaudal pole of LC tend to fire at lower rates than other NE-LC neurons. 3) NE-LC neuron discharge rates anticipate the EEG signs of all S-WC transitions (except PS-to-W, in which discharge activity preceeded only the EMG signs of W); for example, the mean discharge rate during the last sec of SWS before W is higher than the mean rate during SWS or during W. 4) Even during SWS, when NE-LC neurons discharge very slowly, systemic fluctuations in rate accompany EEG spindle activity: The mean discharge rate one sec before spindles (0.43 Hz) is less than the mean rate for SWS (0.53 Hz), while the highest mean rate occurs during spindles (1.11 Hz); the mean rate is then lower for the sec following spindles (0.87 Hz) but remains higher than the mean rate during SWS (all rates differ significantly at $p < .005$ by repeated measures t-tests). These LC impulse rate fluctuations appear to anticipate phasic EEG events within SWS, analogous to the rate fluctuations which anticipate the longer duration EEG signs of SW-C transitions. (Supported by AA 07273 and NS 16209.)

152.14 CATECHOLAMINERGIC MODULATION OF THE CORTICAL SENSORIMOTOR RHYTHM AND THE LIMBIC 40 HZ RHYTHM J. M. Simard*, C. C. Turbes and G. T. Schneider* (SPON: F. J. Clark). Dept. of Anatomy, Creighton Univ., Omaha NE 68178.

In awake, freely-behaving cats with chronically implanted cortical and subcortical electrodes and instrumented for telemetric recording, the differential roles of dopamine and norepinephrine in the management of the state of cortical synchrony (low voltage fast activity vs. the sensorimotor rhythm) and the limbic 40 Hz rhythm were assessed by: 1) comparing the effects of the dextro- and levo-stereoisomers of amphetamine (2.5 mg/kg) on the brain rhythms; 2) assessing the development of tolerance of the brain rhythms to repeated administration of amphetamine. The data were quantified using spectral techniques.

The results obtained indicated that 1) the two isomers of amphetamine were approximately equipotent ($p > .05$) in effecting cortical desynchrony and 2) that within three days of successive daily administration, marked tolerance to the drugs' cortical desynchronizing effect was evident as a return of the sensorimotor rhythm ($p < .05$). Conversely, it was found that 3) the dextro isomer was significantly ($p < .05$) more potent than the levo isomer in activating the limbic 40 Hz rhythm and 4) that the effect of d-amphetamine on the 40 Hz rhythm exhibited no tolerance with successive daily administration.

It was concluded that norepinephrine is a critical modulator of the frontal cortical EEG whereas dopamine is a critical modulator of the limbic 40 Hz rhythm.

152.15 STIMULATION OF LOCUS COERULEUS ALTERS REGIONAL CEREBRAL BLOOD FLOW IN THE RAT. S. M. Feldman[1], S. Baez*[2], R. E. Breger*[1] and G. P. Lu*[2]. Department of Psychology, New York University, New York, NY 10003[1] and Department of Anesthesiology, Albert Einstein College of Medicine, Bronx, NY 10461[2].

To investigate the contribution of locus coeruleus (LC) to the regulation of cerebral circulation, we have examined the effect of LC stimulation on transit time of an intracerebral optical marker. Under pentobarbital anesthesia, a unilateral craniotomy exposed a 1 cm area of parietotemporal cortex in rats. A sealed saline-filled transparent plastic chamber, affixed to the skull, provided a neutral environment for the exposed cortical tissue. Artificial ventilation allowed adjustment to maintain arterial pH, $PaCO_2$ and PaO_2 in normal ranges. The pial microvasculature was viewed microscopically, displayed on a TV monitor, and permanently recorded on tape. A small bolus of colloidal carbon (0.06 to 0.15 ml) was rapidly injected intrajugularly; carbon transit time (TTc) was the interval between first appearance of the visual marker in a selected penetrating arteriole (18 to 25 µm o.d.) and its emergence from underlying brain via selected collecting venules (Caceres, Chung, Baez and Orkin, Fed. Proc., 1975, 34: 749). TTc thus measured circulation time through the cerebrum, which is affected by diameter changes in resistance vessels. Trains of rectangular electrical pulses were delivered to ipsilateral brainstem through permanently indwelling bipolar electrodes for 15 to 20 sec prior to injection of the carbon marker. Stimulation in or near LC (as verified histologically) was accompanied by substantial increases in TTc, with a single exception. The changes in TTc (Mean = +39 ± 9.6%) varied from -1.3% to +77.0%; accompanying changes in mean arterial blood pressure (MAP) varied from -10.2% to +14.5% (Mean = +1.7 ± 3.5%). TTc and MAP are both expressed as per cent changes from control or sham stimulation trials. Effective frequencies of stimulation ranged from 5 to 50 pps. Well placed electrodes required minimal stimulating current to effect large increases in TTc: e.g. 50µa at 25 pps caused a 77.0% increase in TTc, with an accompanying 2.0% increase in MAP. Because changes in MAP and TTc were not inversely related, the small changes in systemic arterial blood pressure can not account for the observed increases in TTc; both increases and decreases in MAP were seen equally. Because regional changes in cerebral vascular resistance would vary directly with TTc, we conclude that the LC stimulation affected regional cerebral blood flow by causing vasoconstriction of intraparenchymal resistance vessels.

152.16 Role of forebrain noradrenaline in self-administration of ethanol. Michael E. Corcoran, Stephen T. Mason, and Hans C. Fibiger. Dept. of Psychology, University of Victoria, Victoria, B.C., Canada; and Division of Neurological Sciences, University of British Columbia, Vancouver, B.C., Canada.

Bilateral injections of 6-hydroxydopamine (6-OHDA) were made into the dorsal tegmental noradrenergic bundle, and the effects of the resulting depletion of forebrain noradrenaline (NA) on oral self-administration of ethanol were examined. When given a choice between water and a 15% (v/v) solution of ethanol on alternate days, NA-depleted rats drank significantly less ethanol than controls. There was no difference in forced intake of quinine-adulterated water by NA-depleted and control rats, however, suggesting that NA depletion does not produce hyperreactivity to aversive tastes. In a separate experiment ethanol rejection thresholds were determined by offering rats a choice between water and an ascending series of concentrations of ethanol; the lowest concentration totally avoided was arbitrarily designated as the rejection threshold. NA-depleted rats showed significantly lower rejection thresholds than control rats and persisted in drinking less ethanol when subsequently offered a choice between water and ethanol at rejection concentration on alternate days for 40 days. These effects of NA depletion on initiation of self-administration of ethanol were presumably not due to a potentiation of the aversive pharmacological effects of ethanol, as NA-depleted and control rats did not differ in acquisition of a conditioned aversion to a novel flavor paired with intraperitoneal injections of ethanol.

To determine whether depletion of forebrain NA would also disrupt an already established pattern of ethanol self-administration, additional rats were allowed to develop a home-cage preference for ethanol solutions over water before injections of 6-OHDA were performed. Although depletions of forebrain NA comparable to those described above were produced, there was no significant effect on intake of ethanol. Similarly, other rats were induced to consume large quantities of 5% (v/v) solutions of ethanol in the schedule-induced polydipsia paradigm, and injections of 6-OHDA were subsequently performed. Once again depletion of forebrain NA had no significant effect on an established pattern of ethanol self-administration.

These results suggest that forebrain NA is somehow involved in the initiation of oral intake of ethanol but that it is not required for the maintenance of established patterns of ethanol self-administration.

152.17 ESTROGEN-INDUCED SUBSENSITIVITY OF DOPAMINE AUTORECEPTORS. L.A. Chiodo, A.R. Caggiula and R.R. Lucik*. Psychobiology Program, Department of Psychology, Univ. of Pittsburgh, Pittsburgh, PA 15260

Oral administration of conjugated estrogens can significantly ameleorate the clinical symptoms of unipolar depression and also increase the efficacy of antidepressant drugs in women. We recently demonstrated that antidepressants induce a subsensitivity of DA autoreceptors in the substantia nigra of rats, and suggested that the resulting increase in DA function might account for their therapeutic effects (Antelman & Chiodo, this volume). In the present study, we asked whether estrogen produces a similar alteration in autoreceptor sensitivity.

We first tested the effects of estradiol benzoate on the decrease in open field activity produced by doses of apomorphine that are throught to preferentially stimulate DA autoreceptors. All doses of apomorphine tested (25, 200, 400, 800 ug/kg, s.c.) reduced square crossings recorded every 5 min. for 20 min., relative to a pre-drug baseline. Moreover estradiol benzoate (EB; 10 ug/kg s.c.), given 48h before the test, significantly attenuated the decrease in locomotion produced by the 3 highest doses of apomorphine, when compared to oil injected controls.

We also measured the sensitivity of autoreceptors electrophysiologically. Females treated as above were anesthetized with chloral hydrate (400 mg/kg, i.p.) and DA neural activity was sampled through glass micropipetts (2M NaCl, 4-12 megohms). We used a dose of apomorphine (4 ug/kg, i.v.) that has been shown to preferentially stimulate these receptors without affecting postsynaptic DA receptors (Skirboll et al., Science, 206, 80, 1979). Estrogen significantly attenuated the ability of apomorphine to inhibit the activity of type B DA neurons (a class of cells that are inhibited by activating environmental stimuli), but did not alter apomorphine's effect on type A cells (cells stimulated by such stimuli) (mean percent inhibition of firing $\pm$ S.E.: Type A; oil = 51.5 $\pm$ 12.9, EB = 72.3 $\pm$ 12.8. $p > .05$; type B; oil = 65.3 $\pm$ 11.7, EB = -2.6 $\pm$ 9.7, $p < .001$).

In summary, we have presented both behavioral and electrophysiological evidence that a single injection of estrogen induces a significant subsensitivity of DA autoreceptors. This provides one of the first demonstrations of a direct effect of estrogen on mesencephalic DA neuronal activity. It might also account, at least in part, for our finding that estrogen potentiates the stereotypy produced by DA agonists (Chiodo and Caggiula, 1978). Finally, the fact that estrogen, at least in the dose and time course used, induced subsensitivity only in the type B neuron provides further evidence that A and B represent two functionally different classes of DA cells.

152.18 AGE RELATED CHANGES IN DOPAMINE AUTORECEPTOR SENSITIVITY. R.R. Lucik*, L.A. Chiodo and A.R. Caggiula. Psychobiology Program, Dept. of Psychology, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Recent evidence suggests that aging is associated with a decline in the functioning of central dopamine (DA)-containing systems. For example, as rats grow older, there is a decrease in DA levels and turnover in the striatum which is accompanied by an impairment in the animals' response to activating stimuli. In the present study we asked if the sensitivity of DA autoreceptors in the substantia nigra also changes with age.

Single unit activity of DA neurons was sampled extracellularly through glass micropipetts (2M NaCl, 4-12 megohms) in 1, 6 and 24 month old male albino rats. As expected, a dose of apomorphine (4 ug/kg, i.v.) that has been shown to preferentially stimulate DA autoreceptors (Skirboll et al., Science, 206, 80, 1979) inhibited the discharge rate in the 6 month old males by 67.7 $\pm$ 6.3% (mean percent inhibition of firing rate $\pm$ S.E.). In contrast, all cells in the 24 month group, and 50% of the cells in the 1 month group increased their activity in response to this dose of apomorphine (group means: -82.4 $\pm$ 31.1% and -28.7 $\pm$ 31.5% respectively). Subsequent administration of a postsynaptic dose of apomorphine (50 ug/kg, i.v.) suppressed discharge rate in all cells of the 1 and 24 month old animals. All neurons sampled increased their activity in response to haloperidol (.2 mg/kg, i.v.), confirming the dopaminergic nature of these cells.

These data suggest that both old (24 month) and young (1 month) animals display a significant degree of DA autoreceptor subsensitivity relative to 6 month old animals. It is possible that in the older animal, the subsensitivity is a compensatory response to an overall decline in DA function, whereas in the young animal, it represents incomplete development of DA regulatory mechanisms. Regarding the fact that a majority of subsensitive cells actually increased their activity in response to a presynaptic dose of apomorphine, two hypotheses might be considered to account for this response reversal. First, the confirmation of the autoreceptor may be altered to such a degree that apomorphine binds to the receptor without stimulating it, and thus exerts an antagonist-like action. Alternately, since both agonist and antagonist receptors appear to exist with respect to apomorphine, perhaps only the agonist receptor becomes subsensitive (or is absent) and thus only the actions of the antagonist receptor are observed.

152.19 CORTICAL MODULATION OF STRIATAL FUNCTION IN THE RAT. B. Scatton, P. Worms*, K.G. Lloyd and G. Bartholini . Synthélabo-L.E.R.S., Research Department, 58 rue de la Glacière, 75013 Paris, France.

The effect of complete surgical destruction of the cortico-striatal projections or selective ablation of the frontal cortex on behavioral and biochemical parameters related to striatal dopaminergic function were investigated in the rat. Bilateral complete surgical destruction of the cortico-striatal projections as well as frontal cortex ablation virtually abolished the cataleptogenic action of haloperidol in the rat. This effect was observed as soon as 3 days after surgery ; the time course of behavioral modifications paralleled changes in glutamate uptake. Thus, glutamate uptake was reduced 2 hours to 16 days following frontal cortical ablation, the maximal effect (- 55 %) being observed after 2 days. Rats bearing such lesions were also found to be more susceptible than sham-operated animals to the stereotypy-inducing effects of apomorphine. In this respect, the duration of stereotyped behavior but not the maximal efficacy of apomorphine was enhanced.

The behavioral changes induced by cortical lesions do not appear to result from changes in striatal dopaminergic and/or cholinergic neuron activity. Thus : 1) acute (2 hours to 7 days) lesions of the cortico-striatal projections or frontal cortex ablations fail to alter baseline levels of, and neuroleptic or apomorphine-induced changes in, striatal homovanillic acid and dihydroxyphenylacetic acid levels in the rat ; 2) striatal acetylcholine (Ach) concentrations were transiently increased 2 hours after frontal cortex ablation, but were unaffected 2-7 days following surgery ; 3) haloperidol decreased and apomorphine increased Ach levels in the striatum to a similar extent in lesioned and sham-operated rats ; 4) finally, lesions of the cortico-striatal pathways failed to affect the ability of apomorphine to reduce the potassium (20 mM)-evoked ^{3}H-Ach release in rat striatal slices preloaded with ^{3}H-choline.

The above findings suggest that the excitatory cortico-striatal (possibly glutamatergic) pathways play an important role in dopamine-dependent behavioral events. As indicated by the biochemical data, the site of this action is likely distal to striatal dopaminergic and cholinergic neurons, and independent of the nigro-striatal feed back activation of dopaminergic neurons.

Other data showing a greater degree of tolerance of cortico-striatal lesioned rats of the increases in striatal dopamine metabolite levels after repeated treatment (11 days) with haloperidol or sulpiride suggest that the cerebral cortex also plays a role in the development of dopamine target cell supersensitivity.

152.20 EFFECTS OF PIMOZIDE ON SIMULTANEOUS DISCRIMINATION PERFORMANCE IN THE RAT. T.N. Tombaugh.* (SPON: W. Webster). Dept. of Psychology, Carleton University, Ottawa, Ontario, Canada K1S 5B6.

The effects of pimozide, a dopamine receptor blocker, were investigated on the ability of a rat to maintain a previously established simultaneous discrimination. Sixteen rats were trained to bar-press for food reward in a two-bar operant chamber. Responding on the bar associated with the appropriate light cue was reinforced on a variable interval 15 sec. schedule of reinforcement. Responses on the other bar were not reinforced. Every 30 sec. the cue randomly alternated between the bars. The status of the cue was counterbalanced across subjects so that an illuminated lamp above the bar signalled reinforced periods (S+) for half of the animals and nonreinforced periods (S-) for the other half. After 20 days of training, 95% or more of all responses occurred during the S+ periods. During subsequent test sessions each animal received 5 doses of pimozide (vehicle, 0.05, 0.10, 0.30 and 0.60 mg/kg) delivered in a Latin Square sequence. Five non-drug days separated each injection. Results showed that pimozide did not disrupt the well established discrimination behavior at any of the doses even though a substantial decrease in rate of responding was observed at the two higher doses. These response decrements were not accompanied by any change in the distribution of responding between the two bars. The relationship between responding and accuracy of responding is consistent with earlier results obtained with a successive discrimination paradigm with pigeons (Tombaugh, Psychopharmacology, 1980, in press). The congruence of these results is important because it demonstrates that pimozide produces similar results regardless of whether the initiation and inhibition of response tendencies occurs sequentially or simultaneously, suggesting that dopaminergic neurons are not essential in the mediation of previously learned associations.

152.21 APOMORPHINE AND S3608 INCREASE LOCOMOTOR ACTIVITY VIA DIFFERENT DOPAMINERGIC SYSTEMS IN THE RAT BRAIN. J. Offermeier* and J.M. Van Rooyen* (SPON: T.N. Chase). Res. Unit for the Design of Catecholaminergic Drugs, Potchefstroom Univ., Potchefstroom 2520, South Africa.

Apomorphine (APO) and S3608 increase locomotor activity (LA) via dopaminergic mechanisms in the rat brain as is evidenced by antagonism of these LA increases by dopamine (DA) antagonists. LA increases produced by these 2 drugs appear to be mediated via different dopaminergic systems, since (a) combination of these 2 drugs at doses producing maximal increases of LA of the drugs given individually results in an additive effect, (b) sulpiride antagonism of LA produced by APO is surmountable but sulpiride antagonism of S3608 is insurmountable, (c) bilateral kainic acid lesions of the nucleus accumbens suppress the activity of DA-sensitive adenylate cyclases in this area as well as S3608-induced LA but not APO-induced LA, (d) S3608 antagonises DA-induced cAMP formation whereas APO is a low-affinity dualist on this system, (e) APO-induced LA is not significantly altered by pretreatment with atropine, whereas S3608-induced LA is clearly potentiated by such pretreatment, (f) lithium carbonate pretreatment suppresses APO-induced LA but potentiates S3608-induced LA and, (g) fenfluramine pretreatment slightly suppresses APO-induced LA but clearly potentiates S3608-induced LA.
It is concluded that APO is an agonist on non-adenylate cyclase dependent DA receptors (D-2 receptors) and S3608 is an antagonist on adenylate cyclase dependent DA receptors (D-1 receptors). These 2 systems are influenced differently by other transmitter systems.

152.22 CHRONIC ADMINISTRATION OF DOPAMINERGIC AGONISTS AND RAT BEHAVIOR: DIFFERENTIATION OF APOMORPHINE FROM ET 495, BROMOCRIPTINE AND TRH. F. Porreca*, A. Cowan and R.J. Tallarida*, Dept. Pharmacol., Temple Univ. Sch. Med., Philadelphia, PA 19140.

A large dose of apomorphine (APO, 20 mg/kg, s.c.) induces aggressive attitudes in male rats (McKenzie, Brain Res. 34: 323, '71). We have found that this dose of APO causes 'sham-boxing' in only 20% of male S.D. rats tested. In contrast, we observed that chronic APO (1 mg/kg, s.c.) at 0900 h and 1800 h elicits a bizarre behavioral syndrome (BBS) in all male and female rats tested. The syndrome is characterized by tail vibration (within 5 d), 'sham-boxing' (after 9-11 d), and an increasing hyperexcitment which includes defecation, mounting (in males only), jumping, cliff- jumping, and climbing. Tail vibration was not observed in rats which were isolated, indicating a social behavior which requires the presence of another rat (mice presented either before or after the APO injection were ignored). In addition, no noise or other sensory stimulus was required to produce the BBS; latency to 'sham-boxing' decreased with repeated injections, being seen within 2-3 min by the 15th d. 'Sham boxing' was always accompanied by intense vocalization. Rats chronically treated with APO and injected with APO circled continuously, almost exclusively in one direction, when placed in a circular container or open field, and did not rear. However, when these animals were injected with saline no circling occurred, but rearing was present.

Chronic s.c. administration of ET 495 (5 mg/kg), bromocriptine (1 mg/kg) or thyrotropin releasing hormone (TRH, 10 mg/kg) for at least 20 d did not give the BBS.

The APO-induced BBS was blocked by d-butaclamol (0.64 mg/kg, s.c. at -20 min) but not by l-butaclamol (0.64 mg/kg) nor by naloxone (5 and 10 mg/kg, s.c. at -20 min). If d-amphetamine (1 and 5 mg/kg, s.c.) was substituted for APO, tail vibration and excessive mounting (but no 'sham-boxing') were seen in males. ET 495 (1,5, and 10 mg/kg, s.c.), when substituted for APO, had effects similar to amphetamine with the exception that 'sham-boxing' occurred at 10 mg/kg if noise was introduced. When APO was substituted for ET 495, bromocriptine or TRH, no signs of a BBS were seen. There was no tolerance to the BBS over 90 d. The BBS was still present 5,10,15,25, and 31 d after the last dose of APO, in animals treated chronically with APO.

These results suggest that a) a long term pharmacological change occurs after chronic treatment with APO which does not occur with ET 495, bromocriptine or TRH; b) the BBS produced by chronic APO may be an example of agonist-induced supersensitivity; and c) the model may provide a means of classifying dopamine receptors in vivo. (Supported by Grant DA 02322 from NIDA.)

152.23 THE COMPARATIVE EFFECT OF CHRONIC ADMINISTRATION OF d-AMPHETAMINE AND APOMORPHINE TO SELECTED MEMBERS OF PRIMATE SOCIAL COLONIES. R.F. Schlemmer, Jr., N. Narasimhachari, and J.M. Davis. Illinois State Psychiatric Institute, Chicago IL 60612.

Street use or supervised administration of large quantities of amphetamines over a short period of time often precipitates a paranoid psychosis. It has been suggested that many of the symptoms of amphetamine psychosis are mediated through central dopamine systems. However, administration of the more selective dopamine agonist apomorphine (APO) to normal volunteers does not induce psychotic behavior. But, only relatively low doses of APO have been used in these studies. Large doses of APO have rarely been given to humans because of the emetic effect. However, APO does not induce emesis in monkeys. Also, chronic administration of d-amphetamine (d-AMPH) to selected members of primate social colonies induces several behavioral changes which resemble those seen in humans during amphetamine psychosis. Therefore, a comparative study of the behavioral effects of chronic d-AMPH and APO in the same monkeys was conducted. In the first experiment, d-AMPH, 1.6 mg (base)/kg, in time-release form was given n.g. every 12 hours for 12 consecutive days to 4 adult Stumptail macaques (Macaca arctoides) from a colony of 5 monkeys. Only 2 monkeys received drug treatment at one time. 1 year later, APO, 0.5 mg (base)/kg, was given i.m. 2 x daily for 12 consecutive days to the same monkeys using a cross-over design as before. Each drug treatment period was preceded by a 2 week baseline observation period including sham drug treatment. Behavioral observation was conducted by a "blind observer" for 1 hour each day during baseline and drug treatment. During treatment, d-AMPH and APO both induced stereotyped behavior and significantly increased activity, checking (vigilance) submissive gestures, and distancing scores of all treated monkeys. Both drugs significantly reduced social grooming initiated by treated monkeys. Some differences were noted, however. APO increased locomotion more than d-AMPH. Only d-AMPH increased self grooming. The results of this study demonstrate many similarities between the behavioral changes seen in monkeys with chronic d-AMPH and chronic APO treatment. Of particular interest is that both drugs induced social withdrawal, increased submissiveness, stereotyped behavior, hypervigilance, and hyperactivity, all of which have been reported during amphetamine psychosis. This study demonstrates the important role of dopamine systems in the mediation of primate behavior and provides additional support for the role of dopamine in the mediation of amphetamine psychosis in humans.

152.24 CENTRAL MONOAMINE CHANGES IN CHRONICALLY STRESSED RATS. Kevin A. Roth*, Ivan N. Mefford* and Jack D. Barchas. Nancy Pritzker Laboratory of Behavioral Neurochemistry, Dept. Psychiatry and Behavioral Sciences, Stanford Univ. Sch. Med., Stanford, CA 94305 and Richard J. Katz*, Mental Health Research Institute, Univ. Michigan, Ann Arbor, MI 48109..

Rats were exposed to a chronic stress procedure designed to maximize the unpredictable nature of various stressors and time of stressor delivery. Stressors, such as water deprivation, individual housing, switching of cage mates, one hour of unpredictable electrical footshock (avg. 1 mA, 1-10 sec. duration; avg. 1 shock/min), and light/dark cycle reversal, were delivered in a semi-random fashion every 1-3 days throughout the day/night cycle for 21 days. Following the chronic stress procedure unstressed controls and experimental animals were sacrificed and the brains dissected. Tissue samples were stored on Dry Ice until assayed. The concentrations of tissue epinephrine, norepinephrine, MHPG, dopamine, DOPAC, HVA, serotonin and 5-HIAA were measured using HPLC with electrochemical detection.

Chronic stress failed to effect the levels of dopamine, its metabolites HVA and DOPAC, norepinephrine, and its metabolite MHPG. Hypothalamic epinephrine levels were decreased over 20% by chronic stress and caudate serotonin and 5-HIAA were both decreased about 30%. These changes may have implications to the underlying neurochemistry of human depression. The chronic stress procedure produces changes in rat behavior that may be similar to human depressed behavior. Preliminary results indicate that the chronic administration of antidepressants prevents the decrease in hypothalamic epinephrine produced by exposure to chronic stress.

152.25 EFFECTS OF CHRONIC NEUROLEPTIC TREATMENT OF CHRONICALLY STRESSED RATS. Ivan N. Mefford*, Kevin A. Roth*, Jack D. Barchas (SPON: James Dewson). Nancy Pritzker Laboratory of Behavioral Neurochemistry, Dept. Psychiatry and Behavioral Sciences, Stanford Univ. Sch. Med., Stanford, CA 94305.

Male Sprague Dawley rats, 250-300 g were injected with haloperidol (1 mg/kg), thioridazine (5 mg/kg), clozapine (10 mg/kg), chlorpromazine (5 mg/kg) or saline once daily for 21 days. A second group was chronically stressed with the drug treatment superimposed. Both chronically stressed and unstressed control groups were maintained (Katz et al., 1980).

Animals were sacrificed and brains removed and dissected for neurochemical analysis. Concurrent determination of biogenic amines was accomplished using HPLC with electrochemical detection (Mefford et al., 1980). Serotonin, 5-HIAA, norepinephrine, epinephrine, dopamine, MHPG, HVA and DOPAC were analyzed in each tissue sample.

We have previously shown that chronic stress leads to decreases in hypothalamic epinephrine and striatal 5-HT and 5-HIAA. Chronic administration of haloperidol to unstressed rats produced a marked depletion of both 5-HT and 5-HIAA in striatum. When superimposed on the chronic stress regimen, chronic haloperidol treatment led to an increase in both striatal 5-HT and 5-HIAA (about 50% in each case, $p < .05$). The same general trends were observed in both hypothalamus and frontal cortex. We are presently screening the neuroleptics to determine if the responses found after haloperidol treatment are a common characteristic of this class of drugs.

152.27 ELECTROCONVULSIVE SHOCK TREATMENT INCREASES RESPONSIVENESS OF FOREBRAIN NEURONS TO SEROTONIN: A MICROIONTOPHORETIC STUDY IN THE RAT. C. de Montigny, Centre de recherche en sciences neurologiques and Département de psychiatrie, Université de Montréal, Québec, Canada.

Even though electroconvulsive therapy is the most effective treatment of major depressive disorders, its mode of action is still unclear.

Electroconvulsive shocks (ECS) (150 V, 10 ms pulses at 50 Hz for 1 s) were administered thrice weekly in the late afternoon for 2 weeks to male Sprague-Dawley rats (200-250 g) under light halothane anesthesia. Paired control rats were similarly anesthetized and given a foot shock. Iontophoretic experiments were carried out 36-40 hrs after the last shock. Five-barrelled glass micropipettes were prepared in a conventional manner. The central and one side barrel, filled with 2 M NaCl solutions, were used for recording and current balancing. The other barrels were filled with three of the following solutions: serotonin (5HT) creatinine sulfate (0.002 M in 0.2 M NaCl, pH: 3.8); 5-methoxydimethyltryptamine (5MeODMT) (0.05 M, pH: 4), (-) norepinephrine (NE) bitartrate (0.1 M; pH: 4), γ-aminobutyric acid (GABA) (0.05 M in 0.05 M NaCl; pH: 4) and acetylcholine (Ach) chloride (0.02 M in 0.2 M NaCl; pH: 4). Recordings were obtained from CA_3 hippocampal pyramidal neurons. Small currents of Ach were used to activated silent or slowly discharging units. Responsiveness to iontophoretic applications of drugs was estimated from the charge $I \cdot T_{50}$ required to reduce the firing rate by 50% {charge $I \cdot T_{50}$ = current (nA) x time (s)}. The same micropipette was used to assess neuronal responsiveness in both the control and the ECS-treated rats of each pair.

A first series of double-blind experiments, carried out under urethane anesthesia (1.25 g/kg, i.p.), revealed a 2-3 fold increase in responsiveness to 5HT in ECS-pretreated rats. In contrast, the effect of NE remained unchanged. In a second series, GABA and 5MeODMT, a 5HT agonist which is not a substrate for the high affinity 5HT reuptake process, were studied. Whereas the effectiveness of GABA was unaltered, the responsiveness to 5MeODMT was enhanced 2-3 times in ECS-pretreated rats. In a third series, a low *cerveau isolé* preparation was used to rule out any possible effect of general anesthesia. The sensitivity to both 5HT and 5MeODMT was found to be increased 3-4 times by ECS pretreatment.

These data indicate that ECS induce a selective increase in the sensitivity of 5HT postsynaptic receptors of hippocampal pyramidal cells in the rat. Tricyclic antidepressants also have been shown to increase responsiveness of forebrain neurons to 5HT (de Montigny and Aghajanian, 1978; Gallager and Bunney, 1979). It is therefore possible that sensitization of forebrain neurons to 5HT contributes to the therapeutic effect of both types of treatment. (Supported by M.R.C. (MA-6444) and C.R.S.Q. grants.)

152.28 ACUTE VERSUS CHRONIC EFFECTS OF SEROTONIN UPTAKE BLOCKERS ON SEROTONIN METABOLISM. Melvin H. Van Woert* and Eunyong Chung Hwang (SPON: T. Elizan). Depts. of Neurology and Pharmacology, Mt. Sinai Sch. Med., New York, N.Y. 10029.

A single injection of a serotonin uptake blocker increases the concentration of serotonin reaching post-synaptic sites, an action which has been presumed to enhance serotonergic neurotransmission. The functional effects of chronic administration of serotonin uptake inhibitors had not been examined. Therefore, we compared the effect of a single intraperitoneal injection with 14 days of treatment with 10 mg/kg of the serotonin uptake blockers fluoxetine, paroxetine, zimelidine, trazodone and amitryptyline on potentiation of the "serotonin syndrome" (lateral head weaving, Straub tail, hindlimb abduction, tremor, hyperactivity, reciprocal fore-paw treading, salivation and piloerection), produced by the monoamine oxidase inhibitor, tranylcypromine (20 mg/kg) alone and tranylcypromine (20 mg/kg) plus L-tryptophan (50 mg/kg) in mice. A single injection of fluoxetine, paroxetine and zimelidine significantly potentiated the "serotonin syndrome" produced by tranylcypromine with L-tryptophan and tranylcypromine alone. This potentiating effect on the "serotonin syndrome" of fluoxetine paroxetine and zimelidine was no longer evident after 14 daily injections of these serotonin uptake blockers. Neither acute nor chronic pretreatment with trazodone and amitryptyline had any effect on the "serotonin syndrome".

Although acute and chronic fluoxetine treatment had similar effects on mouse brain synaptosomal (^{3}H)-serotonin uptake, only chronic fluoxetine administration decreased serotonin synthesis (33%, $p < 0.01$) and (^{3}H)-tryptophan uptake into synaptosomes (26%, $p < 0.01$). Synaptosomal (^{3}H)-tryptophan uptake also was significantly reduced by chronic but not acute treatment with zimelidine, trazodone and amitryptyline. Brain 5-hydroxyindoleacetic acid was decreased by 46% and 52% ($p < 0.001$) after acute and chronic fluoxetine treatment, respectively. Neither acute nor chronic fluoxetine administration had any effect on brain serotonin levels, tryptophan hydroxylase, (^{3}H)-5-hydroxytryptophan uptake or (^{3}H)-serotonin receptor binding.

Our behavioral and biochemical findings suggest that there may be no significant enhancement of brain serotonergic neurotransmission during chronic therapy with serotonin uptake blockers because a reduction in tryptophan uptake and serotonin synthesis counteracts the effects of serotonin uptake inhibition. (Supported by USPHS grants NS 12341, NS 05802 and NS 71631).

152.29 Electroconvulsive Shock and Reserpine: Effects on Adrenergic and Serotonergic Receptors in Rat Brain. Judith A. Butler*, Caren S. Cascio*, Debra A. Bergstrom*, and Kenneth J. Kellar (Spon: F.G. Standaert). Dept. of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, D.C. 20007.

Chronic electroconvulsive shock (ECS) decreases beta-adrenergic receptors in rat cortex. It does not alter alpha adrenergic or 5-HT_1 receptors in the cortex or dopamine receptors in the striatum. The present experiments further examined the specificity of the effects of ECS on neurotransmitter receptors in the cortex and hippocampus and in particular examined the effects of ECS on receptors previously altered by chronic reserpine administration.

Rats were treated with vehicle or reserpine (0.25 mg/kg i.p.) for 30 days and then subjected to either ECS or sham shock (handled and placed to electrodes) for 10 days. One day after the last ECS or sham treatment, the rats were sacrificed and the brains dissected. Beta-, $alpha_1$-, and $alpha_2$-adrenergic receptors were measured using ^{3}H-dihydroalprenolol, ^{3}H-WB-4101, and ^{3}H-clonidine, respectively. Serotonin$_1$ and serotonin$_2$ receptors were measured using ^{3}H-5-HT and ^{3}H-spiperone, respectively.

Chronic ECS reduced beta-adrenergic receptors in rat cortex as we have previously reported. In addition, beta-adrenergic receptors in the hippocampus were reduced to the same exent. Further, 10 days of ECS completely reversed reserpine-induced increases in beta-adrenergic receptors. Eleven days after the last reserpine injection beta-adrenergic receptor binding in the sham-shocked group was increased by 22% compared to vehicle-injected, sham-shocked controls. In contrast, the binding in rats which received reserpine followed by 10 days of ECS was the same as vehicle controls. Chronic ECS had no apparent effect on $alpha_1$ or $alpha_2$ receptors in the cortex, nor on ^{3}H-5-HT binding sites in the cortex or hippocampus. Serotonin$_2$ receptors, measured by ^{3}H-spiperone binding in the cortex were not reduced by chronic ECS. This is in contrast to the effects of chronic administration of tricyclic antidepressants and MAO inhibitors (Peroutka and Snyder Science, in press, 1980).

Data on the specificity of the effects of ECS on reserpine-induced increased neurotransmitter receptors will be presented.

152.30 OPPOSITE AND ANTAGONISTIC EFFECTS OF INTRAHIPPOCAMPAL INJECTIONS OF SEROTONIN AND NOREPINEPHRINE ON BEHAVIOR Fred H. Gage and Joe E. Springer* Chemistry of Behavior Program, Texas Christian University, Fort Worth, TX 76129 On the basis of converging histofluorescent, autoradiographic, microiontophoretic and biochemical assay techniques, NE and 5-HT have been implicated as putative neurotransmitters within the hippocampal formation (HPF).

Convincing evidence for an antagonistic role of 5-HT and NE has been obtained in experiments aimed at elucidating the neurochemical substrate of behavioral arousal and emotional behavior. The HPF has been associated with related behaviors, more specifically the HPF has been suggested to be involved in the integration of internal and external stimuli and in particular appears to function in the recognition of novel stimuli. The present study was designed to answer the following questions: 1)Do intrahippocampal injections of NE and/or 5-HT effect behavioral responsiveness to novel stimuli? 2)Do 5-HT and NE effect behavior in the same direction? 3)Do NE and 5-HT act antagonistically? 4)Do NE and 5-HT respectively have the same effect when injected along the dorsal and ventral axis of the HPF?

Groups of rats were designated by dorsal or ventral HPF cannula placements and then further divided depending upon whether the subject was to receive NE or 5-HT. The animals received an injection and were tested once a day with a two day interval. Five concentrations of the amines were used: .005, .05, .5, 2.5 and 5.0μg/μl in 2μl injected at a rate of 1μl/minutes.

The behavioral tests included two with noxious stimuli, pawlick latency in response to electric shock; one with non-noxious stimulus, ambulatory behavior in response to an open field.

Our results demonstrate a clear dose-dependent change in behavior following both NE and 5-HT injections. NE increased responsiveness of rats in all three behavioral tests. 5-HT decreased responsiveness to noxious stimuli and increased open field behavior. Injections of NE and 5-HT simultaneously antagonized the effects of either transmitter when injected individually. Clear differences are observed for NE and 5-HT depending on whether the neurotransmitters were injected into the dorsal or ventral HPF. These results demonstrated an interaction or balance between 5-HT and NE in the HPF is important in integration of external stimuli into behavioral responses.

152.31 VAGINAL STIMULATION-PRODUCED ANALGESIA IS MEDIATED BY SPINAL NOREPINEPHRINE AND SEROTONIN IN RATS. J.L. Steinman*, B.R. Komisaruk, T.L. Yaksh and G.M. Tyce. Inst. Animal Behavior, Rutgers Univ., Newark, NJ 07102 and Mayo Clinic, Neurosurgical Research and Physiology, Rochester, MN. 55901.

The present findings demonstrate that 1) administration of α-adrenergic (NE) and serotoninergic (5-HT) receptor blocking agents directly to the spinal cord significantly antagonized the analgesic effect of vaginal stimulation (VS), and 2) NE and 5-HT measured in spinal cord superfusate increased significantly in response to VS. The drugs were injected via catheters (PE-10 tubing) passed to the lumbar level of the spinal cord through an incision in the cisterna magna according to the method of Yaksh and Rudy (Physiol. Behav., 17: 1031, 1976). VS (200g force) was applied via a calibrated glass probe assembly (modified 1 cc syringe plunger). Two indices of analgesia were used: latency of tail flick to radiant heat and threshold (in mA) to vocalize in response to tail shock. In pre-injection control tests, VS significantly increased both of these measures: overall mean tail flick latency (from 2.68±.09 *[s.e.m.]* sec. preprobing to 5.43±.16 sec. during probing *[203%↑]*), and the overall $\bar{X}$ vocalization threshold (from $\bar{X}$ = .21±.02 mA preprobing to $\bar{X}$ = .39±.03 mA during probing *[185%↑]*). The rats were then injected perispinally with 20 μL containing 10 or 40 μg phentolamine (Regitine HCl: n=7 and 8, respectively, 10 or 40 μg methysergide maleate (n=8 and 6, respectively) or 20 μL saline (n=7). Testing commenced 15 min. after completion of the injection. Results are reported as % of mean response (threshold or latency) of saline group during VS (*:p<.05). Vocalization threshold of saline group during VS: $\bar{X}$ = .31 mA = 100%; phentolamine; 10 μg: 108.7% ns; 40 μg: 37.1%*; methysergide: 10 μg: 50.0%*; 40 μg: 186/7% ns. Tail flick latency of saline group during VS: $\bar{X}$ = 4.91 sec. = 100%; phentolamine: 10 μg: 88.6% ns; 40 μg: 62.3%*; methysergide: 10 μg: 88.6% ns; 40 μg: 83.5% ns.

In a separate experiment, high pressure liquid chromatography using electrochemical detection was used to measure NE and 5-HT levels in superfusates (30 min. samples) of the spinal cord immediately preceding and during VS (1.5 min. VS on, 1.5 min. off; repeated for 30 min.) in 5 rats. VS increased the mean levels of NE from .01±.01 (s.e.m.) to .17±.03 ng/ml/10 min. and of 5-HT from .29±.12 to .48±.12 ng/ml/10 min. Thus the present experiments indicate that a spinal α-adrenergic mechanism mediates the analgesic effect of VS, and provide evidence that a serotoninergic mechanism may also be involved.

152.32 SEROTONERGIC AND NORADRENERGIC UPTAKE DURING THE ESTROUS CYCLE IN LIMBIC AND HYPOTHALAMIC NUCLEAR REGIONS. Donald C. Meyer, Department of Physiology and Biophysics, University of Louisville School of Medicine, Louisville, Kentucky 40292

The role of hypothalamic and limbic aminergic systems in ovulation in the rat has been investigated by measuring the temporal changes in serotonergic and noradrenergic neuronal uptake during the estrous cycle. Using the pregnant mare serum (PMS) model of induced ovulation and an in vitro uptake system, significant ($p < .05$) decreases in serotonergic uptake were found during the mid to late light period in the amygdala during diestrus. This pattern was repeated during proestrus and estrus only in the amygdala, suggesting a consistent pattern of serotonergic uptake on every day of the estrous cycle. Significant changes in noradrenergic uptake also occurred in the amygdala during proestrus ($p < .05$) suggesting a possible interaction between serotonin and norepinephrine in regulating ovulation.
